SESSION BI01.01: Career Pathways I
Session Chair: Isabel Gessner
Monday Morning, November 28, 2022
Hynes, Level 1, Room 105

10:30 AM *BI01.01.01
What You Want to Do vs What You Can Do Jina Ko; University of Pennsylvania, United States

Growing up, I did not have any professors or scientists around me. I did not know how to become a professor and I never thought about it as my future career. I majored in Bioengineering and French Studies and I was still very naive when I was about to graduate. I did not know too much about different directions that I can take after graduation. For me, there were two options to choose from - either going to industry or continuing being a student - and it was a very easy decision to make. I will be working for 30+ years anyway so why not spend a little more time in academia as a graduate student? Then, the next question was Master's vs. PhD, which was also very easy to answer. If you pursue PhD, Master's degree is included so why not just do PhD right away? That's how I began my life as a PhD student.

I met the best possible advisor during my PhD and everyday was full of joy working with him on great science. I learned so much and I enjoyed the whole process. However, it was not enough to think about becoming a professor because there were always some challenging moments. Many of my research articles were rejected after multiple rounds of review process. Very precious samples that I collected for many weeks turned out to be degraded during that time. We built a microchip that achieved high diagnostic performance, which turned out to be due to some errors and we had to re-do the whole process after fixing the errors. Every time I faced these challenges, it was very frustrating and science was really hard. However, I never wanted to give up on anything and my advisor was always highly supportive, which made me successfully complete my PhD.

At the end of my PhD, there were another two options to choose from - either going to industry or pursuing postdoc - and I decided to do both. I worked in a company as an intern for three months and then I started my postdoc. I wanted to experience both paths so that I can really find out what I like and what I do not like. And I liked both working in a company and in a postdoc lab. From both experiences, I realized that I really enjoy ups and downs and that dynamic situations brought me more joy. This is why I wanted to stay in academia but I was not sure if I would become a good professor. And my PhD advisor told me that I should do what I want to do and don't think too much about if I can do it. And here I am.

Finding a good fit seems like a success to both securing a position and being happy in that position afterwards. It's always helpful to know someone in a department who is excited about your research and can endorse you during the recruitment process. High impact papers are good to have but they do not seem to matter once you pass the first round of screening interviews. Showing your fit, passion, and niche will make people excited about your case and want to have you as a colleague. A life as an assistant professor has been very fun and rewarding. I love working with students and colleagues. It gets very busy with meetings, grant writing, research, and conferences but they are all enjoyable since you are the one who make decisions, not someone else.

11:00 AM *BI01.01.02
Turning Academic Research into Building a Start-Up Martin Wilkovitsch[1,2]; [1]TU Wien, Austria; [2]Velaex Technologies, Austria

After graduating from university, finding early career perspectives in academia or industry can be a challenging task, especially if the actual deep desire is to found an own company. Often, scientists are deterred by this process as there are no clear guidelines that can be followed to guarantee success of a startup company.
Based on the research during my PhD as a chemist at TU Wien I embraced the opportunity and have taken the first steps toward building my own business in the field of life sciences. '*Velaex Technologies*' is a young biotech startup currently incubated in the i[2]ncubator of the Innovation Incubation Center of TU Wien with the mission to "*Bringing Chemistry to Life*".
The focus is to overcome the poor selectivity of conventional cancer chemotherapeutics by improving the site-specificity and especially the safety of those drugs. The basic underlying principle is to precisely deliver and activate drugs **only** at the site of disease by exploiting controllable, ultra-fast *in vivo* chemical reactions. Based on unique molecular designs, our team developed superior chemical tools that outperform current state-of-the-art technologies by several orders of magnitude thereby elevating the standards for the field. With *Velaex Technologies* we aim to provide methods to 'preprogram' the movement of compounds within living systems and thus enable drug targeting strategies with unprecedented efficiency, selectivity, and safety, paving the way to high-precision therapeutics.
As a deep-biotech startup at the interface of chemistry and biology, still with a very strong connection to academia, we are looking forward to discussing

our recent experiences of how to turn an academic research project into starting a business and launching a future startup / spin-off company. We will share our challenges along the way (including finding adequate funding support, mentoring/advisory strategies, building a team,…) especially addressing students, postdocs and other young professionals who envision founding a startup company in the future.

11:30 AM *BI01.01.03
Transitioning from Academia to Industry—How I Found my Way, How I Stayed Engaged and Why I (Still) Love my Job! Jonathan A. Fauerbach; Miltenyi Biotec, Germany

Should I pursuit the academic path and become a Postdoc or even a Professor? Where will I do that and what is my chance of success and survival? What about becoming independent as an Entrepreneur? What is needed for a start-up? How will I be able to bring my ideas and vision to life and convince others to invest on it? What about the industrial market? Should I "sell" my soul? How can I apply? What are the differences? Who can help me trying to figure this out? What is the role of networking? Where can I found support?

These questions and many more where some of the ones I faced when making a career choice and transitioning from academia to industry in 2016.

Throughout my (rollercoaster of) life I have moved from South-America, to North-America to Europe. I worked in Analytical Chemistry, Organic Chemistry, Protein Biophysical, Biochemistry and Cellular Biology labs and teams. I went from Academia, Entrepreneurship to Industry. I completed my Masters and PhD in Chemistry and most recently an Executive MBA. Worked my way from student, to Postdoc, to Group Leader to Manager. And managed to form a family, have two children and provide for us all.
My goal with this talk is to simply share my story, discuss and reflect on the process I went through, overcoming uncertainty and fears, debunking myths and biases, and ultimately offer tools, tips and resources to empower everyone who is at the crossroads of career paths.

Yes! You can do this. You can find your way. It will be awesome!

Keywords: career path, job application, work-life balance

SESSION BI01.02: Mentoring and Work-Life Balance
Session Chairs: Katherine A. Mazzio and Shayandev Sinha
Monday Afternoon, November 28, 2022
Hynes, Level 1, Room 105

1:30 PM *BI01.02.01
Balancing Work and Life While Pursuing an Academic Career Rachel S. Goldman; University of Michigan, United States

As a second generation academician, I learned at a young age that if you love what you do (for a living), your work is your hobby, your collaborators are your close friends, and your students are part of your extended family. Through persistence and luck, I have been fortunate to live this dream in my adult life. In this presentation, I will discuss strategies for pursuing a fulfilling academic career, drawing upon my experiences at the University of Michigan.

2:00 PM BI01.02.02
Creating a Culture of Success Through Holistic Mentoring Yvonne Kavanagh; South East Technological University, Ireland

To have a successful career it is important that leadership skills and resilience are developed as part of the academic journey of a student. This is facilitated and supported by the faculty who supervise research students. Successful careers must be framed in a changing environment where a graduate has choices and teasing out these by exposing the student to many environments is promoted.
As a research supervisor, an important part of the role is the development of successful confident researchers who can be the leaders of tomorrow in either academia or industry. These skills require development through various pathways. In addition to the role as a research leader developing timelines with project and publication milestones, the supervisory role has the capability of being a mentor who supports a holistic approach to leadership development. Being a mentor provides a platform for informal support which guides the student through various stages of their research by supporting and developing other skills. In this area it is important that there is a structure in place which can be replicated for all research students to enable them to reach their full potential.
This talk will focus on some strategies to support research students develop holistic leadership skills.
The approach includes strategies on:
Supporting minorities in materials engineering
Engaging students in exchange programmes
Developing leadership skills through outreach management
Providing leadership opportunities in various areas.
Supporting well being and resilience.

2:15 PM *BI01.02.03
How (Not) to Run an Academic Research Group—Insights on Mentoring and Work-Life Balance Alexandra Zevalkink; Michigan State University, United States

Running a research group and mentoring students is not something that we are explicitly trained to do during our graduate studies. At best, we spend five plus years observing how our Ph.D. or postdoc advisors do it, making a long mental list of what to do (and what definitely NOT to do) along the way. As a non-expert on this subject, my goal is to help you avoid some of the many pitfalls that I encountered, by telling you what worked and what didn't work for me. I'll discuss the realities of work-life balance, and the implications of being both "mom" and "professor". Effective time management skills are certainly a critical requirement for reaching a semblance of equilibrium. However, even with the best laid plans, there are inevitably gaps between how I *plan* to spend my time (e.g., revising and submitting a manuscript) and how I *actually* spend my time (e.g., zoom meetings while entertaining a sick toddler who had to stay home from daycare). I'll discuss how my group management and mentoring approach has evolved over the past six years of my career thanks to trial-and-error and a good deal of "mentoring up" from my endlessly-patient students, and I'll share the toolkit that I've developed in an effort to foster a

diverse, self-driven, collegial, and growth-oriented research group.

2:45 PM BREAK

SESSION BI01.03: Grant Writing and Publishing
Session Chair: Shayandev Sinha
Monday Afternoon, November 28, 2022
Hynes, Level 1, Room 105

3:15 PM *BI01.03.02
The Art and Science of Writing and Publishing Impactful Papers Gopal R. Rao[1,2]; [1]Materials Research Society, United States; [2]MRS Bulletin, United States

The importance of publishing one's research cannot be understated, for scientists in general, but for early career researchers in particular. Publishing papers is part of the scientific research endeavor to communicate our results and move science forward. However, it is important to publish in the right journal and in the right format. The quality of the science is of course foremost when considering a publication, however, the quality of writing and ease of communication are critical for acceptance of papers as well as for subsequent citations. This talk will overview the scientific scholarly publication process, including the process of writing up your research, deciding the journal and format, composing an outstanding manuscript, submitting the paper, and navigating the publications process including managing reviews. There are many nuances to writing and publishing scientific papers, and this presentation will cover several of them.

3:45 PM *BI01.03.03
NSF's Division of Materials Research—Opportunities and Requirements Birgit Schwenzer; National Science Foundation, United States

The National Science Foundation is well-known for supporting innovative and transformative research. Just as importantly though, significant emphasis is placed on training the next generation of STEM researchers and educators as well as increasing diversity, inclusion and equity in STEM as part of the grants awarded. Every single proposal contains a broader impacts section to address these or other aspects, justifying how the proposed research benefits society.

The Division of Materials Research (DMR) supports fundamental materials research through its eight Topical Materials Research Programs (TMRPs): Biomaterials, Ceramics, Condensed Matter and Materials Theory, Condensed Matter Physics, Electronic and Photonic Materials, Metals and Metallic Nanostructures, Polymers, and Solid State and Materials Chemistry. Additionally, there are regularly opportunities to submit proposal for centers and center-type activities. This presentation addresses opportunities to engage with DMR either as a principal investigator on a proposal or as a reviewer.

SESSION BI01.04: Career Pathways II
Session Chairs: Isabel Gessner and Katherine A. Mazzio
Tuesday Morning, November 29, 2022
Hynes, Level 1, Room 105

10:00 AM *BI01.04.02
Being Intentional about the Industry-To-Academia Transition and Other Thoughts on Preparing for an Academic Career Aaron D. Franklin; Duke University, United States

Ask ten professors their opinions about the pros and cons of a post-doctoral transition from industry to academia and you're likely to get ten different answers. Given this variance in perspective, are there any commonalities regarding how to make the transition to a faculty position as successful as possible? In my opinion, there are and I will offer these best practices in this talk. The points I share are based on my experience in transitioning to academia after spending six years on the research staff at IBM. My perspective has been further developed by my observation of faculty recruiting these past 8+ years as a professor at Duke. There are certain things a person can do while in a PhD-level industry position to improve their preparation for, and future opportunities in, a faculty position. Most of these recommended steps must be intentional, meaning they will not often develop naturally in the regular course of working in industry. They include seeking mentoring opportunities, building a teaching portfolio, and maintaining a track-record of innovation. Importantly, these points are also completely relevant to those working in other areas (e.g., government labs) or even PhD students still determining the best first steps to take in their career. There's no perfect recipe for attracting and succeeding in a faculty position, but being intentional in your preparation can certainly help your chances for success!

SESSION BI01.05: Scientific Leadership and Education
Session Chair: Shayandev Sinha
Tuesday Afternoon, November 29, 2022
Hynes, Level 1, Room 105

1:30 PM *BI01.05.01
Inclusive Practices in the Classroom, Laboratory and Workplace Rebecca J. Anthony; Michigan State University, United States

Changing the climate for underrepresented minorities in Materials Science and Engineering, and other STEM fields, is one issue at the forefront of broadening participation in these areas. The solution to effecting this change is not a sweeping singular event, but instead a mobilization of each member of

the community to take action towards diversity, equity, and inclusion (DEI). Across academic and industrial professions, there is an increasing emphasis on a potential job candidate's DEI efforts – with many job applications as well as promotion packets requiring a statement on the candidate's activities and interests around DEI. But for many, deciding what exactly one's interests are – and how to promote DEI in classroom, research lab, and professional settings, can feel daunting to say the least. Additionally, sometimes it can be difficult to envision the change that is needed to reach an improved climate for underrepresented groups. However, small steps taken in all of these settings can go a long way in improving the climate for everyone, and by recognizing these small actions, we can not only learn about how to promote DEI in our own professions but also gain perspective on the activities that can make a big impact, but also suit our personalities and interests.
In this presentation, I will share some ideas for best practices to create an inclusive learning, research, and work environment and how those practices can become structured parts of our professional lives. I will also outline the vision of what an inclusive, diverse, and equitable Materials Science and Engineering workplace and educational space could look like – and how to selectively participate in achieving this vision by leveraging your strengths and interests towards activities that have demonstrated impact in promoting DEI.

2:00 PM BI01.05.02
Embedding Scientific Training in Course-Based Research for Undergraduates—An Example of a Lab Bundle for Clean Energy Research Yiliang Luan; Binghamton University, The State University of New York, United States

Research Experience for Undergraduates (REU) is popular as students can get diverse research experience over the summer. However, course-based research for undergraduates is rare but provides more than just research experience. In such courses, scientific training is usually embedded in individual practical labs for different training purposes, but these discrete contents make it hard for students to utilize their accumulated knowledge in their further research. To resolve this issue, a bundle of successive and interconnected labs enclosed with scientific training based on the study of perovskite quantum dots (PQDs) will be presented as an example. Determination of photoluminescence quantum yield is first set for the practice of basic lab skills such as transfer, measurement, and dilution. Supersaturation synthesis of $CsPbBr_3$ PQDs is adopted followingly due to its simplicity. Microwave synthesis of $CsPbBr_3$ PQDs is used as a transition before the students move to the more complicated hot-injection method. These successive labs are enclosed with scientific research principles such as methods screening, interpretation of method in literature into a practical procedure, impact from the ambient environment, viable controls, and united data analysis. Additionally, these labs are carried out in different teaching modes, including peer-mentor leading, instructor facilitating, and fully independent, which could occur when students start research in a new lab. Eventually, the students not only have sufficient hands-on experience but also can understand the principles of experimental designs and processes. This successive and interconnected lab bundle demonstrates a way to embed the scientific training in the course-based research, which achieves the goals of accumulating research experience, practicing lab skills, and understanding the scientific principles simultaneously at the initial research stage for undergraduates.

2:15 PM BI01.05.03
Innovation Fellowship—Novel Postdoctoral Training to Build a Pipeline of Innovation-Minded Professionals and Promote Commercialization in Academic Units Anastasia Visheratina[1], Dylan Neale[1], Kaylee Steen[1], Elizabeth H. Peters[1], Nadine Wong[2] and Joerg Lahann[1]; [1]University of Michigan–Ann Arbor, United States; [2]Duke University, United States

The Biointerfaces Institute (BI) at the University of Michigan (U-M) is rooted in the mission to advance biomedical discoveries by disrupting the status quo of isolated science and fostering cross-disciplinary technological breakthroughs in nanotechnology, advanced materials, cell engineering, and neural engineering. By co-locating 28 research groups from twelve departments across the U-M schools of Engineering, Dentistry, Medicine, and Pharmacy, forward-thinking collaborations lead to healthcare breakthroughs and advanced learning. To further accelerate the path from basic research to real-world health outcomes, the BI has created a novel postdoctoral fellowship to train the next generation of scientists in commercialization and translation. The Innovation Fellowship provides a blueprint for biomedical research units to train and mentor individuals in a systematic manner that encourages out-of-the-box thinking, experiential learning that supports commercialization efforts, and enhances the network of innovation leaders.
The Innovation Fellowship focuses on five main objectives, with the help of its strategic partners, to develop the Fellows' professional competencies in translation and commercialization. Fellows will receive (1) Innovation & Entrepreneurship Training, (2) Networking and Mentorship, (3) Professional Development Opportunities, and engage in (4) Technology Assessment and (5) Facilitate Project Development at all stages of the commercialization pipeline. In January 2022, BI launched the first of its kind Innovation Fellowship with Dr. Dylan Neale and Dr. Anastasia Visheratina as the inaugural cohort Fellows. During the term, fellows are trained to become a champion of innovation and translation at BI, advance BI's commercialization resources, and collaborate with BI research groups to uncover new projects with commercialization potential. They also engage with stakeholders to understand the opportunities and challenges of potential innovations as well as work with BI teams to advance projects.
Collectively, the Innovation Fellowship is creating a new pipeline of scientifically trained individuals and developing them as commercialization thought leaders to advance precision medicine, detect diseases earlier, restore body function, and improve drug delivery. In my talk, I will give a thorough overview of the Innovation Fellowship, our results, and its influence on my career development.

2:30 PM BI01.05.04
A Framework for Infusing Data Science and Computation into Engineering Curricula Wesley Reinhart, R A. Kimel, Ryan Solnosky and Rebecca Napolitano; The Pennsylvania State University, United States

While data science, data analytics, and machine learning topics continue to grow in popularity with engineering students and employers, so does the gap between practical skills needed in the modern computing environment and fundamental concepts taught in traditional engineering curricula (i.e., mathematical, computational, and statistical foundations). Despite the known benefits of contextualizing data science education to domain-specific knowledge, it remains a significant challenge for faculty without formal training in data science to develop curriculum to support the integration of data-science-related topics with existing curricula. The National Academies have also cited challenges in (i) recruiting and retaining faculty to teach integrated introductory courses in data science and (ii) encouraging industry partnerships to keep the education and training of the workforce well matched to the needs of the industry. Thus, a framework for teaching data science to engineers which considers domain-specific knowledge, ethical problem solving, transferability to new faculty and new institutions, and which encourages industry partnerships is needed.

In this talk, we will describe our current progress and future plans for an ongoing collaborative project between six universities and colleges as a part of the NSF Data Science Corps program. The objectives of this project are to facilitate data science education and workforce development for engineering and related topics, provide opportunities for students to participate in practical learning experiences, and expand and diversify the data science talent pool. To this end, our team is curating curriculum and datasets which will be made available to undergraduate instructors nationwide. These resources are intended to include everything that engineering faculty would need to port any part of this data science education framework into their own courses, reducing the barrier to implementation. Furthermore, they will be developed in collaboration with industry contributors to enable workforce development and build closer relationships between educators and employers of the next generation of engineers.

2:45 PM BI01.05.05

Biomolecular Electronics Experiments Using Nanoscience and Biophysics from an Undergrad Perspective Aderlyn M. Castillo, Keshani G. Pattiya Arachchillage, Subrata Chandra and Juan M. Artes Vivancos; University of Massachusetts Lowell, United States

The scanning tunneling microscope (STM) was the first artifact capable of non-destructively imaging matter with an atomic-scale resolution. Over 30 years ago, Gerd Binning and Heinrich Rohrer shared the Nobel Prize for Physics for inventing the first STM[1]. Beyond topographic imaging, STM offers the possibility of spectroscopic measurements with high resolution (atomic in many cases). This opened the door to single-molecule electrical measurements[2]. The scientific community was astounded when the electronic conductance of individual molecules bound between electrodes could be measured reliably[3] using the scanning tunneling microscope break junction (STMBJ) method. The STMBJ method is a powerful technique for creating single-molecule junctions and studying charge transport in biomolecules. In this method, the current is measured while the STM tip is brought into contact with the sample and retracted from the substrate surface several times[4]. The current recorded *(I*) can be related to conductance (G) by G = I/V, with V being the voltage, and conductance histograms can be constructed by acquiring thousands of curves to determine an individual molecule's conductance[5]. On the other hand, the current-time method provides less yield and is used to study the spontaneous formation of molecular junctions[4]. STM has applications in a variety of other disciplines, including biophysics[6] and biomedicine[5]. From the biophysics perspective, it can be used to detect biomolecular interactions electrically[7]. On the other side, from the biomedicine perspective, it could be used to detect detrimental diseases such as cancer and COVID and its variants[5]
In this contribution/Herein, we show an overview of the STMBJ method applied to the study of biomaterials and individual biomolecules[6] from an undergraduate perspective, in the context of the immersive scholars UML summer challenge. The results include high-resolution STM substrate imaging in air and buffered solution and preliminary trials on molecules and biomolecules. These results, potential problems, and alternative solutions open the doors to further develop STM, automatizing and miniaturizing it to make it a widespread user-friendly nanotechnology tool.

SESSION BI01.06: Virtual Session
Session Chairs: Isabel Gessner and Shayandev Sinha
Tuesday Afternoon, December 6, 2022
BI01-virtual

1:30 PM *BI01.06.02
A Perspective from an Early Career Scientist Working in a National Lab Wanyi Nie; Los Alamos National Laboratory, United States

At the end of the PhD training, it is time to decide the future career path. It can be confusing and a challenging time. Here I will share my path after graduating from Wake Forest University, and pursuing my research career at Los Alamos National Laboratory. I started as a postdoc research associate and then converted to a staff scientist. After my conversion, I have obtained significant experiences about maintaining a research group, raising funding, mentoring students and postdocs. In particular, I will discuss my experience and what I’ve learnt from the grant applications. Further, I will share my experience conducting research, mentoring postdoc and students in a national laboratory environment.

2:00 PM BI01.06.03
Developing Entrepreneurial Mindset in Engineering Students Through a Scaffolded Group Project Designing a Research Proposal Russell K. Pirlo; University of Dayton, United States

Entrepreneurial Mindset (EM) encompasses recognizing and identifying opportunities and applying one's skillset to create value and impact by solving societal problems. The Kern Entrepreneurial Engineering Network (KEEN) promotes a framework for entrepreneurial-minded learning (EML) comprised of three student learning outcomes that contribute to an EM, curiosity, connections, and creating value (the 3 C's). We present a collection of learning modules comprising a semester-long scaffolded approach to developing curiosity and creating value by identifying and addressing technical gaps through a group project writing an engineering research proposal. These modules were designed for and implemented in upper-level undergraduate and graduate-level biomedical engineering courses with the goal of developing all the three C's with emphasis on connections and creating value.
The collection of modules and course project accounted for half the effort in the course, and each module built upon the prior exercises and integrated core course content as well as a self-directed literature search. Project groups included 4-5 students from multiple majors within the undergraduate level. Modules included 'formative exercises' on sub-field exploration, strategic focus, needs finding, value/impact evaluation via quad-chart, technical gap identification, graphical organization of thought through technical approach and instrument diagrams, risk assessment and mitigation, proposal presentations, and a written proposal.
The impact of the modules was evaluated with a pre and post 5-point Likert scale survey. Based on multiple prior instruments evaluating EM, questions addressed students' self-perception of ability in ideation, open-mindedness, altruism, problem-solving, engaging stakeholders, value creation, ability to learn, analyzing market conditions, managing complex tasks, ability to anticipate technological developments, and intrinsic curiosity. Wilcoxon signed-rank statistical analysis revealed significant improvements ($p<0.05$) in students' perception of their ability to manage complex tasks, cope with failure, lead a team to work on a project, actively seek as much information as they can in a new situation, and anticipate technical developments.
Strategies to evaluate the effectiveness of individual assignments to impact specific outcomes will be discussed, including recommendations on question types and using Learning Management System (LMS) metrics in combination with assessment instruments. Finally, the work demonstrates how to leverage research experience in the classroom to train students for careers in academia or industry.

2:15 PM *BI01.06.04

On a Personal Journey from an Industrial Research Lab to Academia Jihui Yang; University of Washington, United States

I am the Vice Dean of College of Engineering and Kyocera Chair Professor in the Materials Science and Engineering Department of the University of Washington (UW). My research interests include Electrochemical Energy Storage, Solid State Energy Conversion, Electrocatalysis, and Transport Properties of Two-dimensional Materials.

In my current role as the principal research administrator, I develop and facilitate faculty-led research, and I focus on integrating research to meet the college's educational goals. More precisely, I am responsible for ensuring ethical, creative, and efficient research conduct. Prior to joining the U.W in the Fall of 2011, I was a Technical Fellow and Lab Group Manager at General Motors Research and Development Center, where I started working as an intern in 1995.

My talk will recount my professional and personal journey from being an intern, scientist, lab manager, faculty member, and how these roles best prepared me for my current role as a university administrator. Therefore, I will share back stories, projects that I worked on, challenges I overcame, the lessons that I learned, and how I have found great satisfaction throughout my journey. Above all else, I would like to share my personal experiences with individuals that wish to make a change within their respective fields.

SESSION CH01.01: Characterization Self-Assembly Process and Its Controlling Factors I
Session Chairs: James De Yoreo and Dongsheng Li
Monday Morning, November 28, 2022
Hynes, Level 1, Room 102

10:30 AM +CH01.01.01
An *In Situ* Look at Interfacial Controls on Crystallization and Self-Assembly in Inorganic and Biomolecular Systems James J. De Yoreo[1,2]; [1]Pacific Northwest National Laboratory, United States; [2]University of Washington, United States

Interfaces play a critical role in solution-based phenomena, such as ion segregation, mineral nucleation, and biomolecular and colloidal self-assembly. The interface alters the distribution of water and ions from that of the bulk, introduces an interfacial free energy that largely determines the free energy barrier for nucleation, and creates an entropic repulsion that acts like a volume exclusion force to drive colloidal assembly. The origin and characteristic length scales of these phenomena are inherently atomic-to-molecular but are manifest in ensemble dynamics and outcomes. Moreover, processes like nucleation and self-assembly arise from fluctuations, making the events that must be probed transient in nature. Consequently, in situ imaging techniques that can capture structure and its evolution, particularly at high speed, are required to build a quantitative picture of such processes. Here I use examples from and in situ TEM, high-speed AFM and fast force mapping studies of interfacial structure, nucleation, and assembly in inorganic and biomolecular systems to elucidate the mechanisms by which interfaces direct these processes, leading to unique pathways, materials and morphologies. The results reveal the importance of surface charge, chemical gradients, colloidal forces, molecular mobility, and solvent organization near interfaces in determining how ordered materials emerge from the solution.

11:00 AM CH01.01.02
Understanding of Non-Classical Crystal Growth via Particle Assembly via *In Situ* Liquid Cell TEM Dongsheng Li; Pacific Northwest National Laboratory, United States

The nanoparticle assembly into structures of superlattices and crystals attracts great attention due to their unique optical, thermoelectric, magnetic, energy storage, and catalytic properties. Understanding of mechanisms of particle assembly and interaction between active species can help to establish conditions to control the assembly process and structures of superlattices and crystals, which are closely tied to the physical and chemical properties. However, little is known about the driving forces and controlling factors during the process of particle self-assembly. In this work, we analyzed dynamic information of the process and investigated the Van der Waals force, steric hindrance, Brownian force, and the hydrodynamic force, based on measured particle positions and velocities by directly observing the process of particle self-assembly and tracking individual particles as a function of time via in situ TEM. We studied the crystal surface interactions as a function of pH, electrolyte type, and concentration. We further studied the crystal growth process via particle-oriented attachment, a special type of particle assembly. The results of this work enable the control of particle assembly and the resulting structures and the design of materials with tailored properties.

Nanostructural Transformation of Photo-Crosslinking Peptides Visualized by *In Situ* Liquid-Phase Transmission Electron Microscopy Junho Hwang and Eunji Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

Peptide self-assembling nanostructures based on diphenylalanine (FF) can have organized beta-sheet secondary structures that can result in the formation of spheres, cylinders, and tubes depending on the strong interaction of phenyl groups between adjacent derivatives. Due to the structural stability and biocompatibility of FF, it has been widely used in biological applications such as drug delivery and tissue regeneration, and its biological significance has motivated numerous research fields including self-assembly and functional biomaterials with mechanical, piezoelectric, and semiconductor properties. Up to now, the conventional bulk solution characterization approaches have been used for the majority of studies on the kinetics, dynamics, and phase transitions of FF assemblies, however, these technologies lack a direct understanding of the dynamics and morphology. In this study, short peptides were modified using a tyrosine-mediated crosslink to adopt the characteristic of the resilin of the dragonfly, vinegar fly, and beetle that photooxidation-reduction can occur and alter the antiparallel structure to generate 1D nanostructure. In this context, protein-mimetic structural evolution was investigated. Through the use of liquid-phase transmission electron microscope (LP-TEM) imaging, the structural conversion of 1D to 3D structures by peptide cross-linking was demonstrated. This result suggests that because of their packing sensitivity and geometrical limitations, the nature-protein motion should be studied to acquire insights for developing peptide-based materials. Furthermore, the observation of the assembly and dynamics of FFs in real-time with LP-TEM would enable us to understand the paths for assembly and phase transformations.

Real-Time Study of Surface-Guided Nanowire Growth by *In Situ* SEM Ernesto Joselevich; Weizmann Institute, Israel

The large-scale assembly of NWs with controlled orientation on surfaces remains one challenge toward their integration into practical devices. During the last decade, we have reported the growth of perfectly aligned, millimeter-long, horizontal NWs of GaN, ZnO, ZnSe, ZnTe, CdSe, CdS, CsPbBr3 and other materials, with controlled crystallographic orientations on different planes of sapphire, SiC, quartz, and spinel. The growth directions and crystallographic orientation of the NWs are controlled by their epitaxial relationship with the substrate, as well as by a graphoepitaxial effect that guides their growth along surface steps and grooves. We demonstrated the massively parallel "self-integration" of NWs into circuits via guided growth and the production of optoelectronic nanosystems, including photodetectors, photodiodes and photovoltaic cells. This talk will focus on our systematic studies aimed at understanding the mechanism of guided nanowire growth based on both in situ and ex situ kinetic studies. Ex situ studies reveal the role of dimensionality in guided growth being controlled by the surface-diffusion of adatoms over the substrate. In situ SEM studies yield beautiful movies of guided nanowires growing in real time, and reveal intricate details of the guided growth mechanism.

SESSION CH01.02: Characterization Self-Assembly Process and Its Controlling Factors II
Session Chairs: Judy Cha and Frances Ross
Monday Afternoon, November 28, 2022

1:45 PM *CH01.02.01
Multi-Modal *In Situ* Characterizations for Phase Transformations of Nanomaterials Judy Cha[1,2]; [1]Yale University, United States; [2]Cornell University, United States

Understanding the dynamic processes of materials synthesis and phase transformation is indispensable for most applications as these processes determine the microstructure and thus the properties of materials. *In situ* techniques can uniquely capture short-lived transient states and time-dependent changes in structure-property relations during the synthesis and phase transformation, thus providing important information and opportunities to engineer the dynamic processes and ultimately material properties.

In this talk, I will discuss several examples of nanoscale phase transformations and syntheses in which the changes in structure and properties were systematically and directly probed by *in situ* TEM (cooling, liquid synthesis, heating, and electrical biasing), *in stiu* Raman spectroscopy, and *in situ* electron transport measurements. These examples will include discovery of metastable and transient intermediate phases during synthesis of metal and metal oxide nanostructures, emergence of new electronic phases via intercalation of metal ions in two-dimensional materials, effects of heterointerface and nanoscale confinement on the thermodynamics of phase transformations in various two-dimensional and quantum materials. In each example, unexpected nanoscale effects and the unique advantages of *in situ* techniques to capture the nanoscale effects will be highlighted. In particular, the importance of multi-modal *in situ* characterization approach will be emphasized, which is necessary to establish structure-property relationships during these dynamic processes.

2:15 PM CH01.02.02
Synthesis of Alkyne-Bearing Nanoparticles by SET CRP Polymerisation Induced Self-Assembly Daniela V. Tomasino[1], Ruairi Brannigan[2] and Andreas Heise[1]; [1]Royal College of Surgeon in Ireland, Ireland; [2]Dublin City University, Ireland

Polymerization-induced self-assembly (PISA) has emerged as a straightforward methodology for the *in situ* preparation of nano-objects with tuneable shape and dimensions.[1,2] Copper catalysed alkyne-azide cycloaddition (CuAAC) is a robust synthetic method with the aim of binding two molecular blocks together through heteroatom linkages (C-X-C).[3]The integration of the two techniques creates a facile strategy for the design of versatile nanoparticles. In this work, the combination of PISA and CuAAC allowed for the preparation and post-functionalization of NPs due to the incorporation of a propargylic

moiety within the hydrophilic shell of the NPs. The NPs were prepared *via* aqueous dispersion single electron transfer living radical polymerization induced self-assembly (SET-LR-PISA). Poly(ethylene glycol methyl ether methacrylate)-*statistical*-poly(propargyl methacrylate) $[P(PEGMA)]_{18}$-*s*-$P(PgM)_5$] was obtained by conventional atom-transfer copolymerization (ATRP). The hydrophilic macroinitiator was then chain extended with 2-hydroxypropyl methacrylate (HPMA) *via* SET-LRP, which induced self-assembly, yielding $[P(PEGMA)]_{18}$-*s*-$P(PgM)_5$-*b*-[PHPMA] NPs. Fixing the mean molecular weight of $[P(PEGMA)]_{18}$-*s*-$P(PgM)_5$] to 6.2 kDa and varying HPMA DP, monomer conversion of the system was investigated *via* ^{1}H NMR and the stability was improved thanks to the addition of tetrabutyl ammonium salt during the reaction. The final diblock copolymer structure was analysed via ^{1}H NMR, GPC. The remaining copper concentration in the final product was assessed by inductively coupled plasma mass spectroscopy (ICP MS) analysis. After having characterized the NPs in terms of size and shape *via* dynamic light scattering (DLS) and transmission-electron microscopy (TEM), the corona was functionalized with various compounds *i.e.* fluorescein azide, methoxypolyethylen glycol azide, mannosyl derivatives; demonstrating that the system provides a unique platform for the preparation of biorelevant modifiable materials though ATRP type polymerisation.

Modification of Molecular Assemblies of Azobenzene Derivatives by Electrical Stimuli Sylvie Godey[1], Hugo Therssen[1], David Guérin[1], Yannick Dappe[2], Thierry Melin[1] and Stéphane Lenfant[1]; [1]IEMN-CNRS, France; [2]SPEC, France

In recent years, molecular switches such as azobenzene adsorbed on metal surfaces have attracted considerable attention due to their potential use in nanotechnology, information storage or molecular electronics [1,2,3]. In particular, the 3,3',5,5'-tetra-tert-butylazobenzene (TBA) molecule is a promising candidate for such studies, due to the four lateral tert-butyl-groups which act as "spacer leg" to reduce the electronic coupling between the active part of the molecule (azobenzene) and the metal surface. This azobenzene derivative switches reversibly between the two isomeric states (*trans*-TBA and *cis*-TBA). This isomerization has already been demonstrated by scanning-tunneling microscopy (STM) using either the electric field induced by the STM tip [4] or by exposure to UV or blue light [5].
Here we report another effect of electric field for one-monolayer TBA coverage on Au(111), both characterized by STM and non-contact AFM (nc-AFM) with sub-molecular resolution using stiff (length extensionalv resonator) probes. These studies enable to observe and characterize an in-situ modification of the formed TBA self-assembly under electrical stimuli.

After the TBA evaporation, molecules are organized on the Au(111) surface in the *trans* isomer with four lobes corresponding to the 4 "legs", with an apparent height of 0.25 ± 0.02 nm. STM imaging at 77K reveals domains only visible in negative polarity; by scanning these TBA assemblies at -2V, bright spots appear with an apparent height of 0.36 ± 0.05 nm confirmed by nc-AFM. These spots are usually associated to the *cis*-TBA induced by the *trans*-TBA to *cis*-TBA isomerization under the presence of an electric field [4]. For domains imaged with both polarities in STM, an in-plane rotation of TBA network is observed in STM and nc-AFM after scanning at negative polarity (-1V). The origin of this in-situ in-plane rotation will be discussed. These results show how crucial are the intramolecular and molecular-substrate forces control and understanding in the perspective of molecular electronics.

2:45 PM CH01.02.04
Interfacial Dynamics of Cu-Cu_2O Nanocatalysts Unveiled Through *In Situ* Electrochemical Polymer Liquid Cell Electron Microscopy Jiawei Wan[1,2], Qiubo Zhang[1], Sophia Betzler[1], Junyi Shangguan[1,2], Qi Zheng[1], Xianhu Sun[1], Xinxing Peng[1], Xin Chen[1,2], Rohan Dhall[1], Karen Bustillo[1] and Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

The catalyst-electrolyte interfaces provide active sites which are fundamental for electrocatalysis. However, measuring structural dynamics of these delicate interfaces at atomic level remains challenging due to the limited experimental capabilities. Here, we report in situ electrochemical transmission electron microscopy (TEM) imaging of the interfacial evolutions of Cu-Cu_2O core-shell nanowires during electrochemical carbon dioxide reduction reaction (CO_2RR) using our newly developed polymer liquid cell. Our direct observations reveal that the catalyst-electrolyte interfacial interaction leads to several structural scenarios during CO_2RR, including Cu mass loss, Cu_2O shell fragmentation, and reshaping and growth of Cu nanoparticles. We find the competitive advantage of Cu-electrolyte interface is responsible for stabilizing Cu^I species, and the abundant grain boundaries with disordered intermediate structures contribute to high catalytic efficiency. Our study offers insights into catalyst-electrolyte interfacial evolutions during CO_2 electroreduction, and it suggests opportunity to study diverse electrochemical processes at the atomic resolution.

3:30 PM *CH01.02.05
Patterning and Self Assembly on 2D Materials Visualized Using *In Situ* Electron Microscopy Frances M. Ross; Massachusetts Institute of Technology, United States

The fascinating characteristics of two-dimensional (2D) materials offer prospects for understanding new physical phenomena and developing innovative functional devices. *In situ* electron microscopy can play a critical role by providing the ability to pattern 2D materials as well as to image during deposition onto their surfaces. We first discuss *in situ* irradiation as a tool to drive local transformations in 2D materials, exploring in particular a rearrangement of the 2D magnet CrSBr that changes the layer orientation, aiming to modulate properties such as magnetic texture. We then explore *in situ* imaging of deposition onto 2D surfaces as a means to understand the growth mechanisms involved and the resulting morphology and defects of the deposited layer. In these experiments, controlled environment and atomic level precision offer unique benefits. The rapid advances in *in situ* TEM instrumentation therefore promise exciting future opportunities to understand and use nanoscale materials reactions to create complex structures based on 2D materials.

4:00 PM CH01.02.07
Light-Patterned Electrochemical Microbubbles for Large-Scale Precision Assembly of Nanocolloids Hyungmok Joh[1], Zhichao Ma[2], Peer Fischer[3] and Donglei (Emma) Fan[1]; [1]The University of Texas at Austin, United States; [2]Max Planck Institute for Intelligent Systems, Germany; [3]University of Stuttgart, Germany

Microbubbles in aqueous suspensions have enabled a variety of applications ranging from pumping, mixing, drug delivery, to nanoparticle assembly. However, as far as we know, it remains a formidable challenge to create arrays of bubbles and we are not aware of a method that permits custom patterns of bubbles to be dynamically formed and refreshed. In this work, we report a novel approach to achieve custom 'on demand' bubble patterns via an opto-electrochemical technique. It permits us to achieve controlled bubble sizes in the range from a few to ~140 micrometers. Entire patterns can be formed in ~1 second, including lattices, rings, squares, and arbitrary 2D images. The required minimum light intensity (532 nm) of ~0.1 W / cm^2 is similar to that of sun light, several orders of magnitudes lower than those of optothermal/optoelectronic printing methods, which makes the reported technique parallel and scalable. Interestingly, the bubble patterns can be used to assemble structures from nanocolloids. For a demonstration, we show that nanocolloids can be arranged into different patterns on substrates with light-addressed electrochemical microbubbles across a dimension of millimeters and at an accuracy of less than 1 um. This forms a new printing technique that is quite general and that enables fast and non-contact particle assembly and manipulation. We expect that it will find application in nanomanufacturing, single-cell biotechnology, and in arranging optoelectronic building blocks.

4:15 PM CH01.02.08
Insights into the Kinetics and Self-Assembly Order of Hybrid Small-Molecule Organic Semiconductor / Quantum Dot Blends During Blade Coating Daniel Toolan[1], Michael P. Weir[2], Richard Jones[3] and Anthony J. Ryan[1]; [1]Department of Chemistry, The University of Sheffield, United Kingdom; [2]The University of Nottingham, United Kingdom; [3]The University of Manchester, United Kingdom

Hybrid organic-inorganic nanocomposite films formed from blends of small-molecule organic semiconductors and colloidal quantum dots are attractive candidates for high efficiency, low-cost solar energy harvesting devices. Understanding and controlling the self-assembly of the resulting hybrid material is crucial in optimising device performance, not only at a lab-scale but for large-scale, high-throughput printing and coating methods. This talk will show how *in situ* grazing incidence X-ray scattering (GIXS) gives direct insights into how small-molecule organic semiconductors and colloidal quantum dots self-assemble during blade coating. Results show that for two blends separated only by a small difference in the structure of the small molecule forming the organic phase, crystallisation may proceed down two distinct routes. It either occurs spontaneously or is mediated by the formation of quantum dot aggregates. Irrespective of the initial crystallisation route, the small-molecule crystallisation acts to exclude the quantum dot inclusions from the growing crystalline matrix phase. These results provide important fundamental understanding of structure formation in nanocomposite films of organic small molecules and colloidal quantum dots prepared via solution processing routes. This works highlights the fundamental difference to structural evolution which can be made by seemingly small changes in system composition. It provides routes for the structural design and optimisation of solution-processed hybrid nanocomposites that are compatible with the large scale deposition manufacturing techniques that are crucial in driving their wider adoption in energy harvesting applications.

SESSION CH01.03: Crystal Nucleation and Growth I
Session Chairs: Jungwon Park and Haimei Zheng
Tuesday Morning, November 29, 2022
Hynes, Level 1, Room 102

8:00 AM CH01.03.01
Self-Assembly of Polystyrene on Graphene Nanoplatelets Surfaces Yu-Chung Lin[1], Tavan Bhatia[2], Haaris Alam[3], Ruijia Zhang[4], Gavin Onghai[5] and Miriam Rafailovich[1]; [1]SUNY Stony Brook University, United States; [2]Staples High School, United States; [3]Portola High School, United States; [4]Ed W. Clark High School, United States; [5]Earl L. Vandermeulen High School, United States

Polymer nanocomposites (PNCs) with a reinforced filler, are significant in engineering applications to enhance functional properties. The key parameter that influenced the final performance is the dispersion of the fillers, the shape of the fillers, and polymer-fillers interfacial properties. Thus, it is crucial to investigate the dynamics of the polymer nanocomposites in the melts to understand the behavior of the PNCs. Here, we are trying to design a polymer blend nanocomposite with a better affinity polymer to the Graphene nanoplatelets (GNPs) and a lower affinity polymer to GNPs to create a percolation pathway.
We probed the relative affinity for GNP in PS and PMMA. Affinity for the nanoparticle inclusion is evidenced by adsorption of the polymer chains which decreases the internal tracer diffusion coefficient . Following the method developed by Hu et al for-silicate clays, we performed the following experiments to determine the impact on the internal chain mobility.[1] We made the following four sets of bilayer samples to measure the tracer diffusion coefficient; PS on PS/dPS, PS on dPS/GNP, PS/GNP on dPS/PS, and PS/GNP on dPS/GNPs, where in all cases the DPS and GNP concentrations were 20 and 2 weight percent, respectively. All the samples were annealed at 150oC for 24 hours then the concentration of deuterium, carbon, hydrogen, and Si ions within the sample were profiled using time-of-flight Secondary Ion Mass Spectrometry (TOF-SIMS). The tracer diffusion coefficients for the four types of samples were, 2.8 x10-17cm2/s, 6 x10-18cm2/s, 3.8 x10-17cm2/s, and 1.1 x 10-17cm2/s, respectively. From the data we see that the largest decrease in the coefficient occurred when the GNP was in both upper and lower layers, indicating adsorption of the PS chains to the GNP. A similar study will be performed for PMMA/dPMMA. It is interesting to note that the diffusion coefficient was higher than the control when dPS was migrating towards an HPS layer containing GNP, while the coefficient was lower than the control when the GNP and the DPS were in the same layer. We, therefore, hypothesized that in addition to the adsorption of GNP to PS, preferential adsorption existed between dPS and GNP relative to the PS GNP interaction. This was further investigated by measuring the contact angle between dPS or PS and a graphene-coated Si surface. From the contact angle and the known surface tension, we obtain work of adhesion of 40.42 mN/m and 60.71 mN/m confirming the higher interfacial energy. DFT calculations were performed by placing PS molecules onto graphene surfaces where the energy for different conformations was calculated. In each case, attractive interactions were obtained confirming the diffusion results. Comparing the dPS to HPS calculations we obtain a measurable difference -0.022 eV for fully adsorbed dPS molecules in agreement with the difference in the work of adhesion measured. Comparing the outcome of this study with that of ref 1, we find that the relative difference in attraction between HPS and dPS has to be considered in the interpretation of the results, and dPS cannot use an indiscriminate tracer molecule.

8:15 AM CH01.03.02
Controlled Synthesis of Targeted Nanoparticles Using *In Situ* X-Ray Synchrotron Techniques with Inline UV-Vis Measurements and Machine Learning Assisted Predictions Sanjit Ghose[1], Matthew Greenberg[2], ChengHung Lin[1] and Ai Kagawa[1]; [1]Brookhaven National Laboratory, United States; [2]Bard College, United States

Metal halide perovskites quantum dots (QDs) have recently attracted attention for use in a wide variety of optoelectronic applications, including solar cells

and light emitting diodes, due to their ease of synthesis, strong light absorption, and chemical tunability. The chemical synthesis of these materials enables precise control over the size, shape, and composition. Despite substantial progress in the synthesis of QDs over the past three decades, issues with scalability and batch-to-batch variation persist. These issues are a symptom of the complexity of crystal nucleation, limited understanding of the QDs formation mechanisms, and poor control over the rapid kinetics of formation. To address these issues, we developed a continuous flow reactor with automated input parameter control during the reaction process. The solution is monitored *in situ* to measure the reactants and intermediates along each stage of the nucleation and growth processes. The ability to rapidly canvas the input parameter space and collect *in situ* Synchrotron X-ray and photophysical data generates large data sets to identify the effects of reaction conditions on reaction outcomes. The data was analyzed to obtain corresponding time resolved structure, morphological information, and photophysical properties. Subsequently, using Artificial Iinteligence (AI) & Machine Learning(ML) algorithms to understand the underpinning mechanisms, we identify variables that control the outcome of the colloidal synthesis, and achieve the targeted structure of the PQDs. In this case, we studied sub-sec snap shots of nanocrystal pre-nucleation, nucleation, and growth processes of room temperature flow synthesis of $CsPbX_3$ (X= Br, Cl, I) at NSLS-II synchrotron X-ray beamlines. This approach enables precise control over the synthesis outcome and enhances the speed of targeted Quantum materials discovery.

8:30 AM +CH01.03.03
***In Situ* Transmission Electron Microscopy Imaging of Nanomaterials Growth and Transformations** Haimei Zheng; Lawrence Berkeley National Laboratory, United States

An understanding of nanoscale materials transformations is significant for the synthesis and applications of nanostructured materials. At the atomic level, heterogeneity and fluctuations may play a governing role in the growth and transformation processes. The recent development of high-resolution liquid cell transmission electron microscopy (TEM) has enabled breakthroughs in our ability to follow the atomic level structural, morphological, or chemical changes of materials. Thus, it has provided an unprecedented opportunity to resolve the growth and transformation mechanisms of materials that cannot be predicted based on thermodynamic equilibrium. I will show our recent development of high resolution liquid cell TEM for imaging of nanoscale materials growth and transformations. With the high resolution liquid cell TEM, we have been able to study the defect-mediated ripening of Cd-$CdCl_2$ core-shell nanoparticles (CSN). Ripening was found to start by dissolution of the nanoparticle with an incomplete $CdCl_2$ shell, and that the Cd core that was exposed to the solution dissolved first. The growth of an Cd-$CdCl_2$ CSN was achieved by generating crack defects in the shell, followed by ion diffusion through the cracks. The healing of crack defects led to a highly crystalline CSN at the end. The formation and annihilation of crack defects in the shell, accompanied by disordering and crystallization of the shell structure, mediated the ripening of CSN in the solution. I will also show our in-situ high resolution liquid cell TEM study of the nucleation of CdS nanoclusters. The growth of semiconductor nanocrystals is classical in colloidal nanocrystal synthesis, and it has been studied for many years. However, this is the first time that we were able to achieve direct observe the growth of semiconductor nanocrystals. Many fascinating dynamic phenomena were achieved, and they provide critical insights on their nucleation and growth mechanisms.

9:00 AM CH01.03.04
Effects of Crystallization on the Conductance of HfO_x ReRAM by *In Situ* TEM Method Baoming Wang[1], Alexandre Foucher[1], Thomas Defferriere[1], Teodor Todorov[2], Martin Frank[2], Franco Stellari[2], Takashi Ando[2], John Rozen[2], Harry Tuller[1] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]IBM Thomas J Watson Research Center, United States

HfO_x is broadly explored as a favored material for resistive RAM (ReRAM) device applications. The microstructure, composition and phase of HfO_x all play fundamental roles in the switching mechanisms and stochasticity governing resistive RAM operations, and understanding the relation between the atomistic properties and final device behavior remains challenging. To guide the design of HfO_x-based ReRAM devices, we applied scanning transmission electron microscopy techniques to investigate the structure-property-behavior relationship during operation *in situ.* We developed a process to fabricate lamella devices that showed switching behavior consistent with the macroscopic state-of-the-art HfO_x ReRAM devices from which they had been cut. We then observed the compositional and structural changes taking place during switching of the device and correlated those with the electrical characteristics. We found that crystallization and grain growth occurs during repeated switching, and that the formation of crystalline regions correlates with increases in conductance. Using electron energy loss spectroscopy, we found that the grains formed during switching are more oxygen-depleted than the original amorphous phase. This hints at the role of oxygen vacancies in the conductance of these ReRAM devices. We also showed that other methods of forming crystalline regions, particularly electron beam irradiation, produce structures that are similar to the original amorphous phase or even more oxygen abundant, and do not contribute to increases in conductance. The combination of operando testing and structural and spectroscopic observation yields unique and detailed information on the processes that control switching. From the comparison of the different crystallization mechanisms, we discuss how the microstructure may be controlled to improve the cycling performance of the devices.

9:15 AM CH01.03.05
Multilayer Growth in Ternary InGaAs Nanowires Revealed by *In Situ* Transmission Electron Microscopy Robin Sjökvist, Marcus Tornberg, Mikelis Marnauza, Daniel Jacobsson and Kimberly Dick; Lund University, Sweden

In Situ transmission electron microscopy (TEM) has proven itself to be an important and powerful tool for unraveling many different aspects of III-V semiconductor nanowire growth, including growth dynamics[1–3] and compositional relationships.[4,5] Recently, the *In Situ* TEM investigations have shown the possibility of having more than one biatomic layer nucleate and grow simultaneously at the growth front of binary compound nanowires growing in the vapor liquid solid (VLS) mode.[6,7] The classical view has been that liquid nanoparticle mediated growth only allows the nucleation and growth of singular layers, separated by incubation periods. The discovery of multiple nucleation events and subsequent growth of multilayers contradicts this previous assumption. The finding is important, since the possibility of multiple nucleations will change the way continuous growth is viewed, and unravels more details about the delicate energy balance at the growth front. Therefore, in order to gain a deeper understanding of the nanowire growth process, and to give new insight into axial nanowire growth, the multilayer growth mode must be further investigated.

In this study, the growth of Au-seeded InGaAs nanowires were investigated using environmental TEM, revealing the occurrence of multilayers in ternary nanowires *In Situ*. The experiments were carried out in a Hitachi HF3300S environmental transmission electron microscope with an open cell configuration, integrated with a metal-organic chemical vapor deposition (MOCVD) system. The MOCVD system was used to supply the metal-organic and hydride precursors for the growth near a resistively heated, partially electron transparent micro-electro-mechanical system (MEMS) chip. Pre-deposited Au nanoparticles on the MEMS chip collected the growth material and initiated the growth of the nanowires. The growth was observed and recorded using a Gatan OneView IS camera, and compositional analysis was carried out through X-ray energy dispersive spectroscopy.

We show that multilayer growth is more prominent in InGaAs than for the binary cases previously shown, and that when multilayer growth occurs, the stacks of layers growing simultaneously can reach much larger sizes.[7] The multilayer stacks are observed in conjunction with defects in the material, such as crystallographic twins and small compositional changes, but also at sharper compositional heterostructures. Importantly, material transport is observed between the simultaneously growing layers, indicating that the final composition of the segment could be affected. We have also observed multilayer growth as an intermediate step to kinking, a process where the nanowire changes growth direction, which is often unwanted. Since composition and

uncontrolled kinking of the nanowire greatly affects its properties and performance, the discoveries are important for device applications. This shows why multilayer growth needs to be further explored, so that it can be controlled and accounted for in future nanowire growth.

***In Situ* Monitoring of 2D Nanocrystal Nucleation and Growth Kinetics by Using Time-Resolved Liquid Interface Grazing Incidence X-Ray Scattering Techniques** Ziyi Zhang and Xudong Wang; University of Wisconsin - Madison, United States

The design and synthesis of high-quality two-dimensional (2D) materials with desired morphology are essential for property control. One critical challenge that impedes the understanding and control of 2D crystal nucleation and growth is the inability of direct observation of the nanocrystal evolution process with high enough time resolution. Here, we demonstrated an in situ X-ray scattering approach that directly reveals 2D nanocrystal nucleation and growth at the air-water interface.[1] A-few-nm thick wurtzite ZnO nanosheets (NSs) were grown through the ionic layer epitaxy (ILE) method with the guidance of an ionic surfactant monolayer at the air-water interface. Fast monitoring of both in-plane and out-of-plane crystal structures were achieved with a time resolution of only a few minutes by applying grazing incidence X-ray diffraction (GID) and grazing incidence X-ray off-specular scattering (GIXOS) techniques, allowing direct observation of the 2D crystal nucleation and growth processes with a unit-cell resolution. We discovered an obvious lattice deformation in the first two surface layers, which is different from the inner bulk phase. This discovery of surface strain in ILE may open a new route toward strain-induced physical property tuning of 2D nanomaterials by surfactant engineering. Our results also uncovered a lateral to vertical growth kinetics switch phenomenon in the ZnO nanosheet growth. This switch represents the 2D to three-dimensional (3D) crystal structure evolution, which governs the size and thickness of nanosheets, respectively. This phenomenon evidences the significance of the surfactant monolayer in ILE NS growth and can guide 2D nanocrystal synthesis with rationally controlled size and thickness. In addition, we show the impacts of different synthesis parameters on the NS growth behavior. Higher surfactant density enhanced the effects of the electrical double layer extending the lateral growth period, and higher Zn^{2+} concentration accelerated the 2D crystal growth, which is both favorable for large NS morphology formation. These results provide fundamental insights into the surfactant templated 2D growth mechanism in the ILE NS synthesis. The successful in situ diffraction characterization expands the toolbox and opens a new pathway to reveal the fast crystal nucleation and growth kinetics at the liquid interfaces by using time-resolved grazing incidence X-ray scattering techniques.

Optimization of Growth and Properties of Unintentionally Doped Single Crystalline Ga_2O_3 Using Pulsed Laser Deposition Kishor Upadhyaya[1], Naga Krishnakanth Katturi[1], Katharina Lorenz[2] and Iman S. Roqan[1]; [1]King Abdullah University of Science and Technology, Saudi Arabia; [2]Instituto Superior Técnico, Campus Tecnológico e Nuclear, Portugal

Although pulsed laser deposition (PLD) is one of the most cost-effective techniques for growing epitaxial thin films, its use for obtaining single-crystal β-Ga_2O_3 is still challenging. In this work, we report on the systematic investigation of the effect of PLD growth conditions on the structural and optical properties of β-Ga_2O_3 thin films grown on different substrates, such as sapphire, Si, p-GaN and Ga_2O_3. X-ray diffraction (XRD) analyses show that the films grown on sapphire and p-GaN exhibit a single crystalline structure along the [-201] direction, while the films grown on Si substrate are polycrystalline in nature with [400] direction as the dominant peak. Increase in the substrate temperature and the number of laser pulses results in a considerable peak shift in 2θ-scans irrespective of the substrate used, indicating presence of strain in the film. The XRD rocking curves are investigated to evaluate the crystal quality with respect to the type of substrate and growth conditions. While Field Emission Scanning Electron Microscope (FESEM) images reveal variations in the morphology, High Resolution Transmission Electron Microscope (HRTEM) characterizations show different structural defects that affect the material quality, the extent of which is observed to depend on the growth conditions and the substrate type. Atomic force microscopy (AFM) analyses further reveal that the surface roughness changes as the temperature increases from 800^0C to 850^0C, as well as due to the increase in the number of laser pulses. For the optimized samples, optical characterizations show a typical Ga_2O_3 absorption curve, while a defect band emission is weak. However, the energy gap of the samples widens as the growth temperature and the number of laser pulses are increased. Raman spectroscopy analyses shows the effect of defects and strain on the material quality. Post-annealing under different conditions is carried out, and structural as well as optical characterizations reveal enhancement in the film properties. The results obtained in this study will assist in the optimization of β-Ga_2O_3 properties, which is essential for its use in optoelectronic and high-power device applications.

Nucleation, Growth and Shape Transformation of Nanoparticles by *In Situ* TEM Jungwon Park; Seoul National University, Korea (the Republic of)

Molecular or atomistic mechanistic understanding of nucleation, growth, and structural transformations of materials have not achieved enough at the nanoscale or below. It is mainly because of a lack of appropriate analytical methods that can obtain in-situ structural information with a spatial resolution at such small length scale along with sub-msec temporal resolution. The in situ, both in liquid phase and dry state, transmission electron microscopy (TEM) offers an opportunity to directly observe diverse classes of chemical reactions. In liquid phase TEM, there are two-types of liquid cell that are widely used: silicon nitride window liquid cell and graphene liquid cell. The former allows real time observation in relatively low spatial resolution but it is possible to incorporate electrical biasing or heating conditions into imaging. The latter suggests an opportunity for high-resolution in situ imaging of materials reactions occurring in thin liquid media. Here we present applications of in situ TEM to study nucleation, crystallization, and shape transformation of diverse types of nanoparticles. We reveal that the early stage of crystal growth is driven by reversible transition between disordered and ordered phases before crystalline phase is stable above a certain size. It is also frequently observed that different types of non-classical pathway, including two-step

nucleation, amorphous-to-crystalline transition, and coalescence of clusters, are heavily involved in different conditions of crystallization of materials. We also present a new development using liquid phase TEM to investigate 3D atomic structures of nanoparticles directly in the colloidal synthesis batch.

Exploring the Dynamics of the III-Sb Nanowires During *In Situ* Growth Mikelis Marnauza, Robin Sjökvist, Marcus Tornberg, Daniel Jacobsson and Kimberly Dick; Lund University, Sweden

Group III-Sb semiconductor nanowires (GaSb, InSb, AlSb and their combinations) are an important material system for potential uses in applications such as quantum electronics, optoelectronics and sensing. This is due to their excellent electrical properties, including high carrier mobility and narrow band gap.[1] Among the III-Sb materials perhaps the most notable examples are InSb and GaSb nanowires which display the highest electron and hole mobilities among III-V nanowires, respectively.[2]
Despite the superior properties of this material system little research has been conducted into it when compared to other group III-V materials, such as group III-As. To a large extent this is caused by the complex growth conditions of antimonides, as elemental antimony exhibits low vapour pressure and surfactant effect.[3] The investigation of this material system is further complicated by the difficulty of growing III-Sb nanowires directly from single crystal substrates often resulting in the need to use III-As/III-Sb heterostructures.[1,4] In these heterostructured nanowires several dynamic effects can take place when switching from the III-As to the III-Sb segment such as unwanted radial expansion, change in crystal structure and facet change. Therefore, exploring the III-Sb growth parameter space has become unrealistic using conventional growth methods like metal organic chemical vapour deposition (MOCVD) which notoriously does not allow examination of the growth dynamics.
In this work, we have investigated the III-Sb nanowire growth process by growing these nanowires in-situ using an open cell Hitachi HF-3300S environmental transmission electron microscope combined with an MOCVD system.[5] To facilitate nanowire growth, metal-organics and hydrides were used as precursors and introduced near a SiN_x micro-electro-mechanical system (MEMS) heating chip covered with pre-deposited Au nanoparticles. To analyse nanowires during growth we employed X-Ray Electron Dispersive Spectroscopy (XEDS) measurements in combination with atomically resolved high-resolution transmission electron microscopy (HRTEM) imaging and videos.
We focus on the III-As/III-Sb heterostructure formation; wherein we have investigated droplet composition during growth, changes in nanowire morphology, and the connection between droplet composition and growth dynamics. Special attention is directed towards the GaAs/GaSb heterostructures where we have demonstrated that radial expansion of the GaSb segment can be minimized by fine-tuning of TMGa flow. Additionally we demonstrate that both excess TMGa and TMSb supply in the vapour phase can lead to kinking of the nanowires.
Results of this study have given insight into the connection between droplet composition and nanowire diameter during III-As/III-Sb heterostructure formation. This knowledge could ultimately be used in fabricating smaller diameter nanowire heterostructures ex-situ, important for device applications.

***In Situ* Investigation of Crystallization Pathway of Solution-Processed Magnesium-Alloyed Zinc Tin Oxide Thin Films** Baran Demir and Rebecca L. Peterson; University of Michigan, United States

Multi-cation metal oxides are a key material class for applications in solar cells, electronics and sensing technologies, as well as batteries and fuel cells. For successful use in these applications, it is crucial to control the material crystallinity. Crystalline metal oxides are valuable for gas sensing applications, where improvement in sensing qualities is linked to the material's crystal structure and quality. Amorphous-phase metal oxides are commercially used for dielectrics in CMOS and as semiconductors in the display backplane industry due to their excellent electrical properties. In particular, zinc oxide alloys exhibit a wide, direct bandgap in the UV. Here, we choose as a base material amorphous zinc tin oxide, an n-type semiconductor with mobility of about 22 $cm^2V^{-1}s^{-1}$ and a bandgap of about 3.0 eV [1,2]. By alloying this material with magnesium, we aim to further increase its bandgap and improve the insulating property of this quaternary alloy. To obtain these improvements, we need to understand and control its crystallization.

Therefore, in this work, we use *in situ* heating grazing incident x-ray diffraction (GIXRD) to examine the effects of magnesium alloying on crystallization of zinc tin oxide (ZTO) thin films. Four ZTO films - one unalloyed and three alloyed with Mg - are deposited on Si/SiO_2 substrates using solution processing. The Mg metal ratio, [Mg]/([Mg]+[Zn]+[Sn]), was 2.5%, 7.5%, 20% for the three alloyed samples. All films were x-ray amorphous after the deposition process. In order to investigate the crystallization pathways and the effect of Mg incorporation, films were slowly annealed up to and beyond their crystallization temperatures. The evolution of crystalline phases was observed by *in situ* heating during x-ray diffraction using Rigaku SmartLab. XRD data was collected from 500°C to 750°C using 20°C increments to extract crystallization temperatures. The data for higher temperatures was collected from 550°C to 1050°C using 100°C increments by using new samples. Heating time of 1 hour was set between each increment.

All of the films have a Zn-to-Sn metal ratio of 7:3 which is close to the stoichiometric ratio in inverse spinel Zn_2SnO_4. For this stoichiometry, the inverse spinel is expected to be the most stable phase. However, our *in situ* XRD shows that the unalloyed film crystallizes predominantly in an orthorhombic structure around 650°C. Similar results have been seen in low-dimensional ZTO structures obtained by solution processing or hydrothermal synthesis [3,4]. At temperatures above 750°C, the unalloyed film begins to show spinel peaks, and this matches the theoretical thermodynamic stability calculations of ZTO systems [5]. When Mg is introduced into the system, a mixed phase film containing inverse spinel and orthorhombic phases forms at temperatures below 750°C. As the Mg percentage increases to 20%, the orthorhombic x-ray peaks completely vanish and the thin film crystallizes into a single spinel phase. This is expected, as spinel is the stable phase for the $Mg_{2-x}Zn_xSnO_4$ system. After a slow cooling process down to 50°C, the spinel peaks disappear from the unalloyed ZTO thin film, whereas they remain for the 20% Mg-incorporated sample. To summarize, ZTO without Mg first crystallizes into an orthorhombic structure before converting toward the spinel phase at higher temperature, whereas Mg incorporation into ZTO strongly promotes the formation of spinel-phase crystals, over orthorhombic. By tailoring the Mg content, the crystal structure and crystallization dynamics can be controlled to obtain the desired materials properties and function.

A Kinetic Isotope Effect in the Formation of Lanthanide Phosphate Nanocrystals Gal Schwartz[1], Uri Hananel[1], Liat Avram[2], Amir Goldbourt[1] and Gil Markovich[1]; [1]Tel Aviv University, Israel; [2]Weizmann Institute of Science, Israel

Studies of kinetic isotope effects in various reactions have been useful for elucidating reaction mechanisms, and it is believed that the same may apply for crystal formation kinetics. We present a kinetic study of the formation of europium-doped terbium phosphate nanocrystals under acidic conditions, including a strong H/D isotope effect. The nanocrystal growth process could be quantitatively followed through monitoring of the europium luminescence intensity, combined with ^{31}P NMR kinetics measurements. Such lanthanide-based nanocrystals may serve as an excellent model system for further studying and gaining a deeper understanding of crystal nucleation and growth processes. We conclude that the observed delayed nucleation occurs due to initial formation of pre-nucleation clusters or polymers of the lanthanide and phosphate ions, which undergo a phase transformation to crystal nuclei and further grow by cluster attachment.

1:30 PM *CH01.04.01
Probing Nanoparticle Optical Properties and Responses with *In Situ* Electron Microscopy Piyush Haluai, Yifan Wang, Martha McCartney and Peter A. Crozier; Arizona State University, United States

The interaction of materials with photons is critical to many technologies including opto-electronic devices, photovoltaics and photocatalysis. The optical response is determined by the real and imaginary parts of the dielectric function which can in turn be impacted by the ambient conditions such as temperature, gas/liquid environment as well as structural factors such as point defects and interfaces. To explore the optical response of materials at the nanometer level, we have developed *in situ* optical illumination systems for transmission electron microscopy (TEM) [1-3]. The system is installed in an FEI Titan environmental TEM and is compatible with both heating, cooling and gas ambients. Materials can be thermally processed in a variety of different gases and illuminated with light. Optical properties and responses can be probed *in situ* with monochromated electron energy-loss spectroscopy (EELS) and electron holography.
In semiconducting devices, separation of electron-hole pairs generated via photon absorption is often facilitated by selective charge transport across heterostructure interfaces. The efficiency of the charge transfer process will depend on materials' thermodynamics and kinetic factors regulated by interface characteristics (such as Schottky barriers). We have been exploring the variation in the charge state of supported metal nanoparticle photocatalysts using *in situ* electron microscopy. Specifically, we have investigated the effect of visible light absorption in Ni supported on Rh-doped strontium titanate particles [4]. During illumination, electrons generated from photon absorption may transfer to the metal nanoparticle changing its charge state. Electron holography allows us to detect phase shifts in the fast electron wavefunction associated with photon illumination.
The optical properties of oxides are strongly affected by the concentration of point defects such as oxygen vacancies and dopants. In dielectric materials, photonic or guided light modes may be present which depend on both the nanoparticles shape, size, and refractive index [5]. For many non-stoichiometric oxides such as CeO_2, the oxygen vacancy concentration can be affected by the temperature and oxygen partial pressure. We are investigating the variation in photonic modes with changes in temperature and gas environment. The change in the photonic modes might be associated with changes in density and oxygen vacancy concentration leading to corresponding variations in the refractive index [6]. The sensitivity of photonic modes to small changes in the optical properties of materials is being explored.

Synthesis and Incorporation of Buffer Components into the Framework of Bioinspired Polyserotonin Keuna Jeon[1,2], Justin Asuncion[1,2], Alexander Corbett[1,2], Tiange Yuan[2], Meera Patel[1,2], Nesha Andoy[2], Oleksandr Voznyy[1,2] and Ruby Sullan[1,2]; [1]University of Toronto, Canada; [2]University of Toronto at Scarborough, Canada

Polyserotonin is a new class of bioinspired nanomaterial with recently demonstrated therapeutic potential in biomedical applications and surface coatings. It is therefore important to establish a robust and rapid method of synthesizing polyserotonin nanoparticles (PSeNP) and films for *in vivo* utilization. Since the formation of PSeNP is based-catalyzed, we report the influence of solution pH, in the presence of different base systems, on the kinetics of PSeNP formation and physico-chemical properties of the resulting polyserotonin. We show that the rate of formation and the size of PSeNP depend on both the nature of the base and the initial pH of the reaction. In addition, we show that buffer components are incorporated into the polymer matrix. While we observe no difference in elasticity of PSeNP synthesized in different buffers, the nanoscale properties of polyserotonin films revealed dissimilarities in surface functional groups influenced by solvent molecules. This presents a significant advance in the polyserotonin synthesis and provides a facile approach in tuning the size and surface functionality of PSe nanomaterial to suit various applications. Furthermore, we show that similar to serotonin, PSeNP also exhibits free-radical scavenging property. Our results demonstrate that PSeNP has the potential to become a key player in the advancement of nanotehcnoogy-mediated antioxidative therapy.

2:15 PM CH01.04.03
Study of Ultra-Thin ALD Grown Gallium Oxide Films by *In Situ* Ellipsometry with Unambiguous Thickness and Optical Property Determination
Florian Maudet[1], Sourish Banerjee[1], Hanno Kröncke[1], Sven Wiesner[1], Veeresh Deshpande[1] and Catherine Dubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

Atomic layer deposition (ALD) of metal oxide is a chemical vapor deposition method that relies on the cyclic self-limited deposition of a metal precursor molecule followed by an oxidizing reactant specie. To study the growth process, spectroscopic ellipsometry is one of the favored *In Situ* characterization as it can be used in a non-UHV environment, and it has a high surface sensitivity. This method can be applied to monitor the evolution of the thickness and of the complex dielectric permittivity of the film. However, as ultrathin films are considered, the relative contributions of the dielectric permittivity and thickness cannot be disambiguated from a model as it is usually done for thicker films. To solve this issue, a fixed dielectric constant is usually considered and only the thickness evolution is studied. However, this is fundamentally incorrect. Each of the four steps during one ALD cycle is indeed specific to a different chemical reaction/mechanism happening on the surface. The optical properties of the precursor molecule absorbed on the surface or of a sub-monolayer film are different from those of a dense layer. Furthermore, a change in the optical properties of the film will be interpreted as a thickness evolution. Here, we present a method to unambiguously determine the thickness and optical properties of the growing oxide in an *in situ* measurement. We apply this method to analyze the evolution of the optical properties in the first stages of the growth of gallium oxide deposited by plasma enhanced ALD. Trimethyl gallium and O_2 plasma are used as a precursor and oxidizing agent respectively. We determine the change in thickness as a function of time for each step of an ALD cycle with a relatively high sampling rate (100 ms). The role of the O_2 plasma exposure time on the growth and optical properties of the films is analyzed and correlated to their electrical properties. The study of the optical properties reveals that a "bulk-like" gallium oxide film is obtained after ~35 PEALD cycles corresponding to a thickness of 2.35 nm. The bandgap of the growing thin film is at first much larger (5.41 eV) than its bulk counterpart (4.97 eV) and then progressively decreases with increasing number of cycles, tending towards the bulk value. Quantum confinement occurring at reduced dimensions is at the origin of the increased band gap value.

2:30 PM CH01.04.05
***In Situ* Imaging of CDW Phase Transition in Two-Dimensional Rare-Earth Tellurides Using 4D-STEM** Saif Siddique[1], James L. Hart[1], Ratnadwip Singha[2], Leslie Schoop[2] and Judy Cha[1]; [1]Cornell University, United States; [2]Princeton University, United States

Rare earth tellurides of the form RTe_3 (where R is a rare-earth element) are quasi-two-dimensional materials, with an orthorhombic crystal structure having two consecutive square-planar Te sheets separated by corrugated R-Te slabs. Peierls instability in the square Te sheets results in charge density wave (CDW) ordering in these materials.[1] The physics involving CDW order in RTe_3 is interesting because of its interplay with other quantum states hosted by this class of materials, such as superconductivity and spin-density waves. A recent report shows the existence of axial Higgs mode in this system which in turn show the unconventional nature of the CDW states and complexity of the associated order parameter.[2] To gain an understanding of the changes in the local structure and to track the complex order parameter across the CDW phase transition, we use 4D-STEM (scanning transmission electron microscopy) for a nanoscale structural characterization. Previous works show the dependence of CDW transition temperature (T_{CDW}) on the thickness of the 2D flakes, which are attributed to the lattice compression/expansion of the inner Te sheets.[3] However, this was never confirmed by atomic-scale imaging. A continuously variable temperature cryogenic TEM specimen holder (developed by HennyZ Co.) is used to image the sample using 4D-STEM, which gives both real- and reciprocal-space information, allowing us to track the CDW phase transition as a function of temperature and nanoscale confinements.

Self-Organized Lateral Polymorphic Regrowth in Ion Irradiated Gallium Oxide Andrej Kuznetsov; University of Oslo, Norway

Gallium oxide is an ultra-wide bandgap semiconductor exhibiting a number of unique properties and promising applications for power electronics and optoelectronics. Importantly, galium oxide can be crystallized in a range of different polymorphs having different structures and, consequently, different physical properties, which can be potentially exploited in the devices. However, gaining control over the polymorphic transitions in a technologically viable way is a challenge. Very recently, a novel method to form such polymorph films was discovered, specifically applying paradoxical idea of the disorder-induced ordering in ion beam irradiated samples [1]. The present talk reviews the data from Ref [1] and extends the description with not yet published data. In particular, including a spectacular ex-situ and in-situ observations of the lateral solid state polymorph regrowth at the interfaces between different polymorphs as well as reporting on the functionalities of the gallium oxide polymorph films and interfaces. Altogether, these novel data pave the way for a new synthesis technology of the metastable polymorph heterostructures and regularly shaped interfaces in device components not atchivable by conventional deposition methods.

3:45 PM CH01.04.07
***In Situ* Studies of Crystalline Polymer Formations via Topochemical Reactions** Chongqing Yang[1], Rebecca S. Khoo[1,2], He Li[1], Christopher Anderson[1,2], Christopher G. Jones[3], Carolin M. Sutter-Fella[1], Jian Zhang[1], Hosea M. Nelson[3] and Yi Liu[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]California Institute of Technology, United States

To address the negative environmental influence associated with the fabrication of synthetic polymers, the development of eco-friendly and sustainable chemistries has been crucial but challenging. Distinct from the conventional solution-based polymer growth, topochemical polymerization (TCP) offers a 'green' way for scalable fabrication of high fidelity polymers without the need of catalysts, auxiliaries, or solvents. With crystallinity embedded during the synthesis, it is also one of the few ways to produce single crystalline polymers suitable for atomic structure determination. However, only a handful of TCP reactions have been reported to date, and it is still challenging to expand new chemistries in this area, due to the difficulty in controlling the reactivity in crystalline solids. Moreover, most of the polymers from TCP reactions have low solubility which renders their characterization and application challenging. In this work, we present that an azaquinodimethane (AQM) family has shown great topochemical reactivity in the forms of single crystals, polycrystalline powders, and thin films under visible light irradiation or heat. The resultant crystalline polymer structures were successfully resolved by single crystal X-ray diffraction (for large crystals), or cryo-EM based microelectron diffraction with 1 Å resolution (for microcrystals). The high efficiency of solid-state polymerization was evidenced by the ultrahigh molecular weight (M_w>10^6 g/mol) of a soluble TCP polymer bearing pendent 3,5-dihexyloxyphenyl groups.

Moreover, the solid-state reactivity of AQMs also shows remarkable functional group tolerance, allowing the introduction of different side groups without decreasing the polymerization efficiency. Notably, the intensity of the absorption peaks of monomers in the range of 400-500 nm undergoes a characteristic decrease upon polymerization. This spectroscopic change provides a distinctive optical feature to track the polymerization process via in-situ UV/vis characterization with a time resolution of 0.1 s. Kinetic studies of AQM polymerization showed a relatively small activation energy of ~19.7 kcal K^{-1} mol^{-1},providing key quantitative information of the easily accessible and fast polymerization process. Further kinetic details were obtained from the temperature-dependent polymerization of AQMs bearing different conjugated aromatic units or chiral sidechains, allowing fundamental understanding of a structure-reactivity relationship of such AQMs. Such insight paves the way for the future design and synthesis of functional polymers in an environmentally friendly way.

4:00 PM CH01.04.08

Characterisation of Nucleation and Growth of Mineral Phases Colin Freeman, Emma Armstrong, Vittoria Fantauzzo, Stephen Yeandel and John Harding; University of Sheffield, United Kingdom

There remains strong interest in the formation of inorganic molecular salts including $CaCO_3$ $CaSO_4$ and KNO_3. These materials are ubiquitous as they are found in nature within geological and biological settings but are also used extensively within industry. They are challenging to study due to the range of speciation and phases that can form out of solution and the strong influence of supersaturation, concentration and interfaces. Computational methods remain a powerful tool for characterising the formation of materials. We can use these techniques to test our fundamental understanding such as classical nucleation theory and step-based growth models. Computational approaches can also provide a detailed atomic scale view of the processes taking place during nucleation and growth which are often beyond the lengthscales of experimental techniques.

We present a set of classical atomic scale simulations on inorganic molecular salts. We demonstrate the use of a new methodology to produce interfacial free energies of these materials which allows us to predict phase formation and morphologies of the crystals to compare with experiment and test the applicability of classical nucleation theory to the formation of these phases. We further explore phase growth by utilising constant chemical potential reservoirs to link simulations to more realistic solution concentrations. We discuss the further potential impact of computational methods in exploring material synthesis.

4:15 PM CH01.04.09

Controlling Crystallisation Using Surface Topography Thomas Dunn, Phillip Lee, Stuart Micklethwaite, Alexander Kulak, Liam Hunter, Zabeada Aslam, Johanna Galloway, Yi-Yeoun Kim and Fiona Meldrum; University of Leeds, United Kingdom

The use of heterogeneous nucleants to trigger crystallisation provides a means of controlling the size/structure of the crystals produced, where they form, and the induction time. However, with the exception of structural matching, there is little rationale for the identification of effective nucleants for many crystals. In this work, we explore the potential of using surface topography to direct crystal nucleation, where evidence is scattered across the literature that nucleation is promoted in features such as pits, pores and scratches. Substrates patterned with natural surface cracks are created in this study. These cracks spontaneously form in brittle materials whose surfaces are under strain. The cracked substrates are then coated with a thin film of a noble metal and chemically functionalised to optimise the surface chemistry. Controlling both the topography and surface chemistry of these substrates is shown to be highly effective in directing the nucleation of a range of substances including various inorganic and organic crystals. The origin and universality of this phenomenon is explored to determine how the topography and chemistry of a surface can promote the nucleation of a specific crystal. Controlling surface topography is therefore a valuable and frequently overlooked tool in controlling nucleation and can be used in the design of effective nucleants.

***In Situ* Study of (1) Aqueous Room-Temperature Synthesis of Crystalline Nano-Ceria and (2) Nano-Zirconia—Transformation from Amorphous to Crystalline Phase(s)** Siu Chan; Columbia University, United States

In-situ studies are presented: (i) Ultra-Small-Angle X-ray Scattering (USAXS) of the formation and growth of nano-ceria (n-CeO_2) (ii) Wide Angle X-Ray Diffraction (WAXRD) of the amorphous-to-cubic crystallization of nano-ZrO_2 in a reducing environment. In the first study, in situ monitoring of characteristics from 1nm as a function of the temperature allowed for the identification of the nucleation and growth of ceria nano-crystals. Monitoring flow rate, temperature and pH of the suspension have permitted real-time studies of the nano-ceria crystalline synthesis from homogeneous solution over many hours. Incubation times for each temperature and minimum critical nucleus-size of 6nm have been identified which yield the interfacial energy of n-CeO_2 in the aqueous solution. Activation energy for growth has been measured to be ~0.5eV. In the second study, pair distribution function and reverse Monte Carlo simulation were applied to provide details of the local structure during the crystallization. The local structure of the amorphous phase bears resemblance to the short-range arrangement of cubic ZrO_2. The amorphous-to-cubic (a−c) crystallization of nanoZrO_2 in a reducing environment was studied. A reverse Monte Carlo (RMC) simulation provided details of the local structure during the crystallization process as well as partial Pair Distribution Function's (PDF's) of Zr−Zr and Zr−O during the crystallization. The number of Zr's next-nearest neighbors of Zr remains 12, whereas the number of O's as nearest neighbors of Zr increases from 6.7 to 7.3 as the amorphous evolves into a cubic structure, suggesting the persistence of a high concentration of oxygen vacancies. The simulated atomic local structure of the amorphous phase bears resemblance to the short-range arrangement of cubic ZrO_2, consistent with the results of X-ray Absorption Near Edge Spectroscopy (XANES) at Zr L_{II} and L_{III}. The amorphous-to-crystalline phase transformation is affected by the environment. Under an oxidizing condition, the amorphous phase crystallizes directly to tetragonal and subsequently to monoclinic zirconia.

Towards the Detection of Spin Charge Accumulation at a Metal/Insulator Interface Using High Energy Resolution STEM-EELS Khalil El Hajraoui[1,2], Vlado Lazarov[2], Quentin Ramasse[1,3] and Demie Kepaptsoglou[1,2]; [1]SuperSTEM Laboratory, United Kingdom; [2]University of York, United Kingdom; [3]University of Leeds, United Kingdom

Magnonics is an emergent field within spintronics utilising the ability to generate and propagate controllably a spin-wave (or magnon) in nm-sized magnetic structures, with a view to build a new generation of devices for data processing and storage. It was also recently demonstrated that magnons can be utilised to convert spin to charge (or charge to spin) currents, a critical step for integration of spin and charge devices. However, despite recent progress in the field, many challenges hinder further practical development due, among other factors, to a lack of experimental methodologies to probe these processes directly at the nanoscale, and in particular in the vicinity of interfaces, thus limiting our fundamental understanding of these phenomena. State-of-the-art monochromated electron energy loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM), which offers the ability to map materials and atomic structures with an angstrom size electron beam and an energy resolution for EELS under 5meV, was proposed to be a leading candidate technique to attempt the detection of magnons at the nanoscale, perhaps down to at the atomic scale, thanks to a recently developed theoretical calculation framework and preliminary experimental investigations [1]. Here, we report on progress in designing experiments building on these initial steps using in-situ STEM-EELS. The prototypical spin-to-charge conversion system considered for this proof of principle attempt consists of Yttrium Iron Garnet (YIG)/platinum (Pt) bilayer, a widely used materials combination where a magnon created by a thermal gradient creates spin accumulation at the YIG/Pt interface, which subsequently diffuses into the nonmagnetic Pt, and via inverse spin Hall effect (ISHE) creates a voltage signal in the Pt layer [2]. We aim to correlate the atomic structure to the spin-to-charge conversion properties in a working device using in-situ heating STEM-EELS, making use of custom-made silicon nitride (Si_3N_4) membranes where a focused ion beam (FIB) lamella extracted from the YIG/Pt device is electrically connected to a specific heater geometry allowing local Joule heating to create the required gradient of temperature along it. Plasmon energy expansion thermometry, a nanoscale temperature mapping EELS technique is used to monitor the temperature at the metal contact as well as the temperature gradient along the FIB lamella, while HR-EELS signal at the interface is correlated to the local structural and chemical environment.

Contribution of Carbon Nanopores Towards the Improved Performance of Ionic Liquid-Based EDLCs at Sub-Zero Temperatures Vladimir Pavlenko[1,2]; [1]Al-Farabi Kazakh National University, Kazakhstan; [2]Nazarbayev University, Kazakhstan

During the presentation an important role of nanopores investigated in electric double-layer capacitors (EDLCs) operating from 24 °C down to −50 °C by using carbons with hierarchical porosity will be discussed. Home-made carbons were prepared using different precursors as the carbon source, while a binary mixture of imidazolium-based fluorinated ionic liquids was used as a solvent-free electrolyte. It will be shown that short-range graphene layers produced with 8-nm silica nanoparticles lead to the creation of transport channels which better accommodate ions. We explain these findings per coulombic interactions among the ions and between the pore wall and the ionic species under confinement and electrochemical polarization conditions. Further, it will be shown that a microporous carbon performs better than hierarchical carbons at room temperature; however, owing to the large fraction of mesopores, the latter exhibit far higher capacitance down to−50 °C. While the ordering of ions in confinement is more critical at room temperature and dictated by the micropores, low temperature performance of supercapacitors is determined by the mesopores that provide channels for facile ion movement and keep the bulk ionic liquid–like properties.

9:15 AM CH01.05.04
Hydrogen Network in a Tetrapeptide Crystal Characterized by X-Ray Diffraction and Raman Spectroscopy Kazunori Motai[1], Masaki Kawano[1], Takehiko Mori[1], Yuji Mochizuki[2] and Yuhei Hayamizu[1]; [1]Tokyo Institute of Technology, Japan; [2]Rikkyo University, Japan

In recent years, much attention has been paid to research aimed at elucidating the self-assembly mechanism of dipeptides, the smallest constituent unit of living organisms [1]. Attempts have been made to develop enzyme-inspired peptide-based supramolecular catalysts and to apply them to green piezoelectric materials that meet the requirements of biocompatible ultra-sensitivity, flexibility, and durability. In understanding their functionality, hydrogen bonds play should be investigated due to their important role in stabilizing the steric structure of proteins and in expressing their functions. The strength of hydrogen bonds has been investigated by single-crystal structural analysis and spectroscopic techniques. Nakamoto et al. found a linear relationship between the stretching vibrational modes of hydrogen bonds and the interatomic distance[2]. Elena et al. have combined angle-resolved Raman measurements and single-crystal structure analysis to investigate the thermal behavior of amino acid derivative crystals[3]. However, these studies were limited to relatively small molecular compounds such as amino acids. In this study, the hydrogen bonding network in peptide crystals was investigated using the tetrapeptide FEFE as a model system. Single-crystal X-ray structure analysis revealed that the crystal structure of FEFE has branched hydrogen bonds. Raman spectroscopy showed that the vibrational frequencies of the amide bonds correlate linearly with their interatomic distances. On the other hand, the lattice expansion-dependent vibrational frequency shift is significantly smaller than in previous studies. Our fragment molecular orbital (FMO) calculations revealed that branched hydrogen bonds affect the strength of hydrogen bonds differently from the Nakamoto diagram.
Branched hydrogen bonds in proteins have been studied using both experimental approaches and computational analysis[4][5]. Our findings differ from previous works investigating amino acids or other small organic molecules and made a connection with natural proteins as a model system of peptides. We believe that this study opens a way for discussing the effects of branched-type hydrogen bonds in various peptide crystals.

***In Situ* Nanoscale Characterization of Electrical and Magnetic Properties of 3D Nanostructures by Combination of AFM, SEM and FIB** Christian H. Schwalb[1], Hajo Frerichs[1], Lukas Stühn[1], Sebastian Seibert[1], Marion Wolff[1], Michele Brugger-Hatzl[2], Lukas Seewald[2], Robert Winkler[2] and Harald Plank[2]; [1]Quantum Design Microscopy GmbH, Germany; [2]Graz University of Technology, Austria

Combining different analytical methods into one instrument is of great importance for the simultaneous acquisition of complementary information. Especially the in-situ combination of scanning electron microscopy (SEM) and atomic force microscopy (AFM) enables completely new insights in the micro and nano-world. In this work, we present the unique in-situ combination of scanning electron and ion microscopy (SEM/FIB) and atomic force

microscopy (AFM) for nanoscale characterization [1-2].
We will present a variety of case studies to highlight the advantages of interactive correlative in-situ nanoscale characterization for different materials and nanostructures. We show results for *in-situ* electrical characterization by conductive AFM for 2D materials as well as electrostatic force microscopy (EFM) of piezoceramic films that enables the precise analysis of grain boundary potential barriers in semiconducting $BaTiO_3$-based ceramics [3]. The grain boundaries were located by BSE-SEM and afterwards measured with in-situ EFM. The barriers were shown to be significantly thinner and more pronounced as the amount of SiO_2 was increased from 0 to 5 mol%. These results can be directly correlated with electron backscatter diffraction (EBSD) measurements in order to link the AFM and SEM data to the crystallographic microstructure.
In addition, we will present results for the in-situ characterization of magnetic nanostructures by combination of SEM and high-vacuum magnetic force microscopy (MFM). For the in-situ MFM measurements we use specialized magnetic cantilever probes that are fabricated using electron beam-induced deposition (FEBID) for high-aspect ratio magnetic tips that surpass standard magentic cantilever tips in lateral and magnetic resolution. The SEM enables to identify the grain boundaries on multilayer thin-film samples or stainless steel in order to measure the magnetic properties directly via MFM with nanometer resolution.

Atomic-Resolution Electron Microscopy of Catalyst Dynamics Fu-Rong Chen[1], Dirk Van Dyck[2], Christian Kisielowski[3], Lars Hansen[4], Martin Ek Rosén[5], Christian D. Damsgaard[6,6], Joerg R. Jinschek[6,6] and Stig Helveg[6]; [1]Hong Kong City University, Hong Kong; [2]University of Antwerp, Belgium; [3]Lawrence Berkeley National Laboratory, United States; [4]Topsoe A/S, Denmark; [5]Lund University, Sweden; [6]Technical University of Denmark, Denmark

Electron microscopy has become a powerful tool in catalysis science. Advances in electron optics and detection have enabled visualizations of catalytic nanomaterials with three-dimensional atomic-resolution and, the advent of gas and liquid cells has enabled *in situ* observations of catalysts immersed in chemical reaction environments as well as *operando* studies through concurrent measurements of catalytic functionality [1]. These developments open up for unprecedented new insights into the labile behavior of catalysts and provide mechanistic and kinetic information on atomic processes unfolding during catalysis. However, the atomic-resolution electron microscopy observations are often intricately modulated by dynamic processes induced by the electron beam, which are difficult to predict but imperative to characterize, quantify and suppress [2]. In this contribution, we outline progress in electron microscopy that advances the chemical relevance of atomic-scale visualizations and present electron microscopy research that aims discerning inherent and induced atom-dynamic processes in catalytic nanomaterials [3-5].

Controlling the Surface Reactivity of Hybrid Ti_3CNT_x MXene via *In Situ* Electrocatalysis Ekenedilichukwu Uwadiunor and Abdoulaye Djire; Texas A&M University, United States

Two-dimensional (2D) carbide and nitride MXenes possess properties that are desirable for a broad range of electrocatalytic applications including hydrogen evolution reaction (HER). These properties include high surface area, hydrophilicity, heterogeneity of redox-active transition metals, and tunable surface functionalities allowing for low HER overpotentials. MXenes are prepared from their MAX precursors by etching of the Al layers, using partial etching we synthesize a hybrid Ti_3CN capable of surface modifications using in situ electrochemistry. In this presentation, we report on the cathodic etching and –O/–OH functionalization of hybrid Ti_3CN upon the application of an external potential for improved HER performance and show that the active sites for HER on this MXene catalyst are located primarily on the –O– and –OH functional groups. The overpotential for the hybrid Ti_3CN improves by 350 mV upon in-situ -O functionalization and reaches -0.46 V vs. RHE at a current density of 10 mA cm^{-2}. Structural and electrochemical characterization results showed that the functionalized hybrid Ti_3CNT_x MXene catalyst is structurally and electrochemically stable. Further insights into the mechanism of simultaneous in situ etching and functionalization were provided by in-situ spectroelectrochemical techniques and the results will be presented. Ultimately, these findings provide a novel path forward to controlling the surface reactivity of MXenes using in-situ functionalization and electrochemical exfoliation.

11:00 AM DISCUSSION TIME

11:15 AM CH01.05.11
Visualization of Ferroelectric Domains with Picosecond Time and Nanometer Length Resolution Burak Guzelturk; Argonne National Laboratory, United States

Engineering domains and domain walls in ferroelectric materials is at the heart of realizing novel nanoelectronic and photonic devices. To this end, electric fields, light, strain and doping have been employed to manipulate domains at the atomic scale. Control of the domain structures with light pulses particularly presents strong potential to engineer electronic and optoelectronic functionalities in these materials in an all-optical fashion. Nevertheless, non-equilibrium photoexcited states in such complex materials could not be resolved in space and time with the desired resolution, i.e., picoseconds and nanometers, due to limitations in available characterization techniques. In this work, we develop a novel characterization approach to visualize nanoscale domain structures in photoexcited ferroelectric thin films over picosecond time with nanometer length scales via time-resolved nanoprobe X-ray diffraction imaging (TR-NXRD) at the Advanced Photon Source. Using this approach, we investigate stripe-domain bismuth ferrite (BFO) thin films that exhibit periodic 71 degree domain walls. Surprisingly, we find that the domain pattern transiently melts following an intense above bandgap laser pulse as revealed by strongly bleached domain pattern contrast. The washout of the domain pattern immediately after the photoexcitation arises due to weakening of the in-plane ferroelectric polarization linked with a large out-of-plane photostriction and rhombohedral-to-tetragonal phase transformation which overall destabilize the domain walls. Furthermore, we find that the dynamic domain evolution is fully reversible as the domain pattern reappears after 10 ns following the excitation laser pulse. Reappearance of the domains is consistent with the fact that the domain structure is pinned by the mechanical boundary conditions between the substate and the thin film. Overall, we unveil a novel way to manipulate stripe domains in BFO thin film at sub-nanosecond timescales by visualizing via TR-NXRD. This technique is further applicable to a broad range of materials to visualize non-equilibrium dynamics across nanoscale spatial heterogeneities critical to uncovering hidden structure-property relationships overlooked before due to the absence of methods that can simultaneous access high spatial and temporal resolution.

11:30 AM CH01.05.12
Real-Time Studies of Filament Evolution in Metal-Filament-Based Resistive Switching Devices Using *In Situ* Transmission Electron Microscopy
Saurabh Pandey and Robert Hull; Rensselaer Polytechnic Institute, United States

Hardware implementation of neuromorphic computing requires the development of artificial synapses that exhibit low power and repeatable and reliable switching into multiple resistance states. Filamentary resistive switching devices are a strong candidate for these artificial synapses, but they are limited by their state resistance dispersion. The state resistances of these devices are determined by the morphology of conducting filament(s) bridging the anode and cathode in these devices. It is therefore imperative to understand the entire filament evolution process in real-time to identify the factors that can influence the final filament morphology. For this purpose, we have developed an in-situ TEM electrical biasing methodology to study filament evolution during the electroforming of Cu/SiO_2/Cu devices at nanometer-scale spatial resolution and sub-second temporal resolution.
To image the real-time filament evolution at electrode-dielectric interfaces and within the dielectric, we have designed and fabricated devices with ~100 nm laterally separated electrodes. We use electron-beam lithography and lift-off to pattern 50 nm thick Copper electrodes onto 50 nm silicon nitride support film substrates to ensure electron transparency. We use ~10 nm of Titanium as an adhesion layer between Copper and Silicon Nitride and another ~ 10 nm of Titanium as a diffusion barrier between Copper and Silicon dioxide. We deposit ~65 nm Silicon dioxide thin film by RF sputtering of SiO_2 target at 200 W and 3 mtorr Argon pressure to conformally fill the electrode gap. We utilize a Gatan in-situ TEM electrical biasing holder and a Keithley voltage source/pico-ammeter to perform a stepped voltage ramp and simultaneous imaging and current measurement during the electroforming of the devices.
We find that the as-fabricated device has high resistance (>1 GΩ). During the voltage sweep, Copper clusters ~5 nm in size initially appear non-uniformly across the anode-dielectric interface. With increasing voltage, more clusters are formed in the dielectric close to the previous clusters along the direction of the electric field. The resulting filaments grow further along the electric field with increasing voltage until clusters are formed at the cathode-dielectric interface and the filament(s) are established. This coincides with a sudden reduction in the resistance (to ~200 MΩs) of the device at ~ 50-60 V bias. The shape and size of individual previously formed clusters also change with time and voltage with some clusters decreasing in size and ultimately disappearing and others increasing in size and merging with other clusters as the filament evolution process progresses. The device resistance increases back to the as-fabricated level (> 1 GΩ) upon the removal of applied bias. The device regains the low resistance state (~200 MΩs) at comparatively low voltage (~20 V) indicating the existence of threshold switching in the device.
Through this work, we are able to provide insight into the filament evolution process at the cluster-by-cluster and filament-by-filament level. This work also lays the framework for our future work on the study of SiO_2 density and composition on filament evolution in these devices.
This work was supported by the NYSTAR Focus Center at RPI, contract #C150117, and made extensive use of cleanroom and characterization facilities in the Center for Materials, Devices, and Integrated Systems (CMDIS) at Rensselaer Polytechnic Institute.

SESSION CH01.06: Characterization of Catalytical, Electrical and Mechanical Properties II

Investigating the Ferroelasticity Governing the Dynamics of Improper Ferroelectric Domain Walls by *In Situ* Biasing 4D-STEM
Michele S. Conroy[1], Steven Zeltmann[2,3], Sinead M. Griffin[3], Jim Ciston[3], Benjamin Savitzky[3], Roger Whatmore[1] and Colin Ophus[3]; [1]Imperial College London, United Kingdom; [2]University California Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

Dynamic conducting ferroelectric domain walls overturn the classical idea that our electronic circuits need to consist of fixed components of hardware.[1] Domain wall topologies in ferroelectrics are an emerging research focus in nano-electronics and potential quantum technologies.[2, 3] However, due to the high energetic cost of creating charged walls in conventional ferroelectrics they are not stable long term. Improper ferroelectrics circumvent this issue as their driving force is not a polar instability, but rather the critical dynamics of symmetry-breaking of the non-polar primary mode. With these benefits there has been a recent surge in improper ferroelectric topology research.[4]

We focus our studies on the improper ferroelectric boracite material system, known for their stable conducting and insulating domain walls and anomalous motion associated with negative capacitance.[5, 6] Boracite is an improper ferroelectric material where the primary order parameter is the physical quantity spontaneous shear strain. As a ferroelastic material the conductivity of the charged walls is governed by the shear strain direction of the neighbouring domains. Thus, traditional atomic resolution STEM polarity mapping will not give a true picture of the ferroelectric properties. In order to understand the mechanism of the wall movement and the fundamental physics governing their formation, strain analysis was completed using four-dimensional scanning transmission electron microscopy (4D-STEM)[7, 8] strain mapping. This strain analysis was then compared to the atomic resolution STEM imaging and polarity mapping.[9]

The dynamic nature of the topologies was first investigated by utilising the applied electric field of the STEM probe.[10] We show long-ranged re-ordering of shear strain during wall motion that is not present when the walls are stationary, and the complexity of the domain walls' local strain as they move through defects such as twin boundaries. Additionally we used an in-situ biasing holder set up in a parallel contact mode to compare to our previous device level work on negative capacitance measurements.[5] When mobile, the insulating domain walls have a very distinct local change in both strain and symmetry compared to the conducting walls. Finally, we explore the motion of higher order topology junctions such as vertices and vortices. Theoretical calculations confirm the shear strain to polarization vector relationship and charged topology energetics. We will present the benefits of 4D-STEM characterization for wall topologies governed by ferroelasticity, over the use of segmented detectors, where differential phase contrast mapping cannot detangle the strain and polar signals. The opportunities time-resolved 4D-STEM characterization methods can bring to the field of ferroelastic governed polar topology physics will be discussed in detail.

Atomic-Scale Insights into Hydrogen Absorption and Desorption in Palladium Nanocrystals Sophia Betzler[1,2], Daewon Lee[1,2], Mark Asta[1,2] and Haimei Zheng[1,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, United States

Hydrogen-induced phase transformations in palladium (Pd) is a topic that has attracted significant interest for many years. The palladium hydride (PdH_x) system consists of a hydrogen-poor α phase and a hydrogen-rich β phase. The α to β transformation involves the large Pd lattice expansion and thus causes specific interfacial structures to accommodate the lattice mismatch strain. Although the bulk PdH_x phase transformations are well-understood, the phase transformations of Pd nanocrystals have recently started to be explained due to advances in in-situ characterization techniques. In-situ environmental transmission electron microscopy (ETEM) and X-ray imaging demonstrated the corner nucleation and propagation of the β phase during absorption of Pd nanocrystals. However, there have been no direct atomic-scale insights into the phase boundaries during the dynamic hydrogen-induced phase transformations in Pd nanocrystals.

In this work, we use the in-situ liquid cell TEM to visualize the hydrogen-induced phase transformations in Pd nanocrystals at the atomic level. We synthesize Pd nanocubes and load them with an aqueous solution into a liquid cell. H_2 gas is generated by the electron-beam radiolysis of water in liquid cells. We image the hydrogen-induced phase transformations in individual Pd nanocubes at the atomic level. During the H_2 absorption, a unique interface is formed. The interface boundary is broadened, and there is a lattice tilt within the boundary. No dislocation is observed. However, during the H_2 desorption, the atomically sharp interface is found with dislocations identified at the interface. We also systematically study the particle size effects on hydrogen-induced phase transformations in Pd nanocubes. Variations in the interfaces suggesting differences in lattice strain relaxation mechanisms are revealed. This research expands our fundamental understanding of the solute-induced phase transformations, and assists the future design of advanced materials for hydrogen storage or other applications.

2:15 PM OPEN DISCUSSION

2:30 PM BREAK

3:30 PM *CH01.06.04
***In Situ* Observation of Crystallization Processes Using LC-TEM with the Support of Machine Learning** Yuki Kimura; Institute of Low Temperature Science, Japan

We have observed the crystallization processes of hen egg-white lysozyme protein [1] and the aggregation processes of amyloid-β protein [2], which is considered to cause Alzheimer's disease, by liquid-cell transmission electron microscopy (LC-TEM). In these observations, it is necessary to examine the issues of water radiolysis and electron damage to the sample due to electron irradiation. For example, in the crystallization experiment of lysozyme protein, the dependence of crystal growth rate on electron dose was observed. Therefore, we determined the threshold electron dose rate at which the crystal growth rate measured under an optical microscope was maintained, and made observations at lower electron dose rate than the threshold. Fortunately, the electron dose rate was not so small, 320 electron nm^{-2} s^{-1}, and therefore, there were no significant problem with observation at low magnifications. However, for observation at a high magnification or when the sample is more sensitive to electron beams, it is necessary to lower the electron dose rate, resulting in a dark image for observation. Although post-processing can brighten the image and increase contrast, we must make decisions about observation and experimental conditions during in-situ observation based on the dark image. We have therefore developed an algorithm of machine learning to enable image sharpening through real-time image processing during in-situ observation [3].

Another challenge for in situ experiments of crystallization is the detection of particles; in a typical in situ TEM, it is difficult to save all images during the experiment. Therefore, using the look back function provided in the TEM camera, recording is started when the phenomenon is confirmed to have occurred, starting with the image from a few seconds earlier. However, because the human eye has difficulty noticing slow phenomena, it may not be possible to record the initial process at the time we notice it. Therefore, we developed a machine-learning algorithm to detect the initial stage of the phenomenon by real-time image processing. This has made it possible to detect nanoparticles generated from solution through nucleation as quickly as possible [4].

By modifying an algorithm for particle detection, we used machine learning to analyze the relationship between the nucleation of nanoparticles from solution and the dissolution process [5]. In aqueous solution, clustering of ions and degradation of clusters are taking place, and we hypothesized that this is recorded as fluctuations in the TEM images. Therefore, we attempted to predict the formation of nanoparticles by machine learning using images taken several images before the time when the particles were formed. By changing the time period for learning, it may be possible to determine how many seconds before the nanoparticles form, clustering is occurring. Also, if particles undergo the same structure as clustering when they dissolve, machine learning should falsely detect the formation of new particles at the moment they dissolve. I will introduce our latest results of in-situ observation of crystallization with a support of machine learning.

Nanoscale Operando Experiments in Environmental Transmission Electron Microscopy for Solid Oxide Fuel Cell Devices Quentin Jeangros[1], Matthieu Bugnet[2], Thierry Epicier[3], Cédric Frantz[1], Stefan Diethelm[1], Dario Montinaro[4], Elizaveta Tyukalova[5], Yevheniy Pivak[6], Jan Van Herle[1], Aïcha

Hessler-Wyser[1] and Martial Duchamp[5,7]; [1]Ecole Polytechnique Fédérale de Lausanne, Switzerland; [2]Univ Lyon, CNRS, INSA Lyon, UCBL, MATEIS, UMR 5510, France; [3]Univ Lyon, Université Claude Bernard Lyon 1, CNRS, IRCELYON, France; [4]SOLIDpower SpA, Switzerland; [5]Nanyang Technological University, Singapore; [6]DENSsolutions, Netherlands; [7]MajuLab, International Joint Research Unit, UMI 3654, Univ Côte d'Azur, National University of Singapore, Nanyang Technological University, Singapore

Solid oxide fuel cells (SOFC) are a class of solid-state electrochemical conversion devices that produce electricity directly by oxidizing a fuel gas. They consist in an anode-cathode duet separated by a solid electrolyte, i.e., a material conducting oxygen ions. The anode is fed with hydrogen or other fuels whereas the cathode is in contact with air, meaning oxygen. Overall, a SOFC operates thanks to the combined action of two external stimuli: a gaseous environment and temperature. Owing to the recent advances in *in situ* and *operando* transmission electron microscopy (TEM), we have set up an experiment to operate a SOFC inside an environmental TEM to identify how the device microstructure determines its electrical properties. To do so, an elementary anode-electrolyte-cathode sandwich was prepared by focused ion beam (FIB) and mounted on a heating and biasing microelectromechanical (MEMS)-based specimen holder (DENSsolutions) and inserted in an Environmental TEM (FEI Titan ETEM), as shown in Fig. 1.
Standard SOFC materials were investigated: the cathode was strontium-doped lanthanum manganite (LSM) co-sintered with yttria-stabilized zirconia (YSZ), the electrolyte was YSZ, and the anode a cermet of NiO co-sintered with YSZ. NiO was first reduced to Ni, leaving pores in the structure due to the volume loss and hence enabling the penetration of the fuel to the triple phase boundaries Ni/YSZ/porosity at the anode side. For practical reasons, we used a single chamber configuration to trigger the operation the cell: the anode and cathode were exposed simultaneously to the oxidant and reducing gases. Due to a difference in the catalytic activity between the electrodes, O_2 should reduce at the cathode, while H_2 should oxidize at the anode, thus leading to a voltage difference between the two terminals.
The reduction of NiO was first performed under a forming gas N_2:H_2 in the ratio 20:1 under 15 mbar up to 750°C (N_2 was constantly used as a mixing gas for safety reasons due to the need of mixing O_2 and H_2 in the single-chamber configuration). The O_2 to H_2 ratio was then increased to trigger the operation of the cell. A small quantity of O_2 was introduced into the microscope, leading to a total pressure of about 16 mbar at 600°C. At this point, the variation of voltage between the anode and cathode was correlated to the gas composition and the anode microstructure (see Fig. 2). The latter was analyzed by means of conventional and high-resolution imaging, diffraction, and EELS (electron energy-loss spectroscopy). The system was cycled several times by decreasing and re-increasing the O_2 concentration in the gas flow, and correlations between microstructure, gas composition, and cell voltage were established, as it will be discussed at the conference. Results were further confirmed by macroscopic *ex situ* tests in an oven using the same materials [1]. The operation of a SOFC in a single chamber configuration was demonstrated using *operando* ETEM. Such *operando* experiments open numerous perspectives to investigate the root cause of failure pathways affecting SOFCs, like poisoning of active sites or coarsening of the Ni catalyst [2].

Reversible Conversion Between Schottky and Ohmic Contact of Zinc Oxide Microwire-Based Device Hue T. Tran, Yugyeong Je, Hyunjeong Jeong and Sang Wook Lee; Ewha Womans University, Korea (the Republic of)

In this study, electromechanical responses of individual ZnO microwires were observed under optical microscopy. In situ electrical measurements and the mechanical manipulation of ZnO microwires were carried out using a homemade micro-manipulation system. Here, the energy barrier height is tuned by inducing piezoelectric polarization charges at the local metal-semiconductor interface when a mechanical deformation was applied to ZnO microwire. As a result, the metal-semiconductor local contact can be transformed from Schottky to Ohmic and vice versa. This work demonstrates a method for controlling the electrical properties of ZnO nanowires to achieve reversible tuning between the Schottky contact and Ohmic contact on one device, which could be potential in developing multifunctional and Ohmic/Schottky-based sensors, switches, rectifiers, and other functional electronic devices.

Catalytic Nanoparticles with Propelled Motion Observed Under Liquid Cell TEM Zhiheng Lyu[1], Lehan Yao[1], Chang Qian[1], Zhisheng Wang[2] and Qian Chen[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]The University of Hong Kong, China

Nanomotors have attracted increasing attention in recent years due to their wide applications in a variety of fields such as drug delivery, self-assembly, and active sensors. However, due to the small size of nanoparticles, their motions are hard to be tracked by conventional optical microscopes with a resolution of hundreds of nanometers. This challenge, on the other hand, can be overcome with the development of liquid cell TEM, which enables the characterization and tracking of nanoparticles with high spatial (down to a few nanometers or even below) and temporal resolution. In this work, we introduce, for the first time, the propelled motion of nanoparticles characterized in the liquid cell TEM driven by catalytic reactions. Pt nanoparticles with asymmetric shapes were chosen as the model system, which reacted with a chemical fuel in an aqueous solution and generated a local concentration gradient around the nanoparticle that served as the driving force. Compared with the same concentration of inert salt, more Pt nanoparticles with propelled and directional motion were observed in chemical fuels, further confirming the existence of catalytic reactions and thus driving force. The symmetry of nanoparticles was also found to play an important role in their movements, with faster motion observed in asymmetric nanoparticles relative to the symmetric ones. We hope this work could provide real-time observation and mechanistic understanding of the propelled motion of nanoparticles driven by catalytic reactions using liquid cell TEM, stimulating more efforts into the design of nanomotors and characterization of their motions with advanced techniques.

4:45 PM CH01.06.08
In Depth Investigations of Graphene Oxide Reduction via *In Situ* TEM Measurements Raul Arenal[1,2,3], Mario Pelaez-Fernandez[1,2], Simon hettler[1,2], Ana Benito[4] and Wolfgang Maser[4]; [1]Instituto de Nanociencia y Materiales de Aragon (INMA), CSIC-Universidad de Zaragoza,, Spain; [2]Universidad de Zaragoza, Spain; [3]ARAID Foundation, Spain; [4]CSIC, Spain

Graphene oxide (GO) strongly attracts research interest due to its use as precursor material for graphene-based material and its high flexibility in terms of functional modification offering promising applications in numerous fields [1-5]. Despite the efforts for investigating its atomic structure, which is critical for knowing its properties, several aspects remain unknown in particular the behavior of the physi-/chemi-sorbed and of the oxygen functional groups (OFGs) during GO reduction. Thus, here we present two different approaches for studying, in depth, the GO reduction via in-situ TEM investigations: thermal reduction and Joule heating. For achieving these comprehensive studies [7,8], we have performed high-resolution TEM (HRTEM) imaging and electron energy-loss spectroscopy (EELS) measurements and coupled (for the second of these studies) with electrical conductivity measurements. In both studies we have identified the transformations of different oxygen functional groups, the desorption of physisorbed and chemisorbed water and the

graphitization of the GO flakes. These in-depth analyses provide a detailed roadmap of the behavior of GO during its reduction. All these findings improve the knowledge of this complex and heterogeneous material, which is crucial for the study of their physical and chemical properties and its future applications.

***In Situ* Growth of Gamma-Cyclodextrin-Based Metal Organic Frameworks on Poly(ethylene terephthalate) Fibers** Fatemeh Mashhadi Abolghasem and JR Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Metal organic frameworks (MOFs) are highly porous materials with large surface areas of 1000–10,000 m^2/ g, which are much higher than those of zeolites and activated carbons. However, when MOFs are used alone in toxic gas removal systems, they are difficult to handle because they are very fragile and often break down into nanosized particles, which have low stability and tend to form agglomerates. Thus, MOFs are often used in composites, where they are embedded in a polymeric matrix, or attached to a matrix surface. A common limitation of MOF fibrous composites is the low binding strength of the MOFs to the substrate. When MOF crystals are coated on a substrate surface, they are often only weakly adhered to the surface and easily fall off. In addition, when MOFs are incorporated into a polymeric matrix, their cavities can be blocked, resulting in a decrease in the surface area and porosity. The growth of self-supported MOFs onto the surfaces of substrates may solve this problem. Specifically, fibrous substrates can provide mechanical support and reduce MOF aggregation, leading to good performance for gas adsorption. Moreover, MOF growth on fibrous substrates enables more than one type of MOF to be incorporated to simultaneously provide multiple functions.
Cyclodextrin-based MOFs (CD-MOFs) are synthesized from the enzymatic degradation of starch and have received much attention toward the green synthesis of MOFs. CD-MOFs have truncated cone-shaped crystals with an external hydrophilic surface owing to the hydroxyl groups and internal hydrophobic cavity covered by glycosidic oxygens and C–H units. The presence of –OCCO– binding groups only in the CD primary and secondary faces is advantageous for fabricating biocompatible and non-toxic MOFs. CD-MOFs are versatile because of the free primary hydroxyl groups present in CD that bind with reactive functional groups for the reversible formation of carbonic acid. These features have led to their applications into gas capture, adsorption, and removal of air pollutants <!--![endif]---->
In this study, an effective strategy was introduced for *in situ* growth of cyclodextrin-based metal organic frameworks (CD-MOFs) through the vapor diffusion method combined with O_2 plasma treatment. A structure of self-supported γ-CD-MOF on poly(ethylene terephthalate) (PET) fibers was developed, and the effect of the *in situ* growth time on its properties was evaluated. The growth rate of γ-CD-MOFs on PET fibers (CD-MOFs–PET) was determined over 136 h, and 24 h growth of CD-MOFs-PET showed the highest surface area and CD-MOFs growth without deformation for air-filter applications. The CD-MOF crystals grown on PET fibers had an average side length of 818 nm. The specific surface area of the CD-MOFs-PET grown with 24 h growth time was 142.88 m^2/g, which was almost 235 times higher than that of the pristine showed a high efficiency of SO_2 gas adsorption performance up to 95% removal using a real-time gas monitoring system. The reusability of CD-MOFs-PET recovered most of its adsorption ability (85–95%) after vacuum oven drying. This study intends to provide an informative discussion of the applicability of textile-based CD-MOFs and the development of reusable filters for the removal of SO_2.

***In Situ* X-Ray Scattering of Atypical Nucleation and Kinetics of Strongly Coupled Nanocrystal Superlattice Self-Assembly** Vivian R. Wall, Christian P. Tanner and Naomi S. Ginsberg; UC Berkeley, United States

Self-assembly of colloidal nanocrystals (NCs) into long-range ordered arrays represents an appealing strategy toward the bottom-up design of hierarchically organized functional and multifunctional materials. These superlattices (SLs) are typically assembled from NCs with long, insulating organic ligands that inhibit strong electronic coupling. Recently, our team has developed a novel method to self-assemble metallic and high dielectric semiconductor NCs with short, multivalent, inorganic chalcogenometallate (ChM) ligands into strongly electronically coupled ordered SLs in ChM electrolytic environments. We are gaining a deeper understanding of the nucleation, kinetics, and phase diagram associated with this self-assembly process as a function of the system and environment composition, in order to better control assembly of these high dielectric semiconductor NCs and extend this method of assembly to semiconductor NCs with more typical, lower dielectric constants. To do so, we employ in situ small angle X-ray scattering (SAXS) to non-perturbatively probe the structure of PbS NC colloid, liquid, and SL phases as a function of time during self-assembly with millisecond time resolution. From fitting in situ SAXS patterns, we calculate the densities of different phases and thereby quantitatively map experimental phase diagrams for the first time. By identifying and exploring different regions of the phase diagram, we have also observed both classical one-step SL nucleation and non-classical two-step SL nucleation, where a liquid of NCs nucleates from colloidal NCs first, and crystallization into a SL occurs from within the liquid phase. This more complex nucleation process has been observed in protein crystallization and predicted for inorganic NC systems, but had not yet been shown experimentally. We have further explored the non-classical nature of this system by quantitatively comparing rates of assembly to classical nucleation theory, as well as by studying NC diffusion and cluster density fluctuations that lead to nucleation, in order to better control the nucleation process and final ordered configurations. The kinetic and dynamic lessons from these novel in situ experiments will help us push forward the goal of assembling strongly coupled SL materials from semiconducting NCs.

CH01.07.04
Photo-Responsive Chiral Supramolecular Polymers Based on C_3-Symmetric Triphenylene Triimides Namhee Kim and Byeong-Su Kim; Yonsei University, Korea (the Republic of)

A new type of C_3-symmetric triphenylene triimides (TTI) bearing different oligo(ethylene glycol) side chains via imide linkages is developed in this study. By exploiting this unique TTI molecule as a building block, a supramolecular polymerization is explored on the basis of π-π stacking and hydrophilic/hydrophobic interaction depending on the type of solvents and rates of heating/cooling process. The molecular chirality of TTI monomer triggers the formation of a preferential helicity in fibrous structures. The stacking type of supramolecular polymerization is highly dependent on the presence of the point chirality of side chains, as evidenced by a collection of spectroscopic analyses including UV/vis and CD spectroscopy together with AFM, TEM, and WAXS. Interestingly, while the fibrous structure in assembled state is maintained due to the intermolecular interaction, the self-assembly does not occur in monomeric state due to the formation of radical anion of imide groups under UV irradiation. This study is anticipated to provide a new direction in the control of the supramolecular chiral assembly.

CH01.07.05
Lateral Particle Migration in Shear-Thinning Fluid Observed with Versatile Dual-View Optical Microscopy Daewkon Jin and Jumin Kim; Ajou University, Korea (the Republic of)

Microfluidics-based technologies have been extensively used to count and sort particles, as well as synthesize functional micro- and nanoparticles. Until now, the dynamics of microparticles or the synthesis process in the microchannel have been observed with conventional optical microscopes equipped with a vertically aligned objective lens. Therefore, there are limitations to the observation of particle dynamics or polymer photopolymerization, which requires direct observation in both the depth and width directions of the microchannel simultaneously. However, existing methods employing holography or micromirrors have the disadvantage of requiring costly optical setups or complicated channel fabrication techniques.
In this work, we demonstrate that it is possible to build up a system capable of simultaneously capturing images in the width and depth directions of a poly(dimethyl siloxane) (PDMS)-based microchannel by installing two objective lenses in the vertical and horizontal directions together with two cameras that are controlled with a trigger. We also showed that by coating the channel side-wall with PDMS and stacking it with a glass slide, the scattered reflection of light caused by the roughness of the channel side-wall as a result of the inevitable channel cutting procedure can be minimized. Using this method, we demonstrated that our system can be used to investigate the three-dimensional distribution of particles in non-Newtonian viscoelastic fluids with shear-thinning viscosities. We expect that our method will be widely used to understand the particle dynamics in numerous solution-based processes employing viscoelastic fluids where the particle distribution is strongly affected by medium viscoelasticity. In addition, we anticipate that this system will contribute to the understanding of the particle synthesis procedures of stop-flow lithography which has been widely used to fabricate non-spherical particles in microchannels.

CH01.07.06
Composite Crystallization of Two Active Pharmaceutical Ingredients Using Polymer-Directed Crystallization Mechanism Juhee Lim and Jonghwi Lee; Chung-Ang University, Korea (the Republic of)

Particle engineering of pharmaceutical and food ingredients by crystallization is important and widely used to meet the complex requirements. By adding a small amount of polymer during crystallization, various properties such as bioavailability, crystal stability, and drug release control can be controlled, and many advantages such as high efficiency and cost reduction can be obtained. This polymer-directed crystallization can trigger crystal formation through a route of non-classical crystallization, which is mediated by the physical adsorption of long-chain molecules. We hypothesized that by polymer-induced crystallization, one polymer could connect crystals of two different drug molecules. Composite drug crystals can obtain advantages such as improved processability and stability, reduced number of drug tablets, and reduced price by making two drugs into one tablet. The two drugs used in this study are the antihypertensive drugs Valsartan (VAL) and Amlodipine besylate (AMB). The polymer dissolved in the solution is adsorbed on the surfaces of the nuclei, and the crystals form an assembly of crystals. OM and SEM showed two different types of crystals. Additionally, crystallinity changes were observed through birefringence observation. The melting point measurements by differential scanning calorimetry showed that the melting point of the two drugs were significantly changed in the composite crystal, indicating significant change in the interaction between the drugs and polymer. Powder X-ray diffraction showed that the crystal form changed according to the composition ratio of the drug. The proton nuclear magnetic resonance confirmed the composition ratio of the obtained crystals, and as a result, it was indicated that the precipitated ratio was like the added ratio. This novel complex crystal manufacturing method may provide new opportunities for convenient production of complex formulations and improved processability and stability.

CH01.07.07
Simulations and Experiments on the Synthesis of 2D Nanomaterials by Resistive Heating of Metallic Wires Beatriz Rodríguez Fernández, Pedro Hidalgo and Bianchi Mendez; Complutense University of Madrid, Spain

Two dimensional materials are synthesized from different techniques like *chemical vapor deposition* or *physical vapor deposition* among others. Thermal oxidation growth has the advantage of its simplicity, but most of the reported synthesis of oxide low dimensional structures by this method, required growth times in the range of hours. A more rapid method of metal oxide structures synthesis, also based on thermal oxidation of metals, is the direct resistive heating of a metallic wires by the flow of an electric current in ambient conditions. The high current density applied during the Joule heating favors the diffusion processes involved in the growth, been considered the underlying mechanism the electromigration processes. Applying external electric fields with different orientations to the current flow during treatments, we are able to inhibit or enhance the ions diffusion and, therefore, the formation of structures.
In this work, we report a simple and effective method to obtain nano- and microstructures in a very fast way with promising applications. Simultaneous COMSOL simulations have been carried out to verify the experimental result. A detailed analysis of the behavior of the current density, potential difference and thermal gradient is presented in order to understand what is happening in the material during the flow of the electric current and how the growth originates on the surface of the wire. Simulations have also been carried out for treatments with electric field application with the purpose of comprehend how the electric field interacts with the material during Joule heating. In summary, the results obtained shed some light to better understand how electromigration processes take part in the formation of the structures. This study encourages in-situ measurements during the growth process by direct resistive heating of a metallic wire, which could also be extrapolated to a wide range of materials.

CH01.07.08
Standard Methodology for Investigating Thermal Robustness of Porous Materials Satyanarayana Bonakala, Anas I. Abutaha, Elumalai Palani, Ayman Samara, Said Mansour and Fadwa El Mellouhi; Qatar Environment and Energy Research Institute (QEERI), Hamad Bin Khalifa University (HBKU), Qatar

With the pressing need of having reliable materials for carbon dioxide capture, metal-organic frameworks (MOFs) have shown promising performance due

to their flexibility sign and tunable functionality by applying reticular chemistry principles. One of the main characteristics of practical MOFs is to design thermally robust candidates for sustainable functionality. Here, we introduce a comprehensive methodology for examining the thermal stability of MOFs by combining theoretical calculations and affordable experimental methods to fully describe its performance under thermal variations. We choose the prototypical MOF, HKUST-1, to assess the methodology by performing density functional theory and classical molecular dynamics simulations and validating with experiments such as in-situ powder X-ray diffraction, differential scanning calorimetry, and thermogravimetric analysis. HKUST-1 shows thermal robustness until a temperature of 240 C at different atmospheric gases with a reversible breathing trend with temperature. This methodology is affordable as it uses minimal experimental testing and can be applied to any MOF materials to explore its suitability for practical applications.

CH01.07.10
***In Situ* UV-vis Spectroscopic Investigation of Feroxyhite Nanomaterial Synthesis by DC Atmospheric Microplasma** Yucheng Lan[1], Grace Farrell[1], Gregory Severn[2] and Willie Rockward[1]; [1]Morgan State University, United States; [2]University of San Diego, United States

Feroxyhite nanomaterials were synthesized in aqueous solutions by DC atmospheric microplasma at room temperature. The chemical reaction during the plasma synthesis was in-situ investigated by UV-vis spectroscopy. Specially, the time-dependent and location-dependent crystallographic quality of the products was detected from the UV-vis spectra, including the bandgap of the nanomaterials and concentration. The effects of voltage, electric strength, and polarity were investigated too. The synthesized nanomaterials were characterized by X-ray powder diffraction, Raman scattering, and electron microscopy too. The mechanism of the plasma synthesis was discussed. Work supported by DOE grant DE-FE0031906 and NSF nos. PHY-1804240, and PHY-2108298, 2108636.

CH01.07.12
Chemical Vapor Deposition as a Novel Method for Synthesizing Two-Dimensional Conductive Metal-Organic Frameworks Thin Films Myeonggeun Choe and Hee Cheul Choi; Postech, Korea (the Republic of)

We demonstrated the synthesis of a conductive two-dimensional metal-organic framework (MOF) thin film with a single-step all-gas-phase chemical vapor deposition (CVD) method. The large-area thin film of the synthesized $Cu_3(HHB)_2$ ($Cu3(C_6O_6)_2$, HHB = hexahydroxybenzene) has a new phase of the structure and highly crystalline edge-on orientation. The $Cu_3(HHB)_2$ thin film microdevices were fabricated by e-beam lithography (EBL), and showed an electrical conductivity value of 110.6 S/cm. Synthesis of conductive MOF thin films by the all-gas-phase CVD method is essential because it contributes to basic research on physical properties and brings them closer to the utilization of conductive MOFs in practical applications.

CH01.07.13
Rotation of Graphene on Cu(111) Surface During Chemical Vapor Deposition and Controlling the Stacking Angle of Bilayer Graphene Hyeyeon Cho and Hee Cheul Choi; Pohang University of Science and Technology, Korea (the Republic of)

Control of stacking angle (θ_S) of bilayer graphene (BLG) is an essential task for the understanding and applications of BLG whose properties largely depend on θ_S. Up to date, BLG is frequently obtained by a layer-by-layer stacking of individual single-layer graphene manually, which is inferior to the potential alternative by chemical vapor deposition (CVD) method in the view of chemical purity. In this presentation, we introduce graphene rotation on Cu(111) surface during the CVD process and its application to obtaining AB-stacked BLG ($\theta_S = 0°$) and 30°-twisted-BLG by edge state engineering of the second layer of BLG. It was found that the graphene could be rotated because of the population changes of BLG, as evidenced by population variation of AB-stacked and 30°-twisted BLG. Since the rotation of graphene is largely affected by the edge state of graphene, it is important to tune the edge state of graphene by growth temperature. Changes in programmed growth temperatures lead to block or accelerate the rotation of BLG and resulted in highly selective growth of AB-stacked or 30°-twisted BLG can be achieved. Both experimental and calculation studies on the unprecedented graphene rotation phenomenon on Cu(111) surface during CVD will be discussed in detail.

CH01.07.14
Strain Modulation of Crystallinity, Orientation and Piezoelectric Properties of Poly(vinylidene)—Poly(methyl methacrylate) Blends Michal Wyskiel[1], Kamal K. Meena[2], Konrad Schneider[2], Krzysztof Janus[1] and Adam Kiersnowski[1]; [1]Wroclaw University of Science and Technology, Poland; [2]Leibniz Institute for Polymer Research Dresden, Germany

Technologically-relevant semicrystalline, electroactive polymers such as poly(vinylidene fluoride) (PVDF) have attracted a lot of attention because of their potential applications in sensors and energy harvesting units. From a viewpoint of basic research, crystallization and crystal phase transitions of PVDF provided an interesting topic to study formation of different crystal polymorphs under the influence of external stimuli such as electric field and mechanical stress. Over four decades of experimental studies on PVDF provided a solid knowledge on relationships between nucleation, crystallization rate, and solid-state recrystallization, which underpinned market development of several high-tech companies in 21st century.
Imparting piezoelectricity to PVDF requires uniaxially, homogeneously and permanently oriented dipole moments of CH_2-CF_2 monomer units in polar crystal polymorphs. There are several technologically-proven strategies to render PVDF piezoelectric. One of the strategies is based on blending of PVDF with poly(methyl methacrylate) (PMMA) and deformation of the blends under the external electric field. PVDF and PMMA are thermodynamically miscible above upper critical solubility temperature. Generally, PMMA reduces the overall crystallinity of PVDF by “trapping” PVDF macromolecules in the PMMA bulk. The “trapping” reduces the crystallization rate. Therefore melt crystallization of PVDF in the PVDF:PMMA blends requires extended annealing at crystallization temperature or slow cooling of the melt. Quenching the molten PVDF:PMMA blends makes them amorphous whereas an appropriate thermal treatment of the fully amorphous blends can cause a preferential formation of polar crystals. Mechanical stress enhances the latter process and causes the crystals to orient along the deformation axis. However, the mechanism of formation of polar crystals after phase separation as well as recrystallization of non-polar polymorphs raise controversies. So does the role of a strain in the case of the blends.
Our study was aimed, therefore, at explaining the role of PMMA on formation of polar polymorphs of PVDF, i.e. the β and γ crystal phases. Our experiments were also supposed to shed light on mechanism of transforming of the isotropic non-polar PVDF polymorph (the a-phase) into oriented polar crystals during deformation in a viscoelastic state. The experimental approach included real-time, in-situ mapping of crystal structure development in the blends of PVDF with four different ratios of PMMA during their uniaxial deformation. PVDF crystal structure was monitored with time-resolved wide angle X-ray diffraction (WAXD) with 30-microns spatial resolution to precisely address the role of local strain on crystal orientation and phase composition. Small-angle X-ray scattering experiments were performed to supplement the WAXD data with variation of the lamellar structure of PVDF upon deformation. Additionally, the ex-situ Fourier transform infrared spectroscopy (FTIR) was used to refine the conclusions from WAXD. The studies performed with the high-spatial resolution enabled finding correlations between the local strain, orientation and the phase composition of the blends, including the γ to β ratios in different samples as a function of blend composition and local strain. In the contribution, we present static phase composition maps of samples under deformation and the evolution of the maps upon varying the strain. We also discuss correlation between Hermans orientation factors and phase compositions. The work can be considered as a fundamental contribution for development of the polymer blends for sensing and energy harvesting applications.

Colorimetric Strain Sensor Using High Refractive Index Iron Oxide Core-Shell Particles Seamin Park, Jungmin Kim and Youngseok Kim; Korea Electronics Technology Institute, Korea (the Republic of)

Three-dimensional photonic crystals have properties that can be useful for detecting physical deformations. Compared with 3D polymer photonic crystals with weak color and high viewing angle dependence, inorganic core-shell particles promise high color purity and reflectivity.
In this study, iron oxide particles (130-160nm) having a high refractive index were prepared through hydrothermal synthesis and then silica was coated with the Stober method. Homogeneously synthesized inorganic particles can be arranged into highly ordered hybrid films using melt shear techniques. Inorganic particle core materials featuring smart soft/hard shell polymers enhance photonic crystal film preparation and provide convenient access to novel photonic materials as sensing platforms.

CH01.07.16
Micro-Encapsulation of Photonic Ink Containing Charge-Stabilized Superparamagnetic Iron Oxide Nanoparticles in Non-Polar Medium Jungmin Kim[1,2], Wonmok Lee[2] and Youngseok Kim[1]; [1]Korea Electronics Technology Institute, Korea (the Republic of); [2]Sejong University, Korea (the Republic of)

Color-tunable surfaces are of great interest in industries such as displays, automobiles, and interiors of buildings. In this study, monodisperse superparamagnetic iron oxide nanoparticles (SPIONs) were used to prepare photonic inks with high color purity and vivid colors due to light absorption. It was then encapsulated and implemented in the form of a stable film. A photonic crystal colloidal array was prepared by stabilizing the charge of Fe3O4@SiO2 core-shell particles(130-160nm) using a charge control agent in a non-polar medium, and color conversion properties were observed. In addition, through a complex coacervation process, the SPION dispersion was processed into a double-layer microcapsule containing gelatin and polysaccharides to secure stability and color tunability by magnetic and electric fields.
These microcapsules exhibited excellent mechanical strength enough to be applied to replica molding and photocuring, thus exhibiting long-term stability while maintaining flexibility and color tunability.

CH01.07.17
Advanced Characterization of Precipitates in Additively Manufactured AA 7075 Aluminium Alloy Irena Paulin[1], Črtomir Donik[1], Stefan Zaefferer[2], Christian Bross[2] and Matjaz Godec[1]; [1]Institute of Metals and Technology, Slovenia; [2]Max-Planck-Institut für Eisenforschung, Germany

High strength Al alloys, e.g. for aerospace applications, obtain most of their strength from hardening by coherent precipitation, e.g. η' and η phases. These precipitates are formed in a sequence of solution annealing and ageing treatments. During this process care must be taken to avoid formation of large incoherent particles, e.g. S-phase. The related mechanisms and processes are well-understood for conventionally produced materials which usually consist of a deformation process which supports the dissolution of precipitates and following annealing. For additive manufacturing (AM) by 3D printing, which in principle is a very promising method to produce morphologically complicated parts, unfortunately, a deformation step does not exist and the process-inherent heat treatment is most inconvenient for precipitation control. Furthermore, as remarked in a recent publication in nature materials, the large solidification interval of high strength Al alloys makes them rather prone to hot cracking during or after printing. Nevertheless, printing of these alloys is of great interest for technological applications but also in the general sense of understanding how to extend the 3D metal printing process to more demanding materials. Also, the 3D printing process may hold advantages for high strength Al alloys as it is known from other alloys that a large number of dislocations are formed which may act as nucleation sites for coherent precipitation.

A parameter assessment has been carried out on the 3D printing process to obtain crack free printing of these alloys. We envisage a number of parameters to check, namely the temperature of the base plate, the laser power/density and the printing atmosphere. The aim of the study is to better understand (and subsequently control) the precipitation process in AM-produced material. Solution and ageing treatments will then be designed to influence and potentially optimize the microstructures. Most of the microstructure characterization work was done by electron microscopy, particularly using the outstanding features of controlled electron channelling contrast imaging (cECCI). This technique allows direct and high resolution observation of defects (dislocations and grain boundaries) on bulk samples.

CH01.07.18
Solid-Liquid Contact Charge Separation and its Consequences Pravash Bista[1], Xiaomei Li[1] and Stefan A. Weber[1,2]; [1]Max Plank Institute for Polymer Research, Germany; [2]Johannes Gutenberg University, Germany

Understanding the effects and origins of slide electrification, i.e., the spontaneous charge separation in sliding drops [1-4], is of great importance in energy harvesting and wetting. We explored the consequences of spontaneous charge separation in drop motion [3]. We found that the electrostatic force on the sliding drop can be up to almost 50% of the total force. This finding shows that self-induced electrostatics should be considered while studying the drop motion. To understand the molecular processes behind slide electrification, we recently proposed a physical model to describe the dynamics in charge separation as successive water drops slide down a neutral hydrophobic surface. We describe this effect using a three-phase contact line voltage that changes or adapts when the surface is in contact with water. This deeper understanding can open the way for surface engineering to achieve desired wetting properties.

Adaptive Two Capacitor Model to Describe Slide Electrification in Moving Water Drops Pravash Bista[1], Amy Stetten[1], William S. Wong[1], Hans-Jürgen Butt[1] and Stefan A. Weber[1,2]; [1]Max Plank Institute for Polymer Research, Germany; [2]Johannes Gutenberg University, Germany

Triboelectric charging between solid surfaces is a well-known phenomenon. It is less obvious that a similar charge separation process can be observed in water drops moving on a hydrophobic surface [1-4]. In so-called slide electrification experiments, neutral water drops slide over a neutral hydrophobic surface, accumulating and leaving behind a net charge [2]. The accumulated drop charge for successive sliding drops decreases and eventually reaches a steady state. On hydrophobic/hydrophilic mixed surfaces, we could even observe a polarity flip in the drop charge upon decreasing the drop rate. To rationalize the charge separation process, we propose an electric circuit model based on capacitors and a voltage generated at the moving three-phase contact line. By introducing a voltage adaptation upon water contact, we can successfully describe drop charge experiments on many surfaces, including the drop-rate-dependent polarity flips. The characteristic adaptation times hint toward molecular processes affecting the solid-liquid charge separation. Thus, our adaptive two-capacitor model enables new insights into the molecular details of the charge separation mechanism.

CH01.07.21
Chiroptical Neuromorphic Phototransistor Based on Self-Assembled Supramolecular Nanostructure of Diketopyrrolopyrrole-Based π-Conjugated Organogelator Hanna Lee[1,2], Changsoon Choi[1], Hyemi Han[1], Seung Ho Song[1], Do Kyung Hwang[1], Jeong Ho Cho[2] and Jung Ah Lim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

Chiral optoelectronic has gathered significant attention in various applications of quantum computation, optical spintronics, bio-sensing, 3D imaging, and encryption. To realize chiral optoelectronics technology, the development of chiroptical optoelectronic devices, which can provide distinguishable electrical signals according to the handedness of circularly polarized (CP) light (i.e., right- or left-circular polarization) is essential. From a viewpoint of materials, chiral π-conjugated molecules of whose chiroptical properties can be effectively controlled by programmable molecular design are one of the key materials to impart the chiroptical activity of the optoelectronic device. So far, many demonstrations of chiroptical π-conjugated molecules and their supramolecular structures have been intensively demonstrated, however, the development of chiroptical optoelectronic devices based on chiral pi-conjugated molecules or their supramolecular structure is rarely reported.
In this work, we propose a chiroptical hybrid phototransistor based on the supramolecular nanohelix of a π-conjugated molecule for neuromorphic imaging technology. To provide highly strong chiroptical activity to the transistor, diketopyrrolopyrrole-based donor-acceptor type orgaogelator (DPP-organogelator) was newly synthesized. Supramolecular nanohelix structure of DPP-organogelator was successfully fabricated under optimized self-assembly conditions and exhibited strong and stable chiroptical properties. The suggested chiroptical hybrid phototransistor based on the DPP-organogelator nanohelix distinguishably detected the circularly polarized light with the different circular polarization directions. Especially, the device exhibited the frequency-dependent plasticity behavior in the photocurrent. Based on this, we successfully developed unique chiroptical imaging sensors showing enhanced contrast in the images obtained under cp light with different polarization directions.

CH01.07.22
Optimization of Balloon Surface Morphology Using Breath Figure Method to Enhance Stent Retention Force Han C. Lee[1,2], Woojin Kim[1], Dong Yun Choi[1] and Gyu M. Kim[2]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of)

Recently, the need for multifunctional medical balloons is increasing for stent delivery, drug delivery, and biosensing applications. To meet this demand, researches were conducted to apply coronary intervention by increasing the drug loading efficiency, which was done by increasing the specific surface area through texturing on the surface of the balloon. In addition, studies have been conducted to apply micro/nanoscale structures to enteroscopy procedures by increasing the frictional force in the human body. Among the various applications of medical balloons, stent delivery is the most commonly used balloon worldwide. Recently, bioabsorbable vascular stents (BVS) have been continuously developed as an improvement of the drug-eluting stent (DES) and bare-metal stents (BMS).
However, despite these advantages, the BVS sometimes dislodges from the balloon in an undesirable place during its delivery to the lesion. This is owing to the phenomenon of using slippery materials, such as Nylon12 and PEBA, to withstand the high-pressure expansion force (more than 20 ATM) of the medical balloon. Despite the issue of stent delivery, research and development related to this issue are insufficient.
In this study, we present a balloon with the porous surface that can increase stent retention strength. A porous film was formed using a thermoplastic polyurethane with high adhesion, and this was applied to the balloon surface. In particular, we focused on increasing the contact area with the stent strut through the 3D porous structure when the stent is crimped on the balloon.
To form a 3D-porous structure, the breath figure method (BFM), a type of self-assembly, is used along with the dip-coating method. Our system is templateless, porogenless, and simple to configure. BFM is a process that self-arranges the condensed droplets on the triple interface of air, water, and solvent using the Marangoni and capillary effects as driving forces.
When the film is in liquid state, that is, before being solidified, the droplets condense on the interface and either float or sink depending on Y_w (surface tension of water), Y_s (surface tension of solution), $Y_{w/s}$ (interfacial tension between water and solution). Accordingly, monolayer or multilayer coating structures can be formed. **I**n this study, we control Y_s with the concentration of the polymer solution and mixing ratio (chloroform + pentane) to control the cross-sectional structure of the coating layer according to the variable surface tension over a wide range. In addition, Y_w is controlled as the concentration of the aqueous solution containing the surfactant F-127 or NaCl. As a result, the decrease in Y_w shows a tendency to create a hemispherical monolayer structure on the surface of the coating layer, and we can observed that this phenomenon is caused by water droplets floating on the liquid interface. On the other hand**,** when Y_w increases, spherical pores are generated in a multilayered structure, because water droplets sink into the polymer solution before the film solidifies. When only Y_s decreases, spherical pores are created, and it is confirmed that they are formed as monolayers. However, as Y_s increases, hemispherical pores are formed as monolayers. These results indicate that the viscosity of the polymer solution during the BFM process is related to the shape of the structure. Consequently, when the stent dislodgement test is performed, the maximum **retention** force is observed as the porosity of the structure increases.

CH01.07.24
Novel Coating-Plus-Irrigation Strategy on Ni-Rich Layered Cathode for Lithium-Ion Batteries Moonsu Yoon[1], Jaephil Cho[2] and Ju Li[1]; [1]Massachusetts Institute of Technology, United States; [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Engineered polycrystalline electrodes are critical to the cycling stability and safety of lithium-ion batteries, yet it is challenging to construct high-quality coatings at both the primary- and secondary-particle levels. Herein, This work applies reactive wetting phenomena to protect electrode particles and their grain boundaries (GBs). We report a novel "coating-plus-irrigation" strategy on an industrially important Ni-rich layered cathode $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ (NCM). Cobalt boride is electronically conductive, and the nanolayers that forms in between grains also conducts Li^+, forming a mixed ionic and electronic conductor (MIEC) network. The cobalt boride coating demonstrates 100% surface coverage of secondary oxide particles (proved by X-ray photoelectron spectroscopy over extended sample area over mm^2, unlike typical literature "proof" using transmission electron microscope over nm^2 local area) as well as facile infusion into all grain boundaries between its primary particles. This is extraordinary considering everything happens at room temperature, without high-temperature alteration to the crystalline bulk of the primary particles, but with drastic changes in the GBs as they are infiltrated by MIEC nanochannels. Thus, the MIEC network protects the secondary particle from cracking and exposing fresh surfaces to the electrolyte, which greatly enhances the cycle stability, especially at high rates. Cobalt boride is used industrially as structural metal coating to improve corrosion and wear resistance, thus it does not easily chip or fracture at nanoscale, making it a mechanically tough MIEC at nanoscale, which can deform to accommodate the anisotropic deformation of the primary particles with lithiation/delithiation.
Such facile kinetics and resulting irrigation network are enabled by the huge chemical driving force from the strong hybridized interfacial bonding from our first-principles calculations. It not only ensures ultra-uniform conformal coating/irrigation, but also de-activates labile surface oxygen of the cathodes. As a result, our strategy offers superior electrochemical performance of high-loading (10.5 mg cm^{-2}, ~2.05 mAh cm^{-2}) and high-electrode-density (3.20 g cm^{-3}) cathodes under high-rate (up to 1,540 mA g^{-1}, ~7 C) and high-temperature (45 ºC) conditions, by simultaneous suppression of the correlated microstructural degradation (stress-corrosion cracking, SCC problem) and side reactions of Ni-rich layered cathodes as well as the cross-over effect on lithium metal anodes (all of them are fully supported by extensive, direct experimental evidences). It also improves the safety according to differential scanning calorimetry, where the exothermal decomposition takes place at higher temperature with less heat generation, which offers a strong proof of the chemical passivation effect we proposed.

CH01.07.26
Electric-Field–Mediated In-Sensor Alignment of Antibody's Orientation to Enhance the Antibody–Antigen Binding for Ultra-High Sensitivity of Sensor Hye Jin Kim[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science (IBS), Korea (the Republic of)

Applying an electric field (*E*-field) during antibody immobilization aligns the orientation of the antibody on the biosensor surface, thereby enhancing the binding probability between the antibody and antigen and maximizing the sensitivity of the biosensor. In this study, a biosensor with enhanced antibody-antigen binding probability was developed using the alignment of polar antibodies (immunoglobulin G [IgG]) under an *E*-field applied inside the interdigitated electrodes. The optimal alignment condition was first theoretically calculated and then experimentally confirmed by comparing the impedance change before and after the alignment of IgG (a purified anti-*β*-amyloid antibody). With the optimized condition, the impedance change of the biosensor was maximized owing to the alignment of IgG orientation on the sensor surface; the detection sensitivity of the antigen amyloid-beta 1-42 was also maximized. The *E*-field-based in-sensor alignment of antibodies is an easy and effective method for enhancing biosensor sensitivity.

CH01.07.27
Grafting Superhydrophobic Moieties on Cellulose Nanofibers via Ionic Bonding Zhuolun Jiang; The Chinese University of Hong Kong, Hong Kong

Magnesium stearate (MS) as a derivative product of stearic acid (SA) biomass was chosen as the superhydrophobic agent for in-situ modification of citric acid (CA) crosslinked and alkaline treated cellulose nanofibers (CNFs). MS is a common food additive and possesses high thermal stability (T_m = 200 °C, T_d = 359 °C).[1]Our approach is taking advantage of ionic bonding and the ion exchange interaction to induce the self-assembly between MS and CA-CNF^-K^+ to prepare the highly hydrophobic and rough CNF substrates, thus obtaining a superhydrophobic biomass-based surface with controlled superhydrophobicity, roughness and self-cleaning function via a simple and green way.[2]
Through vacuum filtration and air drying processes, a MS-CA-CNF disk with distinctly different roughness on each side was prepared, of which the appearance is similar to that of the biowax-mineral hybrid modified paper substrate.[3] Side A is rough, with spherical particles of diameter from 200 to 500 mm and Side B is smooth. Water contact angle test reveals the high hydrophobic Side A (150 °) and hydrophilic Side B. The quite high WCA of Side A cah be explained by its low surface energy and high roughness. X-ray diffraction (XRD) has been used to analyze the crystalline structure of crystalline structures of both sides. Side A displays a similar crystalline diffraction peak to MS while Side B exhibits more similar crystalline pattern to CNFs. Based on this, surface of Side A is speculated to be mainly composed of stearic chains. SEM energy dispersive spectrum (SEM EDS) characterization has specified the distribution and concentration of Mg on Side A and Side B and strongly supported above speculation. The wt% of C, O, Mg elements on both surfaces has been calculated. Quite low concentration of Mg was detected on Side A and Side B. Side A possesses a remarkably higher concentration of C and much lower concentration of O compared with Side B, which may be due to the tight aggregation of stearic chains on Side A. The distribution of Mg on the cross-section of MS-CA-CNF disk has also been tested. The concentration of Mg near the rough surface Side A is much higher than other locations, indicating that Mg^{2+} may act as the linkers between stearic chains and $CA\text{-}CNF^-$ so that MS is able to sit stably on $CA\text{-}CNF^-$.
Based on this, a mechanism has been proposed to explain the self-assembly phenomenon of this disk. Due to the very low surface energy of stearic chains and the ionic binding role of Mg^{2+}, MS will highly self-assemble and be stably attached to $CA\text{-}CNF^-$. As a result, the white layer is mainly composed of stearic chains while Mg^{2+} acts as the bridge between stearic chain and $CA\text{-}CNF^-$. Due to the preferential evaporation of ethanol (EtOH) and better affinity between MS and EtOH, MS will move toward the surface while EtOH is evaporating. The evaporation-induced self-assembly mechanism was once used to explain the different aggregation pattern of zein on bacterial cellulose membrane. The synergetic effect of ionic bonding and solvent effect can assist the self-assembly of MS-CA-CNF and explain the distinctly different water barrier property on each side of disk.

Crystalline-Amorphous Nanocomposites Strengthened and Toughened with Hierarchical and Interconnected Nanostructure Liqiang Wang; City University of Hong Kong, Hong Kong

Amorphous-nanocrystalline dual phase structure were proved to be an effective way for overcoming the strength-ductility trade-off and break the limitation of reverse Hall-Petch effect. Here, we proposed a new strategy to develop a hierarchical and interconnected amorphous-crystalline dual-phase nanocomposite by the nanoscale elements interdiffusion and partition. The nanocomposite consists of three-dimensional continuous crystalline phase (Cr-

Co-Ni-Al) embedded in amorphous network (Al-Ni-Co or Al-O). This unique microstructure can achieve ultrahigh yield strength of ~3.6 GPa with a large homogeneous deformation over 60% strain, effectively suppressing the plasticity instability occurred in conventional nanocrystalline alloy. In situ Transmission Electron Microscopy studies reveal that exceptional strength-ductility combination results from the pronounced dislocation nucleation-movement-annihilation activities promoted by 3D nano-architected dual-phase interface, the homogenous plasticity flow of nano-sized amorphous phase, and deformation-induced devitrification induced self-toughening effect. This strategy breaks through the composites design limitations of conventional nanolaminates and provides a paradigm to develop high-strength and high-ductility dual phase nanocomposites with hierarchical microstructure.

CH01.07.30
Unraveling Acid Etching-Induced Anisotropic Morphology Evolution of ZnO Nanorods by *In Situ* Liquid Cell TEM Fangyuan Liu and Pu-Xian Gao; University of Connecticut, United States

Wet chemical etching of metals, semiconductors, and insulators is a significant technique that enables surface cleaning, micromachining, shaping and engineering of various structural and functional surface and bulk features [1-3]. However, the microscale shape and size evolution of ionic semiconductors such as zinc oxide during the anisotropic wet etching process is less understood owing to the challenge of complex etching mechanism and limited resolution for visualization of the etching process in acidic liquid medium [4]. In this work, via *in situ* liquid cell transmission electron microscopy (LCTEM), we directly observe the shape transformation of ZnO nanorod to pencil-shaped nanostructure during the hydrochloride (HCl) acid etching process. Time-lapse LCTEM images revealed a dynamic etching process along the nanopencil tip front. Specifically, the nano-pencil tip shrinks with a slower rate along [000-1] than that along <10-10> directions, with a rapid cyclic tip dissolution and removal in the acid due to accelerating etching rates along various crystal directions. Thus, the base region of the original nano-pencil tip is revealed as a new tip followed by the repeating of the nano-pencil tip angle shrinking step. The high index surfaces, such as {10-1m} (m=0, 1, 2, 3) and {2-1-1n} (n=0, 1, 2, 3), are found to preferentially expose in different ratios, as attributed to selective Cl^- passivation on Zn-terminated surfaces. The surface energetics calculation suggests the preferential Cl^- passivation over the {10-11} and (0001) surfaces of lower energy than others, leading to preferential surface exposures. These investigations shed light on the understanding of anisotropic wet chemical etching of wurtzite-type semiconductor crystals and the design of new functional materials.

Optimal Sampling Strategies for Controlled Dose *In Situ* and High Resolution Scanning Transmission Electron Microscopy (STEM) Nigel Browning[1,2], Alex W. Robinson[1], Daniel Nicholls[1], Jack Wells[1], Amirafshar Moshtaghpour[1,3], Angus Kirkland[3,4] and Beata Layla Mehdi[1]; [1]University of Liverpool, United Kingdom; [2]Sivananthan Laboratories, United States; [3]Rosalind Franklin Institute, United Kingdom; [4]University of Oxford, United Kingdom

For many imaging and microanalysis experiments using state-of-the-art aberration corrected scanning transmission electron microscopy (STEM), the resolution and precision of the final result is primarily determined by the tolerance of the sample to the applied electron beam dose. In the case of in-situ experiments, where the goal is to image a chemical or structural process as it evolves, the effect of the beam dose can be harder to unravel, as a change in structure/chemistry is the expectation of the experiment – when you are looking for a change in a complex experiment and do actually see one, it is natural to expect that the change you see is exactly the one you were looking for. However, if the dose is not controlled, the kinetics of the observations can be dramatically changed by the beam, leading to a different structure/chemistry than would be expected from an ex-situ experiment under similar reaction conditions. Recent results at the University of Liverpool have shown that the optimal solution for dose control in any form of transmission electron microscopy (TEM) is to form the image from discrete locations of a small electron beam separated by as far as possible in space and time. Instead of forming the image with an extended beam (as with TEM) or from a regular raster pattern (as in conventional STEM) this condition is satisfied ideally by moving the STEM probe over the area of the image using large jumps between the acquisition pixels. This form of STEM imaging presents numerous challenges to the stability of the microscope, but these stability issues can be routinely overcome using either a form of random walk scanning, a calibrated random scanning or a mixture of conventional scanning and rapid beam blanking. The larger than standard jumps between pixel acquisition locations in this methodology creates problems with image interpretation, as the gaps between locations of acquisition are missing information. Fortunately, we can use Inpainting (a form of compressive sensing) to retrieve the missing information and retrieve the full image of the sample. In this presentation, we will discuss the methodology behind the use of sub-sampling and Inpainting, with particular reference to the speed and efficiency of the reconstruction method and the potential for future real-time imaging. In addition, the use of simulations to provide a starting point for image interpretation and the use of deep learning approaches to allow the microscope to adapt its own imaging conditions to the sample being studied, will also be discussed. Finally, this complete integrated artificial intelligence work flow for image acquisition and processing ideally lends itself to integrated image analytics that can be used, for example, to quantify feature sizes and their rate of change directly from the sub-sampled datasets.

In Situ Evolution of Density During Sintering of Ultra-High-Molecular-Weight Polyethylene Ying Zhou[1], Takuya Ohnishi[2] and Alan J. Lesser[1]; [1]University of Massachusetts, Amherst, United States; [2]Tosoh Corporation, Japan

Ultra-high-molecular-weight polyethylene (UHMWPE) nascent powders have been commercially processed by sintering for decades even though key aspects the mechanisms and kinetics of this process are not fully understood. Herein, the density evolution during each stage of the sintering process is presented from resulting in-situ measurements and other characterization methods.
Results show that the α-transition plays a significant role in the early stages of the sintering process. Under no pressure, a large change in the apparent

volume occurs before melting. In contrast, significant densification of the nascent powder is observed to occur as the powder is heated through the α-transition. The volume change during the melt explosion is presented and kinetics of the density change that occurs in the non-equilibrium melt is shown for different process pressures and temperatures. From the in-situ measurements, five distinct processes are identified. These include; room temperature densification, further densification during heating through the α-transition, the melt-explosion, isothermal evolution of the non-equilibrium melt, and the subsequent recrystallization during pressure cooling.
The in-situ measurements are complimented by other characterization techniques to describe how different physical and engineering properties change with process conditions and molecular parameters.

The Demand for *In Situ* Metrology in Microgravity R&D—Redefining Dynamic Processes and Technology Innovation Rose M. Hernandez; International Space Station National Laboratory, United States

R&D in space provides a unique opportunity to benefit life by advancing science and technology in ways not possible in unit gravity conditions. For a decade, research on the International Space Station (ISS) has unveiled alternate outcomes of physicochemical phenomena from those known to occur on Earth. For instance, it is well established that the microgravity environment nearly eliminates density-driven segregation in dynamic processes that can result in nucleation processes with better monodispersity, more uniform structures, and homogenous materials leading to superior properties. Similarly, buoyancy-driven convection is negligible in microgravity making diffusion the predominant transport process. All the above affects interfacial energies and dynamics resulting in different surface energies, surface tension, heat and mass transport rates, crystallization kinetics, multiphase system dynamics, fluid dynamics, etc.; yielding novel materials structures and scientific possibilities.
Analytical capabilities are key to understanding and controlling the dynamics of materials synthesis and assembly that result in some of the most advanced science and products developed in space. In this account, the ISS National Laboratory presents examples of technological breakthroughs that were realized by in-situ characterization, data analysis and process optimization on orbit. From industrial applications such as advanced optical systems and additive manufacturing to biomedical applications like protein crystal growth and tissue engineering, the need for in-situ characterization and in-situ process metrology has become essential for the success and acceleration of projects flown to station. Moreover, capabilities to enable in-situ surface and microanalysis, chemical analysis, spectroscopy, and other advanced imaging techniques are discussed.

9:00 AM CH01.08.05
EXAFS-Based Nanothermometry of Inductively Heated Nanocrystals Daniel J. Rosen[1], Shengsong Yang[1], Emanuele Marino[1], Zhiqiao Jiang[1,2] and Christopher B. Murray[1]; [1]University of Pennsylvania, United States; [2]Stanford University, United States

The ability to heat nanocrystalline materials through magnetic induction has been used in the fields of catalysis, biomedical sciences, and polymer degradation. However, the working temperature to which the inductively coupled material rises is still poorly understood. We use extended X-ray absorption fine structure spectroscopy (EXAFS) in conjunction with thermal imaging to improve the understanding of heating in inductively coupled systems. After extraction of the Debye–Waller factor from the spectroscopy, we obtain the temperature of inductively heated nanocrystals from the correlated Debye model. We combine carbon-supported iron oxide nanocrystals as induction heating agents with platinum nanocrystals as thermal probes. By testing these nanocrystal species as both unattached nanocrystals and heterodimers, we have shown that nanostructured systems show a significant temperature difference of up to 73.60 °C when compared to their local support environment. This result has implications for inductively heated catalysis, magnetic hyperthermia for targeted cell death, and polymer synthesis.

In Operando Correlated Studies in Energy Materials via Combined AFM/ToF-SIMS Platform Anton V. Ievlev; Oak Ridge National Laboratory, United States

The performance of energy storage and conversion devices, including batteries, fuel cells, and photovoltaics, is defined by the delicate interplay of electrical response and charge carrier migration at the nanoscale. Although physical behavior and macroscopic functional response is well established, intrinsic chemical phenomena associated with ionic motion or localized electrochemical reactions can dramatically alter behavior and restrict utility of these materials. Over the last decade, advancements in development of novel characterization tools such as atomic force microscopy (AFM) have revolutionized our understanding of the electrical and mechanical response of materials; however, *dynamic*electrochemical behavior and ion migration remain poorly understood. Recently time-of-flight secondary ion mass spectrometry (ToF-SIMS) has proven to be effective tool for characterization of static chemical states in energy materials. However, its application to study of dynamic electrochemical processes still requires development.
Here we introduce approach based on combined AFM/ToF-SIMS platform for correlated studies of the dynamic chemical phenomena on the nanoscale in operando conditions. Being used for characterization of the perovskite materials it allowed direct observation of the ionic migration within the device in externally applied electric fields, which is important for fundamental understanding of the material functionality. Similarly, this approach allowed to study relaxation processes of the chemical phenomena in ferroelectric materials as a function of sample temperature. Altogether, developed approach enables direct characterization of interplay between chemical and functional response in energy materials and aids in the development and optimization of novel devices.
This research was conducted at the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility and using instrumentation within ORNL's Materials Characterization Core provided by UT-Battelle, LLC under Contract No. DE-AC05-00OR22725 with the U.S. Department of Energy.

Selective Reduction of Ni/Co Metal Nanoparticles from Spinel Oxides Scott T. Misture; Alfred University, United States

In-situ techniques offer insights into reaction mechanisms and microstructure development that may be missed entirely when studying complex materials systems. Nickel/cobalt aluminate spinel is an interesting case study, where reducing atmospheres extract reducible cations from the MAl2O4 spinel starting phase. The spinel materials are chemically highly tailorable, and selectively reduced materials are useful as catalysts for fuel reforming, for example. The microstructures, however, are of critical importance. Here we present a study employing *in-situ* scanning electron microscopy as the primary tool for tracking the processes dynamically. In-situ neutron powder diffraction, Raman spectroscopy, and S/TEM complement the FEGSEM data. The talk will show how we track first the evolution of the faceting of the base oxide particles, then sintering of particles, and finally Ni/Co exsolution and resorption – as functions of temperature and oxygen partial pressure. Reduction of the metal nanoparticles from the oxide yields surface sockets and the time/temperature profiles determine the self-organization of the metal particles on the oxide surfaces, as well as the particle sintering. We find that rapid mass transport occurs on the surface, enabling the metal nanoparticles to diffuse along the surface and coalesce. Using catalysis measurements, we show that the oxide surfaces are in fact oxygen deficient, allowing rapid near-surface oxygen ion transport and that simple control over the reduction reactions yields optimized catalysis behavior. We consider possible mechanisms that enable rapid diffusion of particles on these unique oxide surfaces.

Cinematic Molecular Science Explored by High-Speed Electron Microscopic Video Imaging Koji Harano; National Institute for Materials Science, Japan

Single-molecule atomic-resolution time-resolved electron microcopy (SMART-EM) with a high-speed, high-resolution transmission electron microscope has ushered in the era of "cinematic molecular science", in which the dynamic behavior of organic and inorganic molecules can be studied through real-time video images [1, 2]. High speed imaging without increase of electron dose results in very low electron dose per frame, which often causes a very low signal to noise ratio. We have established a method to improve the image quality optimized for SMART-EM by applying the Chambolle Total Variation (CTV) denoising, which enables tracking of molecular motion with sub-millisecond temporal resolution and sub-angstrom localization precision [3]. Herein we demonstrate in-situ observation of a nanomechanical shuttling motion of a single molecule [4], and cascade reactions of nanocarbons [5,6], as applications of the high-speed SMART-EM. We also introduce a new molecular model, atomic-number-correlated (ZC) molecular model, designed for spreading the microscopic molecular imaging to chemists who are still unfamiliar to electron microscopy [7].

10:45 AM OPEN DISCUSSION

11:00 AM CH01.08.11
X-Ray Tomoscopy Reveals the Dynamics of Ice Templating Paul H. Kamm[1,2], Kaiyang Yin[3,4], Tillmann R. Neu[1,2], Christian M. Schlepütz[5], Francisco Garcia-Moreno[1,2] and Ulrike G. Wegst[4,6]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Technische Universität Berlin, Germany; [3]University of Freiburg, Germany; [4]Northeastern University, United States; [5]Swiss Light Source, Switzerland; [6]Dartmouth College, United States

Still little understood are the complex dynamics of microstructure formation by ice-templating that occur when aqueous solutions or slurries are directionally solidified (freeze cast) into cellular solids. With synchrotron-based, time-resolved X-ray tomography, also termed X-ray tomoscopy, it is now possible to study in situ under well-defined experimental conditions the anisotropic, partially faceted growth of ice crystals in aqueous polymer solutions. Obtaining one full tomogram per second for ~270 s with a spatial resolution of 6 µm it is possible to capture with minimal X-ray absorption the freezing front that typically progresses at 5–30 µm/s. These time and length scales render X-ray tomoscopy ideally suited to quantify in 3D otherwise elusive ice crystal growth phenomena that determine the performance-defining hierarchical architecture of freeze-cast materials, which consists, on the one hand, of a complex pore morphology and, on the other, of ridges, and ‘jellyfish’- and ‘tentacle’-like features, which decorate the cell walls.

11:15 AM CH01.08.12
***In Situ* Pyroelectric Heat Detection for Elucidating Atomic Layer Deposition Thermodynamics and Kinetics** Ashley Bielinski and Alex Martinson; Argonne National Laboratory, United States

The detailed mechanisms, kinetics, thermodynamics, and complexities of even the most well-studied atomic layer deposition (ALD) reactions remain insufficiently resolved experimentally to test present computational hypotheses. We design, implement, calibrate, and electrically model a pyroelectric thin film calorimeter to enable quantitative ALD reaction heat detection. With a thermal and temporal resolution down to 0.1 µJ/cm^2 and 50 ns, this sensitive and ultrafast probe is poised to improve our fundamental understanding of numerous ALD reaction mechanisms through quantitative comparison to first-principles computation predictions. We offer new insight into the thermodynamics and kinetics of the trimethylaluminum (TMA) and H_2O ALD half reactions. The half-reactions produce heat greater than that predicted by computational models based on crystalline Al_2O_3 substrates and closely aligned with the heat predicted by standard heats of formation. Comparing the experimental heat with published computational literature and additional first principles modeling highlights the need to refine our models and mechanistic understanding of even the most ubiquitous ALD reactions.

Atomic Scale Dopant Control Andrew Lupini[1], Ondrej Dyck[1], Mina Yoon[1], Sergei V. Kalinin[2] and Stephen Jesse[1]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

The ability to construct new materials starting from the scale of single atoms could potentially enable new materials and technologies. However, this process involves two separate challenges: How to see where the atoms are, and then how to control where they go. The scanning transmission electron microscope (STEM) provides an answer to the first challenge, with the Z-contrast imaging mode able to reveal the structure and bonding of a variety of materials. Perhaps even more excitingly, the STEM might also provide an answer to the second challenge of how to control the position of the atoms. Working in a high-vacuum system, the atomic-scale probe size obtained in an aberration-corrected STEM allows single atoms to be manipulated in and on a variety of materials, with examples including heavy dopant atoms inside silicon crystals, and a variety of different atoms in graphene. Recent work has highlighted the potential for this technique [1], elucidated the underlying mechanisms [2], and extended the range of elements that can be used [3]. Nevertheless, numerous challenges remain, such as: How do we find the ideal conditions? How do we control the supply of dopants? And to what extent can the atoms be positioned where we want them? [4]

2:15 PM CH01.09.02
Colloidal Templating and Layered Extrusion Assemblies—Unconventional Shapes and Folding Objects Rigoberto C. Advincula[1,2,3]; [1]The University of Tennessee, Knoxville, United States; [2]Case Western Reserve University, United States; [3]Oak Ridge National Laboratory, United States

The preparation of new polymers and colloidal nanomaterials requires hierarchical levels of ordering and structuring: from molecular to macroscopic. The tools and methods are available for evincing order requiring design principles that start from non-covalent interactions all the way to object patterns that can be manipulated by non-lithographic methods. This talk will highlight the templating and assembly methods in: 1) colloidal nanosphere lithography used by our group to produce systems that include: conjugated polymers, electropolymerized molecularly imprinted sensors, electronanopatterning, and polymer brush lithography. 2) Polymer layered systems based on melt extrusion roll-to-roll process, 3) Hard-soft matter bilayers based on reactive ion etching of "origami" like structures. We also demonstrate the importance of surface-sensitive spectroscopic and microscopic analytical tools applied rationally to highlight evidence of order and function. The ability to synthesize and fabricate layered ordered systems results in new material stimuli-responsive properties.

2:30 PM CH01.09.04
Imaging the Conversion of Metal Oxide Nanoparticles into Bimetallic Hollow Nanostructures Through Galvanic Replacement and Etching Reactions Wenhui Wang and Utkur Mirsaidov; National University of Singapore, Singapore

Hollow nanomaterials with controlled chemical composition and morphology are an important class of materials used in many applications, such as catalysis, energy storage, and biomedicine, because of their low mass density, high surface area, and reduced diffusion length for mass and charge transport. Various approaches have been explored for the synthesis of hollow NPs as electrocatalysts with improved activity and selectivity, among which, the GR reaction is frequently adopted due to their effectiveness and low-temperature. However, the mechanism behind the chemical conversion from a template NP to a hollow nanostructure through GR may be more complex than that expected from straightforward electrochemical dissolution. In fact, the hollowing process usually accompanied by dealloying, kirkendall diffusion or etching reactions. For example, it has been reported that the transition of Ag nanocube to a hollow Au structure through GR reaction with HAuCl4 solution is due to the nucleation and propagation of voids within the nanocubes, suggesting that kirkendall effect couples to GR in the reaction between Ag and Au. Apart from metal NPs, metal oxide NPs are also widely used in synthesizing bimetallic hollow nanostructures, while the conversion dynamics and underlying mechanisms are less investigated comparing to that of metal NP templates. Due to the versatile composition and earth abundance of metal oxide NPs, it is vital to understand the GR process on a metal oxide template NP through which hollow nanostructure is achieved.
Metallic shell growth and template removal through which metal oxide NPs are converted into bimetallic hollow nanostructures by GR and etching reactions are complex chemical processes with various short-lived intermediate states. Moreover, the morphological and compositional evolution of a bimetallic hollow nanostructure in catalytic relevant conditions involve with intricate reginal surface reactions at nanoscale. The key questions remain unresolved are as follows. (1) Which surface sites, such as corners, edges, and facets of the metal oxide template, are the most susceptible to GR reaction? (2) How do the shells form and NPs become hollow? (3) How does the reaction conditions control the etching pathways? (4) How does the structure of the bimetallic hollow nanostructures change in catalytic reaction conditions? Capturing the transient stages of these processes and addressing these questions requires an approach that enables direct visualization of these nanoscale processes as they take place.
Here, we use liquid-phase TEM imaging to resolve the details of the GR and etching reactions through which spherical and cubic Cu2O NP templates are converted into bimetallic PdCu hollow nanostructures. We chose to synthesis PdCu NPs because they are promising candidate for CO2 reduction reactions which converts CO2 to value-added industrial chemicals or fuels. Furthermore, we chose Cu2O as a template material because it has suitable redox potential to that of Pd for the GR reaction taking place. In our study, the conversion reactions are initiated by flowing the H2PdCl4 solution into a liquid cell through a fluidic channel. We imaged the conversion process using ultralow electron flux imaging conditions to minimize the effects associated with the electron beam. Our in situ TEM observations show that Cu2O NPs are converted into hollow PdCu nanostructures through uniform growth of PdCu shell together with anisotropic etching of template NP. Moreover, the thermodynamic and kinetic etching pathways of Cu2O NP are controlled by the concentrations of the etchant. Furthermore, we extended our study to test the stability of these PdCu hollow nanostructures under conditions relevant to CO2 reduction reactions. We reveal that Cu dissolute from the skeleton of the hollow nanostructure and redeposition onto the surface of the NP and electrode, which may lead to a low faraday efficiency for hydrocarbon products.

Cryogenic STEM Imaging and Spectroscopy for Energy and Quantum Materials Miaofang Chi; Oak Ridge National Laboratory, United States

Many energy and quantum materials require characterizations to be performed at a low temperature. Recent advancements in cryogenic scanning transmission electron microscopy (Cryo-STEM) are opening new opportunities for related research areas. For example, exotic states in quantum materials usually only occur at low temperatures. Newly developed liquid nitrogen cooling cryogenic stages with desirable stability at both base and variable temperatures enable us to elucidate phase transformations of quantum materials in real space at the atomic scale. Electron beam damage in an electron microscope is often a considerable limitation in analyzing energy materials such as soft or superionics at the atomic scale. *Cooling* the *specimens* to a low temperature *may* help to reduce the beam damage. However, energy conversion and storage materials often contain loosely bonded ions, soft structures, or organic components. Multiple beam damage mechanisms are involved in during electron-matter interactions. Robust atomic scale microscopy analysis becomes challenging. In this talk, I will give several examples to demonstrate how cryo-STEM enables energy and quantum materials research. I will also discuss other critical experimental parameters to be considered during high resolution analysis in order to minimize beam damage. Data analysis and acquisition methods that help to reduce electron dose will also be introduced.

***In Operando* X-Ray Diffraction Investigation of Reduced Graphene Oxide in Aqueous Solution** Maria del Pilar Bernicola Garcia[1], Elena del Corro[1] and Jose A. Garrido[1,2]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]Institución Catalana de Investigación y Estudios Avanzados, Spain

In the recent years, reduced graphene oxide (rGO) has been studied in many different fields due to its remarkable physicochemical properties. In the healthcare applications field, rGO films have been widely studied because of their biocompatibility and biochemical sensing capabilities [1]. Also, rGO can be engineered to prepare films exhibiting large electroactive surface area, large electrochemical potential window, and high electrical conductivity. Regarding to these properties, a fundamental understanding of key aspects of the films processing, such as the evolution of the functional groups during the reduction process of rGO and the role of ionic diffusion, is extremely relevant due to their impact on the stability and the final performance of rGO-based devices.

In this work, by combining ex-situ and in-operando electrochemical and spectroscopic techniques, we investigate the solid-liquid interaction between rGO-based nanoporous electrodes and the environment. We aim to reveal those events happening during electrochemical processes, involving ionic intercalation, charge adsorption and functional groups evolution, that may have an impact on the chemical and structural properties of resulting rGO. X-ray photoelectron spectroscopy (XPS), Raman spectroscopy and contact angle are ex-situ techniques used to follow the evolution of functional groups upon the reduction degree of GO/rGO at different stages (before and after electrochemical treatments) [2]. The number of functional groups are related with the hydrophobicity and conductivity of rGO, and these properties are linked with the electrochemical properties of the material. Ex-situ electrochemical techniques such cyclic voltammetry (CV), charge-discharge techniques and potentiostatic electrochemical impedance spectroscopy (PEIS) are used to evaluate electrochemical properties such as specific capacitance, ion diffusion, electrochemical potential window and charge transfer resistance at different potentials. Mentioned techniques gives us information of the electrode at different stages but information related the chemical mechanisms involved in the electrochemical processes would remain missing. In-operando techniques are an emergency tool that contributes to have a better understanding of the mechanism that take place during the electrochemical treatments.

In this study, we develop a home-made spectro-electrochemical cell for in-operando X-ray diffraction spectroscopy (XRD) which allows us to follow the chemical and structural changes of the rGO material in aqueous solution during different electrochemical processes. With this in-operando technique, we aim to study the ionic intercalation process, the changes on the interlayer distance and its dependence with the applied potential. Such knowledge help us to understand the mechanism that leads to achieve a highly capacitive material. This work aims at expanding the current understanding of the properties of rGO-based nanoporous thin films for their potential use as electrode material in healthcare applications.

4:00 PM CH01.09.08
3D Reconstruction of the Alloying Process of AuAg Nanoparticles by Small Angle X-Ray Scattering Siyu Wu[1], Xiaobing Zuo[2] and Yugang Sun[1]; [1]Temple University, United States; [2]Argonne National Laboratory, United States

The element distribution pattern in a bimetallic nanoparticle system is usually varying during the synthesis, post-processing, and catalysis reactions under operando conditions. The structural complexity of the nanoparticle system brings significant difficulty in determining the relationship between the structures and their physical and chemical properties. Small angle x-ray scattering (SAXS) can be used to characterize size, morphology, and density of a nanoparticle system under operando conditions. We applied SAXS on monodispersed core-shell AuAg nanoparticle system to monitor the growth of Au layers on Ag nanoparticles and the following alloying process when the nanoparticles are heated. The nanoparticle density distribution change caused by the diffusion of Au and Ag atoms is reconstructed by DENsity from Solution Scattering (DENSS) algorithm with a sub-nanometer resolution. The time-resolved series of 3D images enables the quantitative study of the 3D evolution of size, morphology, composition, and element distribution of the alloying AuAg nanoparticle system. The density contrast SAXS imaging protocol established in this work provides a transformative way to "see inside" nanoparticle structure other than the traditional electron microscopic methods.

4:15 PM CH01.09.09
Time-Resolved Study of Phase and Mechanical Developments of Martensitic α' Phase in Ti-6Al-4V Under Laser Processing via Synchrotron X-Ray Diffraction Seunghee Oh[1], Joseph Aroh[1], Nicholas Lamprinakos[1], Andrew Chuang[2], Robert M. Suter[1] and Anthony D. Rollett[1]; [1]Carnegie Mellon University, United States; [2]Argonne National Laboratory, United States

Laser powder bed fusion (LPBF) is one of the most actively studied additive manufacturing (AM) processes. Based on laser melting with sub-millimeter tracks in a metal powder bed, it can build complex and precise parts. The processing involves rapid heating and cooling of the material, which induces unusual microstructural evolution.
Ti-6Al-4V (Ti64) has been extensively studied as an AM alloy because of its unique combination of excellent properties in weldability, strength, density, corrosion resistance, and biocompatibility. This α+β type Ti alloy involves a solid-state phase transformation of β and α around 980 degrees Celsius. Under fast cooling conditions, the high-temperature phase, β, is known to undergo a martensitic transformation, which results in α'+α+β or α' microstructures. The as-printed LPBF Ti64 is typically composed of the martensitic phase, α', because the laser-based processing is accompanied by rapid cooling. It has been reported that the fractions of β and α' strongly affect the ductility and strength of Ti64. Therefore, the resultant microstructures associated with laser processing are important predictors of the material properties of the printed parts. However, the microstructural evolution depends sensitively on the process conditions, and little is known about the transformation of the β phase because of its high reaction temperatures. Moreover, the extremely fast process in a small processing volume makes it more challenging to characterize the development during laser processing.
In this study, an *in situ* synchrotron X-ray diffraction experiment with high temporal and spatial resolution was utilized to observe the rapid phase evolution in melt pools developed by laser melting. Based on the transmission mode setup, the high-energy monochromatic X-ray beam passed through a sample under laser processing, during which the diffracted x-rays were collected on an area detector. The samples were prepared from as-printed Ti64 fabricated in an LPBF system (EOS M290) and sliced into thin plates of thickness 0.4 mm. Metallography provided substantial information that confirmed the results obtained from the X-ray diffraction measurements.
The analysis confirmed that the prepared samples from the as-printed Ti64 are fully martensitic with no β phase present. The dynamic acquisition of 2D diffraction images showed how the martensitic phase evolved before and after the laser melting. The multiple *in situ* measurements at different locations of the melt pool showed how the phase configuration developed in the fully resolidified region and heat-affected zone (HAZ). The variation in the lattice spacing with azimuth (*i.e.*, direction sampled by the diffraction) implied an anisotropic mechanical response in the laser processed regions, which were investigated both qualitatively and quantitively. The changes in the lattice parameter of β and α' during the martensitic transformation indicated how α' evolves with respect to the depth below the surface of the melt pool and how the phase evolution correlated with that of the macro-strain. From the changes in the diffraction profile, it was found that pre-existing micro-strain in the martensitic α' relaxed in the HAZ as a result of the laser processing. The estimated temperature profiles based on thermal expansion facilitated comparisons with expectations from equilibrium phase relationships. The developments of the phase composition and residual strain under laser processing were investigated, which is expected to provide valuable information for

optimizing the laser processing of Ti64.

Electrocatalyst Transformations Under Reaction Conditions—Insights from *Operando* Transmission Electron Microscopy of Well-Controlled Pre-Catalysts See Wee Chee; Fritz Haber Institute of the Max Planck Society, Germany

The conversion of base molecules found in our environment (e.g., H_2O, CO_2) into the valuable chemicals and fuels needed by our modern society via electrocatalysis is currently an active area of research due to its potential for green energy applications. However, for many of these technologies, the search for optimal catalysts is still a laborious process because we lack a robust understanding of the relationship between a catalyst's structure and its catalytic function. It is important to note that the catalytic performance is not solely determined by the starting catalyst (or pre-catalyst) structure, the dynamic catalyst structure that exists under reaction conditions also plays a key role. Moreover, probing this dynamic structure is not straightforward because it may not be retained when we examine the catalysts after reaction in the absence of the electrolyte and applied potential. Here, I will present work from my group studying the dynamical transformations that take place in Cu-based catalysts for the electrochemical reduction of carbon dioxide using *operando* electrochemical cell transmission electron microscopy (EC-TEM). To elucidate the impact of these transformations on catalytic performance, we adopted highly tuneable catalyst synthesis strategies that generate near-identical electrocatalysts for both EC-TEM and benchtop electrochemical and product selectivity measurement setups. Our *in situ* observations indicate that the application of a reductive potential generally leads to drastic structural changes, such as catalyst detachment, fragmentation, and re-deposition, within minutes. I will also discuss how these effects correlate with changes in catalyst activity and selectivity, thereby providing insights that can inform the design of better electrocatalysts.

11:00 AM CH01.10.02
Identification and Characterization for Spherulization in Methylammonium-Guanidinium Lead Iodide Perovskite Material—A Structural and Morphological Investigation of Microstructural Evolution Monika Mukul[1], Selvaraj Kaliaperumal[2], Mamta Rani[1] and Surya Kant Tripathi[3]; [1]DAV University, India; [2]CSIR-National Chemical Laboratory, India; [3]Panjab University, India

Hybrid organic-inorganic perovskite materials (HOIP) have gained tremendous popularity in the past decade for their unique optoelectronic properties for photovoltaic applications. This report presents comprehensive structural and morphological analysis which infuses new insights into the evolution of polycrystalline self-assembled spherulitic microstructures with different hierarchical architectures in HOIP material which are hitherto unattempted. X-ray diffraction (XRD) analysis confirms the formation of guanidinium (GUAI)-rich MAI-GUAI-PbI_2-DMF pure intermediate phase of the dendritic perovskite spherulites and transformation to stable α-tetragonal or quasi-cubic perovskite converted phase of $Ma_{0.75}Gua_{0.25}PbI_3$ material composition with calculated crystal structure parameters; a=b=6.31074 Å and c=6.33810 Å, α=β=γ=90° and a cell volume of 252.418 $Å^3$ via slow crystallization in extreme humidity levels of 92±4% and temperature 24.5±1.5°C. This work also shed light on microstructural heterogeneity of these materials in their intermediate phase. The Field Emission Scanning Electron Microscope (FESEM) analysis unravels the fundamental microstructure of embryonic spherulitic nuclei in perovskites; lamellar arrangements, categorize the mature perovskite spherulitic microislands (PSMs); transcrystalline layers (TCL), spherulite bridges, nucleation of hole, impingement behavior, coupled-PSMs, and defects such as pits and spherulitic microcracks. The inner-core and outer area of all the freshly prepared spherulitic forms are evaluated to range between 203.6-380.5 μm^2 and 974.4-1900.0 μm^2 respectively. To assess the stability of this spherulitic perovskite and understand its phase transformation, XRD and FESEM study has been done after 10 days. New zero-dimensional (0-D) orthorhombic Pmmm(47) polymorph with blood-cell like morphology have been observed in the wheat sheave branches of the aged perovskite sample. Optical microscopic images also confirms the wheat-sheaf like morphology. The UV-Visible results have shown the absorbance peak of 3-D quasi-cubic perovskite phase around 788 nm. Energy-dispersive X-ray analysis (EDX) confirms the stoichiometric homogeneity of intermediate phase with similar value of C, Pb and I atomic ratios from different regions of the thin-film. As from the viewpoint of crystallography and performance, the individual perovskite grains may display very different properties. Thus findings of this work not only enhances the understanding on organic-inorganic spherulitic microstructures but also an attempt to evident the polymeric aspect of HOIPs, intermediate phase, and phase transformation that can serve to improve the morphology and phase stability for higher device performance of HOIPs.

11:15 AM CH01.10.03
Deducing Electric-Field Mediated Peptide Materials Design Julia Robbins, Tiffany Ji and Subhasish Chatterjee; Kean University, United States

Self-assembly of gene-encoded peptide motifs offers a bioinspired strategy for developing the design of functional nanomaterials.The current work illustrates contrasting effects of the electric field in the formation of peptide-based supramolecular materials. We have applied both atomistic and coarse-grained molecular dynamics simulations; our results highlight how the applied electric field can modulate the interaction between the hydrophobic and hydrophilic components of amphiphilic peptides, leading to the formation of dynamic soft materials.

11:30 AM CH01.10.04
Dislocation-Induced Stop-and-Go Kinetics of Interfacial Transformations Xianhu Sun[1], Dongxiang Wu[1], Lianfeng Zou[1], Stephen House[2], Xiaobo Chen[1], Meng Li[2], Dmitri Zakharov[3], Judith C. Yang[2] and Guangwen Zhou[1]; [1]SUNY at Binghamton, United States; [2]University of Pittsburgh, United States; [3]Brookhaven National Laboratory, United States

Engineering materials are typically based on multiphase microstructures produced either through the control of phase equilibria or by the fabrication of different materials as in thin-film processing. In both processes, the microstructure relaxes toward equilibrium by mismatch dislocations (or geometric misfit dislocations) across the heterophase interfaces. Fundamental understanding of mismatch dislocations and their dynamic coupling to phase transformations has been a longstanding topic of study. Unfortunately, directly probing misfit dislocation dynamics has been a major challenge due to their buried nature and the difficulty of direct experimental measurements at the atomic scale. Transmission electron microscopy (TEM) is one of the few tools capable of accessing buried interfaces and has demonstrated its versatility and atomic-scale precision in elucidating the location and configuration of misfit dislocations. However, directly probing the dynamic action of mismatch dislocations during phase transformations is challenging because it requires not only a capability to atomically capture the fast evolution of interfaces but also to apply stimuli to drive the interface transformation. Using the example of $Cu_2O \rightarrow Cu$ interfacial transformation, we demonstrate the unique role of mismatch dislocations in modulating oxide/metal interfacial transformations in an

intermittent manner, by which the lateral flow of interfacial ledges is pinned at the core of mismatch dislocations until the dislocation climbs to the new oxide/metal interface location[1]. Together with atomistic calculations, we identify that the pinning effect is associated with the non-local transport of metal atoms to fill vacancies at the dislocation core. These results provide mechanistic insight into solid-solid interfacial transformations and have significant implications in utilizing structural defects at buried interfaces to modulate mass transport and transformation kinetics.

Laser-Induced Photo-Thermal Reduction—Mechanism & Applications Ehud Greenberg, Nina Armon, Eitan Edri and Hagay Shpaisman; Bar-Ilan University, Israel

Assembly of materials into microstructures under laser guidance is attracting wide attention. The ability to pattern various materials and to form 2D and 3D structures with micron/sub-micron resolution and less energy and material waste compared with standard top-down methods make laser-based printing promising for many applications in sensing, medical devices, and microelectronics. Assembly from liquids provides smaller feature size than powders and has advantages over other states of matter in terms of the relatively simple setup, easy handling, and recycling. However, the simplicity of the setup conceals a variety of underlying mechanisms, which cannot be identified simply according to the starting or resulting materials.
Here, we shed light on one of the mechanisms through systematic analysis of photo-thermal reaction products forming iron oxide and silver at different interfaces. Examination of the nanostructure of deposits on a substrate using high-resolution transmission electron microscopy and selected area diffraction pattern analysis reveals a combination of both amorphous and crystalline moieties. We found that focusing the laser inside the solution leads to exclusive formation of crystalline products, while focusing on the liquid/air interface leads to formation of amorphous products due to kinetic considerations. Ring-shaped microstructures observed on the substrate indicate that microbubbles are involved in the deposition. Our findings suggest that crystalline nanoparticles formed in solution are pinned to the base of the microbubbles. These stationary deposits absorb the laser light, resulting in extensive local heating, which leads to a fast thermal-reaction of the metal ions that are added as amorphous nanostructures. The presence of both crystalline and amorphous nanostructures therefore results from two different mechanisms. Finally, we demonstrate how microfluidics could be utilized to enhance the capabilities of multi-layered laser micro-printing by quickly switching between precursors. The concepts presented here could provide new opportunities for fabrication of multi-layered micro-electronic devices and sensors.

Comprehension of the Behavior of Rectifier Diodes Through the *In Situ* Study of the Electrically Induced Phenomena on the Active Si Component Sara Román-Sánchez[1], Aida Serrano[1], Alberto Moure[1], Jesús López-Sánchez[1], Juan Rubio-Zuazo[2], Adolfo del Campo[1] and José Francisco Fernández[1]; [1]Institute of Ceramics and Glass, Spain; [2]European Synchrotron Radiation Facility, France

Nowadays, there are numerous advanced characterization techniques that offer great versatility in the field of materials. Concretely, confocal Raman microscopy (CRM) or techniques based on synchrotron radiation, such as single-crystal X-ray diffraction (SCD) are of major relevance for carrying out studies in solids. These non-destructive techniques allow exhaustive *in situ* structural analysis at the local scale of several materials, without the need for very specific sample preparation, and achieving high spatial resolution.
Located *in situ* structural studies are of great utility in the semiconductor-based technology field. One of the main limiting factors of these devices is the modifications that may take place on their structure as a consequence of the high electrical current that flows through them when they are in operation. Press-fit rectifier diodes are an application example of Si-based electronic devices, which have a great interest in the automotive industry. Thanks to their ability to allow the current to flow in one direction only and blocked it in the opposite one, they are often employed to transform the alternating current produced by the alternator into a direct current, in order to make it suitable for the power supply of the vehicle. At *in operando* conditions, diodes endure electrical current in the order of tens of A, which leads to the overheating of the device by the Joule effect at temperatures about 250 ºC. This fact may pose a problem, not only because of the thermal degradation of the devices but because of the appearance of structural damage associated with their multicomponent nature. Rectifier diodes are commonly composed of several materials: a silicon semiconductor wafer where the rectifier technology is located, joined to a copper heat-sink and to an epoxy region, whose function is to provide mechanical and electrical protection. Their thermal response is different for each one, leading to the appearance of mechanical stress as a consequence of the mismatch of the thermal expansion coefficients. In addition, other structural variations that the electric current may induce on the active Si, which can influence the behavior of the diode, such as carrier dynamics, may also take place on the devices at *in operando* conditions.
In order to optimize the performance of the diodes, it is essential to know their behavior and the different phenomena occurring during their operation. For that, in this work, an *in-situ* characterization has been carried out using different techniques. First, a preliminary study of the thermal response of the whole diode by infrared thermography revealed the inhomogeneous heating of the device. Then, the structural modifications that the active semiconductor undergoes were evaluated by confocal Raman microscopy and X-ray diffraction in synchrotron (ESRF, Grenoble). Results have allowed discerning the influence of the heating phenomenon caused by the Joule effect from other non-purely thermal phenomena, characteristic of these devices, as well as to identify the presence of different regions located in the Si, whose differences are based on the stress and doping scheme of this component. Experiments were carried out in diodes with different technologies (Schottky, MOS and PN) and proceeding from different providers (different designs), intending to evaluate the influence of different parameters. The study was useful to comprehend the phenomenology induced on the active Si region of rectifier diodes in working conditions in order to increase their useful life by reducing their failure rate.

12:15 PM CH01.10.07
Investigating Iron Corrosion with *In Situ* Liquid TEM Surabhi Agrawal, Mobbassar Hassan Sk, Richard Langford and Stuart Clarke; University of Cambridge, United Kingdom

Corrosion is the environmental degradation of metallic structures over time due to an electrochemical reaction on the surface. Whilst it starts at the surface, it can often get deep into the structure locally, leading to catastrophic structural failures. Understanding corrosion process at the most fundamental level is of great scientific and commercial interest, as it underpins novel and efficient corrosion mitigation approaches and reliable prediction models. Despite the importance of early stages of the phenomena, earlier works have been largely limited to speculation based on ex-situ studies of iron and steel pieces, which are unable to capture many subtle sub-stages of the process. Moreover, removal of samples from the native state necessarily results in quenching/transformation before characterisation. It is important to understand the nucleation stage of the dynamic process under 'real conditions', through in-situ techniques. Here, we demonstrate the use of liquid TEM to study iron corrosion in sodium chloride solution, using a commercially available liquid holder. Two silicon nitride chips is assembled with a spacer in-between, and clamped in a metal holder. Microfluidic connections allow liquid flow, and the spacer sets the liquid layer thickness in the beam path. The sample is a thin film of iron (30-50 nm) deposited, via electron beam evaporation, on one of the silicon nitride membrane chips, before assembly. The sample is imaged in a FEI Philips Tecnai 20 LaB6 TEM. A combination of bright and dark field imaging, and selected area electron diffraction is employed to capture the early reaction stages.

  We address the two key processes – iron dissolution in solution and iron oxide nucleation process. The nature of the nucleation process (homogenous or heterogeneous), corrosion precursor (amorphous or crystallinity) and its evolution is investigated. We find that nucleation initiates on the metal surface, with preferential growth along the grain-boundaries of the iron film (quantified). We also identify the early-stage nuclei to be crystalline, characterised by its diffraction pattern. On the basis of our findings, we present a primary mechanism for nucleation of iron oxides on a reactive iron surface.

12:30 PM CH01.10.08
Microfluidic Supported Emulsion Polymerization and *In Situ* Assemblies for Synthesis of Size and Shape-Tunable Soft Polymer Nanoparticles Nikunjkumar Visaveliya; The City College of New York, United States

Polymer particles are promising nanoscale materials for a wide range of applications in the field of biomedicine, sensing, and labeling. Controlled structural aspects of the polymer nanoparticles such as size, shape, surface topology, morphology, internal softness, interior cross-linking, and core composition determine their impact on the cargo loading capacity and controlled/sustained release, the possibility of endocytosis, and degradability during their biomedical application. The designed interfacial features, on the other side, such as stimuli-responsive surfaces, wrinkling, surface porosity, shell-layer swellability, layer-by-layer surface functionalization, surface charge, surface roughness, and textures regulate nanoparticles' interfacial interactions, controlled assembly, movement and collision, and compatibility with the surroundings like a solvent and biological environments. These characteristics define polymer nanoparticles' overall properties/functions based on homogeneity, stability, interfacial tension, and minimization of the surface energy barrier. If nanoparticles are not uniform in their size or shape, the resultant outcome may be significantly lower directly related to the concept of the structure-function relationship. Therefore, a key requirement is to produce well-defined and uniform polymer nanoparticles with controlled characteristics. However, because polymers are amorphous (or semi-crystalline), flexible, and soft materials, controlling their structural/interfacial features through the single-step process is a challenge. The microfluidic reaction strategy can provide the platform for homogeneous mixing of reactants and the production of uniform particles with controlled assemblies. Here, the state-of-the-art fundamental characteristics of the polymer nanoparticles are presented through experimental results. We have applied a semi-microfluidic approach where initial emulsification has been formed inside the microfluidic channel and the completion of polymerization together with their in-situ assemblies realized externally. In the case of utilizing molecular surfactants, the spherical polymer nanoparticles between the size range of 50 nm and 500 nm were obtained. Besides, we observed that the application of polyionic polyelectrolytes was the key driving force for initiating the in-situ assemblies of the growing polymer nanoparticles during polymerization to form the anisotropic structures. In this way, we created the library of the shape-controlled polymer nanoparticles in the form of ellipsoidal, dumbbell, elongated chain-like, branched-shape, and flower-shaped polymer nanoparticles.

Direct Nanoscale Observation of Thermally Driven Grain Boundary Migration Associated with Their Triple Junction Motion Utkur Mirsaidov; National University of Singapore, Singapore

Thermally activated grain structure evolution in polycrystalline materials has been an important research area due to its scientific and technological significance, since many physical properties of materials are highly dependent on the structure and density of grain boundaries (GBs). GBs and their intersections known as triple junctions (TJs) are the major elements of a complex network in polycrystalline materials, and while the motion of GBs has been extensively studied for decades, the effect of TJs on the grain growth kinetics only recently started to receive due attention. Moreover, many critical details of coupled GB-TJ evolution can only be described at the atomic scale, where direct real-time experimental observations are still lacking. We chose to use cobalt (Co) for its technological importance and two-phase nature, as it normally contains both *fcc* and *hcp* grains. Using *in situ*transmission electron microscopy (TEM), we captured the thermally activated grain growth in a natural nanocrystalline Co film at both the mesoscale and the atomic scale. We found that discreet TJ motion governs the grain size evolution dynamics by initiating or delaying GB migration, whereby TJ displacements are correlated with dynamic dihedral angles and the grain area modification. We linked the changes in mesoscale GB shape with atomic-scale disconnection dynamics, showing how the normal GB migration occurs through a lateral motion of disconnections emitted at TJs. Overall, this study provides experimental evidence for the critical role of disconnection dynamics for the coupled motion of TJs and GBs in a general nanocrystalline metal film.

Rapid Hierarchical Nanostructures of Lamellar Block Copolymer Thin Films via Microwave Annealing Ugur Aslan; University of Houston, United States

Block copolymers (BCP) have been long investigated to achieve periodic nanostructures on silicon substrates which have a wide range of applications from the semiconductor industry to nanoelectronics. The nano periodicity of BCP in different shapes such as cylinders, lamella, spheres, and gyroids, is achieved by self-assembly by manipulating BCP composition nd temperature. While these structures can be achieved by thermal annealing (TA), it is a slow process. In contrast, microwave is a fast, effective and intriguing energy source, and a desirable method for heating various materials. We obtain hierarchically ordered lamellar BCP nanostructures in thin films by short-time microwave annealing on boron-doped silicon substrates, chosen for its high microwave absorption. We investigate the fast ordering kinetics of BCP films in as little as 10s compared to hours in TA, with respect to domain spacings (L_0) formation in parallel lamellar BCP morphology, as measured by island and hole formation characteristics on the film surface. An exciting feature is that ½ L_0 plateau form around the holes within a short time of microwave annealing, that is not typically observed in TA. These ½ L_0 relief structures transition to 1 L_0 when further subjected to extended TA. Lastly, we compared the domain spacing and average hole diameters evolution of microwave annealing of the BCP films with that of TA. We conclude that microwave annealing can be effectively used to obtain parallel, both non-traditional ½ L_0 and traditional L_0 lamellar relief topography structures, in very short times, making it suitable for industrial processing.

Experimental Investigation of Powder Electrical Characteristics and Smoke Behavior in Electron Beam Additive Manufacturing Using AlSi10Mg and 64Ti Powder Takayuki Ishii, Hao Wang, Kenta Aoyagi and Akihiko Chiba; Institute for Materials Research Tohoku University, Japan

Powder bed fusion using an electron beam (PBF-EB) is expected to be applied for medical equipment and aerospace since PBF-EB process can produce object with little thermal strain and contaminant because of high temperature vacuum process.
However, when powders are charged up due to electron beam scanning on powder bed, powders are often spread out because of electrostatic force between powders. This phenomenon is called as smoke phenomenon and is problem in PBF-EB process.
The physical origin of smoke phenomenon is empirically considered to be charge-up, but it is not known in detail what kinds of factor affect occurrence of smoke phenomenon.
In order to clarify the mechanism of smoke phenomenon, we have investigated powder properties and conducted experimental smoke test using AlSi10Mg and 64Ti powder.

In the confirmation of the physical properties of the powder, the electrical characteristics of the powder were investigated using the electrochemical impedance measurement that has been conducted in the previous studies, and the time constant of the powder was analyzed by waveform analysis. The Coulomb repulsion between powders was calculated using the time constant, and it was assumed that smoke is generated when the Coulomb repulsion is larger than the weight of one powder particle, and smoke is not generated when the Coulomb repulsion is smaller than the weight of one powder particle. We predicted the possibility of smoke generation during the building process on this assumption. By comparing the prediction by calculation with the presence or absence of smoke generation (smoke test) by experiment, the mechanism of smoke phenomenon was considered.
In 64Ti, there was a good match between the prediction of smoke generation and the results of the smoke test, proving that the smoke mechanism is due to the Coulomb repulsion. However, in AlSi10Mg, the prediction of smoke generation and the result of the smoke test did not match, suggesting that factors other than the Coulomb repulsion are involved as the smoke mechanism. As factors other than the Coulomb repulsion, the permeability of the electron beam and the temperature rise of the powder due to the electron beam were considered, but none of them can completely explain the mechanism of smoke generation. It was found that detailed discussion on the mechanism is needed in the further study.
In conclusion, it is necessary to consider not only the electrical factor due to the Coulomb repulsion but also other complex factors in the mechanism of smoke generation.

10:00 PM CH01.11.05
The Influence of Polymer Binder on Melting Process and Mechanical Properties in a Novel Laser Deposition Method Using Metal Paste Weicheng Heng[1,2], Kenta Aoyagi[1] and Akihiko Chiba[1]; [1]Institute for Materials Research, Tohoku University, Japan; [2]Graduate School of Engineering, Tohoku University, Japan

Additive manufacturing has been widely applied in many industrial fields including medical, automobile, and aerospace due to the capability on processing products with complex topology design. However, in metal material processing field, the two conventional additive manufacturing methods, powder bed fusion using a laser beam (PBF-LB) and directed energy deposition (DED) still have their own weakness. The lower metal powder utilization rate in PBF-LB and the requirement of support structure for overhanging parts in DED not only increase the production cost, but also cause the waste of raw materials. In order to increase the metal powder utilization rate by reducing the material waste and the economic cost in powder recycle process, a new additive manufacturing method using a laser beam as a heat source has been developed in this research. In this method, metallic paste coated on a base plate is melted by a laser beam, which not only keeps the layer-by-layer processing feature of additive manufacturing, but also reduces the waste of powder by only supplying powder on processing area. Due to the stratification phenomena of the metal powder-organic solvent mixture, the polymer is added in the paste as binder to adjust viscosity. Since polymer has much lower melting point than metal and decomposes at high temperature, it is necessary to reveal the influence of polymer on microstructure and properties of built parts.
In this study, the influence of binder on melting process was investigated via single bead experiment with in-situ observation by high-speed camera. With the increase of binder content under same process condition, the size of spatters became smaller and the amount of spatters obviously increase. Lower brightness of spatter was observed in the scanning process of the sample with higher binder content.
The observation of printed samples and the evaluation of the surface quality were achieved via optical microscope. Comparing with no-binder samples, with-binder samples have smoother edges of melting track and lower roughness surface. Moreover, the same conclusion with high-speed imaging can be drawn from the analyzation on the spatter size distribution: the spatter of high binder content sample has a more concentrated distribution on lower diameter. Some of the spatter generated from the sample with high binder content is hard to be distinguished from raw powder. The melting depth and the hump height were evaluated through the observation of cross section via scanning electron microscope. Lower melting depth and hump height were observed with the increase of binder content. The decomposition of binder is considered as the main reason for these changes.
In the observation on the microstructure of with-binder and pure metal samples, the with-binder sample has finer grain than pure metal sample. The microhardness was evaluated by nanoindentation method to investigate the influence of polymer binder on mechanical properties. The results showed that with-binder sample has higher hardness but lower elastic modulus than pure metal samples. The EPMA analysis revealed that the with-binder samples have more carbon content than pure metal samples, which is considered as the main reason of the difference on their microhardness.

Spherical Confinement, Packing and 3D Electron Microscopy—Structuring and Understanding Hierarchical Matter Da Wang[1,2], Ernest van der Wee[1], Tonnishtha Dasgupta[1], Michiel Hermes[1], Thomas Altantzis[2], Daniele Zanaga[2], Yaoting Wu[3], Daniel Arenas Esteban[2], Ajinkya Anil Kadu[2], Luis Liz-Marzan[4], Christopher B. Murray[3], Marjolein Dijkstra[1], Sara Bals[2] and Alfons van Blaaderen[1]; [1]Soft Condensed Matter, Debye Institute for Nanomaterials Science, Utrecht University, Netherlands; [2]Electron Microscopy for Materials Science (EMAT), University of Antwerp, Belgium; [3]Department of Chemistry, University of Pennsylvania, Philadelphia, PA, United States, United States; [4]CIC biomaGUNE, Basque Research and Technology Alliance (BRTA), 20014 Donostia-San Sebastián, Spain, Spain

The synthesis of monodisperse colloidal particles with controllable size, shape, composition, interaction which act as “artificial atoms” has progressed significantly in the past decades. Studies on the self-assembly of multicomponent colloidal particles with controllable size, component and properties provides insight into the fundamental understanding of formation of hierarchical matter on multiple length scales and bring new opportunities for structuring functional materials with collective and synergistic properties on mesoscale. Here, we will demonstrate that slow drying emulsion droplets containing colloidal particles is a robust way to make hierarchical superstructures, the so-called supraparticles [1] (particles made of particles), which can be applied as building blocks for further step self-assembly. We show that both single component and binary sized colloids interacting with a hard interaction potential self-assembly in a spherical confinement leads to equilibrium phases with icosahedral symmetry when supraparticles are composed of 100,000 particles, which are different from bulk stable structures [1,2]. Intriguingly, an excess of one species in the binary colloidal mixture negates the spherical confinement effect, leading to a bulk-like crystal with a spherical geometry [3]. Moreover, the interplay between the flat facets, sharp corners of convex-shaped hard colloidal particles and spherical confinement can be used to tune both positional- and orientational order of the building blocks in 3D [4]. Quantitative electron tomography allows us to track both positions and orientations of colloidal building blocks at a single particle scale [1-4]. By integrating experiments and computer simulations, we can understand the underlying driving force for the formation of supraparticles. Going one step further, we will outlook the possibility of characterizing 3D structures of colloidal self-assemblies in a realistic condition, which is expected to be beneficial for structure analysis of beam-sensitive materials.

Nanoscale Imaging of Interfacial Phonon Modes and Dynamics by Electron Microscopy Xiaoqing Pan; University of California, Irvine, United States

Crystal defects and interfaces affect the thermal and heat-transport properties of materials by scattering phonons and modifying phonon spectra. Spatially resolved vibrational mapping of nanostructures and defects is indispensable to the development and understanding of thermal nanodevices, modulation of thermal transport and novel nanostructured thermoelectric materials. Through the engineering of complex structures, such as alloys, nanostructures and superlattice interfaces, one can significantly alter the propagation of phonons and suppress material thermal conductivity while maintaining electrical conductivity. There have been no correlative experiments that spatially track the modulation of phonon properties in and around individual defects and nanostructures due to spatial resolution limitations of conventional optical phonon detection techniques. In this talk, we demonstrate that space- and angle-resolved vibrational spectroscopy in a transmission electron microscope makes it possible to map the vibrational spectra of a single interface and a quantum dot. We detect a red shift of several millielectronvolts in the energy of acoustic vibration modes near a single stacking fault in cubic silicon carbide, together with substantial changes in their intensity, and find that these changes are confined to within a few nanometres of the stacking fault.[1] At a high-quality epitaxial Si-Ge interface, localized interfacial phonon modes at ~48 meV.[2] Simulations show that the interfacial phonon modes have an obvious contribution to the total thermal interface conductance. By tracking the variation of the Si optical mode in a phonon map from a single SiGe quantum dot, the nanoscale modification of the composition-induced red shift is observed.[3] We also develop a novel technique to differentially map phonon momenta, providing direct evidence that the interplay between diffuse and specular reflection largely depends on the detailed atomistic structure. Our work unveils the non-equilibrium phonon dynamics at nanoscale interfaces and can be used to study actual nanodevices and aid in the understanding of heat dissipation near nanoscale hotspots, which is crucial for future high-performance nanoelectronics.

Prospect of π* Orbital Mapping in Graphene Using Electron Energy-Loss Spectroscopy Matthieu Bugnet[1,2,3], Manuel Ederer[4], Vlado Lazarov[5], Lian Li[6], Quentin Ramasse[1,2,2], Stefan Loeffler[4] and Demie Kepaptsoglou[1,5]; [1]SuperSTEM Laboratory, United Kingdom; [2]University of Leeds, United Kingdom; [3]Univ Lyon, CNRS, INSA Lyon, UCBL, MATEIS, UMR 5510, France; [4]TU Wien, Austria; [5]University of York, United Kingdom; [6]Univeristy of West Virginia, United States

Electronic states are paramount to most physical and chemical properties of materials. For instance, electronic orbitals are responsible for chemical bonding between atoms of a crystal. Their experimental observation at defects and interfaces would help understanding material properties better and developing nanostructures with novel functionalities. Nevertheless, the visualization of orbitals in real space at the atomic scale is extremely elusive, and is mostly determined by surface microscopy tools, thus only with surface sensitivity. However, using electron energy-loss spectroscopy (EELS) in the scanning transmission electron microscope (STEM) allows to probe electronic transitions from core levels to momentum- and site-projected empty states, *i.e.,* orbitals, in the bulk of the crystal, as demonstrated in rutile [1].
In this work [2], the capability to map individual electronic states in the TEM is explored from a combined experimental-theoretical approach in epitaxially-grown graphene layers, whose inherent 2-dimensionality presents surfaces as structural discontinuities. Core-level EELS spectra were recorded in a Nion HERMES scanning transmission electron microscope, equipped with a high-energy-resolution monochromator, a C_s aberration corrector up to the fifth order, and operated at 60 kV. The experimental signals are interpreted on the basis of inelastic channelling calculations (ICCs) of the energy filtered maps [3].
The extent of the π* ($1s \rightarrow 2p_z$) and σ* ($1s \rightarrow 2p_{x,y}$) state distributions is determined in epitaxial graphene layers observed in side-view, in a 25-nm-thick TEM lamella. Despite higher intensity of the π* fine structures relative to the σ* in between the graphene layers, the absolute π* intensity is higher on the C planes, and as a result π* states appear essentially localized on the graphene layers. However, the π*/σ* ratio map shows intensity maxima in between graphene layers, as highlighted by the π*/σ* and HAADF intensity profiles. All maps are well reproduced by ICCs, as exemplified by the remarkable overlap of experimental and calculated π*/σ* intensity profiles. ICCs also enable an evaluation of the effect of thickness on the orbital contrast. The π* map of an extremely (unrealistically) thin specimen (0.43 nm) displays lobes outside the C planes, and additional intensity is also expected on the C columns. For larger and more realistic thicknesses up to the experimental value of ~25 nm, the π* intensity becomes progressively more important on the C planes than outside, in agreement with experiments. This work highlights the current potential of core-level EELS towards the direct visualization of electronic orbitals in a wide range of materials, which is of interest to better understand chemical bonding among many other properties at interfaces and defects in solids [4].

11:15 AM CH02.01.03
EELS Studies of the Tuning and Robustness of Plasmonic Response in High Aspect Ratio Gold Nanostructures Raul Arenal[1,2,3], Mario Pelaez-Fernandez[1,2], Bruno Majerus[4], Romain Dufour[4], Daniel Funes[5], Jean-Luc Duvail[5] and Luc Henrard[4]; [1]Instituto de Nanociencia y Materiales de Aragon (INMA), CSIC-Universidad de Zaragoza, Spain; [2]Universidad de Zaragoza, Spain; [3]ARAID Foundation, Spain; [4]Universite de Namur, Belgium; [5]IMN - Universite de Nantes, France

For the past couple of decades, plasmonics [1] has been on the spotlight of research, mainly for its varied applications [2,3]. Within this field, the study and tuning of localized surface plasmon resonances (LSPRs) in metallic nanowires has been of importance due to their application versatility; ranging from photonics to electronics, sensors [4], or even chemical analysis through surface-enhanced light spectroscopies [5]. Additionally, recent works have shown it is possible modify the morphology of these nanowires by means of laser irradiation, hence providing a new realm of high aspect-ratio nanostructures with potential new properties [6].

Low-loss electron energy loss spectroscopy (EELS) is a very fitting technique regarding the study of plasmonic resonances in these novel nanostructures, combining a nanometric spatial resolution and a very accurate spectral resolution. In this way, the monochromated EELS studies shown in this work, combined with state-of-the-art discrete dipole approximation (DDA) modelling, show how the plasmonic response of high aspect ratio gold 1D nanostructures can be tuned by means of coupled and non-coupled nanoparticles attached to the tips of gold nanowires, as well as a proof of concept as to how this technique can be used to understand coupling in these nanostructures [7,8]. Specifically, these studies have been carried out on gold nanowires and nanostructures consisting of nanoparticles of various sizes joint to them, producing high aspect-ratio half-dumbbells and dumbbells. The investigation of the surface plasmon resonances has been developed through a non-negative matrix (NMF) decomposition of EELS spectrum images. This high aspect-ratio gold nanostructures sustain Fabry-Perot-like surface plasmon responses from infrared to visible. We show that these resonances can be tuned by means of laser irradiation, where low energy modes stay unperturbed. All these analyses serve as experimental proof of the selective tuning (or robustness) of the plasmonic modes in a specific spectral range, which is of critical interest regarding applications for sensing devices and nano-sources, as well as optical remote control.

Phonon Vibrations Probed Using the Electron Microscope Rebecca J. Nicholls; University of Oxford, United Kingdom

Recent advances in hardware mean we can now probe phonon vibrations in an electron microscope, giving us access to spectra with previously unprecedented spatial resolution and having the benefit of atomically resolved chemical analysis within the same instrument. Interpreting the spectra containing the signal from phonon vibrations is not always trivial, and simulation can be a vital part of maximising the information extracted from the data. There are several different theoretical approaches to simulating spectra, and this presentation will focus on modelling spectra from first principles. I will first discuss why spectra obtained in different experimental geometries (impact and aloof modes) require different theoretical approaches. I will then show how first principles calculations can be used to describe spectra taken in the aloof regime from molecular crystals and that it is possible to distinguish between different crystal polymorphs of the same molecule.

SESSION CH02.02: Ultrafast Electron Microscopy

1:30 PM *CH02.02.01
Ultrafast Pulsed-Beam Transmission Electron Microscopy David J. Flannigan[1,2]; [1]University of Minnesota, United States; [2]Minnesota Institute for Ultrafast Science, United States

Fundamental non-equilibrium chemical, biological, and materials phenomena originate from ultrafast atomic-scale processes, such as electron transfer, bond formation and breaking, and electron-phonon coupling. [Here, ultrafast is defined as spanning femtosecond (fs) to nanosecond timescales.] As noted in the description of this symposium, TEM spatial and energy resolutions are presently more than sufficient for visualizing atoms and resolving low-energy phonon spectra. Arguably then, the final frontier in TEM dimensional resolution is time. Indeed, while millisecond atomic-scale dynamics have been resolved with fast detectors, and nanosecond nanoscale processes have long been studied with laser-based and laser-free pulsed beams, conducting fs atomic-scale studies with TEM has been far more challenging. Nevertheless, significant progress has been made since the seminal work of the late Ahmed Zewail and his group at Caltech, where they first coupled a fs laser oscillator to a modified commercial 120 kV TEM equipped with a conventional thermionic Wehnelt electron gun [1]. This was a watershed moment, motivating the establishment of other 4D ultrafast electron microscopy (UEM) labs and inspiring the development of other methods and uses of fs-precision pulsed electron beams, such as photon-induced near-field electron microscopy (PINEM) and the mitigation of specimen radiation damage [2,3]. Here, in addition to providing an overview of the current status of the field, I will describe the main challenges to imaging dynamics with combined Å-fs spatiotemporal resolution, the general dearth of quantitative information on UEM instrument limits, and the frontiers being pushed to overcome these challenges and limitations. I will also describe how my group has successfully used UEM to directly image ultrafast defect-modulated phonon dynamics and to resolve non-equilibrium topological phenomena, with implications for quantum information transfer and topological phononics [4-7]. I will conclude by sharing my perspective on the current opportunities yet to be fully exploited and the exciting new directions beginning to emerge [8].

Understanding Phonon Coupling in Heterostructure Systems Using Ultrafast Electron Microscopy Thomas E. Gage, Haihua Liu and Ilke Arslan; Argonne National Laboratory, United States

Understanding the transition of optical excitation to full thermal equilibrium in heterostructure systems is of fundamental scientific interest and technological importance. Optically excited nanoparticles initially relax via electron-phonon lattice coupling. Phonons in the nanoparticles will further relax by coupling to the substrate. By choosing a suitable pump wavelength, without exciting the phonon mode of the substrate, a nanoparticle can act as a localized phonon generator. Selecting a graphite nanoparticle on a crystalline silicon substrate, we employ ultrafast electron microscopy (UEM) to visualize the coupling of the optically excited nanoparticle phonon mode to the crystalline silicon substrate with nanometer spatial resolution and one picosecond temporal resolution [1]. Here, using a 515nm/300fs optical pump pulse, we observe intensity oscillations in bright-field UEM mode arising from phonon vibrations of 77GHz in 200nm graphite nanoparticles, which begin at approximately time zero. After a delay on the order of tens of picoseconds, phonon oscillations appear in the silicon substrate propagating radially away from the graphite particles. By utilizing UEM, we explore the parameter space of the optical pump pulse and materials system studying the resulting dynamics observed in both the nanoparticles and substrate to gain a better understanding of the phonon coupling process.

Development of Ultrafast Scanning Transmission Electron Microscopy with Pixelated Detector Takahiro Shimojima[1], Asuka Nakamura[1] and Kyoko

Ishizaka[1,2]; [1]RIKEN CEMS, Japan; [2]The University of Tokyo, Japan

A promising way to improve the time resolution of the electron microscopy is the application of the ultrafast optical pump-probe technique[1]. Previous ultrafast TEM[2-4] and STEM[5] studies reported the morphorogical changes of the nanostructures with the time resolusion being independent of the camera response time (ms). While these results opened a door to investigate ultrafast phenomena in nanoscale materials, it has been difficult to map out the physical quantities.
Here, by combining the ultrafast STEM with the pixelated detector, we improved the time resolution of the differential phase contrast and convergent beam electron diffraction STEM imagings [6]. These methods provide the ultrafast nanoscale movies of physical quantities in nano-materials, such as crystal lattice deformation, magnetization vector and electric field. We demonstrate the observations of the photo-induced acoustic phonon propagation with an accuracy of 4 ps and 8 nm [7], and ultrafast demagnetization under zero magnetic field with 10 ns and 400 nm resolution, by utilizing these methods.

3:15 PM *CH02.03.01
Real-Space Observations of Three-Dimensional Topological Spin Textures and Their Dynamics Xiuzhen Yu[1], Yizhou Liu[1], Kostatian Iakoubovskii[1], Fehmi Yasin[1], Licong Peng[1], Kiyomi Nakajima[1], Kosuke Karube[1], Naoya Kanazawa[2], Taka-hisa Arima[2], Yasujiro Taguchi[1], Naoto Nagaosa[1] and Yoshinori Tokura[1]; [1]RIKEN, Japan; [2]University of Tokyo, Japan

Nanometer-scale electron spin textures, such as two-dimensional (2D) magnetic skyrmions (Sks) and anti-Sks with integer topological indices, attract much attention in condensed matter physics [1-2]. In addition to such 2D textures appearing in cubic chiral-lattice magnets, 3D spin textures, such as Sk strings carrying (anti)monopole (spin hedgehog) (point defects) [3-4] have been observed by X-ray magnetic circular dichroism for mapping the 3D scalar field of Sk strings in a Heusler magnet [5]. The more complicated 3D spin textures, like hopfion and its bundle, have also been theoretically predicted in the chiral-lattice magnets [6] but remain to be experimentally confirmed. Accordingly, there is a demand to develop 3D magnetic imaging with a high spatial resolution to map the vector field in 3D topological objects for identifying tinny defects or nodes. In the present study, we have modified tomographic transmission electron microscopy (TomoTEM) at Lorentz mode (field-free mode) and demonstrated the complete operation of the 3D Lorentz TEM imaging procedure. Furthermore, we simplified the reconstruction routine to map the 3D vector field in magnetic objects, allowing us to process data analyses quickly. Using the 3D TomoLorentz TEM, the 3D spin textures of Sk strings, antiSk, and spin hedgehog have been demonstrated [7]. In addition, the fractional hopfions with non-integer topological indices and their fascinating dynamical phenomena have been revealed under in-plane magnetic fields and pulsed electric currents in a chiral-lattice magnet FeGe [8].

Measuring 3D Chemistry with Fused Multi-Modal Electron Tomography Jonathan Schwartz[1], Jacob Pietryga[1,2], Jason Manassa[1], Yiwen Qian[3], Zichao Di Wendy[4], Yi Jiang[4], Alyssa Fielitz[5], Junsi Gu[5], Peter Ercius[3], Jeffery Fessler[1], Steve Rozeveld[5], Ting Xu[3] and Robert Hovden[1]; [1]University of Michigan, United States; [2]Northwestern University, United States; [3]University of California, Berkeley, United States; [4]Argonne National Laboratory, United States; [5]Dow, United States

In principle, electron tomography used in combination with energy dispersive X-ray (EDX) or electron energy loss (EELS) spectroscopy can characterize complex three-dimensional (3D) material chemistry at the nanoscale [1,2]. However in practice, chemical tomography using core excitation spectroscopy demands high electron doses that almost always exceed the specimen limits (e.g. $> 10^7$ e/Å^2). At best, researchers must choose between measuring 3D structure with high-angle annular dark-field (HAADF) tomography or characterizing chemistry along a single viewing direction. Recent developments in multi-modal data fusion paved new opportunities by substantially reducing the dose requirements for high-resolution chemical imaging [3]. In alignment with the principles of fused multi-modal electron microscopy, we report extending its algorithmic framework into the third dimension.

Here we introduce fused multi-modal electron tomography, a technique that offers high SNR and high-resolution recovery of material chemistry in 3D by leveraging correlated information encoded within both elastic scattering (HAADF) and inelastic scattering (EDX / EELS) signals. Although sparse chemical measurements are severely underdetermined in Fourier space, fusing this data with higher HAADF sampling fills in missing information, improving resolution and reconstruction quality.

We experimentally demonstrate chemical tomography at nanometer resolution using fused multi-modal electron tomography on Cu-SiC nanoparticles. Despite the noisy EDX maps, the recovered chemical tomograms quality is substantially improved over traditional tomography as ~4 nm Cu nanoparticles over a 250 nm field of view is clearly visible. We further illustrate fused multi-modal electron tomography on Au-Fe_3O_4 nanoparticles in a carbon support using core-loss EELS maps. Using the fused multi-modal reconstructions the distribution of the Au and Fe_3O_4 nanoparticles are clearly distinguished in 3D. These results demonstrate fused multi-modal tomography provides direct observation of 3D chemical structure at the nanoscale with high resolution and SNR.

4:00 PM CH02.03.03
Data-Mining of *In Situ* TEM Experiments on CoCrFeMnNi Alloys—4D Reconstruction of Dislocation Dynamics and Sampling of the Energy Landscape Chen Zhang[1], Hengxu Song[1], Daniela Oliveros[2], Anna Fraczkiewicz[3], Marc Legros[2] and Stefan Sandfeld[1,4]; [1]Forschungszentrum Jülich, Germany; [2]CEMES-CNRS, France; [3]École des Mines de Saint Étienne, France; [4]RWTH Aachen University, Germany

During *In Situ* transmission electron microscopy (TEM) straining experiments of high entropy alloys (HEA), pinning points frequently hinder the motion of dislocations. They lead to abrupt changes in the curvature of moving dislocations in the middle of in situ samples. Because their nature remains a key question in HEA, we propose a data-mining strategy for extracting quantitative information from the real-time dynamics of dislocation lines to retrieve the local strength of these obstacles.

An experiment on equimolar CoCrFeMnNi HEA (Cantor alloy) demonstrates the capabilities of our data-mining approach. We show how the 3D dislocation structure can be reconstructed and the force variation along the lines retrieved automatically. A novel coarse-graining method is employed to statistically extract quantitative information on the nature, dispersion and strength of pinning points, along with their evolution upon deformation. This subsequently provides new ideas for understanding deformation mechanisms in high-entropy alloys.

Giant Optical Anisotropy from Tiny Atomic Displacements Resolved Using Theory and Microscopy Rohan Mishra; Washington University in St. Louis, United States

Hexagonal perovskite sulfides of the form $A_{1+x}BS_3$ (A, B = metals) have a quasi-one-dimensional crystal structure with face-shared (BS_6) octahedral chains. Giant optical anisotropy has been reported in one such compound, $BaTiS_3$. Replacing, Ba^{2+} with isovalent Sr^{2+} to form $SrTiS_3$ results in further enhancement of the optical anisotropy. Furthermore, $Sr_{1+x}TiS_3$ is observed to display periodic structural modulations, where the periodicity x can be modulated by changing the synthesis conditions.<!--[endif]----> However, the origins of giant optical anisotropy in these compounds and their connection with structural modulations remain unresolved. Here, we combine density-functional theory calculations with atomic-scale characterization using STEM to reveal that subtle periodic modulations in $Sr_{1+x}TiS_3$ structures and sub-Angström displacements in BaTiS3 enables their record-breaking optical anisotropy. 9:00 AM CH02.04.02
Electronic Structure Engineering Through Atomic-Scale Strain Control in Complex Oxide Heterostructures Peter A. Van Aken; Max Planck Institute for Solid State Research, Germany

In complex oxide systems, the coupling of local atomic configurations and electronic degrees of freedom play a fundamental role in understanding exotic phenomena such as formation of charge ordering, metal-insulator transition and colossal magnetoresistance. Atomic-scale thin film syntheses enable to disentangle these competing interactions and tune novel ground states of materials, which do not exist in bulk crystals. Modifying strain by depositing epitaxial thin films on substrates with different lattice spacing results in a precise control of the local physical behavior. Scanning transmission electron microscopy (STEM) combined with electron energy-loss spectroscopy (EELS) not only provides information on the local atomic structure, but also on the site-specific chemical composition and electronic structure of materials and interfaces. Such direct real-space observations are important to unveil the microscopic origins of macroscopic properties in complex oxides and are essential for possible applications in relevant electronic and spintronic devices.

Here, I demonstrate how strain locally alters physical properties in two different complex oxide systems using STEM-EELS. I will first describe our observation of epitaxial LiV_2O_4 thin films grown on $SrTiO_3$ and MgO substrates. I find that the V-3*d* electrons redistribute in the lattice and become confined or delocalize depending on the epitaxial strain, hereby generating ordered or disordered patterns. I reveal two competing behaviors of the thin films on the two different substrates, a metallic charge-disordered phase on $SrTiO_3$ and an insulating charge-ordered phase on MgO. These findings evidence that charge fluctuations can freeze into an insulating “charge-glass”-like state, when epitaxial strain is applied, which relieves the frustration in LiV_2O_4.

The second part focuses on $La_{0.5}Sr_{0.5}MnO_3$-La_2CuO_4 heterostructures grown on three different substrates, $SrTiO_3$, $(LaAlO_3)_{0.3}$-$(Sr_2AlTaO_6)_{0.7}$ and $LaSrAlO_4$ [1]. I find that charge rearrangements in these systems give rise to two different magnetic phases, an interfacial antiferromagnetic layer and an enhanced ferromagnetic metallic region away from the interfaces. Furthermore, the epitaxial strain controls the magnitude of charge redistribution and

further influences the macroscopic electronic and magnetic structures in these heterostructures differently from the strain affects reported on single-phase films. These results provide a route for understanding, controlling and designing local novel phases in complex oxides heterostructures [2].

9:15 AM CH02.04.03
Atomistic Segregation Behaviors of Ti in Al_2O_3 Grain Boundaries Chuchu Yang[1], Bin Feng[1], Naoya Shibata[1,2] and Yuichi Ikuhara[1,2]; [1]The University of Tokyo, Japan; [2]Japan Fine Ceramics Center, Japan

Grain boundaries (GBs) have a great influence on the properties of polycrystalline Al_2O_3. Doping foreign elements has been known as one of the most popular strategies to alter the GB behaviors and hence material performances in Al_2O_3. Among various dopants for polycrystalline Al_2O_3, titanium (Ti) can strongly affect the resultant properties, such as conductivity [1], GB diffusivity [2] and creep resistance [3]. Although the structure-property relationships in the Al_2O_3 GBs have been widely studied [4], mechanisms of dopant segregation in the GBs are still under investigation. For instance, it is unclear how the GB structures affect the segregation of a certain element and how the dopant segregation affects GB electronic band structures. With the aid of the state-of-the-art scanning transmission electron microscopy (STEM), it becomes possible to uncover atomic segregation sites in doped GBs. In this study, we investigated the atomistic segregation behaviors of Ti dopants in two Al_2O_3 model GBs (Σ7{4-510} and Σ7{2-310}) and the effect of Ti dopants on the GB bandgaps, using STEM, energy dispersive X-ray spectroscopy (EDS) and valence electron energy-loss spectroscopy (VEELS). Bicrystal-based model experiments were performed for the analysis of atomic structures, which enable us to find out the decisive factors governing the GB segregation. Our results indicate that the preferential segregation of Ti at specific atom sites in GBs was mainly driven by the ionic size mismatch between Ti^{3+} and Al^{3+}. Furthermore, VEELS measurements showed that Ti doping has introduced the extra impurity state in Al_2O_3 GB bandgaps.

9:30 AM CH02.04.04
Co-Segregation of Aliovalent Dopants at α-Al_2O_3 Σ13 Grain Boundary Toshihiro Futazuka[1], Ryo Ishikawa[1], Naoya Shibata[1,2] and Yuichi Ikuhara[1,2]; [1]The University of Tokyo, Japan; [2]JFCC, Japan

Impurity doping at grain boundary (GB) is a major strategy to control the properties of polycrystalline materials. The isovalent impurity with a low solubility limit is usually segregated to the specific sites at the GB core and forms the periodic GB structure [1]. However, the segregation behavior of aliovalent impurities is still unclear. Aliovalent impurities should form charged defects that will be compensated by the other charged defects, and therefore segregation behavior would be complex [2]. In this study, we investigated the segregation mechanism of counterbalancing charged defects of Ca_{Al}^{1-} and Si_{Al}^{1+}, which are typical sintering additives for Al_2O_3, at α-Al_2O_3 Σ13 <>/{} GB by scanning transmission electron microscopy (STEM) combined with systematic density functional theory (DFT) calculations.

Atomic-resolution annular dark/bright-field (ADF/ABF) STEM observations revealed that the atomic structure of Ca/Si-doped GB is significantly transformed from that in the pristine Σ13 GB. The energy dispersive x-ray spectroscopy (EDS) in STEM revealed that both Ca and Si are periodically segregated to the specific sites at the GB core. To understand the origin of this GB structural transformation, we first reconstructed the framework GB structure by referring to the ABF-STEM image. The GB energy of the framework structure is 4.17 J m^{-2}, which is much higher than that of the stable Σ13 GB structure (2.40 J m^{-2}). This result suggests that the framework structure may be stabilized by the co-segregation of Ca and Si. To determine the stable segregation sites of Ca_{Al}^{1-} and Si_{Al}^{1+}, the segregation energies of Ca_{Al}^{1-} and Si_{Al}^{1+} are evaluated for all Al sites within 10 Å from the GB core. These atomic sites with minimum segregation energies agree with the Ca/Si segregation sites in STEM-EDS mapping. The minimum segregation energy of Ca_{Al}^{1-} is -4.63 eV, which is much lower than those of other Al sites. On the other hand, the minimum segregation energy of Si_{Al}^{1+} is -0.46 eV, and the site dependence of segregation energy is small. These results suggest that the segregations of Ca_{Al}^{1-} and Si_{Al}^{1+} are induced by the structural stability and the local charge compensation with Si_{Al}^{1+}, respectively. Lastly, we reconstructed the Ca/Si co-segregated Σ13 GB and evaluated the GB energy, and the most stable structure is matched well with the STEM image. The GB energy of the Ca/Si co-doped GB decreases with the increase in the chemical potentials of Ca and Si, and it becomes lower than that of the pristine GB. This result suggests that, as increasing the doping amount of Ca and Si, they segregate to the GB core and induce the GB structural transformation.

Atomic-Scale Insights into the Structural Transformations in Cathodes for Multivalent Metal-Ion Batteries Arashdeep S. Thind and Robert F. Klie; University of Illinois Chicago, United States

Multivalent-metal ion batteries are promising and safer alternatives to lithium-ion batteries for next-generation energy storage devices. Most of the multivalent-metal ions, such as calcium (Ca) and magnesium (Mg), and their respective cathode material systems can be sourced from earth-abundant minerals. Moreover, Ca and Mg-ion batteries, based on high-voltage oxide cathodes show high energy density compared to lithium-ion batteries. This makes multivalent-metal ion batteries a cost-effective proposition for a variety of battery technologies. However, multivalent-metal ion batteries often suffer from poor electrochemical stability. A key challenge in achieving higher performance and stability in these material systems is to understand the fundamental structural changes to the cathode at the atomic scale. Such structural changes during electrochemical cycling include cation disorder, planar defects, phase separation, and (de)intercalation mechanisms. In this work, we combine aberration-corrected scanning transmission electron microscopy (STEM), first-principles density functional theory (DFT) calculations, and STEM simulations to develop a fundamental understanding of the structural changes occurring during electrochemical cycling of Ca and Mg-ions into $FePO_4$ and α-V_2O_5 as cathodes respectively.

During electrochemical cycling of Ca into $FePO_4$, we observe that the large particles (> 100 nm) show Ca intercalation at the surface with the bulk of the particle showing little to no activity. Moreover, the smaller particles (< 50 nm) exhibit a tendency to phase-separate into $CaPO_4$. STEM imaging reveals

the direct atomic-scale evidence of Ca intercalation into the $FePO_4$ olivine structure, where Ca-ions show a preferential arrangement along the [010] orientation. For the Mg-ion batteries, we observe that the Mg intercalation into α-V_2O_5 is heterogeneous and is accompanied by the formation of a network of low-angle grain boundaries. We hypothesize that there is significant phase separation between various phases of $Mg_xV_2O_5$ and V_2O_5, such as the fully intercalated δ-MgV_2O_5 and fully deintercalated α-V_2O_5 phases. Our atomic-scale findings for these two model systems can be leveraged by optimizing the materials synthesis to achieve theoretical operating potentials and performance.

10:30 AM CH02.04.06
Identifying Inhomogeneities in Niobium Superconducting Transmon Qubit Devices Through Advanced Microscopy Akshay A. Murthy[1], Jaeyel Lee[1], Cameron Kopas[2], Stephanie Ribet[3], Josh Y. Mutus[2], Thang T. Pham[3], Anna Grassellino[1], Roberto dos Reis[3], Vinayak P. Dravid[3] and Alexander Romanenko[1]; [1]Fermi National Accelerator Laboratory, United States; [2]Rigetti Computing, United States; [3]Northwestern University, United States

Superconducting qubits have emerged as a platform technology for potentially addressing computational problems deemed intractable with classical computing. Despite recent advances enabling multiqubit designs that exhibit coherence lifetimes on the order of hundreds of μs, defects and amorphous oxides continue to curb device performance by dissipating electromagnetic energy. Experimental and theoretical investigations have led researchers to understand quantum decoherence is dictated by deviations from crystalline order on the nanoscale. Thus, the high-resolution nature of electron microscopy makes it an indispensable tool for identification of decoherence sources. Through a combination of scanning transmission electron imaging and diffraction methods, we interrogate the thin metal films integral for superconducting qubit operation and observe structural and chemical features that can potentially serve as decoherence sources. This includes the presence of localized strain at grain boundaries and metal/substrate interfaces. Such localized strain can induce changes in the superconducting critical temperature and superconducting order parameter. Further, by employing the fluctuation electron microscopy technique, we are able to better understand the medium range order present in the amorphous oxides that inevitably form in these systems. Through this analysis we observe a variation in bond distances in the surface oxide. Such variation can lead to low frequency noise, which helps explain previous experimental data highlighting the lossy nature of this oxide. Equipped with these findings, we seek to intelligently fabricate superconducting qubits and extend coherence times.

10:45 AM CH02.04.07
Characterization of Modulated Nanostructure Using Aberration Corrected Scanning Transmission Electron Microscopy (STEM) Ronit Sawant and Ray Carpenter; Arizona State University, United States

Modulated nanostructures are short-range quasiperiodic composition fluctuations observed in metals, semiconductors, and ceramic alloys and have an important effect on the mechanical, electrical, and magnetic properties of the materials. Their presence is often attributed to spinodal decomposition [1]. The typical wavelength of the modulations ranges from 5 nm to 15 nm in metal alloys [2]. In past, such modulations have been analyzed using x-ray diffraction (XRD), electron diffraction, and diffraction/strain contrast imaging techniques [3]. These investigations gave useful information about the wavelength and strain fields in the modulation but nothing about the composition amplitude of the modulated structure. With the development of field emission sources [4], aberration correctors [5], and ADF imaging for STEM microscopes, measuring the amplitude of the modulation directly and examining the diffused interface is possible. Also, to study the reaction kinetics measurement of the composition amplitude is necessary.
In this study, we measure the composition amplitude of the fluctuations directly using STEM HAADF imaging and energy dispersive x-ray (EDS) spectroscopy. Au-Pt alloys with a symmetrical solid-state miscibility gap are used for the investigation of the modulated structure. Three alloys of compositions 60%Pt, 80%Pt, and 40%Pt are analyzed at different temperatures at various aging times for studying the reaction kinetics. Composition variation and the diffused interface across modulations were successfully mapped using atomic resolution EDS spectroscopy. Results show the wavelength, as well as the composition amplitude of the modulations, increases as the alloy is aged for a longer time. As the reaction proceeds towards equilibrium, the amplitude of the fluctuations should increase and reach the equilibrium composition at the end of the tie line at the selected aging temperature. Although the entire specimen region was modulated, variations in both the wavelength and composition amplitude were observed. 1D and 2D modulation were seen along the <100> directions. These results obtained are in good agreement with the spinodal theories and XRD experimental data [2]. Cellular precipitates were observed along the grain boundary of alloys aged for a longer time. Nucleation and Growth mechanism is responsible for such precipitation reaction and is also a competing reaction along with the spinodal decomposition. Analyzing such cellular precipitates at the grain boundary is very important as it influences fracture behaviors in spinodal alloys. A similar analysis is also being carried out in the Cu-Ti alloy system which has an asymmetrical miscibility gap. The results obtained from this study show that analyzing the compositions of modulated structures using aberration-corrected STEM is possible and therefore a comparison between the spinodal rate theory and experimental kinetics of the modulated structures can be obtained.

Determination of the Thermal Expansion Coefficient of the Nanoparticles with *In Situ* Electron Energy Loss Spectroscopy Bibash Sapkota, Serdar Ogut and Robert F. Klie; University of Illinois at Chicago, United States

Our ability to determine the local temperature of a sample inside the electron microscope column is key in measuring the effects of electron-sample interaction and controlling the beam-induced sample changes. Temperature dependence of the plasmon resonance energy of the material can be used to map the local temperature of the material at the nanoscale [1-2] and to determine its thermal expansion coefficient [3]. In this work, we will study the behavior of plasmon energy of In and $BaTiO_3$ nanoparticles across the phase transition temperature. We will compare the performance of several nanoparticles (Al, Si, In, $SrTiO_3$, $BaTiO_3$) as a nano-thermometer for high-temperature measurement. In addition, we will also utilize a novel approach of non-contact thermometry based on the combination of low-loss electron energy-loss spectroscopy (EELS) with the free electron model to measure the thermal expansion coefficient (TEC) of nanoparticles at the nanoscale. Finally, we will explore the effects (if present) of the particle size, oxygen vacancies, and contamination on this approach of measuring the thermal expansion coefficient as well as the local temperature.

Direct Observation of Non-Brownian Motion of Intercalated Atoms in van der Waals Bonded Interfaces Joachim D. Thomsen[1,2], Yaxian Wang[1], Frances M. Ross[2] and Prineha Narang[1]; [1]Harvard University, United States; [2]Massachusetts Institute of Technology, United States

Diffusion processes in two-dimensional materials govern several phenomena such as phase transformations, growth by chemical vapor deposition, and doping by substitutional and interstitial atoms. Furthermore, intercalation of foreign atomic species into van der Waals (vdW) bonded materials has been studied for tuning of physical properties (electronic, optoelectronic, magnetic), and for uses in energy and battery applications.

Here, we directly image the diffusion of W atoms using high-angle annular scanning transmission electron microscopy (HAADF-STEM) inside hexagonal boron nitride (hBN)-WSe_2-hBN vdW heterostructures. By using thin (~2 nm thick) hBN crystals which consist of light B and N atoms, we can image the heavier W atoms inside this heterostructure in two different interfaces: directly between the encapsulating hBN layers and in the WSe_2/hBN interface. In combination with density functional theory calculations, we find that the motion of the intercalating W atoms is strongly affected by local defects created by the high-energy electron beam. When measuring the diffusion coefficient for W atoms at the two different interfaces, we find, for similar experimental conditions, a diffusion coefficient that is twice as large at the WSe_2/BN interface compared to the BN/BN.

This work shows that atomic diffusion inside vdW heterostructures can be imaged directly and suggests avenues for creating superlattices inside such heterostructures by engineering defect sites.

SESSION CH02.05: 4D STEM

Using Four-Dimensional-Scanning Transmission Electron Microscopy (4D-STEM) for Large Field-of-View Material Property Measurements and Ptychographic Atomic-Resolution Tomography. Colin Ophus; Lawrence Berkeley National Lab, United States

The past decade of development for scanning transmission electron microscopy (STEM) have been enormously successful, driven primarily by three technological innovations: hardware aberration correction, direct electron detectors, and the transformation of S/TEM into a digital science with the rise of computational imaging. In this talk, I will show how these three developments have enabled four dimensional (4D)-STEM experiments where we record full 2D images of the diffracted STEM probe over a 2D grid of probe positions. I will demonstrate large field-of-view mapping of structure, orientation and strain for materials ranging from structural oxides nanowires to 2D materials. I will also show how these methods can also be combined with complementary techniques such as STEM-electron energy loss spectroscopy or x-ray spectro-ptychography, for multimodal characterization of energy materials. I will briefly describe how modern machine learning methods can be used to extend the range of usable sample thicknesses by untangling the complex nonlinear contrast generated from multiple scattering of the electron beam. Finally, I will show results from ptychographic atomic-resolution tomography, which we use to solve the structure of complex encapsulated nanotube-nanowire materials. All of our methods, algorithms, codes and datasets are freely available to the community in order to promote widespread development of these experimental procedures.

2:00 PM CH02.05.03
Diffraction Image Processing for 4D-STEM to Improve ASTAR Pattern Matching Nicolas Folastre[1,2], Sunkyu Park[1,3], Edgar Rauch[4], Arash Jamali[5,1], Jean-Noel Chotard[1,2,6], Christian Masquelier[1,2,6], Laurence Croguennec[3,2,6] and Arnaud Demortiere[1,2]; [1]Laboratoire de Réactivité et de Chimie des Solides (LRCS) – CNRS UMR 7314, France; [2]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), France; [3]Institut de Chimie de la Matière Condensée de Bordeaux (ICMCB) – CNRS UMR 5026, France; [4]Laboratoire Science et Ingénierie des Matériaux et Procédés (SIMaP) – Grenoble INP/CNRS/UJF, France; [5]University of Picardie Jules Verne (UPJV), France; [6]ALISTORE-ERI – CNRS FR 3104, France

The emergence of new energy materials is related to the development of highly controlled poly-crystal materials exhibiting specific and interesting phase transformation, electronic/ionic conductivity, and optical properties. The scanning TEM is one of the most actively developing analytical methods to characterize these polycrystals from microscopic to atomic scales. The interest in the hyperspectral STEM approach that gathers structural and chemical information in a 4D image stack was mainly based on imaging-spectroscopy techniques such as STEM-EDX and STEM-EELS. Last decade, thanks to a new generation of direct electron detectors, imaging algorithms, precession technique, and highly coherent electron beam, a new approach emerged called 4D-STEM in which diffraction patterns in parallel or convergent beam are acquired in hyperimage stack. In parallel beam condition, automated crystal orientation mapping (ACOM) turns out to be a new powerful tool to characterize polycrystalline materials at the nanoscale by mapping crystallographic properties.

This 4D-STEM method using ASTAR-ACOM system allows to build maps of crystalline phase and orientation, using scanning nano-diffraction with precession with nanometer resolution. The recent use of high-speed cameras, pixelated detectors such as CMOS cameras and hybrid-pixel detectors enabled larger areas to be scanned, and a higher resolution close to 1 nm. However, using a CMOS camera in the column implies strong changes in the acquired images in comparison to the use of a NanoMegas conventional external optical camera, as the quality of the image improves with the increased electron sensitivity and the resolution. As the 4D-STEM ASTAR suite has been optimized for images acquired with the Stingray optical camera (phosphorescent screen), the data preparation should be adapted to fit with images acquired using CMOS camera as Oneview Gatan camera.

The goal of the data preparation methods proposed here is to improve the quality of ASTAR pattern-matching using a dataset of diffraction patterns acquired with a CMOS Oneview camera. The high sensitivity of the CMOS camera and the data filtering developed here modify the diffraction images leading to a compromise between image quality and template matching result quality.

First, modifications inside diffraction patterns are estimated through image quality metrics such as signal-over-noise ratio (SNR), peak signal-over-noise (PSNR), structural similarity index measure (SSIM), mean absolute error (MAE), and root-mean-square error (RMSE). Second, the quality of the pattern-matching process on filtered and reconstructed images is evaluated using index and orientation reliability, defined in the ASTAR software. We demonstrate that the experimental data preparation provides great advantages for the pattern-matching quality result, as it reduces noise overfitting, improves structural similarity index measure, and increases the orientation reliability from average values of 10-15 before to 20-30 after filtering.

The data reduction method applied in this work is a registration and reconstruction code for diffraction images acquired using a CMOS camera, which we use to filter and record the diffraction signal and reconstruct the images upstream of the ASTAR suite pattern-matching software. The essential information of each reflection of a dataset (200*200*512*512) such as intensity, size, and position are recorded in a few minutes with an accuracy of the order 10^{-2} px, with a data reduction factor of the order 10^2.

In this work, we show that the mapping of crystal structures and orientations provides essential information for the determination of individual particle lithiation mechanisms of cathode materials for Li-ion and Na-ion batteries, as $Na_xMnV(PO_4)_3$ was used in this study. In addition, this image processing method gives more confidence in phase determinations in such polycrystalline materials.

2:15 PM BREAK

2:45 PM CH02.05.04
Defect Contrast with 4D-STEM, Role of Local Order and Symmetry Stephanie Ribet[1], Colin Ophus[2], Roberto dos Reis[1] and Vinayak P. Dravid[1]; [1]Northwestern University, United States; [2]Lawrence Berkeley National Laboratory, United States

Many important material properties are controlled by defects, which break the local order of structures on the nano to atomic scale. Scanning transmission electron microscopy (S/TEM) is an especially apt tool to study structures and their symmetry at relevant length scales. However, there are intrinsic challenges to characterizing these defects with conventional imaging modalities for some materials due to dose, contrast, and probe-size limitations. 4D-STEM experiments, where a diffraction pattern is acquired at each position in real space, can help overcome these obstacles. The combination of the versatility of the available reconstruction techniques and the rich information contained in a diffraction pattern allows for studies of material properties, such as local symmetry, that would not otherwise be possible. Additionally, the modification of the beam through a phase or amplitude plate inserted in the probe forming aperture of a STEM creates another handle to change final image contrast, while reducing dose and highlighting defects. In this presentation, we will show simulations on a variety of structures and illustrate how virtual detectors and beam modification in a 4D-STEM experiment can be used to highlight important changes in local order of materials. We will compare these results to more conventional imaging techniques in light of realistic parameters, such as electron dose and lens aberrations.

3:00 PM CH02.05.05
Development of a Method to Observe Local Atomic Vibrations by STEM Using a Segmented Detector Koudai Tabata[1], Takehito Seki[1,2], Yuichi Ikuhara[1,3] and Naoya Shibata[1,3]; [1]The University of Tokyo, Japan; [2]JST PRESTO, Japan; [3]Japan Fine Ceramics Center, Japan

Aberration-corrected scanning transmission electron microscopy (STEM) is a powerful technique for directly observing atomic structures and chemistry in local regions of materials. Annular dark-field (ADF) method, in which electrons scattered at high angles are detected by an annular detector, is widely used as a useful tool for direct observation of atomic positions. It is known that the electrons scattered at high angles are dominated by thermal diffuse scattering (TDS) [1], which depends on the atomic number and atomic displacement parameter (ADP) of the atoms. It is considered that anisotropic atomic vibrations cause anisotropic TDS, but conventional annular detectors have not been able to measure local atomic vibrations quantitatively, including anisotropy of vibration. On the other hand, segmented detectors [2] can acquire images from multiple detection areas divided in the azimuthal direction, enabling the acquisition of signals that depend on the direction of electron scattering. In this work, we investigate the possibility of direct observation of anisotropic atomic vibrations by atomic-resolution STEM with a segmented detector. First, we performed image simulations based on the quantum excitation of phonons (QEP) multislice approach [3] and extracted the electrons which have scattered by anisotropic atomic vibrations. STEM observation conditions, such as convergence angle, defocus, accelerating voltage, and detector acquisition angle, were optimized to increase the signal due to anisotropic atomic vibrations. We performed experimental STEM observations for a model sample under thus obtained optimal conditions and quantitatively compared the experimental results with the theoretical simulations. Details will be reported in the presentation.

3:15 PM CH02.05.06
Compressed 4D-STEM—From Conception to Implementation Alex W. Robinson[1], Daniel Nicholls[1], Jack Wells[1], Amirafshar Moshtaghpour[2,1], William J. Pearson[1], Angus Kirkland[2,3] and Nigel Browning[1,4,5]; [1]University of Liverpool, United Kingdom; [2]Rosalind Franklin Institute, United Kingdom; [3]University of Oxford, United Kingdom; [4]Pacific Northwest National Laboratory, United States; [5]Sivananthan Laboratories, United States

Scanning transmission electron microscopy has routinely shown its capability to identify complex structural, mechanical, and electronic properties of crystalline materials. However, there are many more materials where the resolution of the final image is limited by its response to the incident electron beam, and ultimately reliable images and analysis is determined by how beam-sensitive the sample is. Recent developments in compressive sensing for scanning transmission electron microscopy (CS-STEM) has opened new avenues for low dose electron microscopy, as well as increased temporal resolution through subsampling for fixed detector imaging methods such as annular dark field (ADF) and bright field (BF) imaging.

4D-STEM is becoming more common in the field, where at each probe location a convergent beam electron diffraction (CBED) pattern is acquired using a pixelated detector to allow for a higher angular range of information from electron scattering. The CBEDs can then be used to acquire a variety of image types such as (high angle) ADF (HA/ADF), BF, ABF, Centre of Mass, Phase Contrast, Strain Mapping, Holography, and Ptychography. However, due to the nature of the data acquired, the time for acquisition is much slower with respect to fixed detectors, and the data sets are on the order of many gigabytes as opposed to megabytes in standard imaging methods. This means that beam exposure increases and other artefacts such as drift and distortion are heighted through the increased acquisition time.

In order to overcome this, we propose integrating compressive sensing with 4D-STEM to developed a new method which aims to both lower the electron dose and increase speed through real and reciprocal space subsampling. We demonstrate practical implementation of subsampling the pixelated detector and subsampling the spatial probe locations to generate a 4D-STEM dataset that is not only significantly smaller in memory size, but is acquired in

significantly less time than the full acquisition. The data is then reconstructed through an image inpainting algorithm by first recovering the CBED patterns and then in turn using the CBED patterns to recover a variety of subsampled image types. We present the methods and implementation to our STEM, and the potential for ptychographic reconstruction from subsampled data.

3:30 PM CH02.05.07
Local Structure and Polarization in Relaxor and Ferroelectric Tetragonal Tungsten Bronzes Measured by 4D STEM Stephen Funni and Elizabeth Dickey; Carnegie Mellon University, United States

Classical and relaxors ferroelectrics are critical for many modern technologies, notably as functional materials in transducer and capacitor applications. Prominent, commercially used materials in these categories are lead-based, which is undesirable due to lead's toxicity. In the search for lead-free alternatives, tetragonal tungsten bronze (TTB) oxides have been examined due to their flexible chemistry and wide range of properties, including relaxor and classical ferroelectric behavior.[1] TTBs commonly exhibit commensurately or incommensurately modulated superlattices, and an empirical link has been established between superlattice type and ferroelectric order.[2] The modulation includes tilting within the oxygen-octahedral network and related cation displacements. Several studies have attempted to characterize the structure by various methods, though these have been inconclusive to due various inherent technique limitations.[3,4] An Ama2 unit cell was proposed as a commensurate approximation of the incommensurate modulation.[5] This model implies the presence, locally, of one of two possible orientations of the modulation. In this work, we seek to provide more detailed information regarding the structure and origin of ferroelectric properties in TTBs using scanning transmission electron microscopy (STEM).

Current state-of-the-art in STEM, including aberration correction and advanced pixelated detectors, allows precise atomic-scale characterization of materials. In this work, we use 4D STEM (a technique in which a complete electron diffraction pattern is collected for each probe position) to analyze the structural modulation and polarization of two TTB compositions: $Ba_4Nd_2Nb_4Ti_6O_{30}$, a commensurately modulated classical ferroelectric, and $Ba_5Sm_1Sn_3Nb_7O_{30}$, an incommensurately modulated relaxor. We perform two types of experiments at different length scales. The first 4D STEM experiments, nano-beam electron diffraction (NBED), allow us to measure the local modulation orientation and polarization at nanometer-scale resolution over approximately 1 m^2 fields of view from a single dataset. We design custom virtual detectors informed by electron diffraction simulations of the Ama2 cell. To identify the local modulation orientation, we use a virtual detector sensitive to the corresponding superlattice reflections; and for measuring local polarization, we calculate the normalized difference signal between the and disk pairs. The resulting images map these key structural signatures (modulation orientation and polarization) over the scanned region. Next, we study the structure of the materials at atomic resolution using phase contrast imaging from a second set of 4D STEM experiments. We analyze the images using our recently developed vector pair correlation function method [6] to quantify the ordering of atomic displacements on the anion and cation sublattices, determining the correlation length of the modulation and polar distortions on a sublattice-specific basis. By applying 4D STEM characterization to TTBs we relate structural information from both nanometer and atomic length scales to the materials' functional, macroscopic properties.

An Accessible Direct Detection Camera for Transmission Electron Microscopy Imaging, Diffraction and *In Situ* Investigation of Materials from 60 – 200 keV Fernando Castro, Benjamin Miller and Cory Czarnik; Gatan, Inc., United States

The ability of direct detection cameras to collect high-quality data with very low dose rates (e.g. < 20 e^-/pixel/s) in the transmission electron microscope (TEM) makes them effective tools for investigating any beam-sensitive material or reaction, such as studies on monolayer 2D materials [1]. These cameras are usually optimized for 200 – 300 keV TEM operation to support the most popular materials science and cryo-electron microscopy applications but have lower detection efficiency at lower TEM accelerating voltages. As a result, direct detection cameras have limited performance for emerging applications requiring ≤ 80 keV to reduce beam damage or improve scattering contrast. Furthermore, properly operating direct detection cameras typically requires more microscopy expertise than operating a scintillator camera, which can be a barrier to collecting the best possible results.

This presentation highlights Gatan's newest direct detection camera – specifically designed to extend the high-quality imaging capabilities of direct detection technology down to 60 keV while streamlining camera operation to improve accessibility for microscopists of all levels of expertise. In particular, the camera uses a new 2k x 2k pixel sensor for experiments from 60 – 200 keV and is capable of framerates > 40 FPS at full imaging resolution. Results from low-dose *in-situ* heating experiments at ≤ 80 keV are presented to highlight the camera's high performance for materials research and *in-situ* experiments. New DigitalMicrograph software features for streamlining camera control and data processing are also discussed.

The improved performance of this camera below 200 keV will benefit all TEM experiments requiring both low-dose and low accelerating voltage, such as research on lithium-ion batteries, catalysts, electronics, and more.

Atomic-Scale Study of Spinel MgV_2O_4 Nanocrystals for Multivalent Ion Battery Cathodes Francisco J. Lagunas Vargas[1,2], Adriana Lee Purano[1,3],

Grant C. Alexander[1,2], Heonjae Jeong[1,4], Christian Moscosa[1,2], Lei Cheng[1,4], Jordi Cabana[1,2] and Robert F. Klie[1,2]; [1]Joint Center for Energy Storage Research, United States; [2]University of Illinois Chicago, United States; [3]Tecnologico de Monterrey, Mexico; [4]Argonne National Laboratory, United States

Mg-ions based batteries have emerged as a promising candidate in the search for post lithium-ion energy storage. Since Mg ions are divalent, batteries based on their transfer inherently offer higher energy densities than those using Li. Additionally, batteries with Mg metal anodes offer a route towards higher gravimetric energy densities needed for applications in electric vehicles, aircraft, and energy grid storage. While Mg ions are comparable in ionic radii to Li ions, their increased reactivity has complicated the search for compatible cathode materials. To date many systems have been explored but few materials for real-world applications have emerged [1]. To overcome this, a fundamental understanding of Mg electrochemistry and solid-state cathode materials are needed. Here we present a study of a spinel vanadium oxides, a cathode material that has been shown to cycle Mg at capacities greater than 170mAh/g [2], using an aberration corrected cold field scanning transmission electron microscopy (STEM) to develop atomic scale structure-property relationships in the material.
In addition to atomic scale imaging, we will utilize electron energy loss spectroscopy (EELS) to map local changes in the density of states (DOS) of the material and conduct a quantitative chemical analysis of the material using energy dispersive spectroscopy (XEDS).
We will show that MgV_2O_4 crystals tend to form well-defined polyhedra with [111], [001] and [110] surface types. The prevalence of each surface type will be examined through a statistical analysis of imaged crystals and the results will be compared to *in-silico* calculations of the associated energies of each surface type. Additionally, we will present atomic-resolution images of the surface reconstructions observed within the first two-three atomic layers on a variety of surface types. Our analysis will include the atomic-scale effects of electrochemical cycling on the crystals. We will show that upon charging a ~5 nm amorphous layer forms on the crystal surface and notably is the region with most pronounced electrochemical activity. The relationship between the crystal surface type and the depth of the surface layer formation will be explored. Finally, by comparing MgV_2O_4 material at different number of cycles (1,20,50) we will present insights into the failure mechanism associated with this material [3].

CH02.06.06
Advancements in UltraFast Electron Microscopy Darrin Leonhardt[1], Eric Montgomery[1], Chunguang Jing[1], Bart Wyderski[1], Yubin Zhao[1], Spencer Reisbick[2], Yimei Zhu[2] and June Lau[3]; [1]Euclid TechLabs, United States; [2]Brookhaven National Laboratory, United States; [3]National Institute of Standards and Technology, United States

Abstract: With the growing applications of temporally-resolved electron microscopy for probing basic chemical and electronic phenomena as well as reducing beam-induced damage, a multifaceted approach to ultrafast transmission electron microscopy is provided in this presentation. Traditionally accepted laser techniques with fixed image acquisition times have been complemented by ultrafast rf and microwave-driven techniques that can be synchronized with any sample excitation (laser, rf, thermal) with much faster image acquisition times (from days to minutes), thereby enabling more reliable data and microscope efficiency.

Keywords: ultrafast electron microscopy, stroboscopic, time-resolved imaging, high resolution transmission electron microscopy, beam damage.

Originally a basic research tool for materials science, transmission electron microscopes (TEMs) have seen a renaissance, as they have been applied in nearly every technology-based field. They have become the gold standard of high spatial resolution techniques and the ever-increasing applications from quantum dots to cellular 3D tomography and holography demand a much wider range of imaging capabilities. TEMs are used to connect photonics, nanodevice architecture, and biophysics, each with their individual intrinsic response times on the nanoscale. The continued evolution of applications and maturation of basic TEM instruments have not only created additional sectors in the TEM industry (life sciences, nanotechnology, and semiconductor), but have fostered significant growth in these areas that the new market sectors are comparable in size to the once dominant materials science market [1].

Generally, the picosecond regime is common for interrogating basic material phenomena, then longer time scales are generally necessary as material systems get larger physically. Ultrafast TEM (UTEM) was developed using lasers and photocathodes in the mid-2000s to interrogate time-resolved responses to optical stimuli [2]. While ultrafast lasers were a natural enabler for early research in UTEM, the explosive growth of these new applications based on large molecules (proteins, cells) and new 2D/3D architectures (NEMS/MEMS, nanosheets, spintronics) requires broader temporal capabilities due to their widely varying response times. If we include research focused on the mitigation of radiation damage from the microscope's probe beam, an entirely new set of requirements and process space becomes critical. The material recovery time from beam induced damage between probe pulses, process temperature, sample area, etc., may all become variables to the imaging process. Especially in these cases, complementary enabling technologies (rf, microwave) have been used with simplified and typically improved imaging performance.

This presentation will also present the challenges for growing ultrafast techniques [3,4] and compares these complementary methods to laser UTEM techniques [3,4], for electron microscope users to consider when trying to expand their research capabilities. An update on UEM applications supported by recently developed techniques and extraordinary electron beam characteristics [7] as well as implementation perspectives will also be provided.

Origin of 2DEG Modulation at $LaAlO_3/SrTiO_3$ Interface Revealed by In-situ TEM Biasing Sang Ho Oh; Korea Institute of Energy Technology, Korea (the Republic of)

Since its discovery the two-dimensional electron gas (2DEG) forming at $LaAlO_3/SrTiO_3$ (LAO/STO) interface has attracted a lot of research interests of oxide community. Many groups have demonstrated the successful incorporation of 2DEG into field effect transistors or diodes where the field-induced charge modulation is central to the device operation. Although the device technology has been advanced rapidly, the fundamental understanding of the field-induced charge modulation of 2DEG is not fully understood. Here we show comprehensive in-situ analysis of LAO/STO system under electrical stimulus in TEM. Our in-situ inline electron holography successfully visualized the field-induced charge density modulation of 2DEG by the electric field applied normal to the LAO/STO interface. While in-situ electron energy loss spectroscopy (EELS) confirmed no measureable oxygen vacancy migration, atom-resolved STEM-HAADF imaging revealed the polar distortion of B-site atoms in both LAO and STO, which induces the ionic polarization gradient across the interface in the range of -18.6 $\mu C/cm^2$ to 18.7 $\mu C/cm^2$ depending on applied voltages. The field-induced polar distortion adds additional charges at the interface with amount depending on the difference between LAO and STO. Our in-situ TEM study, as opposed to the previously suggested mechanism based on oxygen vacancy migration, demonstrates that the evolution of polar distortion of LAO under field electric field is key to the charge modulation at LAO/STO interface.

Mapping Thermal Signals with STEM EBIC William Hubbard[1], Matthew Mecklenburg[2] and B. C. Regan[2,1]; [1]NanoElectronic Imaging, Inc., United States; [2]University of California, Los Angeles, United States

Contrast in the transmission electron microscope (TEM) is primarily sensitive to physical and chemical properties that are sometimes of only secondary interest compared to electronic and thermal signals, especially when studying electronic devices. Recent advances in scanning TEM electron beam-induced current (STEM EBIC) imaging have enabled mapping of electronic properties in live devices, including resistance, with high spatial resolution. Here we discuss an additional STEM EBIC capability: mapping temperature in live devices. We acquire STEM EBIC images on Si-based samples patterned with electrodes and small MEMS heaters that produce a micro-scale temperature gradient. As an independent calibration, we also measure temperature on samples by performing plasmon energy expansion thermometry (PEET) on aluminum fiducials. We observe a strong, repeatable temperature dependence for both EBIC modes, with the "standard" EBIC mode having a larger temperature response than secondary electron emission EBIC (SEEBIC). The thermal response was similar for all electrode materials tested, and temperature maps can be generated with just a few minutes of acquisition time followed by relatively simple image calculation.

8:45 AM CH02.07.03
Investigation of Atomic Structure Changes on Resistive Switching Oxide Thin Film (Memristor) Applying *In Situ* I-V/TEM Deok-Hwang Kwon; Korea Institute of Science and Technology, Korea (the Republic of)

Combining the power of atomic structure imaging in transmission electron microscope (TEM) and current-voltage (I-V) measurement, in-situ I-V/TEM becomes a powerful tool to characterize the nanoscale of materials while applying voltage simultaneously. Particularly in electronic materials, its significant effectiveness was successfully demonstrated over decades. For example, one of the candidates suggested as the next electronic device for neuromorphic computing, the resistive switching phenomenon (also referred to as Memristor) has been highly investigated. With significant interest in a Neuromorphic computing device, massive research has been conducted on its mechanism and applications.

While the resistive switching phenomenon, which is a straightforward thing, occurs when an external potential is applied to a thin film oxide sandwiched between the top and bottom electrodes, its mechanism has remained controversial due to the lacking of direct evidence. A mobile defect such as oxygen vacancy has been frequently inferred to be the reason provoking the phenomenon; however, their physical form and distribution remained elusive. To resolve this issue, I employed in-situ I-V/TEM and directly investigated the switching mechanism in oxide materials. Various oxide thin films were studied as model systems, such as TiO_2, $SrTiO_3$, and $SrFeO_3$. Since in-situ I-V/TEM enables the operation of electronic devices in TEM while measuring atomic structure changes simultaneously, the switching area was directly probed and visualized. Chemical analysis employing electron energy-loss spectroscopy was carried out, confirming oxidation state changes of transition metals. High-resolution TEM imaging and chemical information reveal the atomistic mechanism of resistive switching. Also, thermodynamic modeling is established. The deep insight found from these results sheds light on pathways to Memristor and Neuromorphic computing.

9:00 AM CH02.07.04
Cryogenic 4D-STEM of the Charge Density Wave Transition in TaS_2 with *In Situ* Electric Biasing James L. Hart[1], Saif Siddique[1], Noah Schnitzer[1], Lena F. Kourkoutis[1,1] and Judy Cha[1,2,2]; [1]Cornell University, United States; [2]Yale University, United States

The layered van der Waals solid TaS_2 exhibits a number of charge density wave (CDW) states. Of particular interest is the commensurate (C) to nearly commensurate (NC) CDW phase transition, which is associated with a strong metal-to-insulator transition (T_c ~150 K). The transition can be driven by electrical pulses, and is promising for two-terminal electronic devices, *e.g.,* for neuromorphic computing. Nevertheless, our understanding of how the C to NC transition evolves in real-space and in nanoscale (thickness) confinements is limited, both as a function of temperature, and more interestingly, as a function of applied electric field. Here, we approach these questions using cryogenic 4D-STEM (scanning transmission electron microscopy) with *in situ* electrical biasing. We use the HennyZ sample holder, which allows for variable temperature analysis from ~100 – 1000 K, and has two electrodes for device biasing. With *in situ* STEM temperature sweeps, we observe resistance versus temperature behavior consistent with conventional TaS_2 devices reported in literature, clearly showing the CDW transitions. At base temperature (~110 K) in STEM, we use sub-microsecond electrical pulses to drive the C to NC phase transition, and observe electrical switching data consistent with *ex situ* devices. To visualize the transition in real-space, we use scanning nano-beam diffraction, wherein the C to NC phase transition is manifested by a ~2° rotation of the CDW wave vector. This work marks a step towards the goal of operating electrical devices within the (S)TEM and directly correlating real-space sample structure with device performance at variable cryogenic temperatures.

Atomic Structure of Organic-Metallic MXenes Revealed by Cryo-STEM and EELS Francisco J. Lagunas Vargas[1], Chenkun Zhou[2], Dmitri V.

Talapin[2] and Robert F. Klie[1]; [1]University of Illinois Chicago, United States; [2]The University of Chicago, United States

MXenes ($M_{n+1}X_nT_x$ with n=1,2) are a large family of two-dimensional transition metal carbides and nitrides [1]. What distinguishes MXenes from other 2D materials is that they can be functionalized with a variety of T_x surface groups. In 2020, *Kamysbayev et al*. demonstrated that these surface groups can drastically alter the MXenes' properties [2]. For example, they demonstrated a surface group dependent superconducting behavior in Nb_2CT_x. In this contribution we will continue to explore the range of possible surface group terminations by studying a new family of MXenes functionalized with organic surface groups. These metallic-organic hybrid MXenes open the door to the rich and complex space of organic chemistry and combine the structural and electron properties of metallic material. Our analysis will focus on developing an atomic-scale understanding of structure-property relationships in these novel materials.
This study will be conducted using atomic-resolution scanning transmission electron microscopy (STEM), electron energy loss spectroscopy (EELS) and x-ray energy dispersive spectroscopy (XEDS). Using these tools in tandem we will gain insights into the local chemical composition and bonding environment with high spatial resolution.
The focus of our study will be to examine Ti_3C_2 terminated with hydrocarbon chains and aromatic benzene rings. Since organic material is well known to decompose at the electron dosages required for high resolution studies, we will utilize in-situ cooling to liquid nitrogen temperatures to stabilize the organic material. Our analysis will show that cooling sufficiently preserves the organic material so that the unique π and σ bonding for the different amines can be observed in C *K*-edge spectra. Additionally, we will demonstrate that atomic resolution images of the material can be acquired while preserving the delicate structure of hybrid MXenes. Our in-situ cooling study will also show dynamic processes that occur in hybrid MXenes as the result of interactions with the electron beam. We will show that highly localized defects can be introduced using the electron probe and that the defects lead to a dynamic reorganization of the MXenes layers. [3]

Conformal Three-Dimensional Interphase of Li Metal Anode Revealed by Low-Dose Cryo-Electron Microscopy Bing Han[1] and Y. Shirley Meng[2]; [1]University of California San Diego, United States; [2]The University of Chicago, United States

Using cryogenic transmission electron microscopy, we revealed three-dimensional (3D) structural details of the electrochemically plated lithium (Li) flakes and their solid electrolyte interphase (SEI). As the SEI skin layer is largely composed of nanocrystalline LiF and Li2O in amorphous polymeric matrix, when complete Li stripping occurs, the compromised SEI 3D framework buckles and wrinkles. The flexibility and resilience of the SEI skin layer plays a vital role in preserving an intact SEI 3D framework after Li stripping. The intact SEI network enables the nucleation and growth of newly plated Li inside the previously formed SEI network in subsequent cycles, preventing additional large amounts of SEI formation. In addition, cells cycled under the accurately controlled uniaxial pressure can further enhance the repeated utilization of the SEI and improve the Coulombic efficiency (CE) by up to 97%, demonstrating an effective strategy for reducing the formation of additional SEI and inactive ‘‘dead’’ Li.

Direct Observation of All Atomic Sites in Zeolite by a Novel Low-Dose STEM Technique—Optimum Bright-Field Imaging Kousuke Ooe[1,2], Takehito Seki[2,3], Kaname Yoshida[1], Yuji Kohno[4], Yuichi Ikuhara[1,2] and Naoya Shibata[1,2]; [1]Japan Fine Ceramics Center, Japan; [2]The University of Tokyo, Japan; [3]JST PRESTO, Japan; [4]JEOL Ltd., Japan

Scanning transmission electron microscopy (STEM) enables us to directly observe atomic structures inside materials, which is powerful in unveiling their structure-property relationships. However, one of the most challenging problems in recent years of (S)TEM research is the atomic-resolution imaging of beam-sensitive materials, which have a low resistance to electron irradiation, such as battery materials, porous materials, and organic materials. The conventional STEM techniques such as annular dark-field and annular bright-field (ABF) imaging modes can robustly visualize atomic structures of electron-resistant materials using single annular detectors. For the beam-sensitive materials, however, there is room to improve the dose efficiency to minimize the irradiation damage because these imaging techniques use only a fraction of transmitted electrons for imaging. Recently, a high-speed segmented detector has been developed, which can record almost all the transmitted electrons by multiple detection channels [1]. Herein, we developed optimum bright-field (OBF) STEM using a segmented detector as a more dose-efficient imaging technique [2]. In the OBF method, a STEM image with the highest signal-to-noise ratio for a given detector is reconstructed via Fourier filters designed based on the phase contrast transfer function and the noise-evaluation theory [3]. OBF STEM has approximately two orders of magnitude higher dose efficiency than ABF STEM, and thus, OBF is promising for low-dose observation. Furthermore, by approximating this filtering process, OBF images can be reconstructed in real-time and displayed in sync with the probe scans as well as the conventional STEM imaging. The real-time display function enables operators to tune aberrations and field-of-view even under the low-dose condition. In this research, we applied the OBF STEM technique to the atomic-resolution imaging of zeolites, which are well-known beam-sensitive materials. The low-dose OBF observation successfully visualized all atomic sites, including even oxygen sites, inside the zeolitic framework. Furthermore, we also observed the twin defects in a zeolite and determined its atomic structure directly in combination with the first-principles calculations.

Reversible Intercalation of Mg^{2+} in V_2O_5 at Elevated Temperatures Leads to Enhanced Electrochemical Performances Yingjie Yang and Robert F. Klie; University of Illinois at Chicago, United States

Barriers to lithium ion battery development, such as the limited energy density of Li-ion batteries and the scarcity of Li, have led to great interest in exploring multi-valent ionic batteries containing earth abundant intercalation elements, such as magnesium or calcium. Reversible intercalation of Mg^{2+} ions is a crucial part in constructing a stable battery, which, when combined with high capacity, charts a promising pathway towards high performance and

future designs of Mg-ion batteries. High levels of reversible Mg^{2+} intercalation have been reported in α-V_2O_5 by cycling assembled cells at an elevated temperature of 110°C, the benefit of which is retained at room temperature.

Experiments were carried out with assembled cells consisted of pressed V_2O_5 powders as the cathode, ionic liquid $MgTFSI_2$-PY14TFSI as the electrolyte, and activated carbon cloths or Mg foil as the anode. After cycling at room temperature and 110°C, the samples were characterized structurally with electron microscopy and X-ray absorption spectroscopy. The ex-situ experiments demonstrate that α-V_2O_5 can intercalate at least one mole of Mg^{2+} reversibly at 110°C, as opposed to <0.6 mole at 25°C. The capacity of the α-V_2O_5 is increased 20-fold, from 16 mAh g^{-1} at 25°C to 295 mAh g^{-1} at 110°C, matching the performance of Li-ion batteries. This increase in electrochemical performance is accompanied by structural changes; the morphology of the α-V_2O_5 powders drastically change from platelets to delaminated layers. Particles with delaminated morphologies show the change in Mg content, which echoes with the change in capacity, calculated to be 1 mol Mg^{2+} per mole α-V_2O_5. These findings pave the road toward reversible Mg-ion batteries with high degrees of Mg^{2+} intercalation and high potential, and current efforts in developing in-situ characterization functionalities will lead to imperative capabilities.

Current research is ongoing to explore in-situ characterization techniques with scanning transmission electron microscope, combined with capabilities of simultaneous heating and electrochemical cycling. If realized, this can open up more possibilities to deepen the understanding of structural and chemical developments during the intercalation process.

10:45 AM CH02.07.09
Dynamic Evolution of All-Solid-State Li-ion Battery Based on LAGP Solid Electrolyte Using *In Situ* Electrochemical TEM Sorina Cretu[1,2], Nicolas Folastre[1,3,4], David Traodec[5], Rainer Straubinger[6], Nynke Krans[6], Martial Duchamp[2] and Arnaud Demortiere[1,3,4]; [1]Laboratoire de Reactivite et Chimie des Solides, France; [2]Nanyang Technological University, Singapore; [3]RS2E-French Research Network on Electrochemical Energy Storage, France; [4]ALISTORE- European Research Institute, France; [5]IEMN, France; [6]Protochips, United States

The increasing request for electric vehicles (EV) demands high energy density batteries, wide temperature compatibility and improved safety technology. Solid-state Li-ion batteries (SSB)[1] could represent a possible future solution for current battery technology as the liquid electrolyte containing flammable organic materials is replaced by a solid electrolyte (SE) removing the safety concerns. Moreover, SSB technology offers the possibility to use high voltage cathode materials as some SE present wide electrochemical window and also opens the possibility to use lithium metal as anode resulting in batteries with a higher energy density[2].
SSB performances improved over the last years, but there are still challenges as interfaces, grain boundaries formation, generation of cracks and dendrites during the cycling which needs to be solved in order to make them a sustainable future battery technology[2–4]. To get a better insight into the limiting parameters of SSB performances comprehensive information about the dynamic process occurring at the interfaces between the solid electrolyte and the electrodes during the electrochemical reaction at nanoscale are essential, thus *in-situ* experiments are being required. *in situ* Transmission Electron Microscopy (TEM)[5,6] represents the perfect tool for understanding the failure mechanism in ASSB as it allows us to visualize the interfaces, will enable us to follow the structural changes using electron diffraction and 4D-STEM as well as the chemical changes using EDX and EELS mapping.
During this study, SSB containing $Li_{1.5}Al_{0.5}Ge_{1.5}(PO_4)_3$ (LAGP) oxide solid electrolyte due to their high stability in the air, LiFePO4 (LFP) as positive electrode and $Li_3V_2(PO_4)_3$ (LVP) as negative electrode allowing us to obtain a full inorganic solid-state battery in one single shot using Spark Plasma Sintering (SPS)[7].
In situ TEM experiment carried out using our microbattery obtained by Focused Ion Beam (FIB) and connected on Protochips chip revealed the simultaneous process of LAGP particle size reduction with the formation of grain boundaries areas between the solid electrolyte grains during the cycling. 4D-STEM analysis performed before and after the *in-situ* TEM cycling experiment revealed the presence of amorphous regions in the SE and electrode mixture after the cycling process suggesting that the grain boundary phase formed after the cycling process is amorphous. The presence of $FePO_4$ (FP) phase structure analyzed by 4D-STEM mapping is consistent with delithiation process occurred over the electrochemical cycling. The phase mapping also revealed a domino-cascasde lithiation process with a clear phase separated between LFP and FP grains. Moreover, the presence of Al-rich areas was spotted in the LAGP in the initial state and those areas represented the weak point in the SE as they were the initial point for crack propagation in the battery. STEM-EDX map analysis was performed before and after the cycling process displayed the unexpected presence of carbon in the pristine SE which possibly increased the electronic conductivity and contributed to the crack propagation. EDX map revealed that oxygen signal from the near vicinity of the solid electrolyte/ positive electrode was also diminished after the electrochemical reaction, most likely reacting with the carbon and leading to the formation of $LiCO_3$ producing possible irreversible changes at the interface solid electrolyte/positive electrode.

11:00 AM CH02.07.10
ETEM Study for Monitoring Oxidation Reaction in $LiFePO_4$ Cathode Materials Arnaud Demortiere; Université de Picardie Jules Verne, France

$LiFePO_4$ is turning out to be one of the best candidates for Li-ion battery cathode materials due to its high retention in cycling, a structural stability of the $FePO_4$ phase and containing no-cobalt [1]. Recent developments show the possibility of significantly increasing power densities with morphology and size modifications. However, the $LiFePO_4$ nanoparticles [2] show significant amounts of structural defects according to the synthetic route used. For instance, the presence of Fe atoms in Li crystallographic sites has a significant effect on electrochemical behavior leading to a decreasing in cation diffusion. $LiFePO_4$ also has a high reactivity to O_2 at moderate temperatures (300-500°C depending on the size) leading to the gradual diffusion of Fe from the core to the surface of the material accompanied by the formation of Fe_2O_3 nanoparticles [2]. Therefore, the composition material $Li_xFe_yPO_4$ exhibits very high degree of crystalline defects. These transformations were evidenced by X-ray diffraction and electron diffraction at different temperatures [3]. These olivine compounds outside stoichiometry have an order of defects leading to the formation of a superstructure.

To get a better insight into the mechanisms related to these transformations, *in situ* investigation in a real-time is necessary. Environmental ETEM, in which a pression of O_2 can be injected, coupled with a heating holder is a perfect characterization platform to monitor oxidation reactivity of $LiFePO_4$ up to 700°C. This project focuses on the study of the structural mechanisms associated with the temperature reactivity of $LiFePO_4$ under an oxidizing atmosphere using environmental TEM (TITAN). The aim is to quantify the kinetics of Fe_yO_x nanoparticle formation, and the appearance of superstructures induced by Fe diffusion from the core to the surface of the material.

After an optimization step of the experimental conditions inside the ETEM, ideal conditions of reaction have been found. For a temperature of 620°C

(DENSolution heating holder), we have started to observe the formation of Fe_yO_x nanoparticle at the surface of $LiFePO_4$ crystals in a pression of O_2 (12 mbar). In the figure 1b, the HAADF-STEM image shows clearly Fe_yO_x nanoparticles with a bright contrast and mainly localized at the surface. The figure 1c exhibits the chips used for the heating experiments. ADF images allow to distinguish the $LiFePO_4$ crystals and the nanoparticle, which can be formed along the surface or with in an elongated way perpendicular to surface. The growth kinetics of these nanoparticles has been quantified from real-time observations. Chemical investigations by EELS spectroscopy using O-K ELNES reveal the strong modification of oxygen valence from $LiFePO_4$ to Fe_yO_x, as shown in the figure 1d. The high resolution TEM analyses of nanoparticles confirm the presence of gamma-Fe_2O_3 structure. The interfaces between $LiFePO_4$ and Fe_yO_x have been characterized and help us to identify preferential pathway of diffusion during the Fe extrusion process. Finally, 4D-STEM investigation [5] was made to identify each structural phases based on electron diffraction pattern spatially resolved, which is present in the LFP crystals after oxidation reaction.

11:15 AM CH02.07.11
Nanoscale Multimodal Analysis of Organic Compounds in Beam-Sensitive Nanoparticles by Monochromated STEM-EELS Maeva Chaupard[1,2], Ruxandra Gref[2] and Marta de Frutos[1]; [1]Laboratoire de Physique des Solides, France; [2]Institut des Sciences Moléculaires d'Orsay, France

Nanomaterials are of great interest for improving existing technologies or engineering new ones. The unique properties of these emergent structures are widely studied in various fields, such as optics, electronics and medicine. As their properties depend on their sizes, local structures and chemical compositions, each nanomaterial requires deep analysis to unravel its specific behaviour. However, most of the used techniques cannot provide information on such nanosystems at the single-particle level.[1] This has led to a strong interest in electron microscopy, which can image the morphology and crystal structure of specimens with atomic resolution. Low-dose cryo-Transmission Electron Microscopy (cryo-TEM) is now commonly employed to study beam-sensitive materials such as organic and hybrid organic-inorganic materials.[2] In addition to imaging, the latest generation Scanning Transmission Electron Microscopes (STEM) equipped with Electron Energy Loss Spectroscopy (EELS) allow a deep characterisation of specimens down to the atomic scale.[3] Thanks to the recent development of monochromated electron sources, spectral resolutions can now reach below 10 meV, allowing access from the far-IR to the X-ray range.[4]
Nevertheless, the analysis of sensitive specimens remains a major challenge for spectromicroscopy. Although recent studies based on vibrational EELS have demonstrated the possibility of damage-free analysis,[5,6] most of them exhibited no or limited spatial resolution. Here, we report damage-free analysis of organic-inorganic nanoparticles at the nanoscale. It was achieved via EELS experiments using a monochromated STEM equipped with a cryo-holder and a direct electron detector (DED) in low-dose conditions (down to 10 $e^-/Å^2$). First, the beam-induced damage was studied in the UV and soft X-ray spectral energy ranges. The DED provides simultaneous acquisition of low-loss and core-loss signals, in order to study the beam-induced chemical reactions. Secondly, the vibrational energy range was explored in the aloof and transmitted modes with a 7 meV spectral resolution. Finally, chemical maps were obtained in the three energy ranges. Here, we demonstrate that STEM-EELS provides damage-free analysis that enables efficient identification of the organic compound distributions across sensitive specimens. Our work opens new possibilities for analysing organic compounds such as polymers and biomolecules.

11:30 AM CH02.07.12
Direct Observation of Formation and Decomposition Processes of Sessile Dislocation by *In Situ* STEM Mechanical Testing Minjian Cao[1], Eita Tochigi[1], Naoya Shibata[1,2] and Yuichi Ikuhara[1,2]; [1]The University of Tokyo, Japan; [2]Japan Fine Ceramics Center, Japan

The mechanical behaviors of crystalline materials are highly influenced by dislocation glide, known as one of the elementary processes of plastic deformation. In the plastic deformation of FCC metals, sessile dislocation is formed by the reaction between dislocations on different slip planes. Since sessile dislocation is very difficult to glide and has an unique dislocation core structure, it is important to elucidate the atomic behavior associated with the pinning mechanism of sessile dislocation. In-situ transmission electron microscope (TEM) mechanical testing is promising to observe nanoscale dynamics in materials directly. However, conventional in-situ mechanical testing has difficulty for atomic-resolution observations, because of the lack of precise and stable mechanical loading systems. In recent years, micro-electro-mechanical systems (MEMS) technology has been improved and precise loading functions can be assembled within a small chip with a few millimeters square sizes [1].
Here, we combined a MEMS loading device with scanning TEM (STEM) and observed the formation and decomposition processes of sessile dislocation in Au at the atomic level. A thin section cut from an Au substrate was fixed on the actuators of the MEMS device by focused ion beam with controlling its crystal orientation to be observed from [1-10] zone axis. The sample was further thinned, and a sharp notch was introduced to its edge part for enhancing stress concentration. Upon loading the sample stepwise, it was observed that two stacking faults on (111) and (11-1) planes extended from the sample edge and joined at an angle of about 70.5 degrees. This deformation phenomenon corresponds to the surface nucleation and glide of 1/6[11-2] and 1/6[112] Shockley partial dislocations, and their reaction to form 1/3[110] stair-rod type sessile dislocation. With further loading, the 1/3[110] stair-rod type sessile dislocation was decomposed into 1/6[11-2] and 1/6[112] Shockley partial dislocations, and the 1/6[11-2] Shockley partial dislocation proceeded into the interior of the sample. The present result shows that the 1/3[110] stair-rod type sessile dislocation does not always act as a pinning point under incremental loading conditions. Details will be disucussed in the presentation.

11:45 AM CH02.07.13
Integrating EIS with *In Situ* TEM in Ceramic Nanofiber Characterization Waynah Lou Dacayan[1], Christodoulos Chatzichristodoulou[1], Zhongtao Ma[1], Wenjing Zhang[2], Kristian S. Mølhave[3] and Søren B. Simonsen[1]; [1]DTU Energy, Denmark; [2]DTU Sustain, Denmark; [3]DTU Nanolab, Denmark

In this work, electrochemical impedance spectroscopy (EIS) was integrated with in situ transmission electron microscopy (TEM) to allow simultaneous electrochemical and structural characterization of functional materials. This is particularly critical in energy conversion technologies where the interdependence of structure and electrochemical properties of the components significantly affect its functionality, consequently governing the overall process efficiency. Presented herein is the application of the EIS-TEM method in the characterization of electrospun nanofiber of $Ce_{0.9}Gd_{0.1}O_{1.95-\delta}$ (CGO), a

popular material for solid oxide fuel/electrolysis cells (SOCs).

The CGO nanofiber was prepared by combining sol-gel synthesis and electrospinning. With the aid of a micromanipulator inside a scanning electron microscope (SEM), a single nanofiber was separated from the electrospun nanofiber sheet and was transferred to a heating and biasing MEMS chip. With a MEMS chip-based holder, 2-probe EIS measurements were conducted in parallel with TEM characterization inside an environmental TEM (ETEM) at different temperatures from 28°C to 600°C in 2.5 mbar pO_2 gas. EELS spectra were acquired in the same conditions to follow the possible change in the chemical state of the CGO nanofiber.

The CGO nanofiber was found to have a relatively low activation energy (E_a), close to the value associated with small polaron hopping in pure and doped ceria which is particularly observed when exposed to reducing conditions. The EELS analysis, however, shows that the average Ce oxidation state is close to Ce^{4+} at all temperatures, confirming that no beam-induced Ce^{4+}/Ce^{3+} reduction happened in the material. Possibly, the low E_a may be associated with the small grain size of the CGO nanofiber, i.e. ca. 10nm. The EELS results also show that by keeping the beam exposure low, no beam damage occurs on the nanomaterial and that reliable EIS measurements in combination with TEM analysis can be done.

Magnetic-Field-Free Atomic-Resolution Scanning Transmission Electron Microscopy Naoya Shibata[1,2]; [1]The University of Tokyo, Japan; [2]Japan Fine Ceramics Center, Japan

Aberration-corrected scanning transmission electron microscopy (STEM) is a powerful technique to directly observe atomic-scale structures and chemistry of individual defects, such as interfaces, inside materials and devices. However, since high magnetic fields (~2T) are always exerted on samples inside the magnetic objective lens, atomic-resolution observation of magnetic materials has been essentially very difficult. In recent years, we have developed a magnetic objective lens system that realizes a magnetic field free environment at the sample position. Using this objective lens system combined with the state-of-the-art higher order aberration corrector, direct atom-resolved imaging in a magnetic field free environment has been achieved. The details of this magnetic-field-free STEM, currently ongoing developments and material application results will be presented.

2:00 PM CH02.08.03
Atomic-Plane Resolved Magnetic and Chemical Imaging by Chromatic-Aberration Corrected Electron Magnetic Circular Dichroism and Electron Energy Loss Spectroscopy Xiaoyan Zhong[1,2,3]; [1]City University of Hong Kong, Hong Kong; [2]City University of Hong Kong Shenzhen Futian Research Institute, China; [3]City University of Hong Kong Shenzhen Research Institute, China

Electron magnetic circular dichroism (EMCD), experimentally verified by Schattchneider et al. [1] in a transmission electron microscope (TEM) is a method of magnetic spectroscopy as analogous to X-ray magnetic circular dichroism (XMCD). In principle EMCD can offer higher spatial resolution and greater depth sensitivity due to the short de Broglie wavelength and penetration of high-energy electrons compared to XMCD. Under convergent beam illumination with a probe size of 1.8 nm in a scanning TEM, we acquired the EMCD spectra of individual antiphase boundary with a rock salt structure interlayer in inverse spinel $NiFe_2O_4$. [2] However, the larger convergent angle leads to the better spatial resolution and the poorer signal-to-noise ratio (SNR) of EMCD spectra.
We developed the method of atomic-planed resolved (APR) EELS imaging via the ground-breaking combination of spatially resolved electron energy loss spectroscopy (SR EELS) technique [3] and chromatic/spherical aberration (C_C/C_S) correction [4-6] under parallel illumination mode. With the combined approach mentioned above, the delocalization of both elastically and inelastically scattered electrons has been reduced effectively, which allows us to acquire chemical information with atomic plane resolution. In the example of $SrTiO_3$, we obtained electron energy loss (EEL) spectra of Ti $L_{3,2}$ edges from the individual atomic planes by using APR EELS.
Furthermore, we developed the method of atomic-planed resolved (APR) EMCD imaging by combining EMCD and APR EELS with the aid of C_C/C_S correction [7]. In the example of Sr_2FeMoO_6, we achieved EMCD spectra and quantitative orbital to spin magnetic moment ratio atomic plane by atomic plane. Combining with advanced capability of structural and chemical imaging by using aberration-corrected transmission electron microscopy, all the information including magnetic polarization, atomic configurations and chemical states can be simultaneously accessed from the very same sample region at the atomic scale.

3:15 PM CH02.08.04
Measuring the Mean Inner Potential of Bernal Graphite Using Off-Axis Electron Holography Avi Auslender[1,1], George Levi[1], Vladimir Ezersky[2], Oswaldo Diéguez[1,1] and Amit Kohn[1]; [1]Tel Aviv University, Israel; [2]Ben-Gurion University of the Negev, Israel

The mean-inner-potential (MIP) of a crystal is the average electrostatic Coulomb potential within a crystal with respect to vacuum. The MIP is a fundamental material property which reflects chemical-bonding and crystallographic surfaces .
We conducted off-axis electron holography experiments on highly-oriented-pyrolytic-graphite (HOPG) in a transmission-electron-microscope to measure the MIP from nanometer-scale volumes of Bernal graphite oriented with respect to the electron beam, along the principal axis or directions in the basal plane. These MIP were related to mean orbital electron radii and diamagnetic susceptibilities in perpendicular planes. Such intrinsic property measurements are challenging because of defect-induced interfaces at basal planes. Indeed, our structural examination of HOPG show stacking faults and planar rotations around the principal-axis, such that measuring intrinsic properties requires probing a volume of $\sim 10^2 \times 10^2 \times 10^2$ nm^3.
Experiments on individual Bernal graphite crystals with (0001) basal, or (1-100), (2-1-10) prismatic planes, resulted in MIP of 10.16±0.40 V, 11.37±0.35 V, 12.66±0.41 V, respectively. First-principles calculations from crystalline slabs confirm these anisotropic measurements with 11.72 V, 13.65 V, 14.56 V, respectively. Additionally, these experiments enabled to measure the mean free path for inelastic scattering in graphite of 197keV electrons at a collection angle of 18mrad resulting in 150.6±2.0 nm.
These measured MIP enable to determine projected mean radii of electron orbitals and volume susceptibilities (SI), assuming spherically symmetric charge distribution, at 0.704±0.015Å, $(-1.99\pm0.08)\times10^{-5}$; 0.744±0.015Å, $(-2.23\pm0.07)\times10^{-5}$; 0.785±0.015Å, $(-2.48\pm0.08)\times10^{-5}$.
The measured orbital radii and diamagnetism in the basal plane are comparable to expected values for carbon s-bond hybridization. Increased MIP on prismatic planes is related to s-orbital components, which decrease due to delocalized electrons between basal planes.

3:30 PM CH02.08.05
Detection of Graded Magnetic Interface in Iron Oxide Core/Shell Nanoparticles via Electron Magnetic Chiral Dichroism Daniel del Pozo Bueno[1,2], Maria Varela[3], Alberto López-Ortega[4,4], Alejandro G. Roca[5], Marta Estrader[2,2], Josep Nogués[5], Francesca Peiró[1,2] and Sònia Estradé[1,2]; [1]University of Barcelona, Spain; [2]Universitat de Barcelona, Spain; [3]Universidad Complutense de Madrid, Spain; [4]Universidad de Castilla-La Mancha, Spain; [5]Catalan Institute of Nanoscience and Nanotechnology, Spain

The Electron Magnetic Chiral Dichroism (EMCD) technique has undergone a significant innovation with the improvement in the spatial and energy resolution of advanced electron microscopes in combination with the advancement of data processing methods, providing a wide range of opportunities to carry out magnetic studies at the nanoscale. This technique is analog to the X-ray Magnetic Circular Dichroism (XMCD), offering a better spatial resolution. It was first postulated by C. Hébert et al.[1] in 2003, and experimentally proved it by P. Schattschneider et al.[2] three years later. It is based on Electron Energy Loss Spectroscopy (EELS), and it identifies the dichroic signals arising from magnetic materials as a difference in intensity in the transition metal white lines (L_3 and L_2) EEL spectra obtanied from two symmetric positions of the spectrometer aperture, and the sample oriented in specific conditions.
In this work, we use this technique to investigate the local magnetization of FeO/Fe3O4 nanocubes with an antiferromagnetic/ferrimagnetic core and shell respectively, which are of great interest due to their appealing magnetic characteristics and prospective uses. The interface structure in these types of core/shell nanoparticles is crucial for adjusting their characteristics, hence in this study we make use of the EELS spectra obtained by the EMCD technique to characterize the composition while studying the local magnetization.
Since only the shell exhibits a ferrimagnetic behavior, during the experiments, which were conducted at low temperatures with two beams configuration, it was required to explore the dichroic signal from the core and shell regions independently. EEL spectra were acquired for this purpose with a spatial resolution of 0.25 nm and an energy resolution of 0.25 eV. The spectra were then classified using clustering techniques[3,4], particularly the k-means algorithm, with each spectrum being identified by its energy loss near edge structure.
As a result, the EMCD measurements along with the EELS analysis (i.e., clustering methods and compositional analysis) have demonstrated that these nanoparticles are composed by four distinct zones, each with a unique magnetic moment, forming an onion-like structure that is concentric. With the magnetic moment being greatest at the surface and decreasing toward the core, and these magnetic zones are spatially correlate with the oxidation and composition gradient[5]. The results demonstrate that the combination of EELS compositional mapping with EMCD can yield incredibly valuable information about the internal magnetic structure and its correlation to the nanostructure of magnetic nanoparticles. Finally, it is important to emphasize the benefits of clustering algorithms in this work for efficiently and accurately analyze the large amount of acquired spectra in the EMCD technique.

Extremely Noisy 4D-STEM Strain Mapping Using Cycle Consistent Spatial Transforming Autoencoders Shuyu Qin[1,2], Xiyue Zhang[3], Chuqiao Shi[4], Jules Muhizi[5], Yichen Guo[1], Xinqiao Zhang[2], Ni Wan[6], Aditi Krishnapriyan[7], Michael Mahoney[7], Yimo Han[4], Nhan Tran[8], Colin Ophus[9], David A. Muller[3] and Joshua Agar[2]; [1]Lehigh University, United States; [2]Drexel University, United States; [3]Cornell University, United States; [4]Rice University, United States; [5]Harvard University, United States; [6]Washington University in St. Louis, United States; [7]University of California, Berkeley, United States; [8]fermilab, United States; [9]Lawrence Berkeley National Laboratory, United States

Atomic-scale imaging of 2D and quantum materials benefits from precisely extracting crystallographic strain, shear, and rotation to understand their mechanical, optical and electronic properties. One powerful technique is 4D-STEM (4-dimensional scanning transmission electron microscopy), where a convergent electron beam is scanned across a sample while measuring the resulting diffraction pattern with a direct electron detector. Extracting the crystallographic strain, shear, and rotation from this data relies either on correlation strain measurement method (e.g., implemented in py4DSTEM) or determining the center of mass (CoM) of the diffraction peaks. These algorithms have limitations. They require manual preprocessing and hyperparameter tuning, are sensitive to signal-to-noise, and generally are difficult to automate. There is no one-size-fits-all algorithm.
Recently, machine learning techniques have been used to assist in analyzing 4D-STEM data, however, these models do not possess the capacity to learn the strain, rotation, or translation instead they just learn an approximation that almost aways tends to be correct as long as the test examples are within the training dataset distribution.
We developed a novel neural network structure – Cycle Consistent Spatial Transforming Autoencoder (CC-ST-AE). This model takes a set of diffraction images and trains a sparse autoencoder to classify an observed diffraction pattern to a dictionary of learned “averaged” diffraction patterns. Secondly, it learns the affine transformation matrix parameters that minimizes the reconstruction error between the dictionary and the input diffraction pattern. Since the affine transformation includes translation, strain, shear, and rotation, we can parsimoniously learn the strain tensor. To ensure the model is physics conforming, we train the model cycle consistently, by ensuring the inverse affine transformation from the dictionary results in the original diffraction pattern.
We validated this model on a number of benchmark tasks including: A Simulated 4D TEM data of WS_2 and WSe_2 lateral heterostructures (noise free) with a ground truth of the strain, rotation and shear parameters. Secondly, we test this model experimental 4D STEM on 2D-heterostructures of tungsten disulfide (WS_2) and tungsten diselenide (WSe_2).
This model shows several significant improvements including: 1. When tested on simulated data, the model can recover the ground truth with minimal error. 2. The model can learn the rotation and strain on noisy diffraction patterns where CoM failed, and outperforms correlation strain measurement method. 3. Our model can accommodate large and continuous rotations difficult to obtain with other methods. 4. Our model is more robust to noisy data. 5. Our model can map the strain, shear and rotation; identify dislocation and ripples; and distinguish background and sample area automatically.
Ultimately, this work demonstrates how embedding physical concepts into unsupervised neural networks can simplify, automate, and accelerate analysis pipelines while simultaneously leveraging stochastic averaging that improves robustness on noisy data. This algorithmic concept can be extended to include other physical phenomena (e.g., polarization, sample tilt), can be used in automated experiments, and can be applied to other applications in materials characterization.

4:15 PM CH02.09.02
Automated Deep Learning Analysis of Large Sets of High-Resolution Transmission Electron Microscopic Data Nina Gumbiowski[1], Kateryna Loza[1], Marc Heggen[2] and Matthias Epple[1]; [1]University of Duisburg-Essen, Germany; [2]Forschungszentrum Jülich GmbH, Germany

High-resolution transmission electron microscopy (HRTEM) is a valuable technique in materials research, especially for nanoscopic materials like metallic nanoparticles. For these materials size, shape and structure determine their biological, chemical and physical properties and subsequently their possible applications. HRTEM can image the size, shape and structure of these nanoparticles both *ex-situ* and *in-situ* (e.g. during annealing experiments). Large quantities of data can be generated by HRTEM with sub-second time resolution. However, the manual analysis of large sets of HRTEM images is tedious and time-consuming and almost not feasible for large sets of *in-situ* data. Here we present a program based on deep-learning techniques such as semantic segmentation and image classification by convolutional neural networks (CNN).
First a semantic segmentation CNN was trained on labelled HRTEM images of metallic nanoparticles to separate the particles from the background. This network was used to allow the extraction of particle shape-related parameters like circularity, equivalence diameter, and Feret diameter. The program needs only a few seconds to analyse a single HRTEM image to yield all the shape-related parameters of interest. The trained CNN can also be used for transfer learning for *in-situ* datasets that contain more background noise. This enables the generation of time-resolved shape-related data of experiments with hundreds or thousands of individual images. Apart from the shape-related information, HRTEM images can also give information about the internal crystallinity of the nanoparticles. To gain crystallographic information, a classification CNN was trained to classify single particles with respect to the crystallographic nature of individual particles (e.g. single-crystalline, polycrystalline).
Such an automated HRTEM image analysis not only speeds up the evaluation of single HRTEM images but it enables to fully use the capabilities of HRTEM on *in-situ* experimental datasets. Furthermore, it reduces fluctuations in the analysis due to a possible operator bias in manual evaluation. This can give more insight into nanoparticle structures and facilitate more in-depth nanoparticle analysis.

Convolutional Neural Networks for Anomaly Detection in Scanning Transmission Electron Microscopy Enea Prifti, Robert F. Klie and James Buban; University of Illinois at Chicago, United States

Identifying point defects and other structural anomalies using scanning transmission electron microscopy (STEM) is important to understand a material’s properties caused by the disruption of the regular pattern of a crystal. Thanks to the high spatial resolution of aberration-corrected transmission electron microscopes, atomic-resolution images with a field of view of several hundred nanometers can be taken. Such data, which often contains thousands of atomic columns need to be analyzed. This process has been done manually in the past, but recent developments in machine learning (ML) can be very useful to speed it up. In this contribution, we will utilize a convolutional variational autoencoder (VAE) which, after being trained with a set of bulk samples, generates an example (prediction) of given input images based on the trained features. We will demonstrate that the performance of a VAE in replicating an input image can be used to differentiate between bulk or defects. In the case of a bulk input, the VAE can replicate well the input within a threshold value that can be set by testing the predictions. For a defect input, the VAE will fail to output a prediction within the set threshold, allowing for a clear and automatic distinction of defects.

4:45 PM CH02.09.04
Multi Clustering Detection of 4D-STEM Diffraction Patterns Using NMF Approach Junhao Cao[1,2], Nicolas Folastre[2], Nicolopoulos Stavros[3], Partha Pratim Das[3] and Arnaud Demortiere[2]; [1]Laboratoire de Réactivité et Chimie des Solides (LRCS), France; [2]Centre National de la Recherche Scientifique, France; [3]NanoMEGAS, Belgium

Scientific instruments extracting information from materials have recently been improved using devices enable to generate a huge amount of data. The convergence of different techniques, such as direct electron detectors, image processing algorithms, precession technique and high coherent electron beam, leads to the emergence of a new family of hyperspectral analyze called 4D-STEM in which a 4D stack of diffraction patterns are acquired from a scanning region. The result of the 4D mapping extraction provides crucial information about material properties with a high spatial resolution, including signatures of the local structure, orientation, deformation, electromagnetic fields, and other sample-dependent properties.

A single 4D-STEM map can consist of 40k electron diffraction patterns. As a result, scientists need to automatically process datasets using intelligent algorithms and follow a statistical approach. Pattern matching strategy has been used to process 4D-STEM using ACOM software, which is based on the evaluation of a cross-correlation coefficient between experimental pattern and well-known crystallographic structure.
On the other hand, machine learning (ML) has been used in many fields with its strong powerful ability to process datasets such as classification, regression, or clustering. Unsupervised learning is a significant subset of its system, in which the aim is to automatically detect the distribution and the relationship in the huge of unlabeled data in order to discover the similar type of groups in the dataset. Based on the deep application of Machine Learning (ML), the result of material characterization or clustering in the huge dataset has been obtained automatically and clearly by some unsupervised algorithms.

The 4D-STEM acquisition was made using a Tecnai FEI 200kV, equipped with a Gatan Oneview camera operating at 50 frames per second with a scan step size of 2 nm. The large dataset has been acquired with 10,000 diffraction patterns. In our team, we developed in Python an unsupervised method called non-negative matrix factorization (NMF) to discover the grain mapping clustering in the 4D-STEM dataset. Given a 4D-STEM dataset, we firstly transform its 4D form into a 2D array as a consequence of adopting the input request of NMF; secondly, the new dataset corresponds to each clustering generated by the result of matrix decomposition using NMF. Finally, the grain mapping clustering yielded from each new clustering dataset.

Simultaneously, the best number of cluster points chosen depended upon the result of the mean-loss graph after the procedure of Matrix Decomposition with the help of NMF, the different clustering results in different components had been discussed. The influence of different denoising processes was studied on the convergence of NMF components and the accuracy of clustering mapping.

5:00 PM CH02.09.05
Semi-Supervised Machine Learning Workflow for Analysis of Nanostructured Morphologies from Transmission Electron Microscopy Images
Shizhao Lu[1], Brian Montz[2], Todd Emrick[2] and Arthi Jayaraman[1,1]; [1]University of Delaware, United States; [2]University of Massachusetts Amherst, United States

In the field of materials science, microscopy is the first and often only accessible method for structural characterization. There is a growing interest in the development of machine learning methods that can automate the analysis and interpretation of microscopy images. Typically training of machine learning models require large numbers of images with associated structural labels, however, manual labeling of images requires domain knowledge and is prone to human error and subjectivity. To overcome these limitations, we present a semi-supervised transfer learning approach that uses a small number of labeled microscopy images for training and performs as effectively as methods trained on significantly larger data sets. Specifically, we train an image encoder with unlabeled images using self-supervised learning methods and use that encoder for transfer learning of different downstream image tasks (classification and segmentation) with a minimal number of labeled images for training. We test the transfer learning ability of two self-supervised learning methods: SimCLR and Barlow-Twins on transmission electron microscopy (TEM) domain images. We demonstrate how this machine learning workflow facilitates fast analysis of TEM images of materials containing nanowires, specifically classification of nanowire morphologies (e.g., single nanowires, nanowire bundles, phase separated) as well as segmentation tasks that can serve as groundwork for quantification of nanowire domain sizes and shape analysis. The applicability of the machine learning workflow is further extended to classification of nanoparticle morphologies and identification of different type of viruses from TEM images.

Uncovering Magnetic Structures with Scanning Transmission Electron Microscopy Juan C. Idrobo; University of Washington, United States

Understanding the variables that controls the size, switching, and pining of magnetic domain and structures spans the fields of fundamental physics, materials science, as well as storage and logic device technologies. Here, I will discuss our efforts in using scanning transmission electron microscopy (STEM), within differential phase contrast (DPC) imaging and electron energy-loss spectroscopy (EELS), to detect and measure magnetic phases of materials with atomic, and near atomic, spatial resolution. I will discuss the limits of the aforementioned techniques to resolve contributions from spin and orbit to magnetism, and how topological and chiral phases of matter could be investigated in the near future with an electron microscope.
This research was supported by the Center for Nanophase Materials Sciences, which is a DOE Office of Science User Facility. This research used resources of the National Energy Research Scientific Computing Center, which is supported by the Office of Science of the U.S. Department of Energy under Contract No. DE-AC05-00OR22725 with the DOE, and sponsored by the Laboratory Directed Research and Development Program of Oak Ridge National Laboratory, managed by UT-Battelle, LLC, for the U.S. Department of Energy.

8:30 AM CH02.10/EQ08.08.02
Deep Learning Facilitated Analysis of Defects and Alloying in 2D Magnetic Materials Mads A. Weile[1], Julian Klein[2], Thang Pham[2], Rami Dana[2], Xavier Roy[3], Daniel Chica[3] and Frances M. Ross[2]; [1]Technical University of Denmark, Denmark; [2]Massachusetts Institute of Technology, United States; [3]Columbia University, United States

The advent of two-dimensional (2D) magnets [1] enables a myriad of opportunities in nano-spintronics and memory devices. A key requisite for creating nanoscale magneto-electric devices is atomic-level engineering in which materials and stacks are designed with specific properties in mind. An emerging material that is promising for atomic-level control is the magnetic semiconductor CrSBr. [2] Utilizing CrSBr requires understanding the magneto-electric [3] and magneto-optical [4] properties of the defects, involving structural characterization of individual defects by microscopy. Studies on defects are, however, often limited by the fact that few-layer samples are not stable under imaging conditions, resulting in more defects or low signal-to-noise ratio

(SNR) images [2]. Recently, the emergence of machine learning (ML) in the microscopy field has opened opportunities for faster and more accurate analysis than conventional methods in SNR-dominated systems [5]. Merging ML with high-resolution microscopy techniques like scanning transmission electron microscopy (STEM) and scanning tunneling microscopy (STM) provides means to discover new key insights even in materials only a few layers thick.

Here we study defects and dopants in CrSBr and its alloy $CrSBr_xCl_{1-x}$ using a combination of high-resolution microscopy (HAADF-STEM and STM) and advanced ML techniques. We investigate the quantity, type and distribution of defects with the motivation to understand their structural, electronic and magnetic properties. We apply machine learning in the form of convolutional neural networks to analyze alloys and defects and discuss its applicability to multilayer systems. Overall, we conclude that CrSBr and related compounds are interesting material platforms for applying high resolution microscopy techniques in combination with ML to study their defect properties. We expect that understanding how defects affect the structure of CrSBr and related compounds will lead to new insight into the possibilities of engineering tailor-made magneto-electric and magneto-optical devices. Furthermore, we expect that the ML models for investigating such defects can serve as a foundation for finding defects in a variety of similar materials in this challenging setting.

Prediction of Electronic Density of States at Ground State from ELNES/XANES Izumi Takahara, Poyen Chen, Kiyou Shibata and Teruyasu Mizoguchi; The University of Tokyo, Japan

Energy-loss near-edge structure (ELNES) and X-ray absorption near-edge structure (XANES) are powerful tools for characterizing the local atomic and electronic structures of materials. ELNES/XANES is produced by the electronic transition from a core orbital to conduction bands, and thus it basically provides the information reflecting the partial density of states (PDOS) of the conduction band at the excited state of a given material. Although ELNES/XANES gives us valuable information such as chemical bonding and the charge state of a specific atom, the knowledge that can be extracted from the measurements is limited to the information reflecting the conduction band at the excited state. If the information reflecting the entire PDOS at the ground state can also be extracted from ELNES/XANES, materials properties based on PDOS can be evaluated directly from a single spectral measurement and materials developments would be accelerated.
In this presentation, we introduce a novel machine learning (ML) based method for determining the PDOS of valence and conduction band at the ground state from the ELNES/XANES spectra simultaneously. We have carried out density functional theory (DFT) calculations on various structures of Si and prepared a database of Si-K ELNES/XANES and the corresponding PDOS at the ground state. On this database, we have trained a ML model to predict the entire PDOS spectra at the ground state from the ELNES/XANES spectra directly. In the result, our model successfully reproduced the characteristics of the PDOS spectra near the Fermi level. Therefore, we envision the utilization of the ML could be powerful for widening the application of the ELNES/XANES measurements including simultaneous mapping of structure and property in a transmission electron microscope.

9:00 AM *CH02.10/EQ08.08.04
Direct Imaging of Topological Phase Transitions in Polar Skyrmions, Merons and Anti-Merons in Oxide Heterostructures Yu-Tsun Shao[1], Sergei Prokhorenko[2], Yousra Nahas[2], Sujit Das[3], Zijian Hong[4], Ruijuan Xu[5], Swathi Chandrika[1], Fernando Gómez-Ortiz[6], Pablo García-Fernández[6], Long-Qing Chen[7], Harold Y. Hwang[5], Javier Junquera[6], Lane W. Martin[8], Laurent Bellaiche[2], Ramamoorthy Ramesh[8] and David A. Muller[1]; [1]Cornell University, United States; [2]University of Arkansas, Fayetteville, United States; [3]Indian Institute of Science, Bengalore, India; [4]Zhejiang University, China; [5]Stanford University, United States; [6]Universidad de Cantabria, Spain; [7]The Pennsylvania State University, United States; [8]University of California, Berkeley, United States

Emergent topological textures such as polar vortices and skyrmions in ferroelectric heterostructures have drawn great interest due to the richness of underlying physics and the potential applications in next generation nanodevices. Although concepts like topological protection and phase transitions as a function of temperature, strain, electric field and superlattice periodicity have been already explored in polar topological defects (vortices), the counterparts for polar topological solitons (skyrmions and merons) remain in its infancy. To understand and explore the microscopic details of these transitions requires a characterization method which can track the detailed 3D structure of individual dipole textures. By combining the full four-dimensional phase space information collected by a new generation of direct electron detectors which quantitatively records the momentum distribution of transmitted electrons at every beam position (4D-STEM), dynamical diffraction simulations, and ptychographic phase retrieval algorithm to process the data, we have been able to robustly image the local polarization and chirality in each polar texture.

Upon heating a lifted-off, freestanding $[(PbTiO_3)_{16}/(SrTiO_3)_{16}]_8$ superlattice membrane, we study the strain-driven emergence of tetratic meron lattice from a disordered liquid-like skyrmion state, accompanied by a change in chirality. In the case of freestanding $(SrTiO_3)_{16}/(PbTiO_3)_{16}/(SrTiO_3)_{16}$ trilayer membranes, we explore the creation and annihilation of polar merons and anti-merons in self-assembling labyrinthine patterns when perturbed by the electric-field gradient generated from the focused electron probe. Theoretical insights into this highly degenerate, frustrated system suggest that the transition among various metastable states originates from the intrinsic topological instabilities.

Prediction of Carbon K Edge Spectra of Organic Molecules Using a Graph Neural Network Kiyou Shibata and Teruyasu Mizoguchi; The University of Tokyo, Japan

Recently, in the context of materials informatics, there have been many attempts to replace expensive first-principles calculations with predictions based on low-cost machine learning (ML) models. Although databases of structures and electronic states of various materials are already being developed and play an important role in the study of ML models, it is necessary to expand not only the number of data in the databases but also their contents in order to construct ML models that represent a wide variety of physical properties.
Among various physical properties, we are focusing on the core-loss spectra, which are not only computationally available but also experimentally

measurable by transmission electron microscopy and synchrotron facilities. The core-loss spectra, which are excitation spectra from a core orbital to unoccupied orbitals, directly reflect partial electronic state densities (PDOS) of states excited state and indirectly contain information on ground-state PDOS, and thus on properties related to PDOS. In the context of these backgrounds, we have been performing first-principles calculations on the K-edge core-loss spectra of each independent carbon site in the organic molecules in the QM9 data set [1], which have carbon numbers of 8 or less. We have already reported that the molecular C-K edge spectra can be used to predict the molecular properties [2], and we have recently published these organic molecular C-K edge spectral database [3]. We expect that this database will be used as benchmarks for organic molecule spectral informatics or for the analysis of experimentally obtained spectra.
In this presentation, we present the results of developing a ML model using a graph neural network with the organic molecular structures and an excitation carbon site therein as input and the corresponding site C-K edge spectra as output. After training on the database, our ML model is generally successful in reproducing spectral outlines such as rough features and major peaks.

4D-EELS—A Comprehensive Character Technique for the Study of Local Properties Peng Gao; Peking University, China

Phonon plays a fundamental role in mechanical, electrical, optical, and thermal properties of materials. The description of phonons is known as phonon dispersion, i.e., the phonon energy is plotted as a function of the momentum. For practical materials that inevitably contain interface/defect that discontinues the chemical bonds, new phonon modes emerge locally. Although the interface/defect phonon modes are widely discussed in theory, the experimental measurement has been challenging as it requires the combined spatial, momentum and spectral resolutions to probe localized phonon mode at interfaces/defects. Recently, we propose a four-dimensional electron energy loss spectroscopy technique based on the scanning transmission electron microscopy- electron energy loss spectroscopy. By scanning the electron beam in real space of sample while monitoring both the energy loss and the momentum transfer, we are able to reveal position- and momentum- dependent lattice vibrations at nanometer scale with high efficiency. The space, momentum and energy resolutions can be delicately balanced by carefully adjusting experimental parameters, and thus widely tunned to optimize the data acquirements for specific samples under study.
In this report, we firstly show the principle of 4D-EELS. Then we show some application examples, including the interface phonon dispersion relation for an epitaxial cubic Boron Nitride/Diamond heterointerface [1], and the local phonon dispersion and defect scattering in Boron Nitride Nanotube [2]. We also reveal the interface phonons in AlN on Si and Al [3] and dislocation phonons at Si/Ge interface [4], and discuss how they possibly affect the local interface thermal conductivity. Finally, we prospect 4D-EELS will provide comprehensive information of sample beyond position- and momentum-simultaneously resolved phonon spectra, such as Electron Magnetic Circular Dichroism [5] and so on.

Optimal Structural Determination with Focused Probe Electron Ptychography Timothy J. Pennycook, Chuang Gao, Christoph Hofer, Daen Jannis, Armand Béché and Jo Verbeeck; University of Antwerp, Belgium

Over the past decade advances in camera technology have greatly facilitated 4D scanning transmission electron microscopy (STEM) and electron ptychography. A wealth of information on the probe position dependence of the scattering can be discerned from 4D STEM data, which electron ptychography uses to provide an especially useful means of directly imaging atomic structures. In essence ptychography solves the so called phase problem in electron microscopy, determining the relative phases of the scattered beams. As the phase of the beam electrons is altered by even the weakest of specimen potentials, efficient detection of phase provides a very efficient form of imaging. The dose efficiency of ptychography far exceeds that of Z-contrast annular dark field (ADF), now a mainstay for local atomic structure determination in materials science [1]. However ptychography can also significantly exceed the dose efficiency of phase contrast imaging in plane wave illumination TEM [2], the mainstay technique for the most beam sensitive materials such as proteins. Such TEM based phase contrast provides intensity images rather than actual images of the phase. Furthermore TEM phase contrast images are often complex and difficult to interpret being the result of using the aberration function as a virtual phase plate, with the resulting contrast transfer function generally oscillating to positive and negative values. Ptychography provides a simple single signed transfer function controlled by the convergence angle without the need for aberrations, which would be detrimental to simultaneous ADF imaging.

In addition to pure dose efficiency ptychography also fills another important deficiency of ADF imaging. Light atoms are often hidden in the strong scattering from neighboring heavy elements in the ADF signal. Addressing this gave rise to the popularity of the annular bright field (ABF) modality. Recently centre of mass (CoM) based methods such as integrated CoM have become more popular as they provide superior dose efficiency compared to ABF. However the dose efficiency of ptychography exceeds all of these, and allows heavy and light elements to be seen most clearly. Similarly, the greater dose efficiency should allow more sensitive examination of charge density for looking at effects from bonding, for instance. The ability to correct for the residual aberrations post collection is also a clear advantage for ptychography compared to CoM methods, and is indeed very important for separating true

effects of charge density from those of aberrations.

Phase imaging with electron ptychography is however not entirely free from complications. It can be more difficult to discern different elements than with ADF Z-contrast. Furthermore, as sample thickness increases the projected potentials cause increasingly large changes in the phase of the scattered beams, which eventually wrap around because phase values exist only in the range of 0 to 2π. Thus complex contrast reversals can also occur in ptychography. However these can be simply compensated for by a small defocus. Ensuring that the structures reflect reality is greatly facilitated by simultaneous Z-contrast imaging, easily available with focused probe ptychography. Thus with focused probe ptychography one can have the best of both worlds, Z-contrast and highly efficient phase imaging. With event driven camera technology this can be performed without any loss of speed compared to conventional rapid scan STEM [3].

Solving A Century-Old Problem—Three-Dimensional Atomic Structure of Amorphous Materials Jianwei (John) Miao; University of California, Los Angeles, United States

Amorphous materials such as glass, rubber and plastics are ubiquitous in our daily life and have broad applications ranging from telecommunications to electronics. However, due to the lack of long-range order, the 3D atomic structure of amorphous materials had eluded direct experimental determination for more than a century. One experimental method that can in principle address this grand challenge is atomic electron tomography (AET). AET combines high-resolution tomographic tilt series with advanced computational algorithms to resolve the 3D atomic structure of materials without assuming crystallinity, which has been applied to image grain boundaries, anti-phase boundaries, stacking faults, dislocations, point defects, chemical order/disorder, atomic-scale ripples, bond distortion and strain tensors with unprecedented 3D detail. Recently, we advanced AET to determine the 3D atomic positions of monatomic amorphous materials, namely a Ta thin film and two Pd nanoparticles. We observed that pentagonal bipyramids are the most abundant atomic motifs in these amorphous materials. Instead of forming icosahedra, the majority of pentagonal bipyramids arrange into pentagonal bipyramid networks with medium-range order. Molecular dynamics simulations further reveal that pentagonal bipyramid networks are prevalent in monatomic metallic liquids, which rapidly grow in size and form more icosahedra during the quench from the liquid to the glass state. Furthermore, we also used AET to determine the 3D atomic positions of a multi-component metallic glass and quantitatively characterized the short- and medium-range order. We discovered that, although the 3D atomic packing of the short-range order is geometrically disordered, some short-range-order structures connect with each other to form crystal-like superclusters and give rise to medium-range order. We identified four types of crystal-like medium-range order - face-centred cubic, hexagonal close-packed, body-centred cubic and simple cubic - coexisting in the amorphous sample, showing translational but not orientational order. These observations provide direct experimental evidence to support the general framework of the efficient cluster packing model for metallic glasses. We expect that these results pave the way for the determination of the 3D atomic structure of a wide range of amorphous materials, which could transform our fundamental understanding of non-crystalline materials and related phenomena.

Deterministic Creation and Annihilation of Point Defects in 2D Materials Utilizing Electron and Ion Beam Irradiation Maksim A. Sultanov, Wei-Ying Chen, Yulin Lin, Yasuo Ito, Benjamin Diroll, Thomas Gage and Jianguo Wen; Argonne National Laboratory, United States

Deterministic creation of quantum emitters has long been a topic of study for quantum information science (QIS). It is also indispensable to develop techniques enabling deterministic annihilation of vacancy-center quantum emitters. In this work, we utilize irradiation modes of both e-beam and ion beam to introduce point defects in a monolayer of both $MoSe_2$ and h-BN. An aberration corrected transmission electron microscope (TEM) enables observations with time-resolved atomic-resolution imaging, including dynamic creation and annihilation of defect sites in the monolayer. In situ high-resolution TEM reveals that the annihilation of vacancy clusters using the electron beam can be achieved with an optimal electron beam dose rate. In-situ annealing of irradiated samples has been explored to understand the formation mechanism of desired quantum emitters. Coupled with ex-situ photoluminescence, these approaches allow us a detailed study of the deterministic quantum emitter creation and the correlation with their optical behaviors in 2D materials.

Work performed at the Center for Nanoscale Materials, a U.S. Department of Energy Office of Science User Facility, was supported by the U.S. DOE, Office of Basic Energy Sciences, under Contract No. DE-AC02-06CH11357. The correlation of point defects with optical behaviour is supported by QIS research funding from the U.S. Department of Energy, Office of Science User Facility. Ion irradiation was performed in IVEM-Tandem Facility at Argonne National Laboratory.

***In Situ* Electrochemical Liquid Cell Electron Microscopy Study of Electrode-Electrolyte Interfaces** Haimei Zheng; Lawrence Berkeley National Laboratory, United States

The electrode-electrolyte interfaces often play an important role in electrochemical devices, such as batteries or fuel cells. An understanding of the electrode-electrolyte interfacial phenomena can be significant for understanding the device failure mechanisms and improving the device performance. Our development of electrochemical liquid cell transmission electron microscopy (TEM) has enabled direct observation of many dynamic phenomena at electrode-electrolyte interfaces in nanometer resolution and in real time. With the in-situ electrochemical liquid cell TEM setup, we have been made achievements on the studies of lithium dendrite growth, solid electrolyte interphase (SEI), the electrode configuration on alkali metal deposition, etc. We have also studied lithium striping. As we know that an understanding of lithium stripping is as important as that of lithium plating to achieve significant advances in using lithium metal anodes for high-energy rechargeable batteries. However, there have been limited studies on lithium stripping compared to lithium plating. With in-situ electrochemical liquid cell TEM, we directly observed and compared the stripping behavior of the in-situ grown lithium dendrites and lithium nanograins on the electrodes. We found the sporadic lithium stripping behavior of lithium deposits regardless of their morphology. In addition, SEI chemical mapping with high spatial resolution showed a SEI loss at the end of the lithium metal stripping, illustrating the importance role of SEI in the subsequent cycles.

11:00 AM *CH03.01.02
Cryo and *In Situ* Electron Microscopy Diagnosis Guided Design of Materials for Rechargeable Battery Chongmin Wang; Pacific Northwest National Laboratory, United States

In Situ and operando electron microscopy enable direct observation of process under dynamic operating condition of a device, representatively such as: real time observation of structural and chemical evolution of rechargeable batteries under battery operating condition; finding the active sites of catalyst; monitoring of mass transport during oxidation and reduction; observing nucleation and growth process in a liquid; visualizing defect generation and interaction during deformation; and capturing the response of materials to external stimuluses. In this presentation, I will focus on recent progress on using ex-situ, in-situ, operando and cryo-scanning transmission electron microscopy for probing into the structural and chemical evolution of electrode materials for lithium ion batteries, representatively such as Li and Si anode. I will highlight several recent key observations, which even appear to be well documented, while essentially are poorly understood, therefore limiting the advances of both cathode and anode for better batteries. It would be expected that this presentation can stimulate new ideas as how to attack the bottlenecks for advancing electrode materials design for better batteries. In perspective, challenges and opportunities for developing in-situ electron microscopy for probing both functional and structural materials will also be discussed.

11:30 AM CH03.01.03
Theoretical Understanding of Heterogeneous Nucleation During Lithium Electrodeposition Aashutosh N. Mistry and Venkat Srinivasan; Argonne National Laboratory, United States

Lithium metal anodes are required to transform the present-day Li-ion batteries for storing more energy. A key challenge is to ensure uniform electrodeposition of lithium when the cell is being charged. While most previous studies examine the efficacy of various mechanisms in regularizing an uneven interface[1,2,3], the formation of the uneven interface is poorly understood. Whenever lithium deposits on a surface other than pristine lithium, nucleation is observed[4]. Physics-based understanding of this step is essential to identify the factors that govern nucleation and cause nonuniform growth. In this talk, we propose a theoretical description of lithium nucleation and growth during electrodeposition. We show that nucleation during electrodeposition differs from the metallurgical understanding of melt solidification. We correlate such theoretical understanding with experimental observations. We discuss material property targets to tune the nonuniformity associated with the nucleation and early time growth of electrodeposited lithium.

11:45 AM CH03.01.04
Characterization and Modeling of High Rate Performance in High Specific Energy Li-Metal Batteries Shashank Sripad[1], Anthony D'Angelo[2], Xu

Yan[3], Brennan Campbell[3] and Alexander Bills[1]; [1]Carnegie Mellon University, United States; [2]24M Technologies, United States; [3]Kitty Hawk, United States

One of the key bottlenecks in developing next-generation Li-metal batteries is simultaneously achieving high rate performance along with high specific energy (>400 Wh/kg). Rate performance and specific energy are crucial for enabling applications such as electric aircraft. This study demonstrates the performance of a Li-metal that cell leverages the use of an ultra-thick cathode (>3 times the thickness of conventional cathodes) which presents a path to low-cost manufacturing while coupling it with a Li-metal anode achieves high stack and cell-level specific energies. The discharge rate and discharge current density are characterized in the context of an electric vertical takeoff and landing aircraft. We use a combination of cell-level characterization with novel test protocols along with cell and interface modeling to examine the heterogeneities in current densities. We also develop pathways and approaches to improve the overall discharge rate at the cell level. The tools, methods, and modeling framework presented here will find utility in characterizing Li-metal batteries for high-rate and high-performance applications.

SESSION CH03.02: Multiphysics in Lithium Batteries

1:30 PM *CH03.02.01
Learning Heterogeneous Reaction Kinetics from Images of Li-Ion Battery Nanoparticles Martin Bazant; Massachusetts Institute of Technology, United States

Nanoscale heterogeneity, which often controls the overall rate of electrochemical reactions, is notoriously difficult to measure or model. Here, we show that reaction kinetics and surface heterogeneity can be learned from operando scanning transmission X-ray microscopy (STXM) images of lithium iron phosphate (LFP) nanoparticles undergoing driven phase transformations in Li-ion batteries. Combining a large dataset of STXM images with a thermodynamically consistent electrochemical phase-field model, PDE-constrained optimization, and uncertainty quantification, we extract the LFP free energy and local reaction rate, and verify their consistency with theoretical models. We also simultaneously learn the spatial heterogeneity of the reaction rate, which we find closely matches the carbon-coating thickness profiles obtained through auger electron microscopy. The chemo-mechanical model is validated by ex-situ STXM and X-ray ptychography images. The 6.8% error between the learned model and over 180,000 pixels of image data is close to the experimental noise. Our results unlock the potential of learning nonequilibrium properties from image data that are difficult to measure in traditional electrochemical methods and offers a new non-destructive method of characterizing reactive surface heterogeneity.

2:00 PM CH03.02.02
Microscopic *Operando* Diagnosis of Li Plating During Full Cell Fast Charging Bingyuan Ma and Peng Bai; Washington University in St. Louis, United States

The fast-charging becomes crucial for electronic devices and electric vehicles (EVs). However, it can result in Lithium (Li) plating on the graphite anode that aggravates the cell degradation and increases the safety risk. In this work, we fabricate Li-ion full cells in transparent glass capillaries as the model system for the practical Li-ion sandwich cells to probe the dynamic evolution in graphite anodes during the fast-charging process and under low temperatures. We observed that Li plating can occur before the cell is fully charged even at a low C-rate and at room temperature. The onset of Li plating is always accompanied by some features in the full cell voltage signal. Our *operando* experiments provide the direct proof that the subtle features in the electrochemical responses are caused by the Li plating, which can be utilized to improve battery management strategy. Mathematical simulations confirm that the local overpotential due to the strong concentration polarization is the root cause of the axial reaction heterogeneity in lithiated graphite and the Li plating. At low temperatures, such polarization becomes stronger and leads to earlier Li plating during the fast charging.

2:15 PM CH03.02.03
***Operando* Three-Dimensional Mapping of the Two-Phase Reaction Inside Single Cathode Nanoparticles** Yifei Sun; Cornell University, United States

The battery stability is related to nanoscale processes such as the structural evolution during the (de)intercalation. The two-phase reaction - one type of structural evolution - is generally considered a slow kinetic process. Yet many high-rate materials such as $LiFePO_4$ experience phase separation during (dis)charge. Thus, nanoscale characterization techniques are needed to understand the (de)lithiation mechanism and its interplay with local defects in phase-changing materials.

Disordered spinel $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) is a promising high-voltage cathode material that experiences an extended period of two-phase reaction when cycling. Operando Bragg coherent diffractive imaging (BCDI) is a powerful technique that maps nanoscale heterogeneity inside the materials. In this study, we measure consecutive diffraction patterns of a single LNMO nanocrystal operando. With the improved phase retrieval algorithm, we map the three-dimensional strain field of the nanocrystal while it undergoes a structural two-phase reaction. The strain mapping confirms two-phase behavior at the single grain level and reveals different mechanisms upon charge and discharge. With its unique ability to track buried single defects, BCDI also elucidates the critical role of local defects in relieving the coherency strain at the interphase during the phase transformation. This nanoscale understanding of reaction kinetics provides new insights into the development of next-generation durable batteries with faster kinetics.

2:30 PM CH03.02.04
Electrochemically Based and Coupled Characterization of Heterogeniety within Battery Electrodes and Interfaces Amy Marschilok[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Batteries are ubiquitous in our everyday lives and often appear as black boxes. However, the chemistry inherent to their function is diverse and complicated. Examples of mechanistic insight gained from electrochemistry-based and electrochemistry-coupled characterization of battery electrodes and interfaces will be highlighted in this presentation. This will include approaches to distinguish productive and parasitic regions in functional energy storage materials and systems.

2:45 PM BREAK

SESSION CH03.03: Lithium Nucleation and Growth
Session Chairs: Peng Bai and Yan Yao
Monday Afternoon, November 28, 2022

3:15 PM *CH03.03.01
***Operando* Analysis of Li Plating on Graphite Anodes During Fast Charging of Li-Ion Batteries** Neil P. Dasgupta; University of Michigan, United States

The rapidly growing EV market is increasing the demand for fast-charging (<15 min) of high-energy-density Lithium (Li)-ion batteries. However, state-of-art Li-ion batteries with thick graphite electrodes suffer from Li plating when charged at >4C rates. Therefore, to inform mitigation strategies for Li plating under fast-charging conditions, there is a need to improve our fundamental understanding of the Li plating process.

In this work, I will present two recent studies on *operando* detection and characterization of Li plating on graphite anodes. In the first study, plan-view *operando* video microscopy was performed on >3 mAh cm^{-} graphite electrodes during 6C charging [1]. During a 6C charging half-cycle, the cell was used to visualize the spatial heterogeneity of SoC across the electrode surface, and the nucleation and growth of the plated Li. During the subsequent open circuit voltage (OCV) rest and discharge steps, the re-interaction of the plated Li into graphite was also studied. Furthermore, a 3D understanding of the changes across the electrode volume was developed by performing *ex situ* cross-sectional microscopy. Finally, pouch cells were fabricated to confirm the voltage signature associated with dead Li formation in a commercially relevant cell format.

In the second study, we built upon this understanding to demonstrate a new method for *operando* detection of Li plating during fast charging, using incremental capacity (IC) analysis [2]. To identify the electrochemical signature of plating, 3-electrode pouch cells were assembled, allowing for a correlation of the IC curve with the onset of Li nucleation. This was validated using post mortem microscopy, to demonstrate the ability to uniquely identify the onset of Li plating with high resolution. This provides a pathway towards advanced control and mitigation strategies to enable fast charging while eliminating the most deleterious side reactions within the cell.

3:45 PM CH03.03.02
Suppressing Chemical Corrosions of Lithium Metal Anodes Bingyu Lu[1], Wei-Kang Li[1], Diyi Cheng[1], Bhargav Bhamwala[1], Miguel Ceja[1], Wuriguluma Bao[1], Chengcheng Fang[2] and Y. Shirley Meng[3]; [1]University of California, San Diego, United States; [2]Michigan State University, United States; [3]The University of Chicago, United States

The lithium (Li) metal anode is essential for next generation high energy density rechargeable Li metal batteries. Although extensive studies have been performed to prolong the cycle life of Li metal batteries, the calendar life, which associates with chemical corrosion of Li metal in liquid electrolytes, has not been quantitatively understood. Here, by combing the Titration Gas Chromatography (TGC) method and Cryogenic Focused Ion Beam (Cryo-FIB), we established a quantitative relationship between the chemical corrosion rate and electrochemically deposited Li morphology in various liquid electrolyte systems. We identified that the corrosion rate is dominated by the porosity of the deposited Li. The larger the porosity of deposited Li has, the faster the corrosion rate will be. We further proposed strategies to mitigate the chemical corrosion on Li thus to extend the calendar life of Li metal batteries. By strictly controlling the stacking pressure during Li plating, Li deposits with ultra-low porosity can be achieved, suppressing the corrosion rate to 0.08 ± 0.16%/day compared with 1.71 ± 0.19%/day of the high-porosity Li.

4:00 PM CH03.03.03
Understanding the Effect of Surface Energy on Dendrite Growth in Lithium Metal Batteries Madison Morey and Emily Ryan; Boston University, United States

Lithium metal batteries have shown promise in combating the limitations of lithium ion (Li-ion) batteries, including having a theoretical capacity that is an order of magnitude greater than that of the Li-ion battery. However, a main hinderance is the uncontrolled growth of Li dendrites on the anode during cycling. These dendrites lead to a decrease in coulombic efficiencies and can pierce the separator or break off forming “dead lithium” resulting in short circuit and thermal run away. While there has been extensive research into the growth and morphology of Li dendrites, little is known about the nucleation process of Li along the anode surface. The Li growth process is influenced by several factors including surface heterogeneities such as lattice defects and grain boundaries, the overpotential, local lithium ion (Li^{+}) concentrations and varying surface energies along the anode.

Due to the nature of the anode surface, it is difficult to observe the complex physics experimentally. Therefore, computational modeling is a powerful tool for understanding dendrite nucleation. It resolves the electrode-electrolyte interface where dendrite growth occurs and can track the complex chemical and physical phenomena contributing to dendrite nucleation and growth. Here a detailed model is presented that uses an extended, concentration dependent Butler-Volmer equation (eBV) with an additional term for nucleation to describe the rate of reaction at the electrode-electrolyte interface. By utilizing the eBV with the nucleation term, the rate at which Li is locally deposited on the anode surface can be carefully tracked along with other important phenomena, i.e. current density, overpotential, and Li^{+} concentrations. In addition, the nucleation term allows tracking of the growth rate of Li nucleates along the surface when influenced by changes in surface energy.

The model is used to study how defects in the anode surface effect dendrite growth. These defects include lattice defects such as substitutional impurities, interstitial impurities, and vacancies in the Li-metal crystal lattice. In addition to surface defects, grain boundaries can also lead to a change in surface energy. Results show that when defects that decrease the surface energy are present, we see a more homogenous growth, while defects that increase the surface energy led to more growth. Thus, understanding the effects of nucleation locations and rates of dendrite growth could lead to the design of engineered surfaces to extend Li metal battery lifetime and performance.

***In Situ* Li Growth Mechanism at Initial Stage by Liquid Phase Transmission Electron Microscopy** Yonggoon Jeon, Hayoung Park, Woo Jun Chung

and Jungwon Park; Seoul National University, Korea (the Republic of)

High energy density and cycling stability of Lithium-ion batteries(LIBs) are receiving great attention as LIBs have been essential goods in our life from portable devices to Electric Vehicles(EVs). Lithium metal anode material is one of the most promising options for next generation battery system. Although it has many advantages such as high theoretical capacity, low density and lowest standard electrochemical redox potential, irregular Li deposition on the anode is the biggest obstacle for practical application. Therefore, It is important to understand the dynamics of Li nucleation and growth in the early stages, because it has a decisive influence on uneven surface formation that determines the performance and safety of Lithium Metal Batteries(LMBs). In this aspect, the initial stage of Li plating in Ethylene carbonate/Diethyl carbonate (EC/DEC, 1M $LiPF_6$) and 1,3-Dioxolane/Dimethoxyethane (DOL/DME, 1M LiTFSI) are investigated by in situ liquid phase transmission electron microscopy. The formation of large Li particles accompanied by low nucleation density and rapid growth is observed in DOL/DME electrolyte, whereas small-sized Li particles are formed with features of high nucleation density and slow growth rate in EC/DEC electrolyte, and the difference in initial nucleation and growth is closely related to SEI structures determining its mechanical and kinetic property. Heterogeneously distributed ionic species in the organic-rich outer layer from EC/DEC induce structural instability and uneven Li^+ flux, which leads to cracks on the SEI and low kinetics, revealing many nucleation sites and slow growth, respectively. In contrast, flexible components such as amorphous alkoxide and poly(DOL) and uniform multi-layered Li_2O on the surface in the SEI from DOL/DME improve structural stability and ionic conductivity, which facilitates less nucleation sites and fast growth rate. This results are expected to shed light on the understanding of Li dendrite growth in LMBs and rational design of the next-generation battery.

Capacity Recovery via Rest Induced Revival of Isolated Lithium in Lithium Metal Batteries Wenbo Zhang, Philaphon Sayavong, Xin Xiao, Solomon Oyakhire, Rafael Vilá, David Boyle, Sang Cheol Kim, Mun Sek Kim, Sarah Holmes, Stacey F. Bent and Yi Cui; Stanford University, United States

Li metal is a promising high energy anode material for future generation rechargeable batteries. However, Li metal anodes face the obstacle of rapid capacity decay, which must be overcome before Li metal battery (LMB) technology can be commercially embraced. The heterogeneity of Li metal morphology[1] and solid electrolyte interphase (SEI)[2] are two factors which contribute to capacity decay by promoting uneven stripping, leading to the eventual disconnection and isolation of Li metal. Electronically isolated Li cannot partake in electrochemical reactions and therefore contributes to lost capacity. A recent work has demonstrated the recoverability of isolated Li using an electric field to drive spatial progression towards the electrode[3], opening a new path to fight capacity decay in LMBs. Hence, a better mechanistic understanding of isolated Li revival through in-operando studies is essential for future work toward improved inactive capacity recovery. However, the phenomenon of isolated Li recovery has not been documented in prior in-operando optical studies most likely due to the large differences in conditions between optical setups and standard cell architecture.

Here we present a novel in-operando optical cell setup which maintains the pressurized environment and performance of standard coin cells, enabling the first-time imaging of Li metal isolation, reconnection, and recovery. Furthermore, this new optical cell platform is used to demonstrate the degradation of residual SEI during rest and how this evolution improves the recoverability of the isolated Li in subsequent cycles. These observations of enhanced lithium recovery after discharged state resting are corroborated by improved cycling performance using a hybrid continuous/rest cycling protocol. Coulombic efficiencies (CE) greater than 100% are achieved in the first rested cycle following continuous cycling. Additionally, titration gas chromatography results also show decreased quantities of isolated Li on current collectors after the rest cycle compared to those which ran continuous cycles, verifying the recovery of isolated Li from prior cycles. By connecting the observations from this novel optical cell with the unique cycling protocol, we reveal not only new insights on the mechanics of isolated Li reactivation, but also inform how residual SEI degradation can enhance inactive capacity recovery.

4:45 PM CH03.03.06
Theoretical Analysis of Reaction Inhomogeneity and Lithium Plating Onset at Fast Charge Rates Aleksandar Mijailovic[1], Guanyi Wang[2], Jian Yang[2], Wenquan Lu[3], Qingliu Wu[2] and Brian W. Sheldon[1]; [1]Brown University, United States; [2]Western Michigan University, United States; [3]Argonne National Laboratory, United States

Inhomogeneous lithium intercalation of porous electrodes can lead to lithium plating during fast charging. Previous work has demonstrated the effects of inhomogeneous reactions in cathodes and anodes, both on particle and macroscale (i.e., cell) length scales. The effects of mass transport, ionic transport, electrode thermodynamic behavior and reaction kinetic behavior on lithium plating have been studied in the context of reaction inhomogeneity; however, a complete theoretical understanding on how these effects interplay to accelerate lithium metal plating has not been established at high C-rates. Here, analytical and numerical analysis is used to develop a more complete understanding on how these coupled, nonlinear physical and electrochemical effects act together to cause lithium plating. Specifically, it is shown that analytical solutions, which are functions of several nondimensional numbers (the "reaction inhomogeneity parameter" in particular), can predict onset of lithium plating at high C-rates in half-cell anodes. This analytical prediction of lithium plating exhibits surprising accuracy against a calibrated graphite half-cell model, which has highly non-linear behavior (e.g., in the open circuit voltage). These results are compared against *in situ* and *ex situ* experimental observations of lithium plating onset during fast charging. Applications for design and optimization of electrodes with complex architectures are discussed. This work attempts to clarify and unify findings in complicated numerical models to provide guidance in mitigating Li metal plating at high rates.

Quantitative Evaluations of Reaction Heterogeneities in Thick Battery Electrodes Using Operando Focused Beam X-Ray Diffraction Tianyi Li, Fan Wang, Xinwei Zhou, Yuzi Liu and Yang Ren; Argonne National Laboratory, United States

Recently, the use of thick electrodes in lithium-ion batteries has drawn extensive attention as it effectively promotes the cell-level energy density by reducing the fraction of inactive components such as separators and current collectors. However, the spatially non-uniform reaction can easily arise within a thick electrode design due to the sluggish electrolyte transport. Understanding the heterogeneous reaction and preventing its happening are therefore critical as it may result in inferior rate performance, fast capacity degradation, and even safety hazards. Our previous modeling study has demonstrated that the dependence of equilibrium potential on the state-of-charge (SOC) of active materials strongly influences the degree of reaction non-uniformity. Motivated by the modeling predictions, this study aims to experimentally evaluate the reaction heterogeneities in thick electrodes by employing operando focused beam X-ray diffraction (XRD). We will compare two types of nickel rich cathode materials (LiNi0.8Mn0.1Co0.1O2) with different crystallinities, therefore, quantitatively assess the degree of reaction along the depth direction in electrodes with different charge and discharge rates. A detailed comparison between the experiments and simulations will help us better understand the origin of reaction heterogeneities in electrodes and guide the design of battery materials and structures in the future.

CH03.04.02
Interfacial Studies of Silicon Anode Cycling and Solid Electrolyte Interphase (SEI) Formation on Highly Curved Surfaces Hyewon Jeong, Nathan J. Fritz, Beniamin Zahiri and Paul Braun; University of Illinois at Urbana-Champaign, United States

Silicon is a promising high-capacity anode material for lithium-ion batteries (LIBs) with ten times higher specific capacity (4200 mAh/g) than leading carbon-based anodes (372 mAh/g). However, silicon expands up to 300% by volume during lithiation, which leads to mechanical failure upon cycling. This further results in electrical contact loss and continuous solid electrolyte interphase (SEI) formation from the decomposition of electrolytes on exposed silicon surfaces. To address these challenges, it is paramount to make a uniform and mechanically durable silicon coating on a current collector and stabilize the SEI for extended cycling. Previous efforts include silicon deposition on a 3D-architected nickel scaffold to enable higher silicon loadings and accommodate the volume expansion of silicon during lithiation. Nonetheless, the characteristics of mechanical failure in 3D structure are complex and make it harder to understand silicon expansion and SEI formation simultaneously. Here we reduce the geometry of the 3D nickel scaffold to basic geometries, such as positive, negative, and neutral curvatures to better understand how each highly curved surface plays its role in silicon expansion, SEI formation, and its composition in 3D structured anodes. We adopted chemical vapor deposition (CVD) to achieve conformal and uniform silicon coatings on nickel current collectors and cycled the electrodes at slow rates to form a stable SEI. The intact interface between SEI and silicon anode with the aforementioned curvatures was characterized via a focused ion-beam, followed by scanning transmission electron microscopy (STEM). We used STEM, combined with energy dispersive X-ray spectroscopy (EDS) and electron energy loss spectroscopy (EELS) to investigate the chemical composition and bonding environments of SEI layers at the interface. This approach enabled us to explore how silicon layer changes by tracing oxygen and carbon and the elemental composition of the following SEI layer upon cycling. Our work integrates electrochemistry and high-resolution electron microscopy to reveal for the first time how curvature correlates to chemo-mechanical properties of silicon and SEI formation mechanism. This fundamental understanding should lead to more effective tuning of the properties of next-generation silicon-based batteries.

CH03.04.03
Beyond the Water Electrolysis Potential—A Systematic Study for Different Ionic Carriers on the Electrolyte Performance for Free-Standing Carbon Nanotube Supercapacitors Juveiriah M. Ashraf, Myriam Ghodhbane and Chiara Busa; Technology Innovation Institute, United Arab Emirates

To eliminate electrolyte leakage, the development of safe and flexible supercapacitors necessitates solid-state electrolytes that integrate high mechanical and electrochemical capabilities. *Quasi*-solid-state electrolytes, which constitute a polymer matrix along with an aqueous electrolytic phase, are a viable answer to this problem. Recently, gel electrolytes have gained a lot of attention in flexible and wearable electronic devices due to their remarkable advancements. However, the limitation in the high-performance of such gels hinders the practical usage of such devices. On the electrochemical perspective, the gel electrolyte performances strictly rely on the type of ionic carrier (acidic, alkaline, or salt-based), size of the ion, solvent concentration, type of polymer, as well as the interaction between the polymer and other components. Moreover, the performance of the electrolyte differs with the electrode-electrolyte interface and thus is highly dependent on the electrode material. For this reason, it is vital to carry a parametric study to evaluate the effect of the above stated.

Most studies in literature focus on limited voltage windows, up to 0.8 V or 1 V, below the electrolysis potential of water. However, it is important to study the efficacy of these electrolytes for larger voltage windows for employment in broader applications. The aim of this study is to investigate the effect of several ionic carriers (namely H_3PO4, KOH and LiCl) for a cell voltage exceeding the water electrolysis potential (1.2 V), that is, up to 1.5 V. The solvent concentration of the architecturally engineered PVA-based electrolytes' performance in free-standing CNT supercapacitor is also evaluated. In addition, the dependency of the electrolyte's mechanical structure for long-term stability is further studied by using the optimized concentration of each (H_3PO4, KOH and LiCl) by freezing and de-freezing the gel to form membrane-like films because of the creation of increased physical cross-linking with this cycle. The supercapacitors are studied for their capacitance, charge/discharge capabilities as well their long-term stability to determine the optimum electrolyte.

CH03.04.04
Understanding and Controlling Interfacial Reactivity of Silicon Electrodes—Impact of Electrode and Electrolyte Composition Mallory Vila[1], Wenzao Li[1], Lisa Housel[2], Shan Yan[2], Lei Wang[2], David Bock[2], Esther S. Takeuchi[1,2], Kenneth J. Takeuchi[1,2] and Amy Marschilok[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Silicon is an attractive negative electrode material for lithium-ion batteries (LIBs) because of its high theoretical capacity (3579 mAh g–1), low cost, and demonstrated ability to store Li-ions. However, Si experiences limited capacity retention due to significant volume change on (de)lithiation and repeated formation of the solid-electrolyte interphase (SEI) as the silicon evolves with cycling. These factors can contribute to high internal resistance, low Coulombic efficiency, and decreased capacity over cycling.
Appropriate formation of the SEI through electrolyte modification is a promising strategy to address this issue. Previous studies have evaluated the effectiveness of electrolyte additives on the SEI and capacity retention. While it has been long recognized that the electrode/electrolyte interface is critical, it has proven challenging to probe directly often requiring recovery of the active electrodes with subsequent examination risking change from their functional environment. Cell reactions including SEI formation can be elucidated by coupling information from a variety of methods including electrochemistry, x-ray photoelectron spectroscopy (XPS) of recovered electrodes, and isothermal microcalorimetry (IMC). Outcomes from a series of investigations on the reactivity of silicon electrodes of several compositions and electrolyte environments will be highlighted.

CH03.04.05
Characteristic Dual-Domain Structure of Reduced Graphene Oxide and Its Guidance to Higher Specific Capacitance Jun Beom Kim and Sang Ouk Kim; KAIST, Korea (the Republic of)

Reduced graphene oxide (rGO) has been regarded as an attractive material for diverse energy storage applications such as fuel cells, batteries, and

supercapacitors. Graphene synthesized by the chemical vapor deposition method or graphene oxide (GO) produced by oxidative exfoliation process from graphite has critical
drawbacks of poor scalability or poor electrical conductivity to be used as electrochemical electrode materials. In contrast, rGO addresses those limitations of graphene and GO by providing considerable conductivities of both electron and ion due to simultaneously existing components of graphene and GO as well as the advantage of high-yield mass production. For successful applications of rGO to high-performance electrochemical energy storage devices as electrode materials, both high electrical conductivity of rGO and high ion accessibility from the electrolyte to rGO are crucial requirements. The electrical conductivity of rGO,
however, has a trade-off property of ion accessibility. If the electrical conductivity were enhanced by increasing the degree of reduction of rGO [28–32], the ion accessibility from the electrolyte to rGO would decrease due to diminished hydrophilicity with the reduction of the GO component. Thus, optimization between electrical conductivity and ion accessibility is necessary for successful applications of rGO to high performance
electrode material. Investigations on the changes of the above two intrinsic properties with the reduction level of rGO had been rarely reported thus far. Furthermore, fundamental and scientific investigations on the nature of rGO surface, e.g., characteristic domain structures of rGO with reduction levels have been never reported.
In this study, the electrical domain structures of rGO were investigated by the conductive atomic force microscopy (C-AFM) technique. This analysis was expected to reveal the amounts and configurations of graphene and GO domains. If the characteristic 2D domain structures were revealed and controlled with reduction level, the optimized domain structure would guide to higher performance of rGO-based electrode
materials. The specific capacitance of rGO freestanding sheets was discussed with their characteristic domain structures. In addition, hybrid composite sheets of Fe2O3 and MnO2 ceramic particles mixed with rGO were examined for further enhanced specific capacitance.

CH03.04.06
Synergetic Effect of Surface-Controlled and Diffusion-Controlled Charge Processes of NiP/CoP@NF for High Energy Density Supercapacitor MooYoung Jung; Korea University, Korea (the Republic of)

Since the rapidly increasing concerns about contamination of the environment and demand for energy storage systems, the development of high energy density supercapacitors has been essential. Although the commercial electrode for the supercapacitor has been carbon-based material, other transition metal-based electrode materials, which are pseudocapacitive or battery-like materials, have been researched by lots of academic or commercial groups due to the low energy density of carbon material. In this study, by combining the pseudocapacitive MOF-derived CoP material with the battery-like NiP material, high energy density NiP/CoP electrode material was fabricated. NiP/CoP@NF exhibited superior specific capacitance of 1154.4 F g^{-1} at 1 A g^{-1}, exhibiting the mixed charging mechanism of both CoP and NiP materials. An asymmetric supercapacitor (ASC) showed a high energy density of 27.7 Wh kg^{-1} at the power density of 800 W kg^{-1} with cycle retention of 86.36% at 10000 cycles.

CH03.04.08
Observation of Ir 5d Orbitals in Epitaxial IrO_2 Thin Films Using Resonant Inelastic X-Ray Scattering Seohyoung Chang and Kyeong Jun Lee; Chung-Ang University, Korea (the Republic of)

Transition metal oxides have been considered one of the alternative material systems for energy conversion and storage systems due to their intriguing physical and chemical properties. Specifically, IrO_2 exhibits high activity and better stability under oxygen evolution reaction (OER) than other 4d transition metal oxides, e.g., ruthenates [1]. Ir 5d orbital states in IrO_2 can play an important role in the OER process because of interactions between d orbitals near Fermi level and adsorbates. However, understanding of the process of the model system is yet incomplete due to experimental limitations, specifically spectroscopic techniques.

Here, we measured 5d orbital states in IrO2epitaxial thin films grown on TiO_2 substrates using Ir L_3-edge resonant inelastic x-ray scattering (RIXS). Using the RIXS technique, we systematically investigated 5d orbital states near Fermi level and understood the transition between specific orbitals coupled with orientations and strain. For instance, our RIXS measurement demonstrated that the 5d d_{x2-y2} orbital in the plane of edge-sharing of octahedra along [001] dominantly contributed to about 2eV energy loss signal. We propose that the in-situ RIXS techniques combined with an electric field can understand the OER process and explore emergent physical properties.

CH03.04.09
A Mesoporous Ternary Transition Metal Oxide Nanoparticle Composite for High-Performance Asymmetric Supercapacitor Devices with High Specific Energy Manar M. Hazaa and Nageh K. Allam; The American University in Cairo, Egypt

We report on the optimized fabrication and electrochemical properties of ternary metal oxide (Ti–Mo–Ni–O) nanoparticles as electrochemical supercapacitor electrode materials. The structural, morphological, and elemental composition of the fabricated Ti–Mo–Ni–O via rapid breakdown anodization are elucidated by field emission scanning electron microscopy, Raman, and photoelectron spectroscopy analyses. The Ti–Mo–Ni–O nanoparticles reveal pseudocapacitive behavior with a specific capacitance of 255.4 F g^{-1}. Moreover, the supercapacitor device Ti–Mo–Ni–O NPs//mesoporous doped-carbon (TMN NPs//MPDC) device exhibited a superior specific energy of 68.47 W h kg^{-1} with a corresponding power density of 2058 W kg^{-1}. The supercapacitor device shows 100% coulombic efficiency with 96.8% capacitance retention over 11000 prolonged charge/discharge cycles at 10 A g^{-1}.

CH03.04.10
Highly Stable Supercapacitor Devices Based on Three-Dimensional Bioderived Carbon Encapsulated g-C_3N_4 Nanosheets Manar M. Hazaa, Nageh K. Allam, Loujain G. Ghanem and Mahmoud A. Hamza; The American University in Cairo, Egypt

Owing to the increasing demand for sustainable and eco-friendly energy storage devices such as supercapacitors, it is vital to continuously search for highly stable and cost-effective electrode materials with high energy and power densities. Herein, a 3D/2D metal-free mesoporous composite of graphitic carbon nitride (GCN) and bioderived carbon (Bio-C_x) is investigated as an energy storage electrode material. This composite overcomes the low conductivity and low capacitance limitations of GCN while enjoying its high corrosion resistance, high nitrogen content, and unique 2D structure. The GCN/Bio-C_x composite exhibits a fairly wide operating potential window of 1.2 V in 0.5 M H_2SO_4 aqueous electrolyte with a high capacitance of 300 F/g at 1 A/g. This high performance was ascribed to the huge number of available active sites, large surface area, and the unique 3*D*/2D structure. The assembled device employing the GCN/Bio-C_x composite as the positive electrode and mesoporous nitrogen-doped carbon (MPNDC) as the negative electrode showed an ultrahigh-energy density of 53.72 Wh/kg and a power density of 900 W/kg. The GCN/Bio-C_x//MPNDC device retains ∼100% of its initial capacitance after 13 000 charge/discharge cycles with 100% Columbic efficiency.

CH03.04.11
NMC Microparticles with Core-Shell Structure for Cathodes in Li-Ion Batteries Javier Garcia-Alonso[1], Svitlana Nahirniak[2], David Maestre[1], Bilge Saruhan[2], Ana Cremades[1] and Bianchi Mendez[1]; [1]Universidad Complutense de Madrid, Spain; [2]German Aerospace Center (DLR), Germany

The increasing necessity for improvement in energy storage technologies, especially of the mature Lithium-Ion Batteries (LIBs), relies on the advances in the characterization techniques and the materials used in the device. Advanced microscopy and spectroscopy techniques, including *in-situ* measurements, can provide valuable insights to face some of the challenges that this technology faces. In recent years, Ni-Mn-Co (NMC)-based cathodes have gained relevance due to their high specific capacity and thermal stability leading to an improvement of the performance of the LIBs. So far, different approaches have been pursued to improve the synthesis mechanisms, and diverse characterization techniques have been employed in the study of the NMC materials at the microscale.
In this work, NMC core-shell microparticles have been studied by a combination of techniques including scanning and transmission electron microscopy (SEM, TEM), X-ray diffraction (XRD), energy dispersive x-ray spectroscopy (EDS), Raman spectroscopy and X-Ray Photoelectron Spectroscopy (XPS), including i*n-situ* techniques as well. Micro-Raman and XRD results indicate the formation of Li-Ni-Mn-Co-O complex oxides presenting the usual layered structure of NMC (R-3m) with the presence of reduced quantities of other structures like spinel phases. This layered structure is directly related to the high capacity and structural stability of NMC cathodes when the battery is cycled. In-situ thermo XRD measurements indicate an enhanced formation of NiO as the temperature increases up to 900 ºC. The analyzed microparticles exhibited a rounded appearance with an average diameter of 4 µm and variations in their morphology as a function of the temperature used during the synthesis, as observed by SEM and TEM. In-situ SEM observations also lead to assess the morphology evolution of the particles with increasing temperature. EDS analysis with variable beam acceleration voltage confirms the presence of a Ni-rich core and a Mn-rich shell with submicrometric dimensions. The presence of Ni allows for a higher capacity but a lower structural stability when cycling, while Mn allows for higher structural stability but lower capacity. Co in small quantities can mitigate the cation disordering inside the crystal structure. SEM and EDS measurements confirm that the morphological and compositional properties of the particles were maintained after the Li introduction. Micro-Raman spectroscopy was also used to understand the variations in the crystalline structure of the particles as a function of the synthesis route and the Li insertion. Finally, in-situ XPS measurements at temperatures up to 500 ºC and a variable pressure, shows variations in the Mn(3s) and O(1s) core levels, as well as in the electrical conductivity of the samples. These results can lead to achieve a deeper knowledge of the properties of the NMC microparticles in the search of improved performance in LiBs.

CH03.04.12
Development and Implementation of *In Situ* Mossbauer Spectrometry for the Study of Battery Cathode Materials Simon Ji and Hillary Smith; Swarthmore College, United States

Mossbauer Spectroscopy has proven to be a very useful tool for studying the local electron dynamics in iron-containing battery materials. In the hunt for more economical and sustainable battery cathode materials, NaFePO4 has emerged as a lower-cost and safer alternative to LiFePO4. We report the development and characterization of an electrochemical cell for in situ Mossbauer spectroscopy measurement. The in situ setup is used to study changes in the local structure of iron atoms during initial discharge and charge in NaFePO4 half-cells. We will compare these results to previous in situ studies of LiFePO4. Finally we will compare the initial charge and discharge spectra to those after multiple cycles to provide insights into changes in the cathode material that may result in cell degradation.

CH03.04.13
On the Connection Between Slurry Rheology and Electrochemical Performance of Graphite Anodes in Lithium-Ion Batteries Joseph Sullivan; The University of Rhode Island, United States

Most current lithium-ion battery anodes are prepared from a slurry containing graphite, polyvinylidene fluoride (PVDF), n-methyl-2-pyrrolidone (NMP), and small amounts of conductive carbon black (CB). The rheology of this four-component slurry is an important indicator of its microstructure, that affects the structure of the dried electrode. This in turn has consequences on the electrochemical performance of the anode. We modulate the rheology of the slurry by choosing three different commercially available carbon blacks that are used in lithium-ion batteries and establish a connection between slurry rheology and electrochemical performance. We show that the storage modulus is the key factor that impacts the electrochemical performance.

CH03.04.15
Insights into Battery Systems using In-situ and Operando Characterization Methods Nahian Sadique[1], Shan Yan[2], Lisa Housel[2], Lei Wang[2], David Bock[2], Esther S. Takeuchi[1,2], Amy Marschilok[1,2] and Kenneth J. Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Electrochemical energy storage systems, specifically batteries, have become a key component in our society. As demand increases for electric vehicles, and integration of intermittent renewable energy sources, so does the need for high performing, reliable, and cost-effective battery systems to power the applications. Further, as the applications evolve demands for advances in the technology place new requirements on future generations of batteries. Batteries are highly researched and ex situ measurements on components outside of the functional environment have been a standard approach for decades. However, these are often ultimately destructive techniques that risk distortion of the original chemical environment and do not capture kinetic phenomena. More recently, in situ characterization on a system in a functioning environment but inactive during the measurement and operando measurements during system operation have become more prevalent with the potential to yield unprecedented mechanistic insights. The appeal of these approaches is evidenced by a ~350% increase in publications regarding ‘‘batteries and operando’’ techniques over the past 5 years. Further, coupling the time dimension with spatial resolution, in situ and operando characterization over multiple length scales and time domains becomes a powerful approach.
The research presented will provide case studies of in situ and operando techniques including the use of synchrotron methods applied to several battery systems. The complementary insights gained from the multiple characterization approaches used will be highlighted in terms of insight into functional electrochemistry.

CH03.04.16
Interfacial Behavior of Thio-LISICON Solid-State Electrolyte Under External Pressure Yifan Wu and Shou-Hang Bo; Shanghai Jiao Tong University, China

External pressure can greatly affect the cycling performance of solid-state batteries, although pressure-driven changes in electrochemical processes are still not fully understood. For instance, $Li_{10}GeP_2S_{12}$ (LGPS) is known to strongly react with lithium metal. However, under external pressure, with the use of additional Li_6PS_5Cl (LPSCl) outer layers forming a sandwich structure, stable cycling over 1800 cycles can be achieved (*Nature, 2021, 593, 218–222*). This finding motivated us to investigate the interfacial behavior of Li/LGPS under external pressure (*i.e.*, 7.5 MPa) to shed light on the improved electrochemical performance. Our results indicate that the growth rate of the interfacial resistance is substantially decreased while the cycle life before open-circuit failure is substantially extended under MPa-scale external pressure. The reactivity between lithium metal and LGPS is extremely severe,

forming island features upon cycling. Using selected area Raman spectroscopy, these "islands" were confirmed to be interfacial decomposition products (primarily Li_2S). Observations were in line with the expected volume expansion of LGPS when reacting with lithium metal. Exertion of the MPa-scale external pressure may take effect in applying mechanical contraints on volume-expanding reactions, thus improve cycling performance with reactive lithium metal. In addition, a lithium depletion layer was founded formed in the interface region by elemental mapping of lithium with time-of-flight secondary ion mass spectrometry (ToF-SIMS), which can contribute to extra interfacial resistance. Chemo-mechanical degradation processes, which are essentially multi-field coupled, were also captured and analyzed with a home-built *in situ* apparatus. *In situ* X-ray diffraction collected at synchrotron light source evidenced the formation of Li_2S as a dominant interface component at the Li/LGPS interface. Moreover, with help of X-ray tomography conducted *in situ*, we tracked the morphology evolution at the interface. Crack initiation, propagation and crosslinking in LGPS and void formation and suppression in lithium metal were followed. With above-mentioned observations, our work marks an important step to understanding the interfacial electrochemical behavior of the Li/LGPS interface under external pressure.

CH03.04.17
Product Selectivity Change by Ag Nanoparticle Modification on Metal Cathode Electrodes for Electrochemical CO_2 Reduction Kazuki Koike[1,2], Takeharu Murakami[2], Satoshi Wada[2], Atsushi Ogura[1,3] and Katsushi Fujii[2]; [1]Meiji University, Japan; [2]RIKEN Center of Advanced Photonics, Japan; [3]Meiji University MREL, Japan

Electrochemical CO_2 reduction is an effective technique for reducing atmospheric CO_2 concentration, which is one of the causes of global warming. In addition, product control of CO_2 reduction is important for carbon capture and utilization (CCU). The products of CO_2 reduction are known to vary depending on the metal cathode material and the applied voltage. Thus, modification of metal cathode has been studied to control the kinds of products, including the single-crystal surfaces index, alloying with different metals, and the arrangement of multiple metals. In this study, Ag nanoparticle modifications on several kinds of metal surfaces were investigated.
The Ag nanoparticles were sprayed on the electrode surface using a spray machine to modify the electrodes. The evaluations were performed by H-type cells with electrochemical cyclic voltammetry and chronopotentiometry. The reduced products were evaluated by gas chromatography. The surface condition of the electrode before and after the reaction was also evaluated.
It was found that the metal cathode electrode modified with Ag nanoparticles improved the CO_2 reduction ability to CO compared with the bare metal electrode. The surface evaluation results showed that the surface showed dispersed Ag oxide nanoparticles on the metal surface, and it has the possibility of the improvement of CO_2 reduction.

CH03.04.18
Stable Zn Metal Anode Enabled by a Zincophilic Polyanionic Hydrogel Layer Jin-Lin Yang and Hong Jin Fan; Nanyang Technological University, Singapore

The practical application of Zn metal anode for aqueous batteries is greatly restricted by the catastrophic dendrites growth, intricate hydrogen evolution and parasitic surface passivation. Herein, a polyanionic hydrogel film is introduced as a protective layer on Zn anode with the assistance of saline coupling agent (denote as Zn-SHn). The hydrogel framework with zincophilic $-SO_3^-$ functional group uniformizes the zinc ions flux and transport, and such hydrogel layer chemically bonded on Zn surface obviously suppresses the dendrites formation by guiding the 3D Zn accumulation. Consequently, very stable and reversible Zn stripping and plating at various currents and capacities is achieved. A full cell by pairing the Zn-SHn anode with a NaV_3O_8-1.5 H_2O cathode shows a capacity of around 176 mAh g^{-1} with a capacity retention around 67 % over 4000 cycles at 10 A g^{-1}. The presented polyanionic hydrogel film protection strategy paves a new way for future Zn anode design and safe aqueous batteries construction.

CH03.04.19
Characterizing 2D Materials (Graphite, GO, and GNP) via Physical, Electrical and Electrochemical Techniques Sonjoy Dey and Gurpreet Singh; Kansas State University, United States

The characterization of different materials, specifically carbonaceous materials, requires combinations of different microscopic and spectroscopic techniques. Among the various Spectroscopic techniques widely used for the characterization of 2D materials, electrochemical impedance spectroscopy (EIS) is a robust, simple, non-destructive, and powerful electroanalytical technique that provides a considerable amount of information about kinetics happening inside a battery in a comparatively short period. The spectrum produced due to the EIS measurement gives a couple of important information to the user, such as the reactions occurring in the cathode and anode in separated features. Furthermore, if the time constants are resolvable, EIS provides ample information about the resistance arising from each kinetic step during the electrochemical reaction in the electrodes. Keeping this in mind, this study concerns the characterization of three different carbon allotropes (Graphite, GNP and GO) via different spectroscopic techniques such as Raman Spectroscopy and X-ray photoelectron Spectroscopy. These materials were then used in a sodium-ion half-cell setup as cathode material. Afterwards, three different carbon allotropes were examined and differentiated using EIS due to the discrepancy in the impedance of electrodes with varying depths of charge/discharge cycles. Furthermore, the study involved the investigation of reaction mechanism and kinetics during sodiation/disodiation. Therefore, it was found that electrochemical performance tests and EIS data can embellish the previously obtained results from the spectroscopic techniques and enhance the understanding of fabricating better anodes for sodium-ion batteries.

SESSION CH03.05: Solid-State Electrolytes and Novel Liquid Electrolytes

8:30 AM *CH03.05.01
Mechanistic Origin and Role of Heterogeneities in Solid-State Batteries Partha P. Mukherjee, Bairav Sabarish Vishnugopi and Kaustubh G. Naik; Purdue University, United States

Solid-state batteries (SSBs), consisting of a lithium metal anode and an inorganic solid electrolyte, promise to simultaneously improve the energy/power density and safety as compared to the conventional lithium-ion batteries. However, the complex nature of solid-solid interfaces in SSBs pose a wide range of challenges including the morphological instability of the metal anode, microstructure-driven kinetic and transport interactions in the cathode, and interphase formation. To address these limitations, gaining fundamental understanding of the myriad heterogeneities at scales, and their implication on the electrochemical-transport-mechanics interactions at such solid-solid interfaces is critical. In this presentation, we delineate the underlying role of

heterogeneities on the failure onset, degradation, and electrochemical performance of solid-state batteries. The mechanistic interactions due to the spatio-temporal heterogeneity of the underlying electrochemical-thermal-mechanics coupling will be examined.

9:00 AM *CH03.05.02
Elucidating Interfaces in Solid State Batteries Using Advanced Scanning Transmission Electron Microscopy (STEM) Miaofang Chi; Oak Ridge National Laboratory, United States

Designing next-generation energy storage systems, such as solid-state batteries, faces numerous challenges, many of which are related to interfaces. Elucidating interfacial phenomena requires knowledge, not only of atomic-scale structure and chemistry but also of correlated local charge distribution and ion transport that are difficult to probe with existing characterization techniques. Several emerging scanning transmission electron microscopy (STEM) techniques, such as four-dimensional (4D)-STEM, monochromated EELS (electron energy loss spectroscopy), atomic-scale cryogenic and *in situ* environmental microscopy, allow the behavior of electrons, ions, and atoms to be probed, opening opportunities to tackle complex dynamic interfacial questions. In this talk, I will demonstrate how we advance and utilize these techniques to (1) reveal the origin of unexpected dendrite growth within all-solid-state batteries, (2) probe interfacial ion transport behavior, and (3) map space charge region at solid-solid interfaces. Perspectives for the future advancements of these new STEM techniques for research into emerging energy materials and systems will also be provided.

9:30 AM CH03.05.03
Localized Overlimiting Ion Polarization Preceding Metal Penetration in Lithium-Ion Conducting Electrolytes Peng Bai; Washington University in St. Louis, United States

Next-generation high-energy batteries require rechargeable metal anodes, but hazardous dendrites tend to form during recharging, causing short-circuit risk and capacity loss, even with hard and stiff ceramic electrolytes, by mechanisms that still remain elusive. In this presentation, we will first demonstrate a rigorous analysis of the lithium dendrite formation in liquid electrolytes, through the intimate combination of operando experiments and transport models. Our results demonstrated the necessity to differentiate Li whiskers from Li dendrites, induced by different physical processes. Resolving the interfacial instability and metal whiskers led to an ideally smooth, non-porous, ingot-type Na metal plating, which enabled the anode-free Na metal full cells with a record-high retention rate of 99.93% per cycle at 3C charge and discharge. Novel electrochemical tests of garnet-type cubic $Li_{7-x}La_3Zr_{2-x}Ta_xO_{12}$ ceramic electrolytes confirmed a similar overlimiting ion polarization and dendrite initiation mechanism mainly through grain boundaries. Our theoretical and experimental discoveries suggest that both liquid and solid electrolytes follow a similar ion polarization process before the onset of localized metal penetration. The success of alkali metal batteries relies on the rational control of both the interfacial kinetics and the bulk ion transport.

9:45 AM BREAK

10:15 AM *CH03.05.04
Multidimensional Characterizations for All-Solid-State Batteries Yan Yao; University of Houston, United States

All-solid-state batteries (ASSBs) are regarded as one of the future energy storage technologies capable of competing with the state-of-the-art Li-ion batteries. Despite significant development, the room temperature long-cycle performance of lithium metal ASSBs still remains a challenge. The failure of a solid-state Li battery may be linked to two primary causes: interfacial resistance increase and Li dendrite growth. The former may be further attributed to electrolyte decomposition and interfacial void formation (*i.e.,* loss of physical contact). Electrolyte decomposition happens in two ways: oxidative decomposition at the cathode active material-electrolyte interface and reductive decomposition at the Li (including dendrites)-electrolyte interface. The complex origins of battery failure necessitate multidimensional characterizations using a combination of tools capable of quantifying the void and dendrites, identifying the chemical and mechanical natures of the Li dendrites and electrolyte decomposition products, and monitoring the processes in situ. The tools must also cover a sufficiently large scale, have a spatial resolution of a few nanometers, and be sensitive enough to detect subtle changes in chemical and mechanical properties. These considerations led us to a suite of methods for structural, chemical, and mechanical characterizations that include PFIB-SEM, ToF-SIMS, and nanoindentation-based stiffness mapping. We fabricated solid-state micro-cells with electrochemical performance comparable to their bulk-type cells. Electrochemical tests with temperature control and external pressure monitoring of solid-state cells were demonstrated in an air-free vessel with an integrated in-situ cell test platform. We investigate the function of an interlayer between lithium metal anode and solid electrolyte in preventing lithium dendrite formation and allowing reversible lithium plating and stripping over 1000 cycles. With these in-depth understandings, we will be able to predict and optimize the physical and chemical changes that occur in solid-state Li batteries during operation.

This work was supported by the U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy (EERE) under the Vehicle Technologies Program under Contract DE-EE0008864.

10:45 AM *CH03.05.05
Understanding Materials Dynamics in Solid-State Batteries Matthew T. McDowell; Georgia Institute of Technology, United States

Solid-state batteries offer the promise of improved energy density and safety compared to lithium-ion batteries, but electro-chemo-mechanical evolution and degradation of materials and interfaces can play an outsized role in limiting their performance due to the all-solid nature of these systems. Here, I will present my group's recent work using *in situ* and *operando* experiments to understand interfacial evolution and stress changes in solid-state batteries with lithium metal and alloy anodes. *Operando* X-ray tomography is used to reveal interfacial dynamics in solid-state batteries with Li metal anodes. Segmentation and detailed image analysis enable correlation of interfacial contact loss to electrochemical behavior of symmetric cells, and the loss of interfacial contact area at the Li metal interface is found to cause current constriction and cell failure. The unique aspects of interfacial evolution in anode-free solid-state batteries associated with localized lithium depletion, as revealed by X-ray tomography and cryo-FIB, are also discussed. Finally, stack pressure evolution during cycling of full solid-state batteries is measured *in situ* and correlated with fundamental processes within electrode materials and the properties of composite electrode structures. Cells with alloy-based anodes are found to exhibit large (megapascal-level) changes in stack pressure during cycling, with stable capacity and stress changes over long-term cycling. Together, these findings show the importance of controlling chemo-mechanics and interfaces in solid-state batteries.

11:15 AM CH03.05.06
High-Precision Quantifications of Dendrite Initiation Dynamics in Garnet Solid Electrolytes Rajeev K. Gopal and Peng Bai; Washington University in St. Louis, United States

Solid-state electrolytes have the potential to stabilize lithium metal anodes, which hold the promise to increase the energy density of lithium-ion batteries. However, lithium metal dendrites that occur locally at the solid-solid interface plague the solid-state lithium metal cells during charging, rendering high safety risks in practical applications. While multiple explanations have been proposed, understandings of the dynamics preceding and causing the metal

penetration in solid electrolytes are still not conclusive. Here, by testing hundreds of highly consistent LLZTO samples and utilizing a novel operando technique on conventional cell geometry, we observed consistent and statistically significant phenomena. The characteristic time to dendrite initiation was measured and coincided with the Sand's time scaling traditionally reserved for liquid electrolytes, indicating similar transport limitations in garnet solid electrolytes. Deviations in scaling and additional normalization were also explored. This new fundamental understanding not only explains the electrochemical origin of dendritic initiation but also provides future insight into optimal all-solid-state battery design.

SESSION CH03.06: Thin-Film Solid-State Batteries
Session Chairs: Kent Griffith and Hui Xiong
Tuesday Afternoon, November 29, 2022
Hynes, Level 1, Room 103

1:30 PM *CH03.06.01
Thin Film Solid State Li-Ion Batteries as Model Systems for Understanding Interface Effects A. A. Talin; Sandia National Laboratories, United States

Rechargeable, thin film solid-state Li and Li ion batteries (TFSSLBs) with high specific power and energy density are highly desirable to energize an emerging class of miniature, autonomous microsystems that operate without a hardwire for power or communications. TFSSLBs are also attractive for fundamental studies aimed at understanding how battery geometry, dimensions, composition and the resulting interfaces affect performance. For example, thin film fabrication methods enable precise control over electrode and electrolyte thickness, morphology, geometry and interface area. Furthermore, TFSSLBs are vacuum compatible, meaning that techniques that generally require vacuum or controlled ambient such as SEM, TEM, auger electron spectroscopy, secondary ion mass spectroscopy, neutron depth profiling and Kelvin probe force microscopy can be readily applied to characterize TFSSLB, often in operando mode. In my presentation, I will discuss recent experiments aimed at precisely measuring the Li concentration and electric potential profiles across TFSSLBs. When coupled with first principles informed models, the results provide new insights into the factors that determine electrode/electrolyte interface resistance and to materials selection strategies for achieving stable, high performance solid state batteries.

2:00 PM CH03.06.02
Direct Imaging of the Structural and Morphological Evolution of Epitaxial $LiCoO_2$ Films During Charge and Overcharge Widitha Samarakoon[1,2], Jiangtao Hu[1], Miao Song[1], Mark Bowden[1], Nabajit Lahiri[1], Jia Liu[1], Le Wang[1], Timothy Droubay[1], Hua Zhou[3], Zhenxing Feng[2], Jinhui Tao[1] and Yingge Du[1]; [1]Pacific Northwest National Laboratory, United States; [2]Oregon State University, United States; [3]Argonne National Laboratory, United States

Capacity decay of layered cathodes in high voltage applications underscores the need to utilize accurate and precise techniques to understand the underlying mechanisms. Here, we use well-defined epitaxial $LiCoO_2$ (LCO) films on $SrRuO_3/SrTiO_3$ (SRO/STO) with controlled orientations and defect structures along with *in situ* electrochemical atomic force microscopy to probe the structural and morphological evolutions during the charge and overcharge processes. We quantitatively show the morphological changes in both reversible delithiation regime and irreversible over-delithiation regime, and correlate the overall electrochemical behaviors to atomic scale defect evolutions in the films. We also observe a significantly lower charging capacity for LCO/SRO/STO(111) compared to that of LCO/SRO/STO(001) films of the same thickness, which is ascribed to the different types of atomic scale defects formed during the film growth process. Our high-resolution scanning transmission electron microscopy (STEM) and electron energy loss spectroscopy (EELS) studies reveal that the antiphase boundaries in LCO/SRO/STO(001) act as viable channels for Li migration but are more susceptible to irreversible phase transitions, which then blocks subsequent Li diffusion. The use of $LiCoO_2$ thin films also allows us to design epitaxial interfaces and integrate multilayers which can serve as model materails systems for subsequent studies.

2:15 PM CH03.06.03
Unraveling the Stable Cathode Electrolyte Interface in All Solid-State Thin-Film Battery Operating at 5V Diyi Cheng[1], Ryosuke Shimizu[1], Minghao Zhang[1] and Y. Shirley Meng[2,1]; [1]University of California, San Diego, United States; [2]The University of Chicago, United States

Spinel-type $LiNi_{0.5}Mn_{1.5}O_4$ (LNMO) is one of the most promising 5 V-class cathode materials for Li-ion batteries that can achieve high energy density and low production costs. However, in liquid electrolyte cells, the high voltage causes continuous cell degradation through the oxidative decomposition of carbonate-based liquid electrolytes. In contrast, some solid-state electrolytes have a wide electrochemical stability range and can withstand the required oxidative potential. In this work, a thin-film battery consisting of a LNMO cathode with a solid lithium phosphorus oxynitride (LiPON) electrolyte is tested and their interface before and after cycling is characterized. With Li metal as the anode, this system can deliver stable performance for 600 cycles with an average Coulombic efficiency > 99%. Neutron depth profiling indicates a slight overlithiated layer at the interface prior to cycling, a result that is consistent with the excess charge capacity measured during the first cycle. Cryogenic electron microscopy further reveals intimate contact between LNMO and LiPON without noticeable structure and chemical composition evolution after extended cycling, demonstrating the superior stability of LiPON against a high voltage cathode. Consequently, we propose design guidelines for interface engineering that could accelerate the commercialization of a high voltage cell with solid or liquid electrolytes.

2:30 PM CH03.06.04
Quantitative Elemental Analysis of Silicon Thin-Film Anodes with 100-nm Depth Resolution Xiaoyang Ji, Nathan J. Fritz, Paul Braun and David Cahill; University of Illinois at Urbana-Champaign, United States

The depth distribution of Li as well as other light elements, i.e. C, O, and F, in the electrodes of lithium-ion batteries is significant for understanding mass transport during cycling. In our work, we take advantage of the proton nuclear reactions with Li and F in addition to the elastic scatterings with all elements in electrochemically deposited silicon thin film anodes, and determine the depth distribution of Li, C, O, F, and Si quantitatively at different cycling states of silicon anodes. A high depth resolution of ~20 – 80 nm in nuclear reactions and elastic scatterings is achieved with a glancing exit angle (~80°) of the proton beam, while the resolution of nuclear reactions is higher due to scattered alpha particles with 8-MeV energy. The Li residue is twice of the Si amount in the first ten cycles, indicating rapid accumulation of trapped lithium in the silicon anode. The relative Li atomic concentration compared to Si decreases by ~10% – 50% in the deeper position of the anode. Meanwhile, the amounts of C and O increase by ~100% after the first cycle, but the amounts remain in the later cycling. We also observe larger atomic concentrations of O and F near the surface of the silicon anode, indicative of solid electrolyte interphase (SEI) formation. The quantitative analysis of the heterogeneous element distribution by this non-destructive technique will be useful to further understand the SEI formation and growth and the mechanism of lithium trapping in cycled silicon anodes.

3:15 PM *CH03.07.01
Designing Cathode Microstructures in Lithium Batteries Feng Lin; Virginia Tech, United States

The propagation of redox reactions governs the electrochemical properties of battery materials and their critical performance metrics in battery cells. The recent research progress, especially aided by advanced analytical techniques, has revealed that incomplete and heterogeneous redox reactions prevail in many electrode materials. Advanced high-capacity cathode materials are mostly polycrystalline materials that exhibit complex charge distribution (the valence state distribution of the redox-active cations) due to the presence of numerous constituting grains and grain boundaries. The redox reactions in individual grains typically do not proceed concurrently due to their distinct geometric locations in polycrystalline particles. As a result, these unsynchronized local redox events collectively induce heterogeneous and anisotropic charge distribution, building up intergranular and intragranular stress. Therefore, these polycrystalline materials may exhibit weak mechanical stability, leading to undesired chemomechanical breakdown during battery operation. Grain engineering in polycrystalline materials provides a large playground to modulate the materials properties beyond controlling the chemical composition, and electronic and crystal structures. In particular, the anisotropic ion-conducting pathways in layered oxides make the grain crystallographic orientation a critical factor in determining the modality of the redox reactions in these materials.

This presentation will discuss our recent progress in the design, synthesis, and characterization of cathode microstructures in lithium batteries.

First, we will discuss how the charge distribution is guided by grain crystallographic orientations in polycrystalline battery materials. We elucidate the spatially resolved charge distribution in lithium layered oxides with different grain crystallographic arrangements and establish a model to quantify their charge distributions. While the holistic “surface-to-bulk” charge distribution prevails in polycrystalline particles, the crystallographic orientation-guided redox reaction governs the charge distribution in the local charged nanodomains. Compared to the randomly oriented grains, the radially aligned grains exhibit a lower cell polarization and higher capacity retention upon battery cycling. The radially aligned grains create less tortuous lithium-ion pathways, thus improving the charge homogeneity as statistically quantified from over 20 million nanodomains in polycrystalline particles. This study provides an improved understanding of the charge distribution and chemomechanical properties of polycrystalline battery materials.

Second, we will discuss how the grain arrangement affects the thermal stability of polycrystalline cathode materials in rechargeable batteries. We performed a systematic in situ study on the Ni-rich polycrystalline cathode materials to investigate the fundamental degradation mechanism of charged cathodes at elevated temperatures, which is essential for tailoring material properties and improving performance. Using multiple microscopy, scattering, thermal, and electrochemical probes, we decoupled the major contributors to the thermal instability from intertwined factors. Based on our findings, the cathode grain microstructure has a forgotten yet important role in the thermal stability of polycrystalline rechargeable batteries. Oxygen release, as an important process during the thermal runaway, can be regulated through engineering grain arrangements. The grain arrangement can modulate the macroscopic crystallographic transformation pattern and oxygen diffusion length in layered cathodes to offer more possibilities for cathode material design and synthesis.

3:45 PM CH03.07.02
Reaction Heterogeneity During the Solid-State Synthesis of Ni-Rich Layered Oxide Revealed by *In Situ* Multiscale Investigation Hayoung Park[1], Hyeokjun Park[2,1], Sungsu Kang[1], Yonggoon Jeon[1], Jihoon Kim[1], Kisuk Kang[1] and Jungwon Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Research Institue of Standards and Science, Korea (the Republic of)

Nickel-rich layered oxides are regarded as promising next-generation cathode materials for high-energy lithium-ion batteries. However, their commercialization has been hampered by their inferior cycle stability, which stems from chemo-mechanical failures ranging from primary to secondary particle. In this work, we investigate the solid-state synthesis of $LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ in real-time to better understand the structural and/or morphological changes during phase evolution. Multi-length-scale observations (aberration-corrected transmission electron microscopy (TEM), in situ heating TEM and in situ X-ray diffraction, etc.) reveal that the kinetic competition between the intrinsic thermal decomposition of the transition metal hydroxide at the core and the topotactic lithiation near the interface determines the overall synthesis, which results in spatially heterogeneous intermediates at the low temperature. The thermal oxidation of the precursor leads to the formation of intergranular voids and intragranular nanopores which are destructive to cyclability. Furthermore, we demonstrate that the pseudo-equilibrium synthetic pathway which promotes topotactic lithiation can mitigate the generation of defective structures and effectively suppress the chemo-mechanical failures.

4:00 PM CH03.07.05
Defect and Interface/Interphase Engineering in Electrode Materials for Metal Ion Batteries Hui Xiong; Boise State University, United States

Rechargeable batteries are promising energy storage technologies to provide high energy and high power for applications such as electric vehicles and electrical grids. Recent studies have shown enhanced electrochemical charge storage in electrodes that contain intentional structural defects (e.g., vacancies and interstitials) or with tailored interfaces/interphases. In this talk, recent works in my group including engineering defects in electrode materials through ion irradiation as well as interface/interphase engineering in metal ion batteries (e.g., Li ion and Na ion batteries) will be discussed. *In situ* and *operando* characterizations that help elucidate the structural and microstructural evolution of the battery materials will be discussed. Perspectives regarding new pathways to design and engineering defects and interfaces in electrode materials with enhanced energy/power for rechargeable batteries will be given.

SESSION CH03.08: Precision Characterization Techniques

8:30 AM *CH03.08.01
Quantifying Functional Variability Between NMC Particles Using Single-Particle Electrochemistry Yiyang Li; University of Michigan, United States

Heterogeneity is a commonly observed in battery materials at a variety of length scales. While heterogeneity at the electrode or cell level can be studied and understood based on porous electrode transport losses, the intrinsic heterogeneity and variability in electrochemical properties between individual particles is much more challenging to unravel. Most research into particle-level variability utilize microscopy, but this approach is only able to indirectly measure the electorochemistry using a spectroscopic signature. In this work, we present our research utilizing single-particle electrochemistry to directly quantify the electrochemical properties of single particles. By electrochemically cycling many commercial polycrystalline NMC battery particles under nominally identical conditions, we show that the area-specific resistance vary by as much as 5 times within a batch of commercial battery particles. We combine these experimental results with a porous electrode model to show how the electrochemical variability between individual particles ultimately affects the overall macroscopic behavior of the battery electrode.

9:00 AM *CH03.08.02
Evaluating Electrochemical, Chemical and Spatial Heterogeneities During Degradative Oxygen Evolution at Battery Cathodes Using a Novel Scanning Electrochemical Microscopy Toolbox Abhiroop Mishra, Dipobrato Sarbapalli and Joaquin Rodriguez-Lopez; University of Illinois at Urbana Champaign, United States

Lattice oxygen loss during cathode charging is one of the main limitations for high-voltage lithium ion batteries and a critical player in various surface cathode phenomena including densification cathode electrolyte interphase (CEI) formation, and electrolyte degradation processes. Thus, developing techniques capable of evaluating the degradative O_2 evolution phenomena with high versatility, e.g. with (electro)chemical and spatial resolution and the capability to correlate to other surface phenomena, is pressing towards understanding and designing better cathodes. In this presentation we will discuss a novel in situ oxygen detection strategy using scanning electrochemical microscopy (SECM) in the substrate generation/tip collection mode. By approaching the tip to the substrate within a few microns, we are able to collect the generated O_2 within few milliseconds after its generation at the cathode with unprecedented sensitivity and signal to noise ratio. This allowed us to generate plots that quantified the rate of oxygen evolution vs. electrode potential. Our first results on $LiCoO_2$, $LiNi_{0.33}Mn_{0.33}Co_{0.33}O_2$ and $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ revealed an unprecedented two-stage oxygen evolution behavior from commercial cathodes with an unreported feature at ~3.3 V vs Li^+/Li during the first charge cycle. At the main oxygen evolution features above ~3.3 V vs Li^+/Li, SECM mapping highlighted spatial and temporal heterogeneities as the tip was positioned on different evolution sites and at different times. Further exploration using the feedback mode of SECM enables us to correlate the state of the surface to its charge transfer properties. Since such an interface could also be the source of reactive oxygen species (ROS), we have deployed generation-collection techniques and surface-interrogation SECM methods to quantify and evaluate the properties of ROS and radical intermediates formed at the interface, thus highlighting the chemical versatility of our approach. Our SECM toolbox is a unique complement to other methods used to characterize interfacial processes at battery materials, and requires very little sample preparation, being capable of addressing large format electrodes down to individual particles. This tool will help create new prospects for quantitative and spatially resolved investigations of degradation processes in operating lithium ion battery cathodes.

9:30 AM CH03.08.03
***Operando* Small-Angle Scattering and Cryo-Electron Microscopy to Quantify the Multiphase Nanostructure in Beyond Intercalation-Type Battery Cathodes** Christian Prehal[1], Jean-Marc von Mentlen[1], Heinz Amenitsch[2], Lionel Porcar[3], Stefan Freunberger[4] and Vanessa Wood[1]; [1]ETH Zurich, Switzerland; [2]Graz University of Technology, Austria; [3]Institut Laue-Langevin, France; [4]ISTA (Institute of Science and Technology Austria), Austria

Beyond intercalation-type batteries, such as Li-sulfur (Li-S) batteries could be game-changers in many respects: a theoretical specific capacity among the highest of all batteries paired with low cost and sustainability of sulfur. However, insufficient understanding of the mechanism that reversibly converts sulfur into lithium sulfide (Li_2S) via soluble polysulfides hampers the realization of high-performance Li-S cells. Developing (*operando*) experimental techniques with seamless sensitivity from atomic to sub-micrometer length scales is crucial to identifying physicochemical mechanisms and important structure-property relationships.
Here we present *operando* small- and wide-angle X-ray scattering (SAXS / WAXS) and *operando* small-angle neutron scattering (SANS) to track the growth and dissolution of solid deposits from atomic to sub-micron scales during charge and discharge (*Prehal et al., preprint: https://doi.org/10.21203/rs.3.rs-818607/v2*). Stochastic modeling based on the SANS data allows quantification of the chemical phase evolution in real space (*Prehal et al. PNAS 118, e2021893118, 2021 & Prehal et al. Nature Communications 11, 4838, 2020*). Cryo-scanning transmission electron microscopy with electron energy loss spectroscopy (cryo-STEM/EELS) provides complimentary local structural information. It verifies the model input for analyzing the *operando* scattering data via stochastic modeling. We show that the deposit nanostructure in Li-S batteries consists of the known nanocrystalline Li_2S and a second solid discharge product which we identify as smaller, solid Li_2S_2 particles. Knowing this has important consequences on how to influence the reaction, discharge capacities, and rate performance. Based on the example of Li-S batteries, we demonstrate that structural information on mesoscopic length scales (1 – 1000 nm) is key to understanding complex transformations such as the electrodeposition and stripping of insulating materials in beyond-intercalation-type battery cathodes. *Operando* SAXS/SANS, cryo-STEM/EELS, and stochastic modeling combine the advantages of integral time-resolved structural information, local element-specific microscopy, and quantitative data analysis.

The Role of SEI Heterogeneity on Charge Transfer Reactions at Li/SEI/Electrolyte Interfaces Yue Qi; Brown University, United States

Two kinds of charge transfer reactions are critical for the performance and life of lithium battery: the desired *ion transfer* reaction occurring during each charge/discharge cycle, , and the undesired *electron transfer* reactions leading to the parasitic chemical decomposition of the electrolyte and solid electrolyte interphase (SEI) formation/growth. The heterogeneous multi-component nature of SEI dominates its ionic and electronic transport properties

and controls these two charge transfer reactions. Density Functional Theory (DFT)-informed multiscale modeling has been providing valuable insights under the scarcity of quantitative experiments. For example, the LiF/Li_2CO_3 interface was demonstrated to increase the ionic conductivity of mixed SEI nanocomposite by forming an ionic space charge region near the interface and promoting more Li-ion interstitials in Li_2CO_3, although LiF itself has low Li-ion conducting carriers and conductivity. On the other hand, the grain boundaries (GBs) in SEI facilitate electron transport pathways, as all GB structures, especially amorphous GBs, have smaller bandgaps than their corresponding single crystals. Some GBs, such as the symmetricLi_2S Tilt Σ3 GB and the amorphous LiF GB, showed empty electronic states lower than the standard Li^+/Li^0 depositing potential. The electron leakage through these grain boundaries will lead to continuous SEI growth and the trapped electrons will facilitate Li metal nucleation inside of SEI. Therefore, a new DFT-informed-phase field model is developed to capture the Li and SEI morphology change simultaneously due to these two charge transfer reactions.

10:45 AM CH03.09.02
First-Principles Modeling of Vinylene Carbonate Reactivity at Li-Metal Electrode—New Insights on SEI Formation Initial Steps Michele Pavone, Francesca Fasulo and Ana B. Muñoz-Garcia; University of Napoli Federico II, Italy

The metallic lithium (Li) represents the most promising anode material among the next generation of solid-state lithium batteries [1]. An efficient strategy to achieve durable and effective Li-anode batteries is by engineering the solid-electrolyte interphase (SEI) with purposely designed molecules. To this aim, the vinylene carbonate (VC) is one of the most used additives in conventional electrolytes. Some recent experiments proved that the VC promotes the formation of a stable and protective SEI layer between Li metal and electrolyte [2, 3]. Unless the well-known SEI composition, it is difficult to control the VC reactivity, that involves dissociation and polymerization at the electrode surface. Therefore, to dissect these tangled processes, here we present new atomistic insights on VC-Lithium SEI formation via first-principles calculations by Density Functional Embedding Theory (DFET) [4, 5]. Such approach has potentialities for modeling complex reactions at hybrid interfaces in electrocatalysis: it is well suited to combine the best feasible approaches for molecular species (in this case, hybrid HF-DFT for VC molecules and derivatives) and for Li metal electrode (semi-local GGA density functional).
Our results highlight different VC dissociation pathways, with formation of reactive radical species and localized cluster of Li_2O and Li_2CO_3. The use of hybrid-DFT-in-DFT embedding is crucial for obtaning energy barriers and qualtitative results in agreement with experiments [3]. Overall, the energetics and structural features of these intermediates improve the current understanding of SEI formation process and can be exploited to drive the reactions toward the desired interfacial properties.

Unveiling the Role of Electrolyte on Solid-Electrolyte Interphase Formation and Structure of Li Deposit Yaobin Xu[1], Dingchuan Xue[2], Hao Jia[1], Ruyue Fang[2], Ji-Guang Zhang[1], Wu Xu[1] and Chongmin Wang[1]; [1]Pacific Northwest National Laboratory, United States; [2]Pennsylvania State University, United States

The morphology of electrochemically deposited lithium (EDLi) plays critical role on the cycling stability and safety performance of Li metal batteries. However, However, formidable challenges and shortcomings of Li metal electrode are currently plaguing its practical application, and the two greatest ones are safety and cycle life. Both of which are associated with the dendritic Li deposition morphology.[1-4] Especially, the key parameters that control the morphologies remain largely obscure. Here we use cryogenic transmission electron microscopy (cryo-TEM) to probe, at atomic level, the features of solid electrolyte interphase (SEI) on Li particle and Li whisker formed in the same coin cell using carbonate electrolyte and ether electrolyte. In the carbonate-based electrolyte, the SEI layer on the Li whisker and Li particle is similarly monolithic amorphous structure, but the composition and spatial distribution of the chemical species within the SEI are distinctively different for Li particle and Li whisker. In the ether-based localized high concentration electrolyte (LHCE), the SEI layer on the Li particle leads to a mosaic structured SEI with few Li_2O nanoparticles embedded, and rich of sulfur (S) in composition, especially at the outer layer SEI (mainly from anion salt decomposition), while the SEI layer of Li whisker displays bilayer structure. The distinctive difference of SEI on Li particle and Li whisker from the same coin cell delineates insight on the direct correlation between features of SEI layer and Li morphology, leading to possible tuning of crucial structural and chemical features of SEI to regulate the morphology of Li deposit.

Dissolution of the Solid Electrolyte Interphase and its Effects on Lithium Metal Anode Cyclability Philaphon Sayavong, Wenbo Zhang, Solomon Oyakhire, David Boyle, Yuelang Chen, Sang Cheol Kim, Rafael Vilá, Sarah Holmes, Mun Sek Kim, Stacey F. Bent, Zhenan Bao and Yi Cui; Stanford University, United States

Despite their potential to provide higher energy density rechargeable batteries, Lithium metal anodes (LMA) suffer from low cyclability. The cycle life of LMA is largely tied to the stability and physicochemical properties of the solid electrolyte interphase (SEI), a nanoscale layer that mitigates the thermodynamic instability of Li metal towards the electrolyte. Using cryogenic-TEM, recent studies by Boyle *et. al.* and Huang *et. al.* suggest that dissolution of SEI components can introduce nanoscopic interphasial heterogeneities in LMAs.[1,2] Dissolution compromises the efficacy of the passivation layer since additional electrolyte and Li must be consumed to repair the partially dissolved SEI, resulting in a thicker and more heterogeneous layer.[3,4] Despite its significance, fundamental understanding of SEI dissolution using electrolytes optimized for LMAs remain lacking. More importantly, it is difficult to gauge on how much SEI dissolution can affect cyclability without a quantitative and systematic study of the process.

In this presentation, we will report the utilization of *in-operando* electrochemical quartz crystal microbalance (EQCM) technique to systematically quantify and compare SEI solubility using ether-based electrolytes for LMAs. Correlating SEI solubility results with performance metrics obtained from coulometric experiments allowed us to establish a correlation between solubility, passivity, and cyclability. Building upon this, we illustrate that cycle life can be further extended for one of the best electrolytes by shifting the SEI solubility equilibria. This suggests that the cycle life of a state-of-the-art electrolyte can be extended by decreasing SEI dissolution, illustrating that solubility is another knob that can be tuned to effectively improve cyclability.

Together with EQCM, X-ray photoelectron spectroscopy (XPS) and nuclear magnetic resonance (NMR) spectroscopy results, we reveal that solubility is dependent on not just the SEI's composition, but also the properties of the electrolyte. We show that comparing SEI solubilities solely based on its composition becomes less reliable for high-performance electrolytes. Our analyses indicate that the differences in the amount of anion-derived component in their SEIs become small enough that the physical and chemical property of the electrolytes start to play a more significant role in dissolution. This crucial piece of information could aid in future design of more passivating and stable SEIs by not just tuning the SEI composition, but also tuning the physical and chemical property of the electrolyte to minimize SEI dissolution even more effectively.

A Comparison of Solid Electrolyte Interphase Evolution on Highly Oriented Pyrolytic and Disordered Graphite Negative Electrodes in Lithium-Ion Batteries Joshua Russell[1], Haoyu Zhu[1], Zongtang Fang[2], Lan Li[1,3], Jeremy May[4], I. Francis Cheng[4], Paul H. Davis[1], Eric Dufek[2] and Hui Xiong[1,3]; [1]Boise State University, United States; [2]Idaho National Laboratory, United States; [3]Center for Advanced Energy Studies, United States; [4]University of Idaho, United States

During the initial cycling of lithium ion batteries (LIBs), the reaction of negative electrode with electrolyte will result in the formation of a thin film on the electrode surface. This film is referred to as solid electrolyte interphase (SEI), the stability of which is essential for practical LIBs. The most commonly used negative electrode material in LIBs is graphite, due to its low working potential for reversible lithium intercalation/deintercalation (≈0.1 V vs Li^+/Li), relatively high theoretical capacity of 372 mAh g^{-1},and good cycling stability. Previous studies have indicated that in graphite, the basal to edge plane ratio, particle size, pore size, degree of crystallinity and surface chemical composition affected the formation of SEI and its stability. The presence of defects in graphite is also a very important factor for SEI formation but has been rarely studied. Here, we investigated the SEI formation on an almost perfect graphite - HOPG (Highly Oriented Pyrolytic Graphite) - and a synthetic defective carbon film - GUITAR (pseudo-Graphite from University Idaho Thermolyzed Asphalt Reaction) - through operando electrochemical atomic force microscopy (EC-AFM). It was found that the defects on GUITAR promoted the electrolyte decomposition and SEI formation at a higher potential. Furthermore, the SEI particles evenly formed and densely packed on the GUITAR surface with a particle size of 172 nm ± 83nm and a thickness of about 60 nm. The SEI thickness on this defective electrode surface is three times of that on HOPG (about 20nm). It is also noteworthy that on HOPG, the formed SEI only partially covered the electrode surface, along with the graphite layer delamination from the step edge and bulging on the basal plane. This study showed direct evidence of how structural defects affect SEI nucleation and growth upon cycling.

Uncovering Nanoscale Factors of Graphite Solid-Electrolyte Interphase Formation— From Molecular Layers to 3D Nanoarchitecture Yue Chen[1,2], Wenkai Wu[3], Avishek Dey[4,2], Robert Palgrave[4,2] and Oleg V. Kolosov[1,2]; [1]Lancaster University, United Kingdom; [2]Faraday Institution, United Kingdom; [3]Swansea University, United Kingdom; [4]University College London, United Kingdom

The solid electrolyte interphase (SEI), a passivation layer formed on the battery electrode-electrolyte interface [1], defines fundamental battery properties - its capacity, cycle stability and safety. While understanding the SEI formation holds keys to these, such studies are complicated by the diversity of interlinked surface reactions and complex nanoarchitecture of the anode active material and electrical double layer (EDL) [2]. Such nanoarchitecture predetermines the electrolyte supramolecular interactions, electrical charge and ion transport therefore dominating the initial SEI formation. To date, the real space molecular arrangements of electrolyte solvents/anions inside the EDL and their effects on the SEI formation remain elusive [3].

In this work, we resolve this complex puzzle, using novel solid-liquid characterization tool with a nanoscale spatial resolution for accessing the whole evolution process from initial molecular-scale EDL structures, toward nanoscale 3D SEI structures. We introduce *in-situ* electrochemical 3D nanorheology microscopy (3D-NRM) [4] combined with magnetic excitation molecular-level solvation force spectroscopy and molecular dynamics simulations to explore a matrix of two morphologically dissimilar but chemically identical surfaces of typical carbon electrode material (basal and edge graphene planes) and different solvent-electrolyte systems (strong and weakly solvating electrolytes, as well as ionic liquid electrolyte). These approaches allowed us to get direct insight into the atomistic pictures for the underlying influence of cation's intercalation and solvation structures on the initial SEI formation.

We found that in the traditional ethylene carbonate (EC) based electrolyte, the strong coordination and co-intercalation of EC solvent dominate the electrolyte decomposition, causing the "swelling" of graphite carbon edge planes and thick SEI accumulations, confirming that SEI formation is graphite crystal plane dependent. At the same time, in the weakly solvation and ionic liquid electrolytes, where the first cation solvation sheath is occupied by the fluorine rich anion, the negatively polarized electrode surface builds up a unique and ordered EDL structure resulting in the preferential reductive decomposition of the anion and creating a highly sought after robust SEI layer. We also observe that the solvent/anion coordination structures with lithium/sodium cation within EDL vary from the bulk electrolyte, modifying the LUMO level of the electrolyte and affecting it electrochemical stability. Our understanding of these key interfacial structural factors in SEI formation allows targeting an electrochemically and mechanically robust surface passivation layer and guiding the development of efficient and safe rechargeable batteries.

Heterogeneous Damage and Network Evolution in Composite Electrodes of Li-Ion Batteries Kejie Zhao; Purdue University, United States

We assess the heterogeneous electrochemistry and mechanics in a composite cathode using synchrotron X-ray tomography, machine learning, and microstructure-resolved computational modeling. We visualize the morphological defects at multi-scales ranging from the macroscopic composite, particle ensembles, to individual single particles. Particle fracture and interfacial debonding are identified in a large set of tomographic data. The mechanical failure of active particles is highly heterogeneous. The difference originates from the polarization of the electrolyte potential, various local conducting environments, and thus the non-uniform distribution of the activation energy for the charge transfer reaction. We model the kinetics of intergranular fracture and interfacial degradation to assess the heterogeneous mechanical damage in composite electrodes. We quantify the influence of the mechanical damage on the metrics of battery performance. The mechanical failure disrupts the conduction path of electrons and results in significant polarization and capacity loss in batteries. More interestingly, the interfacial failure may reconstruct the conductive network and redistribute the electrochemical activities that render a dynamic nature of electrochemistry and mechanics evolving over time in the composite electrodes.

Mechanics of Fibre Debonding in Structural Battery Composites Kai Guo, Keith Foo, Bharathi M. Srinivasan and Sridhar Narayanaswamy; Institute of High Performance Computing, Singapore

The concept of providing power in the form of structural energy storage devices, for example structural supercapacitors and structural batteries, are a potentially viable strategy to achieve both high energy density and a load bearing structure. Structural battery composites, a subclass of composite materials, can provide mechanical integrity and energy storage capability simultaneously. A candidate architecture of a structural battery composite are carbon fibres embedded in an electrolyte matrix material. Mechanical failure mechanisms in structural battery composites are not yet well understood, especially when external mechanical loads are applied. We present modelling results for fibre debonding, a key failure mechanism in a structural battery composite made from carbon fibres and polyethylene oxide (PEO) matrix. We derive the energy release rate for fibre debonding under both electrochemical and mechanical loadings using the solution to the Eshelby's inclusion problem. We discuss the coupling effects of Li content in carbon fibres and external mechanical loads on fibre debonding and provide guidelines for reliable operation of the composite structure.

***In Situ* Optical Methods to Quantify Macroscopic Stress Developed on Electrode Materials During Lithiation** Mayukh Nandy, Todd Houghton, Haiwei Wu, Hongbin Yu and Candace Chan; Arizona State University, United States

With the advent of mobile electronics, the need for durable high energy density storage devices like lithium-metal batteries has surged many folds in recent times. To transform the electronics industry, this need must be met as more rigid, bulky devices are replaced by their thin, lightweight yet high-performance counterparts. However, the mechanical stress induced due to electrochemical deposition of Li on the surface of the current collector of lithium-metal batteries still remains a major area of concern, directly affecting the durability of the cell. In this paper, two novel non-contact in-situ techniques are used to characterize mechanical stress experienced by electrodes during Li electroplating. Optically transparent electrochemical cells were prepared with a soft Li metal sheet as the reference electrode and Cu coated PET sheet as the working electrode or current collector. Lithium hexafluorophosphate solution in ethylene carbonate and diethyl carbonate (1.0 M LiPF6 in EC/DEC=50/50 v/v) is used as the electrolyte. The first characterization method involves a camera setup to monitor the bending angle during charge and discharge cycles. The second technique uses the reflection of a helium neon laser beam off the shiny PET surface. The displacement of the reflected beam is observed and further quantified to obtain the change in bending angle. Both methods are sensitive to structural changes during lithiation. Before Li deposition, the cell is first activated using a LSV (linear sweep voltammetry) method at 5mV s-1 and the ending voltage is set to 0 V. During this process, a minor amount of Cu oxide layer on the surface of Cu coated PET is gradually lithiated and the Solid-Electrolyte Interphase (SEI) layer is formed, which is ready for inducing further Li metal deposition. The change in bending angle was recorded with and without the SEI layer formation. Other parameters like charge density, charge time, number of charge-discharge cycles, and idle time between cycles were varied to observe the difference in bending. The angle change is then used to quantify stress. This type of in-situ stress measurement method is particularly useful to test the reliability of electrodes in cells by studying the physical changes of those materials and their surfaces as they interact with lithium.

Revealing the Interaction of Li and Na in Layered Oxide Host by Synchrotron X-Rays and Scanning Transmission Electron Microscopy Grant Hill and Chong Liu; University of Chicago, United States

Insertion materials are key for electrochemical energy storage, but also have important applications in the areas of electrochemical ion separations, desalination, and catalysis. For ion separations, electrochemical extraction with layered cobalt oxides is a promising method for the separation of Li from Na-rich resources. However, the resulting composition and phase of the host material from co-insertion of cations and its relationship to Li separation performance has not been explored. Here, we developed a core-shell structured $(NaLi)_{1-x}CoO_2$ via non-Faradaic ion-exchange using parent $Li_{1-x}CoO_2$ with Na ions. Using synchrotron X-rays and scanning transmission electron microscopy, we reveal the phase separation of low vacancy Li-phase (core), high-vacancy Na-phase (shell), and intermediate phase. The spatial distribution and chemical composition of these phases play critical roles to the Li selectivity. Additionally, we investigate the relationship between alkali cation vacancy on the extent of ion-exchange. Using electrochemical intercalation, this material successfully extracted Li from 1:20,000 Li to Na solution to 7.6:1 Li to Na, which is a Li selectivity of 1.5×10^5 over Na. Therefore, this material has

potential application in Li extraction from seawater and other Li containing brines. Beyond application, heterogeneity characterization of ion-exchange and co-insertion processes allows for a deeper understanding of phase transformation and ion transport phenomenon in insertion materials. These insights may guide development of new materials for electrochemical ion separations, energy storage, and other applications.

3:45 PM CH03.11.05
Altering Ca2+ Solvation Dynamics at the Electrolyte/Electrode Interface with Cations and Anions Feipeng Yang[1], Kun Qian[1,2], Yang Ha[1], Zengqing Zhuo[1], Scott A. McClary[3], Ana Sanz-Matias[1], Nathan Hahn[3], David Prendergast[1], Kevin R. Zavadil[3] and Jinghua Guo[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]The University of Akron, United States; [3]Sandia National Laboratories, United States

Calcium, with its safe, economic, and nontoxic nature, is considered a promising candidate in multivalent battery technologies. It offers the promise of a more than two-fold increase in the volumetric capacity compared to the monovalent lithium-ion batteries. The understanding of the solvation and charge transfer mechanism at the electrolyte/electrode interface and how different types of cations and anions will affect the calcium solvation at this interface is the key to developing novel calcium batteries. To probe the Ca2+ coordination at the electrolyte/electrode interface as a function of the type of anions, total electron yield (TEY) mode soft X-ray absorption spectroscopy (XAS) sensitive to the interfacial speciation has been employed under operando electrochemical conditions. Meanwhile, total fluorescence yield (TFY) mode XAS is sensitive to bulk speciation. Calcium bis(trifluoromethanesulfonyl)imide (CaTFSI2) in tetrahydrofuran (THF) is an attractive electrolyte because of its oxidative stability and high solubility in various solvents. Combining calcium L-edge soft XAS with resonant soft X-ray scattering (RSoXS) through a patterned interface, the solvation and desolvation dynamics of calcium at the electrolyte/electrode interface was deciphered, and the influence of a second cation and anion were investigated. These in-situ/operando synchrotron-based spectroscopic and scattering characterization will answer the fundamental questions regarding the solvation and charge transfer at the electrode/electrolyte interface and benefit the future development of calcium-ion batteries.

SESSION CH03.12: Advanced Characterization of Li-Ion Batteries

8:30 AM *CH03.12.01
A Macro-to-Nano Zoom Through the Hierarchy of a Lithium-Ion Battery Yijin Liu; SLAC National Accelerator Laboratory, United States

Lithium-ion battery (LIB) is featured by structural and chemical complexities across a broad range of length scales and, ultimately, it is the hierarchy of the battery structure that determines its functionality. It worth highlighting that, the battery degradation is further complicated as the battery is integrated into and operated for powering a compact system. For example, in a set of commercial wireless earbuds, multiple lithium ion batteries in different forms are integrated and each one of them has to frequently interact with their peers, the battery management units (BMU), the printed circuit boards (PCB), microphones, sensors in the device. The study of the battery function, degradation, and failure mechanisms requires a thorough and systematic investigation from the structural, chemical, mechanical, and dynamic perspectives. X-ray-based characterization techniques are playing an important role in this research field.

In this talk, I will review my group's research activities over the past few years by presenting a macro-to-nano zoom through the hierarchy of a standard battery cell using a suite of state-of-the-art X-ray techniques. Damage, deformation, compositional and chemical heterogeneity at different length scales are visualized and are associated to different degradation phenomena and mechanisms. Our results highlight the importance of the battery cathode material's mechanical properties, which evolve upon battery cycling and could significantly impact both the immediate and the long-term cell behaviours. Finally, I will briefly discuss our recent efforts in conducting in-device battery failure analysis, which can provide valuable insights for the next-generation device design. I hope this presentation will ignite enthusiasm and ideas for future collaborations.

9:00 AM CH03.12.02
Synchrotron X-Ray Fluorescence Microscopy for Studying Materials Degradation in Rechargeable Batteries Yuxin Zhang[1], Anyang Hu[1], Luxi Li[2] and Feng Lin[1]; [1]Virginia Tech, United States; [2]Argonne National Laboratory, United States

The X-ray fluorescence microscopy (XFM) is a powerful technique that possesses the following advantages: (1) simultaneous detection of multiple elements with high sensitivity, favorably in the sub-ppm range; (2) sufficient spatial resolution; (3) capability of *in situ* measurements under operating conditions and (4) large-area scanning (μm to mm) to ensure statistical representativeness. It is widely applied in the biological and medical areas while receiving less attention in rechargeable batteries. Herein, using the aqueous batteries as a platform, we systematically demonstrate the application of XFM in the battery field. The ex-situ measurements can inform the degradation issues of traditional cathode materials ($LiFePO_4$, $LiMn_2O_4$, and $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$) in different electrolytes and quantify the dissolved transition metals (TM) during electrochemical cycling, establishing the correlation between TM dissolution and electrochemical performance. On the other hand, the in-situ experiments can unravel the spatiotemporal evolution of TM in the electrodes and electrolytes upon cycling. Therefore, we are able to use the home-designed in situ cell to directly investigate the electrode-electrolyte interfacial reactions. For example, the evolution of the diffusion layer formed by TM dissolution can be visualized under different electrochemical protocols, and the dissolution/redeposition dynamics of TM can be revealed at the single-particle resolution and electrode-scale statistical analysis. The present work shows the capabilities of XFM in the rechargeable battery field and potentially serves as a guideline for future XFM-related studies.

9:15 AM CH03.12.03
Lithium-Ion Battery Electrode Manufacturing Model Using X-Ray Computed Tomography Characterization Data Jiahui Xu[1,2], Alain C. Ngandjong[1,2], Chaoyue Liu[1,2], Franco M. Zanotto[1,2], Oier Arcelus[1,2], Arnaud Demortiere[1,2,3] and Alejandro A. Franco[1,2,3]; [1]Laboratoire de Réactivité et Chimie des Solides (LRCS), UMR CNRS 7314, France; [2]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), FR CNRS 3459, France; [3]ALISTORE-European Research Institute, FR CNRS 3104, France

Nowadays, in face of the increasing need for lithium-ion batteries (LIBs), how to achieve higher energy densities while maintaining or reducing costs has been widely studied. To achieve optimization of the performance of batteries, it is essential to understand the influence of parameters at each stage of the LIBs manufacturing process on the architectures of the electrodes, which affects the energy, power, lifetime and safety of the LIB cells.
Non-destructive techniques, such as X-ray computed tomography (XCT), are widely used to obtain the microstructure of electrodes, enabling volume-based 3D characterization. However, the characterizing the spatial location of the carbon binder domain (CBD) in the electrode volume is challenging due

to the nano-features and the similarities between X-ray attenuation coefficients of carbon and pores. Extensive works have been done recently to improve the characterization of CBD, such as combining separate scans of high-attenuating $LiNi_xMn_yCo_{1-x-y}O_2$ (NMC) and low-attenuating CBD[1], using X-Ray holographic nano-tomography[2], and using convolutional neural network-based image segmentation methods[3].
The ARTISTIC project[4], funded by the European Research Council, aims at developing a digital twin that enables predicting the electrode architectures and their electrochemical performances from the parameters used at each stage of the LIBs manufacturing process. Such a digital twin is supported by a combination of multiscale modeling[5-9] and machine learning (ML)[10]. In this work, we present our new computational approach to simulate the manufacturing process of cathodes by taking into account CBD and the realistic shape of $LiNi_{0.33}Mn_{0.33}Co_{0.33}O_2$ (NMC111) active material particles obtained by X-ray micro-computational tomography (µ-XCT)[11]. Our methodology encompasses coarse-grained molecular dynamics (CGMD) to simulate the different manufacturing stages, from the slurry, to the drying and the calendering of the resulting electrodes. The µ-XCT data is segmented through a Random Forest algorithm available in the Image J Trainable Weka segmentation plugin to extract the active material (AM) phase. Then a Watershed-based algorithm is used to separate the individual secondary particles. The input of CGMD model is prepared by substituting the down-sampled voxels of the individual particles by spherical primary AM particles with equivalent volume. The new model captures the variation of the electrode microstructure in the manufacturing process from the particle scale, and the effect of the manufacturing parameters on the electrode heterogeneity. We discuss the changes in porosity, tortuosity factor, electronic conductivity, different phases distribution and pore network during the calendering process and compare them with the µ-XCT results, which show reasonable agreements. In addition, our approach allows capturing the deformation of the secondary particles during the calendering process, as well as their possible variation of orientation.

Characterization and Modeling of NMC Particle Architectures Donal Finegan; National Renewable Energy Laboratory, United States

The sub-particle architecture of LiNixMnyCozO2 (NMC) considerably influences the performance of electrodes in Li-ion batteries, yet quantifying sub-particle properties and identify favorable particle architectures remains extremely challenging. In this presentation, progress towards quantifying sub-particle properties that are relevant to the electrochemical and mechanical performance of NMC particles will be covered. Techniques include using accessible and high-throughput 2D electron backscatter diffraction (EBSD) and 3D focused ion beam (FIB) EBSD to quantify the morphology and orientations of sub-particle crystallographic grains. Furthermore, using image-based NMC particle architectures, continuum-level models were developed to spatially and temporally resolve mechanical strain within NMC particles as the morphology of sub-particle grains evolves during lithiation and delithiation. A range of different image-based particle architectures with varying particle size and grain size were explored via continuum level models and the influence of sub-particle architectures on the life and high rate performance of electrodes is clarified.

9:45 AM BREAK

10:15 AM CH03.12.05
Study of Heterogeneous Aging Inside Different Pouch Cell Formats with Equal Chemistry (NMC 622/ Graphite + Silicon) and Operando Monitoring of the Aging Mechanisms Alexia Bichon, Sylvie Geniès, Philippe Azaïs, Didier Buzon, Sébastien Fiette and Olivier Raccurt; Université Grenoble Alpes, France

Lithium-ion batteries (LIBs) present a major challenge for the coming decade as they could be massively implemented in the EVs in order to replace combustion engines. Although they have been extensively studied, some issues remain, particularly with regard to fast charging and the resulting aging mechanisms. When it comes to the choice of electrode materials, compromises must be made between high energy density, safety and fast charging capability. In order to get performant batteries in these three topics, a better understanding of cell behavior at all scales is needed.

The objective of our study is to understand the impact of the cell format on the development of non-uniform aging [1] by establishing links between different scales: materials, electrodes and cell. There are currently several cell formats on the market ranging from a few mAh to several Ah, packaged in flexible or hard cases and with the electrodes stacked or wound. In order to control the different parameters that can influence the aging, we chose to manufacture the electrodes (NMC 622 (LiNi0.6Mn0.2Co0.2O2) / Graphite + 10% SiOx) and the cells in our lab. By doing this we were able to know the precise chemistry of the electrodes and electrolyte, and to assemble them in the formats we desired. Two different formats were studied: one with a single layer pair of electrodes of 30 mAh and another one, a multi-layer stack of 500 mAh. Having the same chemistry allows for comparison of aging behaviors [2] with minimal influencing parameters, except for cell design. The cells experienced the same protocols at different C-rates and different temperatures and were stopped at different state of health (SoH).

We monitored electrochemical responses of both positive and negative electrodes independently with a reference electrode, allowing the operando follow-up of the aging behaviors. One of the main concerns with LIBs aging is the growth of lithium plating, which is the metallic deposition of lithium ions on the surface of the negative electrode. The growth of lithium dendrites is a major safety issue because they can pass through the separator and create an internal short-circuit in the cell, causing a thermal runaway that can set the battery on fire. Therefore, following the negative electrode potential is crucial to determine the conditions of apparition of lithium plating. We noticed that the depth of discharge of the previous cycle highly influences the next charging profile of the negative electrode. That could bring an explanation about the sudden decrease in capacity observed frequently after the checkup cycles at low current in discharge performed regularly during the cycling test and used to evaluate the effective capacity.

We performed post-mortem analyses in order to correlate electrochemical response of each electrode, capacity fade, and local heterogeneous degradation mechanisms. Using visual inspection, surface analysis techniques such as EDS and XPS, impedance spectroscopy and XRD mapping, we tracked lithiation and degradation heterogeneities at different scale levels: material, electrode and cell.

Origin of Structural Degradation in Li-Rich Layered Oxide Cathode Tongchao Liu and Luxi Li; Argonne National Laboratory, United States

Li and Mn-rich cathode materials (LMR) that utilize both cation and anion redox can yield substantial increases in battery energy density. However, even though voltage decay issues cause continuous energy loss and impedes its commercialization, prerequisite driving force for this phenomena is a mystery. Here, with *in-situ* nanoscale sensitive coherent X-ray diffraction imaging (BCDI) techniques, we reveal that nanostrain and lattice displacement accumulate continuously during cell operation. Evidence unequivocally shows that this effect is the driving force for both structure degradations and oxygen loss that triggers the well-known rapid voltage decay in LMR. By further leveraging micro to macro length characterizations that span atomic structure, primary particle, multi-particle and electrode level, we demonstrate that the heterogeneous nature of LMR cathodes inevitably causes pernicious phase displacement/strain which cannot be eliminated by conventional doping or coating methods. These results affirm that lattice displacement and nano-strain, which represent commonly occurred but less detectable dynamic structure evolutions, play an undeniable role in structure decomposition and voltage fade. With these fundamental discoveries, we propose mesostructural design as a strategy to mitigate lattice displacement and inhomogeneous electrochemical/structural evolutions, thereby achieving stable voltage and capacity profiles. These findings highlight the significance of lattice strain/displacement in causing voltage decay and will inspire a wave of efforts to unlock the potential of the broad-scale commercialization of LMR cathode material.

10:45 AM CH03.12.09
Developing Operando Liquid-State NMR Spectroscopy of the Electrolyte Inside an Operating Li-Ion Battery to Follow Its State of Charge Khashayar Bagheri[1,2], Vincent Sarou-Kanian[1,2], Michael Deschamps[1,2] and Elodie Salager[1,2]; [1]CNRS, CEMHTI UPR3079, Université d'Orléans, France; [2]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), FR CNRS 3459, France

Electrochemical energy storage devices, such as Li-ion or Na-ion batteries, supercapacitors, or hybrid capacitors, are essential for the energy transition. The entire device characterization (*In situ*) is one of the key elements to obtaining a global understanding of the charge and degradation processes. Nuclear Magnetic Resonance (NMR) spectroscopy is one of the techniques of choice thanks to its ability to detect, non-destructively and with atomic selectivity, the liquid, semi-liquid, crystalline, and amorphous contents of the sample.

Operando NMR spectroscopy of Li-ion batteries is challenging due to the strong heterogeneity of the battery, which results in broadening and distortions of the NMR spectrum. Up to now, most Operando NMR studies used ^{7}Li NMR spectroscopy to follow lithiation and degradation processes of electrodes displaying highly shifted peaks (lithiation of graphite and silicon, lithium plating). Although the liquid electrolyte located inside the battery provides a narrower and stronger In situ NMR signal, it has not been fully exploited until now.

We will present our efforts to use the liquid ^{1}H NMR signal of the electrolyte solvent (ether carbonates) to "spy" on the electrodes while benefitting from the higher sensitivity of ^{1}H NMR compared to ^{7}Li NMR. Contrary to lithium atoms, hydrogen atoms in the electrolyte solvent are not a direct probe of the state of charge of the electrode. The ^{1}H NMR spectrum of the electrolyte is however highly sensitive to heterogeneities and interfaces in the battery, especially at the interface with the electrodes.

We demonstrate that the strongly distorted ^{1}H NMR spectrum of dimethyl carbonate (DMC) in the battery can be used to track the state of charge of the electrodes. A careful analysis of the effect of battery components such as current collectors, separators, and electrodes with various states of charge will be presented. It provides a framework and descriptors for characterizing the distortion of the electrolyte ^{1}H NMR spectrum arising from the electrodes, with the goal to apply this technique for fast Operando NMR characterization of operating batteries.

11:00 AM CH03.12.10
1D Magnetic Resonance Imaging, High Resolution 2D and Spin Counting Nuclear Magnetic Resonance for Batteries Michael Deschamps[1,2], Elodie Salager[2] and Vincent Sarou-Kanian[2]; [1]University of Orleans, France; [2]CNRS, France

In batteries and supercapacitors, the variation of lithium concentration profiles can be probed with *operando* 1D magnetic resonance imaging (MRI) of spin bearing atoms, while limiting the signal losses stemming from short relaxation times and broad lines in static systems. In such cases, one can observe interesting effects pertaining to the electrode porosity.[1] In model systems with materials displaying low diamagnetic susceptibilities, pulsed-field-gradient diffusion measurements shows the negative effect of carbon black addition on lithium ion self-diffusion.[2]

High-resolution Magic Angle Spinning NMR, on the other hand, can be performed on a wide variety of materials, and provide a wide range information on many atoms such as ^{7}Li or ^{6}Li, ^{23}Na and 2D correlation experiments can provide information on defects or phase separation in battery materials.[3]

Moreover, in favorable systems such as lithium titanates, it has been shown that surface fluorination with XeF_2 greatly improves the electrochemical properties. In such systems, high resolution MAS-NMR can help quantify the amount of fluorine in the structure, and the ^{19}F chemical shift analysis yields information on the fluorine environment. Moreover, spin counting strategies based on HMQC experiments can provide the number of fluorine atoms which are coordinated to lithium ions and help understand what kind of structures are created locally upon fluorination.[4]

Origin of Particle Evolution in SnO_2/ZnO Core/Shell NW-Based Lithium-Ion Battery Anodes Jasmin-Clara Bürger[1], Serin Lee[2], Sebastian Gutsch[1], Jan Büttner[1,1,1], Anna Fischer[1,1,1], Frances M. Ross[2] and Margit Zacharias[1]; [1]University of Freiburg, Germany; [2]Massachusetts Institute of Technology, United States

Oxide-based active core/shell heterostructures as Lithium-ion battery anode materials, such as the combination of tin oxide (SnO_2) and zinc oxide (ZnO), are known for their improved charge rate and real (measured) specific capacity compared to those of the individual, uncombined materials, due to synergetic effects. In this study, SnO_2/ZnO core/shell nanowires (NWs) with varying ZnO coating thickness are analyzed before and after charge/discharge chronopotentiometry. As well as standard electrochemical analysis, structural and compositional measurements were made using scanning electron microscopy and transmission electron microscopy of as-prepared and post-mortem SnO_2/ZnO core/shell NWs. For small cycle numbers, including the first charge/discharge step and a small number of subsequent cycles, the microscopy techniques revealed a pronounced morphological change in which the straight nanowires converted to a wirelike assembly of connected nanoparticles with increasing ZnO coating thickness of the SnO_2/ZnO core/shell NWs. This behavior was not observed for uncoated SnO_2 NWs, which retained a recognizable NW structure after cycling. Thus, the structural changes known to occur during cycling are not solved by the NW-based morphology, although the material does not fully pulverize. By electron diffraction and scanning transmission electron microscopy-energy dispersive x-ray spectroscopy, the particles formed were investigated crystallographically and compositionally. We discuss these observations in terms of the elemental distribution and lithiation reactions of the materials involved and the possible strategies for optimizing electrical properties and cycling behavior. We also compare the results to the cycling behavior of NWs with different coating materials.

2:00 PM CH03.13.02
Structural and Chemical Evolution in Metastable Niobates During Li-Ion Battery Cycling Kausturi Parui and Megan M. Butala; University of Florida, United States

Electrochemical energy storage systems, such as rechargeable intercalation batteries, are a reliable and efficient medium of portable energy storage, enabling portable electronics and electric vehicles. Intercalation batteries operate on the basic principle that during discharge (delivery of energy), cations (in our case, Li-ions) diffuse along the chemical potential gradient, and during charge these cations diffuse uphill against the chemical potential gradient. Hence, the performance of the battery depends upon the reversible insertion/extraction of a charged species. Niobium oxides, including their Wadsley-Roth phases, have recently drawn interest for intercalation electrodes. Depending upon synthesis conditions, various stable and metastable polymorphs of Nb_2O_5 can result. With an interest in understanding the underlying storage mechanisms, such as those related to their ionic diffusion and capacity, we have used diffraction and total scattering to characterize their initial structures and cycling products. The knowledge of these underlying mechanisms can inform electrode design, including lowering energy barriers along diffusion pathways and mitigating disadvantageous structural changes.

Suppression of Segregated Species in Solid Oxide Fuel and Electrolysis Cell by Infiltration of Hf—Enhanced Activity and Stability Sanaz Koohfar[1], Tyler Hafen[2], Jenna Pike[2], Elango Elangovan[2] and Bilge Yildiz[1]; [1]Massachusetts Institute of Technology, United States; [2]Oxeon Energy, United States

Perovskite oxide solid oxide fuel and electrolysis cells (SOFC/SOEC) are one of the most promising energy storage/conversion devices. Solid oxide electrochemical cells have the advantage of fuel flexibility, lower carbon emission, and high efficiency due to high-temperature operation (800 C) which makes SOFC/SOEC more favorable compared to conventional electrolysis devices. However, the operational stability of SOFC/SOEC stands as a major obstacle to the commercialization of these devices. $La_{1-x}Sr_xCo_{1-x}Fe_xO_3$ (LSCF) is commonly used in solid oxide electrochemical cells as the oxygen electrode because of the high ionic and electronic conductivity that are essential for oxygen exchange reactions. The high efficiency of LSCF oxygen electrode suffers from degradation over a long period of operation in both fuel and electrolysis modes. Segregation of A-site cation Strontium (Sr) and Lanthanum (La) on the surface of LSCF perovskite electrode has shown to be one of the main factors hindering the long-term stability of these devices. It has been shown that the segregation of Sr and La blocks the active sites which are vital for oxygen exchange.
In this work, we show that the stability and activity of porous LSCF perovskite oxide are enhanced by infiltration Hafnium (Hf) through a quantitative electrochemical impedance spectroscopy measurement. An increase in stability of LSCF is directly correlated with the suppression of Sr and La on the surface of LSCF. We use a three-electrode configuration to study the evolution of cathode and anode independently in a symmetric cell of LSCF in ambient air at 800° C. X-ray photoelectron spectroscopy (XPS) and electrochemical impedance spectroscopy (EIS) are used to quantitively measure oxygen exchange activity and surface chemistry concentration ratios of LSCF as a function of applied polarization. Our results show a significant improvement in oxygen exchange reactions that lead to enhanced activity and stability of LSCF over 300 hours of operation.

3:15 PM CH03.14.02
Probing the Catalytically Active Region in a Nanoporous Gold and Copper Gas Diffusion Electrode to Enhance Highly Selective Carbon Dioxide Reduction Aidan Q. Fenwick[1], Alex Welch[1], Xueqian Li[1], Ian Sullivan[1], Joseph DuChene[2], Chengxiang Xiang[1] and Harry A. Atwater[1]; [1]California

Institute of Technology, United States; [2]University of Massachusetts Amherst, United States

We report the use of a nanoporous gold (np-Au) catalyst for CO2 reduction in a gas diffusion electrode (GDE) and characterize the role of wetting in electrochemical performance. The np-Au catalyst has pores on the order of 20 nm and is crosssectionally isotropic, enabling Faradaic efficiencies for CO of greater than 95% across a wide range of potentials and a maximum partial current density for CO of 168 mA/cm2. Secondary ion mass spectroscopy and in-situ copper underpotential deposition were employed to provide insights into catalyst wetting. At a typical CO2 flow rate of 50 SCCM, approximately half of the catalyst is in contact with the electrolyte during operation and the dry region exists in the bottom half of the nanoporous catalyst. We discuss implications of the nanoporous GDE wetting characteristics for catalyst performance and the design of improved GDE architectures that can maximize the catalytically active area. An analogous nanoporous copper (Np-Cu) catalyst was prepared by electron beam vapor deposition of Cu/Al followed by selective chemical etching of the Al. The morphology and catalyst stability under applied potential were studied before and after electrolysis.

3:30 PM CH03.14.03
X-ray Nano-Imaging of Defects in Thin-Film Catalysts via Cluster Analysis Aileen Luo[1], Oleg Y. Gorobtsov[1], Jocienne Nelson[1], Ding-Yuan Kuo[1], Tao Zhou[2], Ziming Shao[1], Ryan Bouck[1], Mathew J. Cherukara[2], Martin Holt[2,2], Kyle M. Shen[1,3], Darrell Schlom[1,3,4], Jin Suntivich[1] and Andrej Singer[1]; [1]Cornell University, United States; [2]Argonne National Laboratory, United States; [3]Kavli Institute at Cornell for Nanoscale Science, United States; [4]Leibniz-Institut für Kristallzüchtung, Germany

Functional properties of transition-metal oxides strongly depend on crystallographic defects; crystallographic lattice deviations can affect ionic diffusion and adsorbate binding energies. Scanning x-ray nanodiffraction enables imaging of local structural distortions across an extended spatial region of thin samples. Yet, localized lattice distortions due, for example, to line defects remain challenging to detect and localize using nanodiffraction, due to their weak diffuse scattering. Here, we apply an unsupervised machine learning clustering algorithm to isolate the low-intensity diffuse scattering in as-grown and alkaline-treated thin epitaxially strained $SrIrO_3$ films. We pinpoint the defect locations, find additional strain variation in the morphology of electrochemically cycled $SrIrO_3$, and interpret the defect type by analyzing the diffraction profile through clustering. Our findings demonstrate the use of a machine learning clustering algorithm for identifying and characterizing hard-to-find crystallographic defects in thin films of electrocatalysts and highlight the potential to study electrochemical reactions at defect sites in operando experiments.

3:45 PM CH03.14.04
MOF Promoted Ternary Transition Metal Chalcogenide Embedded Carbon Fabric for Ultra-Long Life Flexible Energy Storage Application
Roshan M. Bhattarai, Shirjana Saud and Young S. Mok; Jeju National University, Korea (the Republic of)

Flexible-portable electronic devices have been deemed the future of innovative electronics. Due to the nature of such electronics, conventional power sources may no longer fulfill their physical and/or electrochemical necessities; hence, innovation in flexible power sources is a crucial requirement. Herein, we realized an ultrastable flexible electrode that can be used in various energy storage applications such as supercapacitors and batteries. Firstly, the flexible and conductive carbon fabric was electrochemically deposited with a nickel nanoseed layer (Ni/CC). Then, the ZIF-67 organometallic framework (MOF) nanostructures were grown over the Ni/CC substrate. As grown, nanostructures were then embedded inside the carbon fabric strands through a precise optimization process of varying the calcination temperature and gas concentrations. The Ni-Co-C co-embedded carbon fabric was then sulfurized via a series of carefully optimized hydrothermal conditions. Thus obtained metal sulfide embedded carbon fabric shows an excellent capacity when tested as a supercapacitor electrode in a three-electrode configuration. Moreover, when paired with the biomass-derived activated carbon, the asymmetric supercapacitor device shows almost 100 % of capacity retention even after 40 thousand charge-discharge cycles. Furthermore, several bending and twisting cycles were run to examine the integrity of the active material and no discernible capacity fading is observed. Hence, a unique metal chalcogenide composite electrode/substrate configuration has been proposed as a highly stable electrode material for flexible energy storage applications.

4:00 PM CH03.14.05
Strategic Tuning Of 2D Transition Metal Oxynitride System for Electrochemical Charge Storage Jacob Som[1], Manosi Roy[1], Kaushik Sarkar[1], Brooke Smith[1], Darrah Dare[2], Xiaochuan Lu[3] and Dhananjay Kumar[1]; [1]North Carolina Agricultural &Technical State University, United States; [2]Cornell University, United States; [3]North Carolina Agricultural & Technical State University, United States

Electrocatalytically highly active titanium oxynitride (TiNO) thin films were fabricated using a pulsed laser deposition method for energy storage applications. The elemental composition and nature of bonding were analyzed using x-ray photoelectron spectroscopy (XPS) to reveal the reacting species and active sites responsible for the enhanced electrochemical performance of the TiNO electrodes. A study of the SEM images before and after electrochemical cycling showed a negligible degradation of TiNO sample, suggesting the TiNO electrodes are stable under the cycling conditions. Symmetric supercapacitor devices were fabricated using two TiNO working electrodes separated by ion transporting layer to analyze their real-time performance. The galvanostatic charge-discharge studies on the symmetric cell, fabricated using TiNO films deposited at 300 °C, exhibited the highest specific capacity of 69 mF/cm^2 at 0.125 mA/cm^2 with an energy density of 7.5 Wh/cm^2. The performance of this supercapacitor (300 ºC TiNO) device is found to be ~ 22 % better compared to that of 500 ºC TiNO supercapacitor with a capacitance retention ability of 95% after 1000 cycles. The thin film fabrication temperature can be employed as a simple and effective tuning strategy to rationally modulate the morphology and the structure of the thin film to achieve a high charge storage performance.

Spatiotemporal Pattern of Lithiation State in 18650-Type Cell Observed by Compton Scattering Spectroscopy Kosuke Suzuki[1], Naruki Tsuji[2], Kirsi Jalkanen[3], Jari Koskinen[3], Kazushi Hoshi[1], Ari-Pekka Honkanen[4], Hasnain Hafiz[5], Yoshiharu Sakurai[2], Mika Kanninen[3], Simo Huotari[4], Arun Bansil[6], Hiroshi Sakurai[1] and Bernardo Barbiellini[7,6]; [1]Gunma University, Japan; [2]Japan Synchrotron Radiation Research Institute (JASRI), Japan; [3]Akkurate Oy, Finland; [4]University of Helsinki, Finland; [5]Carnegie Mellon University, United States; [6]Northeastern University, United States; [7]LUT University, Finland

Compton scattering technique is a unique technique to visualize the lithiation state on commercialized lithium-ion cells in-situ and in-operando. This technique characterized by high-energy synchrotron X-rays allows a non-destructive observation of a reaction in closed electrochemical cells and enables

analysis quantitatively of the concentration of the lithium. In this study, the Compton scattering technique is applied to a 18650-type cylindrical lithium-ion cell and observed a spatiotemporal pattern of lithiation state, called Turing pattern [1].
The Compton scattering was carried out at the high-energy inelastic scattering beamline BL08W of the SPring-8. X-rays that were monochromatized to 115.56 keV were used. Compton scattered X-rays were measured by Ge solid-state detector. The scattering angle was fixed to 90 degrees. The state of charge of the sample cell was controlled using a potentiostat/galvanostat.
By analyzing obtained Compton scattered X-ray energy spectrum, the change of lithiation state in both the cathode and anode with the charge-discharge cycle is observed and the position of each component of the cell is shifted during the charge is visualized. Moreover, we observed lithiation state oscillation patterns by a depth-resolved analysis of the cathode electrode. This oscillation corresponds to the timescale of the charging curve and the dominating wavelength of the oscillation is related to the size of the grains of the active material. The reason for the appearance of this lithiation oscillation is due to the different mobilities of lithium ions and electrons. Therefore, the existence of the lithiation oscillation implies that the cell can have an optimal cycle speed with a more homogeneous flow of ions.

8:15 AM *CH03.15.02
Solid-State NMR/MRI Studies of Heterogeneities in Solid-State Batteries Yanyan Hu; Florida State University, United States

Heterogeneities in solid-state batteries affect ion/electron transport and microstructure formation. Solid-state NMR is sensitive to heterogeneities of local structures and dynamics on the atomic, nano-, and meso-scale. Therefore, we have employed advanced NMR spectroscopy and relaxometry to understand how structural heterogeneity affects ion dynamics and transport properties. In addition, heterogeneities on the mesoscale such as at electrode-solid electrolyte interfaces and around grain boundaries promote microstructure formation, which limits critical current densities thus power densities of solid-state batteries. Magnetic resonance imaging combined with tracer-exchange NMR probes how these heterogeneous features evolve under external stimuli and how they affect Li microstructure formation with both spatial and temporal resolution.

8:45 AM CH03.15.05
Study of the Lithium-Plating Phenomenon by *Operando* Nuclear Magnetic Resonance Characterization and Simulation of the Phenomenon for the Optimization of Li-Ion Battery Fast Charge Abdelmounaim Akchach[1,2], Sylvie Geniès[2], Marion Chandesris[2], Alexis Martin[2] and Michel Bardet[3]; [1]Université de Grenoble Alpes, France; [2]CEA-LITEN Grenoble, France; [3]CEA-IRIG Grenoble, France

Li-ion batteries (LIBs) are now ubiquitous in our daily lives and are of tremendous importance for our society, with applications ranging from small electronic devices to electric vehicles, but their limited lifetime still presents a great challenge for the generalization of transport electrification; they must be able to accept fast charges, even at low temperatures. However, during charge process at these conditions, formation of metallic lithium on the surface of the negative electrode made of graphite can occur and accelerate the capacity loss of the battery and thus the autonomy of the vehicle. On the other hand, the deposition of lithium metal being rather on the surface of graphite, the interface with the separator has its importance. It has been observed that the pores of the separator can become clogged, blocking the passage of ions and creating local polarizations. In addition, if lithium metal grows in the form of dendrites, the separator can be perforated, which can lead to an internal short circuit in the battery. This degrading mechanism known as Lithium- plating is therefore a key research axis to extend the life of batteries.

Therefore, a more global understanding, in real time, of this phenomenon and its kinetics in function of the local conditions within the negative electrode in a functional lthium-ion cell is needed. In order to develop this understanding, it is crucial to perform operando analytical measurements on a working cell that allow monitoring different states-of-charge (SOC) repeatedly, in principle throughout their life cycle, giving access to a multitude of analytical data compared to a single ex-situ or post mortem analysis. In our study, we perform measurements by ^{7}Li *operando* Nuclear Magnetic Resonance (NMR) on practical configuration: $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ (NMC811)/graphite pouch cells made with industry-grade electrodes and under realistic cycling conditions. This non-invasive and non-destructive technique, is sensitive to both structure and dynamics. The ^{7}Li NMR signal of Li ions in graphite electrode was recorded during electrochemical cycling over a wide range of rates enabled us to analyse intercalation processes in the electrode, changes of Li-ion mobility, and Li metal deposition on graphite at high current rate due to an inhomogeneous distribution of ions induced by limitation of diffusion on solid and liquid phases. In our operando experiments, with a CC fast charge and a subsequent CV period at 4.2 V, Li deposition starts at around 3.5 V well before the full lithiation of graphite and continues even during the voltage floating. At the end of the CV phase, and due to the drop of the current, the lithium plating starts to interact with its environment by intercalating in the graphite structure or reoxidizing during the following discharge to transform into cyclable lithium.

Another method used to detect the lithium plating is the anode potential measurement through a reference electrode. This method allows us to precisely measure the potential of each electrode rather than following the evolution of the cell voltage. Thermodynamically, anode lithium plating occurs when the anode potenital drops below 0 V (vs Li^{+}/Li). Therefore, by performing *operando* NMR measurements with instrumented cells, we monitor the anode potential which allows the lithiation of the graphite electrode and the apparition of lithium plating to be correlated.

The experimental results are used to implement and validate a multi-physics Newman-based model at the scale of the electrode. It allows varying all the influential parameters and model the evolution of discharge capacity loss, sudden capacity loss, and capacity recovery via physics-based mechanisms on the performance model. These different contributions will be more detailed on the presentation.

Thermodynamic Analysis on a Formation Mechanism of Metastable Carbides During Tempering of Fe-C Martensite Masanori Enoki[1] and Hiroshi Ohtani[2]; [1]Tohoku University, Japan; [2]Toyota Physical and Chemical Research Institute, Japan

The steels obtain quite hard microstructures by martensitic transformation, however, as-quenched martensites cannot be used industrially because of their brittleness. Therefore, a heat treatment called 'tempering' is applied to improve the balance between strength and toughness. During the tempering process, various metastable carbide precipitates are formed with temperature increasing, and their dispersion in the microstructure has a significant influence on the strength of the steel. Therefore, extensive research has been conducted on metastable carbides in this system, however, it is hard to observe the details of metastable carbides by experiment because of the microscopic nature of precipitates in the early stage of aging. Moreover, the reason why precipitates having higher carbon concentration such as η-carbide (Fe_2C) are formed before more stable cementite (Fe_3C) has not been fully considered. For this reason, in this study, thermodynamics analysis based on first principles calculations was applied to reveal the behavior of solid-solution carbon in the matrix during the preliminary stage of the tempering process and the formation mechanism of η–carbide and cementite.

To clarify the thermodynamic behavior of carbon during the preliminary stage of tempering of martensite, structure models were constructed in which carbon occupies three octahedral interstital sites (denoted as a-site, b-site, and c-site) in BCT-Fe and BCC-Fe. Using these models, the cluster expansion and variation method was applied to evaluate the free energy of formation of solid solutions. Furthermore, the thermal equilibrium distribution of carbon was obtained by Monte Carlo simulation using the effective cluster interactions obtained by cluster expansion method. From the atomic arrangement obtained by this method, the clustering of carbon was observed, and the transition to metastable carbides was investigated from the ordered structure obtained by extracting the clustering region. The nudged elastic band (NEB) method was applied to evaluate the energy barrier in the transition process.

The Monte Carlo simulations for BCT-Fe and BCC-Fe showed well-defined clustering of carbon atoms. Furthermore, the free energies evaluated by the cluster expansion and variation method showed two-phase separations between Fe and Fe_2C compositions, suggesting that these clusters are formed by two-phase separation based on ordering. Two different carbon clusters were identified between BCT-Fe and BCC-Fe. In this study, the energies of transformation from these clusters to η-carbide were further determined from the NEB method. The carbon configuration formed in BCC-Fe resulted in a transition to η-carbide with no energy barrier. On the other hand, in BCT-Fe, the energy barrier of phase transition was found to be comparable to the diffusion energy barrier of carbon atom. The energy barrier values of transition process calculated by the NEB method were compared, and the series of processes for metastable carbide formation was considered as follows. The η-carbide preferentially precipitates at the beginning of tempering, and cementite is newly formed at a higher temperature stage with the rearrangement of carbon atoms. Furthermore, because the barrier energies of Fe lattice deformation obtained from NEB calculations are small, we also argue that the diffusion of carbon atoms plays an important role in the formation of metastable carbieds.

11:15 AM DS01.01.03
Uncertainty Reduction and Quantification in Computational Thermodynamics Richard Otis; NASA Jet Propulsion Laboratory, United States

Uncertainty quantification is an important part of materials science and serves a role not only in assessing the accuracy of a given model, but also in the rational reduction of uncertainty via new models and experiments. In this contribution, recent advances and challenges related to uncertainty quantification for Calphad-based thermodynamic and kinetic models are discussed, with particular focus on approaches using Markov chain Monte Carlo sampling methods. General differentiable and probabilistic programming frameworks are identified as an enabling and rapidly-maturing new technology for scalable uncertainty quantification in complex physics-based models, including those for Calphad. Special challenges for uncertainty reduction and Bayesian design-of-experiment for improving Calphad-based models are discussed in light of recent progress in related fields.

11:30 AM DS01.01.04
Uncertainty Driven Computational Thermodynamics Noah H. Paulson and Joshua Gabriel; Argonne National Laboratory, United States

In computational thermodynamics, statistics and uncertainty quantification are critical for evaluating the confidence in predictions and models with substantial potential for impact on materials development and qualification. The role for statistical techniques, especially Bayesian analysis, is not limited to obtaining uncertainty intervals on phase boundaries. These methods can drive the development of selection criteria for the best combinations of datasets and thermodynamic descriptions that support each other for a given material system. We present the results of such uncertainty driven investigations into thermodynamic model development for unary and binary metallic systems. Specifically, we share statistical approaches to Bayesian model selection, parameter inference, uncertainty quantification/propagation, and the automated weighting of both experimental and computed datasets. This will be accompanied by a discussion of the use of statistical techniques in thermodynamics to inform critical design choices and gleaning scientific insights.

SESSION DS01.02: Metastability

1:45 PM DS01.02.01
Predicting and Accessing Metastable Phases Vancho Kocevski, James A. Valdez, Benjamin K. Derby, Yongqiang Wang, Ghanshyam Pilania and Blas Uberuaga; Los Alamos National Laboratory, United States

Metastable forms of matter are invaluable to our everyday lives, from advancing technology to understanding biological processes, with their unique properties often offering novel functionality. Despite their importance, synthesizing metastable phases is more art than science, often either serendipitous or trial-and-error. Insight into the amount of stored energy needed to form a metastable phase can aid in their fabrication. Here, we calculate metastable phase diagrams, from which we extract the metastability threshold – the excess energy stored in the metastable phase relative to the ground state. Using lanthanide sesquioxides (Ln_2O_3) as a case study, we demonstrate how metastable phase diagrams provide new insight into their synthesis and irradiation behavior. We find the metastability threshold above which metastable phases cannot be synthesized from thermal decomposition, explaining why non-equilibrium synthesis is required for fabrication of certain metastable phases. We also discuss a reverse relation between the metastability threshold and kinetics at increased temperatures, and their influence on the formation of metastable phases. Lastly, we successfully predict the sequence of metastable phases induced by irradiation in Lu_2O_3, forming three metastable phases with increasing irradiation fluence and displaying unique irradiation behavior not observed in other materials.

2:00 PM +DS01.02.03
Selectivity in Materials Synthesis with Hyperdimensional Phase Spaces James R. Neilson; Colorado State University, United States

A significant challenge in materials synthesis is to rationally control composition and structure of materials to achieve desired properties. Unfortunately, metastability or glacial reaction kinetics inhibits the search for and synthesis of functional materials. Yet, solid-state metathesis reactions, which have an expanded, hyperdimensional, compositional space from that of the products, often avoid formation of unreactive intermediates. Furthermore, the nominally spectating elements can even impart selectivity between different products. Experimental in situ investigation of reactions (e.g., with synchrotron X-ray powder diffraction) sheds light on how intermediates in the reaction dictate the local chemical potentials that define the reaction pathway. Selectivity results when intermediates provide a direct thermochemical connection between the reactants and a targeted compound, as illustrated for myriad complex manganese oxides. With this discovery, we now envision an approach for predictive, prescriptive materials synthesis and reversible conversion.

Direct DFT Calculation of the Bulk and Nanoscale Stability of Icosahedral Quasicrystals Woohyeon Baek and Wenhao Sun; University of Michigan, United States

The discovery of quasicrystals forced solid-state chemists to revisit traditional assumptions about crystallinity, bonding, stability, and materials formation. Underlying all these questions is a fundamental question: are quasicrystals thermodynamically stable or metastable, but prefer nucleation due to a low surface energy? Density Functional Theory (DFT) is often used to evaluate thermodynamic stability, but quasicrystals are aperiodic and cannot be calculated under periodic boundary conditions. Here, we present a new technique to directly calculate the bulk and surface energies of quasicrystals in DFT. We compute the energies of large quasicrystal nanoparticles, and then fit the bulk and surface energies of the nanoparticles using a Gibbs-Thomson relationship. Using this technique, we evaluate the Tsai-type ScZn and YbCd icosahedral quasicrystals, whose structures have been resolved with atomistic resolution. From the bulk and surface energies, we construct size-dependent phase diagrams, enabling us to determine the bulk and nanoscale (meta)stability of icosahedral quasicrystals.

Synthesis-Structure Relationship Guided by Intermediate and Remnant Metastability Akira Miura[1], Hiroaki Ito[1], Yuki Nakahira[2], Yosuke Goto[3], Yoshikazu Mizuguchi[4], Chikako Moriyoshi[5], Nataly Carolina Rosero-Navarro[1] and Kiyoharu Tadanaga[1]; [1]Hokkaido University, Japan; [2]QST, Japan; [3]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [4]Tokyo Metropolitan University, Japan; [5]Hiroshima University, Japan

With increasing demands for producing new functional ceramics materials, the components of materials tend to increase. However, as the number of components increases, the number of metastable and thermodynamically competing phases increases [Science Advances 2016 e1600225]. Kinetic understanding is essential to guide a synthesis-structure relationship of these metastable and thermodynamically competing phases. In-situ measurement is a powerful technique for understanding kinetics and various reactions have been studied [Journal of the American Chemical Society 2016 11031: Advanced Materials 2021 2100312].

Metastable phases can be classified as intermediate and remanent metastability.[Chemistry of Materials 29 (2), 479-489] Intermediate metastable phases are intermediates trapped by kinetic barriers that have never reached the lowest free-energy phase. In contrast, remanent metastable phases are remnants of thermodynamic conditions where they were once the lowest free-energy phase.[Science Advances 2016 e1600225] By understanding these metastable mechanisms, we can rationally design the synthesis recipes.

Here, we investigated the kinetics of solid-state synthesis reactions of Li_3YCl_6/Li_3HoCl_6 solid electrolytes between LiCl and YCl_3/$HoCl_3$ powders via in-situ synchrotron X-ray diffraction at different heating rates. The ion radii of Y^{3+} and Ho^{3+} are comparable, so similar reaction mechanisms can be expected. Both reactions formed Li_3YCl_6/Li_3HoCl_6 with disordered Y/Ho before forming Li_3YCl_6/Li_3HoCl_6 with ordered Y/Ho sites. However, the reversibility of these disorder-order transitions differed; that of Li_3YCl_6 was nonreversible while that of Li_3HoCl_6 was reversible. Therefore, Li_3YCl_6 with ordered Y and Li_3HoCl_6 with disordered Ho were found to be stable phases near room temperature.

Accordingly, Li_3YCl_6 with disordered Y and Li_3HoCl_6 with ordered Ho were metastable phases near room temperature. Interestingly, these metastable phases can be classified as intermediate and remnant metastable phases. Li_3YCl_6 with disordered Y was the intermediate metastable phase, which was obtained by heating at a medium temperature not to reach thermodynamic stable Li_3YCl_6 with ordered Y. On the other hand, Li_3HoCl_6 with ordered Ho was the remanent metastable phase, which was once stabilized at high temperature and only available upon quenching. Therefore, even though ion radii of

Y^{3+} and Ho^{3+} are similar, different kinetics between Li_3YCl_6/Li_3HoCl_6 exhibit distinct contrast in the synthesis-structure relationship. We anticipate that f orbital of Ho can change their kinetics.

Materials Thermodynamics at Extreme Conditions—Towards Knowledge-Based Design of Metastable Materials with Advanced Functionalities
Igor A. Abrikosov; Linköping University, Sweden

Recent advances in high-pressure high-temperature (HPHT) experiment allow one to synthesize materials at TPa compression and temperature above 2000 K [1], paving the way towards discoveries of new materials and observations of novel physical phenomena. The exciting capabilities offered by the HPHT synthesis puts on the agenda a challenging task of knowledge-based design of metastable materials with advanced functionalities. At the same time, profound effect of the extreme conditions on the chemistry and physics of materials requires proper theoretical analysis. We review recent advances in theoretical description of materials thermodynamics at extreme conditions, which combines first-principles electronic structure theory with machine learning (ML) tools. We demonstrate that explicit treatment of lattice dynamics is essential for accurate calculations of thermodynamic properties of materials at elevated temperatures, leading to qualitative improvement between theory and experiment for such key targets as mixing enthalpies and phase diagrams. We show that using ML interatomic potentials allows to greatly increase efficiency of simulations at extreme conditions preserving, and even improving their accuracy [2]. Moreover, employing the transfer learning approach, it is possible to predict highly sensitive materials properties, like elastic moduli, without explicit first-principles calculations [3].

Importantly, we demonstrate feasibility of discovering metastable materials with advanced functionalities in HPHT synthesis followed by decompression to ambient conditions. First, we present the case of rhenium nitride pernitride $Re_2(N_2)(N)_2$, discovered at HP (40 to 90 GPa) [4]. Theoretical analysis demonstrated that it should be (meta-)stable, metallic, ultraincompressible and very hard not only at the synthesis pressure, but also at ambient conditions. Experimentally, $Re_2(N_2)(N)_2$ was recovered at ambient conditions, and a route to scale up its synthesis was developed.

Next, we demonstrate that decompression of materials synthesized at HPHT conditions could lead to phase transitions to metastable polymorphs with properties more exciting than those of the original HPHT phases. In particular, it is possible to using HPHT experiments in a search for layered materials, precursors of novel 2D-materials. We illustrate this concept by discoveries of the triclinic phase of beryllium tetranitride tr-BeN_4 [5] and pentagonal (*p*-) phase of NiN_2 [6]. For the former, theoretical analysis predicts that BeN_4 monolayer, the beryllonitrene, represents a qualitatively new class of 2D materials that host anisotropic Dirac fermions. Realization of an ideal Cairo tessellation in *p*-NiN_2 provides high-pressure route to pentagonal 2D materials.

4:15 PM *DS01.02.08
Synthesis and Thermodynamics of $GeNCr_3$—A New Nitride Superconductor with Orthorhombic Antiperovskite Structure Andreas Reitz[1], Hanna Pazniak[2], Chen Shen[3], Harish Singh[3], Alexandra Navrotsky[1], Hongbin Zhang[3], Ulf Wiedwald[4] and Christina S. Birkel[1,3]; [1]Arizona State University, United States; [2]Institut Polytechnique de Grenoble, France; [3]Technische Universität Darmstadt, Germany; [4]Universität Duisburg-Essen, Germany

In contrast to ternary oxides, the number of known ternary nitrides is an order of magnitude lower, which is partially the result of their lower free energy of formation and lower thermodynamic stability. This challenges experimentalists to continuously explore the synthetic parameter space and push towards new nitride phases. Here, we demonstrate the synthesis of a hitherto unknown orthorhombic structure of $GeNCr_3$, which typically crystallizes in a tetragonal structure. As derived from DFT calculations, formation energies of both phases are similar, and we show that orthorhombic $GeNCr_3$ can be stabilized by choosing lower reaction temperatures. According to detailed thermodynamic analysis, the new compound is stable up to 500 °C and exhibits the same phase transitions as the tetragonal phase at higher temperatures. However, its electronic structure is vastly different. According to our theoretical calculations, the new orthorhombic compound exhibits superconducting behavior with a T_C of 7.2 K, which is due to electron-phonon coupling, while the tetragonal $GeNCr_3$ is an antiferromagnet.

4:45 PM DS01.02.09
Thermally-Quenched Metastable Phases in Correlated Electron Systems Hiroshi Oike[1,2,3], Akiko Kikkawa[3], Naoya Kanazawa[1,3], Manabu Kamitani[3], Yasujiro Taguchi[3], Masashi Kawasaki[1,3], Yoshinori Tokura[1,3,1] and Fumitaka Kagawa[1,3,4]; [1]The University of Tokyo, Japan; [2]JST, Japan; [3]RIKEN Center for Emergent Matter Science, Japan; [4]Tokyo Institute of Technology, Japan

A large number of electrons that correlate with each other in crystals form ordered phases, such as magnetic orders and superconductivity, analogously to correlated atoms forming crystals. Whereas the most stable phase is uniquely determined once thermodynamic parameters are fixed, it has long been known that metastable crystals can be obtained when their transformation to the most stable phase is kinetically avoided by thermal quenching. It is intriguing whether the principle of quenching can also be applied to correlated electron systems. However, the cooling rates used in measurements of electronic properties are usually limited to a range between 10^{-3}-10^{-1} Ks^{-1}, and thus the ubiquity of this principle had not been tested. We have been investigating metastability in correlated electron systems with rapid cooling techniques that produce a cooling rate up to 10^8 Ks^{-1}.

Here, we present two cases, metastable magnetism in a chiral magnet MnSi [H. Oike et al., Nature Phys. 12, 62 (2016).] and metastable superconductivity in a transition-metal dichalcogenide $IrTe_2$ [H. Oike et al., Science Adv. 4, eaau3489 (2018).]. MnSi is a long-studied magnet without inversion symmetry, and, in the last decade, has been attracting a great deal of attention as a material hosting magnetic skyrmions [Y. Tokura and N. Kanazawa, Chem. Rev. 121, 2857 (2020).]. Two kinds of interactions are acting between electron spins in MnSi; ferromagnetic interaction that aligns neighboring spins in the same direction with each other and Dzyaloshinskii-Moriya interaction that twists neighboring spins. The competition between these interactions underlies a variety of spin structures in MnSi, such as spiral phase, where spins are aligned in a plane and modulated in a direction perpendicular to the plane, and skyrmion lattice phase (SkL), where vortex-like spin swirling objects form a lattice. We applied thermal quenching to the phase transition from SkL to spiral phase and found that SkL exists as a metastable state in a temperature range where a spiral phase is free-energetically most stable. Thus, the principle of quenching is demonstrated to work for magnetism.

Then, the principle is deployed to creation of metastable superconductivity. In correlated electron systems, a superconducting phase often has a slightly higher free-energy than other ordered phases of electrons. Therefore, if the formation of such competing orders is kinetically avoided by quenching, a superconducting state is expected to emerge. The target material $IrTe_2$ undergoes a complex ordering phenomena where the valence of the two-fifths Ir ions

changes from trivalent to tetravalent and accordingly the network structure formed by Te ions deviating from divalent also changes [K.-T. Ko et al., Nature Commun. 6, 7342 (2015).]. We applied thermal quenching to the complex ordering and found that a phase without the ordering exists as a metastable state at low temperatures. As we expected, the metastable phase exhibits superconductivity highlighting that the principle of quenching opens up new frontiers in the exploration of quantum phenomena.

Thus, the ubiquity of the principle is being demonstrated in correlated electron systems. Because such quenching experiments have only been carried out on a limited number of materials, it is expected that new quantum phases will be pioneered when they are applied to a wide variety of materials. More importantly, there may be similarities between correlated atoms and correlated electrons in the mechanism of metastability, as well as similarities in the methods of creating metastable phases. I hope that general concepts would be found through this presentation and subsequent discussions.

SESSION DS01.03: Thermodynamics of Oxides and Functional Materials
Session Chairs: Scott McCormack, Alexandra Navrotsky, Richard Otis, Jiayu Peng and Wenhao Sun
Tuesday Morning, November 29, 2022

Recent Advancements in Thermodynamic Properties of Zircon Structure-Type Materials Xiaofeng Guo[1], Andrew Strzelecki[1], Xiaodong Zhao[1], Paul Estevenon[2], Hongwu Xu[3], Nicolas Clavier[4] and Rodney Ewing[5]; [1]Washington State University, United States; [2]Commissariat à l'énergie atomique et aux énergies alternatives, France; [3]Los Alamos National Laboratory, United States; [4]Université de Montpellier, France; [5]Stanford University, United States

Zircon structure-types are ternary oxides with an ideal chemical formula of ATO_4 ($I4_1/amd$), where usually A are lanthanides and actinides, with T = As, P, Si, V. This structure accommodates diverse chemistry on both A- and T-sites, giving rise to more than seventeen mineral end-members of five different mineral groups, and forty-five synthetic end-members. Because of their diverse chemical and physical properties, the zircon structure-types are of interest to a wide variety of fields and may be used as ceramic nuclear waste forms and aeronautical environmental barrier coating, to name a couple. To support advancement of their applications, many studies have been dedicated to the understanding of their structural and thermodynamic properties. The emphasis in this review will be on recent advances in the structural and thermodynamic studies of zircon structure-type ceramics, including pure endmembers (*i.e.,* zircon ($ZrSiO_4$), xenotime (YPO_4)), and solid solutions (*i.e.,* $Er_xTh_{1-x}(PO_4)_x(SiO_4)_{1-x}$). Specifically, we provide an overview of the crystal structure, its variations and transformations in response to non-ambient stimuli (temperature, pressure and radiation), and its correlation to thermophysical and thermochemical properties. We hope this up-to-date summary of knowledge of zircon-type materials will help researchers to continue advancing the use of zircon-type materials for applications, such as actinide waste forms and for aeronautical engineering as environmental barrier coatings.

8:30 AM *DS01.03.02
Materials Design for Extreme Environment Applications Using Rare Earth Oxides and Silicates Mackenzie J. Ridley, Cameron K. Miller, Kristyn D. Ardrey, Kathleen Tomko, John A. Tomko, Mahboobe Jassas, Patrick E. Hopkins and Elizabeth J. Opila; University of Virginia, United States

The seventeen rare earths (Sc, Y, and the 15 lanthanides) provide an ideal materials design space for manipulation of phase, composition, and properties. The wide range of cation sizes results in oxygen coordination numbers varying from six to nine, a large number of polymorphs, (see the figures below) and many possible multicomponent rare earth compounds. This variety enables control of properties such as thermal expansion, thermal conductivity, and thermochemical stability in steam and molten siliceous deposits, all important for high temperature coating applications in extreme environments. In this presentation, control of properties through design of rare earth oxides, rare earth monosilicates, rare earth disilicates, and both rare earth apatites and calcium-stabilized rare earth apatite phases are presented with corresponding experimental validation of property control.

9:00 AM DS01.03.03
Stability Design Principles of Manganese-Based Oxides in Acid Jiayu Peng[1], Livia Giordano[1], Timothy Davenport[2] and Yang Shao-Horn[1]; [1]Massachusetts Institute of Technology, United States; [2]Raytheon Technologies Research Center, United States

The utilization of low-cost, non-precious catalysts (e.g., metal oxides) in clean energy technologies in acid (e.g., proton exchange membrane fuel cells and electrolyzers) has been severely hampered by the instability of these catalysts at low pHs. While first-row late transition metal oxides based on Fe, Co, and/or Ni have been found with comparable or higher catalytic activity for the alkaline oxygen reduction and oxygen evolution reactions than the precious-metal-based counterparts (e.g., Pt and IrO_2), such oxide catalysts are not stable in acid. Mn-based oxides are more acid-stable than those based on late transition metals at moderately acidic pHs, but they still corrode and deactivate in strong acid and after long operation. To address this issue, extensive efforts over the past decades have been focused on mixing active, yet unstable oxides (e.g., Mn oxides) with corrosion-resistant oxides to generate more stable catalysts. However, having a higher fraction of corrosion-resistant elements also results in less catalytically active oxides, indicating an activity-stability trade-off.

To design oxide catalysts (such as Mn-based oxides) with an optimal trade-off or even bypass this limitation, it is essential to establish their stability descriptors in acid. These descriptors can offer a fundamental understanding of oxide dissolution and provide guiding principles to enhance their intrinsic stability. Unfortunately, while the mechanistic insights into the bulk/surface instability of oxides under alkaline or neutral conditions have been established previously, the stability design principles of these oxides in acid are still lacking.

In this work, we employed a library of Mn-based oxides with diverse structures and valence states to establish oxide stability descriptors in acid based on intrinsic electronic structure and energetic parameters. Using time-dependent dissolution experiments and first-principle calculations, greater amounts and faster kinetics of oxide dissolution in acid were correlated with lowered Mn oxidation states, which are accompanied by decreased covalency, weakened Mn-O bonds, and reduced free energy barriers for key reaction steps, including protonation, vacancy formation, and ion solvation. Such design principles were shown broadly with a computational screening across a vast chemical space of ~1,000 Mn-based oxides, where an Mn oxidation state of +4 was found to give rise to the lowest energetic driving force for the dissolution of Mn-based oxides in acid. Moreover, limiting the percentage of ionic metal substituents in oxides and using more acidic substituents were shown to stabilize Mn-based oxides in acid.

Such design principles and mechanistic insights for stabilizing Mn-based oxides in acid are crucial for a wide variety of applications, such as proton exchange membrane fuel cells and electrolyzers. In addition, we envision this method can be extended to a broader chemical space to develop more universal, fundamental relations between the chemistry and electronic structure of transition metal compounds and their stability in acid for clean energy

applications.

9:15 AM DS01.03.04
Effect of Metal, Topology and Dimensionality on the Thermodynamic Stability of ZIFs Gerson Leonel[1], K Jayanthi[1], Joseph Marrett[2], Tomislav Friiscic[2] and Alexandra Navrotsky[1]; [1]Arizona State University, United States; [2]McGill University, Canada

Zeolitic imidazole frameworks (ZIFs), exhibit remarkable properties including high porosity, and surface area. Their high moisture stability makes them useful for industrial applications. The stabilizing effect of metal nodes (Co(II), Cu(II), and Zn(II)) across different topologies and dimensionalities (2D or 3D) remains unexplored. By employing room-temperature acid solution calorimetry, we quantify the change in enthalpy ($\triangle H^0_f$) for forming the frameworks relative to endmembers (metal oxide plus linker). Enthalpies of formation for Co-ZIF-L, Zn-ZIF-L, SOD-Co(MeIm)$_2$, SOD-Zn(MeIm)$_2$, *dia*-Co(MeIm)$_2$, *dia*-Zn(MeIm)$_2$, and *dia*-Cu(MeIm)$_2$ are -44.72 ± 0.76, -73.74 ± 0.91, -15.49 ± 0.86, -20.45 ± 0.94, -46.18 ± 0.75, -31.63 ± 1.26, and -15.03 ± 1.40 kJ.mol^{-1}, respectively. Zn(II) has the greatest stabilizing effect in the 2D dimensionality (ZIF-L) and SOD topology. Co(II) has the greatest stabilizing effect in the *dia* topology. The stabilizing effect of metal nodes is dependent on both topology and dimensionality of the framework.

9:30 AM BREAK

10:00 AM *DS01.03.05
Novel Insight into Defect Behavior of Irradiated Materials—Combined Neutron Total Scattering and High Temperature Calorimetry Investigation Maik K. Lang; University of Tennesee, United States

We present neutron total scattering combined with high-temperature calorimetry as a new strategy for the characterization of radiation effects in materials. Irradiation experiments were performed at the GSI Helmholtz Center with heavy ions of specific energy of 11.4 MeV/u. The use of such ions (penetration depth: ~100 µm) produces the sufficiently large irradiated sample mass (~150 mg) required for bulk structural and thermodynamic analysis. Neutron scattering was performed at the Nanoscale Ordered Materials Diffractometer at the Spallation Neutron Source (Oak Ridge National Laboratory). High temperature oxide melt solution calorimetry and differential scanning calorimetry was utilized to investigate the thermodynamic properties and energetic evolution using the same set of irradiated samples. We studied various ion-induced structural modifications, such as defect formation (CeO_2), disordering ($Er_2Sn_2O_7$), and amorphization ($Dy_2Ti_2O_7$). Our analytical approach demonstrated that irradiation-induced modifications are more complex than previously thought with distinct processes occurring over different length scales and temperature regimes.

10:30 AM *DS01.03.07
Thermal Expansion of Metal Diborides (MB_2 | M = Ti, Zr, Nb, Hf, Ta) up to 3150 C Scott J. McCormack[1], Fox Thorpe[1], Elizabeth Sobalvarro[2], Gabriella King[2], James Cahill[2], Wyatt Du Frane[2] and Joshua Kuntz[2]; [1]University Of California, Davis, United States; [2]Lawrence Livermore National Laboratory, United States

Metal diborides (MB_2 | M = Ti, Zr, Nb, Hf, Ta) are considered an ultra-high temperature refractory ceramic due to their relatively low reactivity and high melting point. While these properties are appealing, they also make it difficult to fully characterize their thermochemical and thermophysical properties up to melting. This work will discuss in-situ high temperature X-ray diffraction measurements up to ~3150 C using a conical nozzle levitator system equipped with a 400 W CO_2 laser. The high temperature X-ray diffraction data was used to calculate anisotropic coefficients of thermal expansion. The coefficients were compared amongst the five diborides (MB_2 | M = Ti, Zr, Nb, Hf, Ta). It was found that the anisotropy could be related to the atomic displacement parameters of the metal cations. These thermophysical measurements will be critical in developing ultra-high temperature material systems for applications in hypersonic vehicles, nuclear fission/fusion reactors, and spacecraft.

11:00 AM DS01.03.08
Enabling Permanently Nonvolatile Memory Using Materials Thermodynamics Yiyang Li; University of Michigan, United States

The ability to store information using nonvolatile memory is a crucial pillar for computing and modern society. The most common nonvolatile memory, Flash memory, retains state by trapping charge within energy wells; however, such “kinetic” memory will revert back to the thermodynamic equilibrium and therefore lose information, especially under high temperatures and ionizing radiation. A more resilient nonvolatile memory would instead switch between two or more thermodynamically equilibrium states. Using “thermodynamic” memory, there will be no driving force for the material to leave one state for another, and can yield permanent nonvolatility even without kinetic barriers. Composition phase separation, whereby materials with different compositions can have the same chemical potential, provide one avenue towards engineering materials with multiple equilibrium thermodynamic states.

We present our research on how to utilize composition phase separation in nonvolatile, on-chip memory. One promising nonvolatile memory is the resistive random access memory (RRAM), which switches states through the migration of oxygen vacancies in transition metal oxides. It is widely assumed that RRAM is a “kinetic” memory, which retains state because of slow oxygen vacancy diffusion kinetics. However, the experimentally attained retention time is about 10 orders of magnitude longer than the characteristic oxygen diffusion time. Instead, we show that RRAM is a “thermodynamic” memory that retains state using composition-driven phase separation. Moreover, we show how phase separation can also be used to engineer new types of nonvolatile electrochemical memory. These results show the critical importance as well as potential opportunities of modern thermodynamics to memory and other device technologies.

11:15 AM DS01.03.10
Deep Learning-Accelerated Explicit Solvation Thermodynamics in Molten Salts Yu Shi[1], Stephen Lam[2] and Thomas Beck[3]; [1]University of Cincinnati, United States; [2]University of Massachusetts Lowell, United States; [3]Oak Ridge National Laboratory, United States

Molten salts are an emerging class of ionic liquids that are used in several advanced energy applications including next-generation nuclear reactors, batteries, and thermal energy storage.
In these applications, predicting corrosion and phase change behavior remains a critical challenge. This requires predicting the solvation of structural metals, atmospheric impurities, and a variety of chemical products that are generated during operation. Due to complex structural ordering in these fluids, explicit solvation modeling that includes all atoms surrounding a solute, is required. Furthermore, the need for precise solvation thermodynamics necessitates the use of methods that are chemically accurate (E~1-4 kJ/mol). In this work, we simultaneously address these challenges by combining quasichemical theory (QCT), ab initio molecular dynamics (AIMD) simulation based on dispersion-corrected density functional theory (DFT), and deep learning (DL) potentials to accurately predict the solvation free energy of solute ions in molten salt. First, QCT provides an exact partitioning of solvation free energy into three steps that can be directly simulated: 1) formation of a small cavity in solution, 2) insertion of a solute ion into the cavity, and 3) relaxation of cavity and solution around the solute ion. These contributions are determined by thermodynamic integration requiring extended simulation

time and length-scales that are inaccessible to AIMD. As such, ab initio-accurate (<4 meV/atom) neural network potentials were trained to accelerate MD simulation by several orders of magnitude. Lastly, DFT-interaction energies are corrected using Møller-Plesset perturbation theory (MP2) to accurately account for the effects of dispersion and periodic boundary conditions in a finite-size simulation cell. In this work, we show that deep learning potentials can accurately predict molten salt thermodynamics and local coordination structures. We demonstrate the combined methods (DFT-DL-QCT) on molten NaCl, in which we obtain the total excess potentials of Na^+ and Cl^- ions. Moreover, we highlight that dispersion and finite size errors in DFT result in significant errors (13.7 kJ/mol) in calculating solvation free energy, which must be corrected. The calculated excess chemical potential for Na+/Cl− was predicted to be -164.8±2.2 kcal/mol, which is in excellent agreement with the benchmark experimental value of -163.5 kcal/mol from thermochemical tables. Here, chemical accuracy in predicting solvation thermodynamics of molten salts is achieved for the first time. These results provide validation of these combined methods for predicting excess chemical potentials, which can be directly used for determining the solubility, corrosion potential, and volatility of dissolved gases and metals in molten salts. This provides motivation for using DFT-DL-QCT to understand solute chemistry in a wide range of molten salt systems in advanced energy applications.

SESSION DS01.04: New Phase Diagram Frameworks

1:30 PM *DS01.04.01
Statistical Mechanics Approaches to Predict Generalized Free Energy Descriptions Anton Van der Ven; University of California, Santa Barbara, United States

The thermodynamic properties of crystalline materials are determined by excitations that occur at the electronic and atomic length scales. Important sources of entropy include chemical disorder, vibrational excitations and magnetic disorder. Atomic and electronic degrees of freedom within a high symmetry parent crystal can lead to symmetry-breaking ordering reactions. The thermodynamic properties of a high symmetry parent crystal and its symmetry-breaking derivative structures can be encapsulated within a generalized free energy description that is a continuous function of composition, strain and suitably defined symmetry-adapted order parameters. This talk will describe methods to calculate generalized free energies with first-principles statistical mechanics approaches. Systematic approaches to identify order parameters for chemical and magnetic ordering reactions and for martensitic structural transformations will also be described. The importance of anharmonicity and magnetic degrees of freedom in determining phase stability in multi-component crystals will be illustrated for technologically important structural and functional materials. Approaches to quantify uncertainty in statistical mechanics simulations will be described.

2:00 PM DS01.04.02
A Robust Framework for the Determination of Magnetic Properties from First-Principles Calculations Guy C. Moore[1,2], Matthew K. Horton[1] and Kristin A. Persson[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Moving from the atomistic picture of magnetism to larger length scale models is an important challenge for the design and discovery of technologically relevant magnetic materials. This problem requires increased care for correlated electron systems, such as transition metal oxides, in which multi-body interactions are difficult to model using conventional density functional theory (DFT). In the extension to DFT+U+J, Hubbard U and Hund J values account for on-site coulomb interactions between localized electrons. These Hubbard U and Hund J values are computed using a customized linear response computational workflow suitable for high-throughput DFT applications. We present a framework for obtaining magnetic exchange constants from DFT+U+J using the established single-particle Green's function approach, which can be used to study finite-temperature behavior of lattice models using Monte Carlo methods. The Heisenberg exchange constants are highly sensitive to two important prerequisites: the magnetic ground-state, as well as U and J values. We explore the sensitivity of the magnetic ground state and resulting exchange constants to U and J values. Additionally, we have implemented and benchmarked a "source-free" exchange-correlation magnetic field in VASP. This source-free functional, paired with a custom particle swarm optimization strategy, SpinPSO, has resulted in improved agreement with a variety of magnetic ground-states measured by neutron diffraction. This ground-up computational approach will allow for the discovery of magnetic materials with technological applications ranging from spintronics to cost-effective magnetocaloric materials for magnetic refrigeration.

2:15 PM DS01.04.03
Duality Between Compositional Phase Diagrams and Chemcial Potential Diagrams Jiadong Chen and Wenhao Sun; University of Michigan, United States

Equilibrium phase diagrams are not well-poised to evaluate materials stability under dissolution and growth—for example, corrosion and etching; synthesis and deposition; or solid-solid interfacial reactions. These non-equilibrium situations would be better analyzed by phase diagrams that visualize the tendency for a material to gain or lose chemical species; e.g., with a chemical potential axis. Here, we present a generalized phase diagram framework to mix composition and chemical potential axes, providing a new stability representation that applies to these non-equilibrium situations. Our theoretical framework relies on the geometric duality between convex hulls and half-space intersections; and leads to a computational platform that scales easily to describe high-dimensional phase boundaries and multi-phase coexistence regions. We discuss how to evaluate and interpret the axes, widths, stability windows, and driving forces on the chemical potential diagram, and importantly, how to connect these to real-world laboratory conditions. Altogether, these mixed composition and chemical potential diagrams enable materials scientists to evaluate stability in more diverse chemical environments.

Modern Applications of Classical Thermodynamics to Strained Solids— Multiphase Multidomain Temperature-Strain-Stress Diagrams Bo Wang[1,2] and Long-Qing Chen[1]; [1]The Pennsylvania State University, United States; [2]Lawrence Livermore National Laboratory, United States

It has been well established that strains or stresses can have profound effects on the thermodynamic stability of phase and domain states of solids, and they can be judiciously utilized to tune solid state phase and domain microstructures and thus physical properties. Here, we propose a general thermodynamic framework to efficiently construct multidomain and multiphase diagrams of arbitrarily strained or stressed solids, in analogies to the well-known temperature-composition phase diagrams. We demonstrate the general approach by obtaining the temperature-strain-stress phase and domain diagrams of

diverse solids, including proper ferroelastic ZrH_2, strongly correlated electron material VO_2, ferroelectric $PbTiO_3$, and unconventional ferroelectric $Hf_{0.5}Zr_{0.5}O_2$ with coexisting nonpolar and polar phases. Our thermodynamic theory offers a powerful, yet easy to implement, theoretical tool for understanding the thermodynamics of any strained solids and for guiding the strain engineering of their properties.

The Geometry of Phase Boundaries on High-Dimensional Phase Diagrams Wenhao Sun[1], Jiadong Chen[1] and Matt Powell-Palm[2]; [1]University of Michigan, United States; [2]University of California, Berkeley, United States

There are four main varieties of phase diagrams today: 1) Temperature–Pressure; 2) Temperature–Composition; 3) Ellingham (T, μ_{O2}); and 4) Pourbaix diagrams (pH, Redox potential). However, these 2D phase diagrams do not account for many other forms of thermodynamic work that may be operative during nucleation and growth—such as surface, elastic, electromagnetic and electrochemical work. Here, I will describe a process to lift 2D phase diagrams into higher dimensions, exposing these additional forms of thermodynamic work on the axes. In particular, this involves deriving the geometry of high-dimensional phase boundaries and phase-coexistence regions, which leads to generalized forms of Gibbs' Phase Rule and Clausius-Clapeyron relations. From this geometric foundation, we can construct and deploy phase diagrams with any axes of mixed intensive or extensive variables—providing a powerful new theoretical framework for the design and synthesis of advanced functional materials.

Holistic Integration of Experimental and Computational Datasets Together with Simplified Models for Rapid Establishment of Diffusion Databases Ji-Cheng Zhao and Wei Zhong; University of Maryland, United States

Discrepancies between experimental and computational datasets are usually hard to reconcile. For the case of diffusion coefficients, large amounts of both experimental and computational data are available to allow careful assessments of the degree of agreements and disagreements. Such rigorous and systematic assessments allow us to take advantage of the best of both datasets and provide complementary data to be used to establish the most reliable diffusion databases. In addition, simple and yet general mathematical models for binary and multicomponent metallic solid solutions are developed to facilitate future database establishment. This talk will use many examples to illustrate the power of such holistic integration and the new models. The talk also calls for systematic calculations and machine-learning predictions of both self-diffusion and impurity (dilute) diffusion coefficients of all elements in fcc, bcc and hcp crystal structures.

4:15 PM DS01.04.07
Connecting Features of Phase Diagram to Diffusive Flow in Alloys Arindam Raj[1], Naijia Liu[1], Yujun Xie[2], Sungwoo Sohn[1], Guannan Liu[1] and Jan Schroers[1]; [1]Yale University, United States; [2]University of California, Berkeley, United States

A general quantitative understanding of microstructure-property-relationships (MPRs) relationships remains elusive, as microstructures are generally very complex, cannot be directly reconstructed by the characteristics of their constituents, and are multiscale in nature (10^-9 m – 10^-3 m). We investigate alloys with different phases, viz., solid solutions, intermetallics, and eutectics to demonstrate the diffusive characteristics of these phases under stress gradient. We draw conclusions about the diffusive response of these phases in alloys based on the diffusing flux. Experimentally, this is realized through thermomechanical nanomolding, where we spatially separate the diffusing flux from the alloy feedstock into the pores of the nanomold. The length and composition of these rods can provide us with the diffusion rate and the composition of the diffusive flux. Here, we can probe ~10^11 distinct spots over the microstructure parallelly. We explain these results on the basis of fastest Gibb's free energy degradation rates.

A Gaussian Process Based Saddle-Point Search Method for Temperature-Dependent Energy Surfaces Seyyedfaridoddin Fattahpour and Sara Kadkhodaei; University of Illinois at Chicago, United States

In this work, we present a unique saddle-point search method based on a Gaussian process regression of the temperature-dependent energy surface to simultaneously sample the temperature-dependent energy surface and converge to the saddle point. We showcase the use of this method for solid-state diffusion in bcc phases of titanium and zirconium. These phases are chosen because they exhibit harmonic phonon instabilities, implying that the thermodynamic equilibrium state does not correspond to a local minimum on their Born-Oppenheimer energy surface. Therefore, saddle point search schemes cannot locate the diffusion transition state according to forces drawn from the Born-Oppenheimer energy surface [1]. Instead, forces drawn from an effective temperature-dependent energy surface are necessary to correctly guide the search scheme towards the transition state. In our method, a Gaussian process is used to estimate the temperature-dependent effective energy surface based on stochastically sampled atomic configurations along the transition path. We utilize the dimer and nudged-elastic band algorithms for the saddle point search on the temperature-dependent effective energy surface. Our method provides a useful alternative to methods such as molecular dynamics, which directly simulate diffusive hops.

A Predictive Surface Tension Model for Binary Metallic Solution Yoongu Kang and In-Ho Jung; Seoul National University, Korea (the Republic of)

Surface tension is very important thermodynamic energy which determine the phase stability in nano-sized materials. For liquid metallic system, many surface tension models have been proposed to reproduce the experimental data but none of the models can predict the surface tension of liquid metallic solution without any model parameters. In this study, we developed a new predictive surface tension model for liquid metallic solution which can predict the surface tension of binary liquid solution only from unary surface energy data. By using well quantified thermodynamic properties like enthalpy and entropy of mixing of binary bulk liquid solution, the surface composition and surface tension of liquid metal can be predicted from the new model. The present model was tested for 50 binary solutions having ideal, positive and negative interaction. In particular, the present model can give successful results for the liquid solutions with strong positive deviation or negative deviation from ideal solution, which have not been well predicted by any previous models.

***Ab Initio* Study of the Thermodynamic Properties of Amorphous Bismuth Under Pressure** Flor B. Quiroga Bañuelos[1], David Hinojosa[1], Isaías Rodríguez[1], Alexander Valladares[2], Renela M. Valladares[2] and Ariel A. Valladares[1]; [1]Universidad Nacional Autónoma de México, Instituto de Investigaciones en Materiales, Mexico; [2]Universidad Nacional Autónoma de México, Facultad de Ciencias, Mexico

The physicochemical properties of amorphous metals and bulk metallic glasses, when subjected to extreme conditions such as low temperatures or high pressures, make them attractive materials for important technological applications [1]. To fully exploit their benefits, it is necessary to understand the electronic and vibrational contributions to their thermodynamic properties, and first-principles calculations have helped to elucidate the physics of this complex materials. Recently, we explored the effects of negative pressures on the superconducting transition temperatures of amorphous Bismuth through the *ab initio* calculation of its electronic structure [2]. Now we will go into studying the thermodynamic properties of this system by calculating the vibrational densities of states (vDoS) using an *ab initio* approach. Specifically, in this work we calculate the vDoS, heat capacity and enthalpy for 3 amorphous samples, two of them subjected each to a positive and to a negative pressure. The amorphous samples were generated by *ab initio* molecular dynamics and our *undermelt-quench method* [3] applied to supercells of 216 atoms with densities: 10.89, 9.81, and 8.91 g cm^{-3} corresponding to a volume of 90%, 100% and 110% of the original volume, respectively. Results will be presented and discussed.

Heat Capacity of Dense Post-Stishovite Silica Glass from Fast-Scanning Calorimetry Laura Bonatti, B Brugman, Tamilarassan Subramani, Sergey Ushakov, Kurt Leinenweber and Alexandra Navrotsky; Arizona State University, United States

Stishovite is a high-pressure phase of SiO_2 which transforms into a dense glass when heated at ambient pressure to ~500°C. The properties of post-stishovite glass are more similar to densified silica formed by compression above 10 GPa than to standard fused quartz. Despite widespread thermal data on crystalline and glassy SiO_2 phases, the heat capacity of the dense, post-stishovite glass has not been measured. We calibrated a Mettler Toledo Flash DSC 2+ to determine quantitively the mean heat capacity for post-stishovite glass, as well as crystalline stishovite and TiO_2 in the temperature range of 200 to 350 ºC. The calibration was performed using the heat capacity of alumina, titania and zirconia, with an uncertainty of under 17%. Our measured Cp for titania and stishovite agrees within 9% of the reported literature values. The heat capacity for the post-stishovite glass was within 6.6% of the reported literature value for the heat capacity of stishovite between 200 to 350 ºC. The developed methodology allows for obtaining quantitative thermochemical data on solid samples in micrograms amounts that are too small for other methods, e.g. new high pressure phases quenched from diamond anvil cell experiments.

DS01.05.03
Iron-Poor Ferrites for Low Temperature CO_2 Conversion via Reverse Water-Gas Shift Thermochemical Looping Eddie Sun, Jimmy Rojas, Gang Wan and Arun Majumdar; Stanford University, United States

CO_2 utilization via the reverse-water-gas-shift (RWGS) reaction for the production of CO and then to long chain hydrocarbons is a potentially scalable method to mitigate rising global CO_2 emissions, if appreciable CO yields can be achieved at low reaction temperatures. Here, we report that $Fe_{0.35}Ni_{0.65}O_x$ achieves, to the best of our knowledge, a record high experimentally measured CO yield of 80 mL-CO/g_{MOx}/cycle at low reaction temperatures (500°C for both oxidation and reduction steps) in a chemical looping (CL) process. This reported yield is an order of magnitude higher than previously reported RWGS-CL metal oxides at 500°C. We identified the composition of the metal oxide $Fe_{0.35}Ni_{0.65}O_x$ using the Calculation of Phase Diagrams (CALPHAD) methodology to screen and filter through many combinations of metal oxides. We then experimentally tested this $Fe_{0.35}Ni_{0.65}O_x$ metal oxide for chemical looping RWGS and utilize x-ray characterization techniques and CALPHAD to find that a spinel-to-metallic phase transition gives $Fe_{0.35}Ni_{0.65}O_x$ its noteworthy CO yield and oxygen capacity. We emphasize the importance of thermodynamics calculations and CALPHAD screening to quickly search through the vast design space of metal oxides to greatly reduce the amount of necessary experimentation.

DS01.05.04
A High-Throughput Framework for Lattice Dynamics Zhuoying Zhu, Junsoo Park and Anubhav Jain; Lawrence Berkeley National Lab, United States

Lattice dynamics of materials are fundamental to their thermal properties, mechanical properties, as well phase transition behaviors. Among thermodynamic quantities that directly follow from harmonic phonons are vibrational free energy, entropy, and heat capacity, which can be easily obtained from well-known methods like density-functional perturbation theory. Obtaining anharmonic IFCs (third-order and higher), which determine thermal expansion, thermal conductivity, and dynamical stability has remained a challenge for longer.

We herein present our generalized automated workflow for lattice dynamical properties. Under the high-throughput framework, we can obtain both harmonic and anharmonic IFCs with HiPhive package and calculate quantities like three-phonon scattering and lattice thermal conductivity using ShengBTE. For phonon dispersions with imaginary modes, one more step of renormalization will be added to obtain temperature-dependent real and stable phonons before computing the thermodynamic quantities.

DS01.05.05
Exploration of Relationship Between Phonons and Cathode Behavior of Battery Materials Using Density Functional Theory Solomon R. Murdock and Hillary Smith; Swarthmore College, United States

$LiFePO_4$ is a widely used battery cathode material. Both the rising cost of lithium and the environmental impact of lithium mining has sparked interest in

alternative high performance cathode materials. $NaFePO_4$ has been proposed as an alternative to $LiFePO_4$ due to its similar chemical formula. Despite this similarity, the ground state structure of $NaFePO_4$ is maricite while $LiFePO_4$ has a triphylite structure. Both maricite and synthethetic triphylite $NaFePO_4$ have been observed to display poor cathode performance as compared with $LiFePO_4$. We performed Density Functional Theory calculations using VASP (Vienna Ab Initio Simulation Package) to determine the phonon dispersions and density of states for $LiFePO_4$, maricite $NaFePO_4$, and triphylite $NaFePO_4$. The relationship between cathode performance and lattice dynamics is explored for all three materials. A better understanding of the relationship between cathode performance and lattice vibrations will aid in the development of cathode technology.

DS01.05.06
A Cluster Expansion of the FeMnNiAlCr High Entropy Alloy Andrew Pike and Geoffroy Hautier; Dartmouth College, United States

Experimentally, determination of the phase diagram of a five-component high entropy alloy (HEA) is extremely difficult due to the vast number of combinations of compositions and conditions. While computations of phase diagrams from density functional theory (DFT) at 0K are somewhat commonplace, incorporating the temperature effects and disorder present in a real HEA are not handled well directly from DFT. A cluster expansion uses data from DFT to build a model Hamiltonian, which can then incorporate these effects. I will present a cluster expansion for the FeMnNiAlCr HEA system and discuss the search for useful, novel phases in this system from first principles.

DS01.05.08
A Simulation Study on Dynamic Behavior of Equilibrium Polymer-Linked Colloidal Gels Taejin Kwon, Tanner Wilcoxson, Delia Milliron and Thomas Truskett; The University of Texas at Austin, United States

Colloids with limited valence such as patchy particles can form equilibrium gels that are thermodynamically stable. Polymer-linked colloidal gels are promising candidates due to the possibility to tune valence using the macroscopically controllable ratio of linkers to colloids. Still, an understanding of the dynamics of such networks, and how they relate other systems such patchy colloids, is lacking. Using simulations of a coarse-grained model, we show that linked-colloidal networks exhibit dynamic hallmarks of viscoelastic equilibrium gels. Our results demonstrate that network bond persistence time controls structural relaxation. We also find the re-entrant structural and dynamic behavior as a function of linker concentration, centered at the stoichiometric ratio. Increasing or decreasing linker concentration from the stoichiometric ratio results in reduced network connectivity and shorter structural relaxation times. These results provide fundamental insights and suggest new macroscopic strategies for tuning the network connectivity and the dynamical response in colloidal networks.

DS01.05.09
Impact of Materials Property Uncertainty on the Thermodynamic Models of Materials and Reaction Chemistry Joshua Gabriel, Noah H. Paulson and Angel Yanguas-Gil; Argonne National Laboratory, United States

Materials property data is used in the design of engineering components and in the simulation of reactions for process engineering predictions. In this work we present the impact of uncertainty in the fundamental material properties of heat capacity, enthalpy, and Gibbs free energy on two important tools for materials and process design: phase diagrams for alloys and reaction simulators predicting the equilibrium product distributions of reactions. Specifically, we present applications of Bayesian inference and automated weighting of datasets to quantify uncertainty for materials property models in aluminum, the Cu-Mg phase diagram, and the equilibrium product distribution of precursor gas mixtures relevant for silicon carbide synthesis. In thermodynamic models of aluminum [1], we show the importance of selecting computational datasets compatible with experimental datasets in obtaining a thermodynamic property model. In the Cu-Mg phase diagram, we show that the inclusion of unary data for Cu and/or Mg, as part of uncertainty quantification efforts, increases the uncertainty around invariant points in the phase diagrams by 5%. We also present a cost-effective path forward utilizing uncertainty propagation and compare it with the co-optimization of unary and binary data. Finally, we show how the Bayesian automated weighting approach resolves unphysical discontinuities not associated with phase transitions in the context of silicon carbide synthesis in addition to showing the uncertainty in product distributions.

DS01.05.10
Thermodynamic Assessment of Heat Capacity and Entropy in Fragile Glasses Colby Stoddard and Hillary Smith; Swarthmore College, United States

The bulk metallic glasses Pt80-xCuxP20 where $14 < x < 27$ exhibit high fragility and a sharp glass transition. This results in a large excess entropy of the liquid phase over the crystalline phase. We used a combination of differential scanning calorimetry (DSC) and inelastic neutron scattering (INS) measurements to characterize the thermodynamics in these Pt-Cu-P glasses across a range in compositions. The isobaric heat capacity and vibrational entropy of the amorphous solid, crystalline solid, and supercooled liquid phases are assessed with DSC and INS, respectively. These data are used to calculate the difference in enthalpy, total entropy, vibrational entropy and Gibbs free energy between the solid and liquid phase. A significant increase in heat capacity is observed at the glass transition, but this does not correspond to a large change in the vibrational entropy. Insights into the effect of fragility on these thermodynamic parameters will be discussed.

Understanding Static and Dynamic Local Structure—The Nature of Local Dynamic Order in $CH_3NH_3PbI_3$ and $CH_3NH_3PbBr_3$ Michael F. Toney; University of Colorado Boulder, United States

Local atomic structure often differs from the global average structure as measured with diffraction and yet the local structure has a profound impact on properties. This structure-function relationship applies in many materials classes, ranging from organics to Li-ion battery cathodes to perovskites. Accurately characterizing this local structure has proven challenging but recent advances in diffuse scattering (“between” Bragg peaks) has enabled local structure determination. In this talk, I will discuss the importance of local structure and how this can be quantified and will demonstrate this for organic-inorganic hybrid halide perovskites. These materials are a recently re-invigorated class of semiconductor that have demonstrated very high efficiencies for

solar cells after just over a decade of research. While the importance of lattice dynamics and dynamical (dis)order have been recognized in these materials, their nature is only poorly known and understood. We used X-ray and neutron diffuse scattering coupled with molecular dynamics to quantify the nature, size, and time scale associated with dynamical local order in $CH_3NH_3PbI_3$ and $CH_3NH_3PbBr_3$ perovskites. We observe that the nominally cubic perovskite consists of dynamical, two-dimensional sheets of lower symmetry tetragonal regions of about 3 nm diameter with several picosecond lifetimes. The implications on halide perovskite properties will be discussed.

9:30 AM DS01.06.02
Enhancing Efficiency and Scope of First-Principles Quasi-Harmonic Approximation Methods Through the Calculation of Third-Order Elastic Constants Angelo Bongiorno; College of Staten Island - CUNY, United States

In this paper we present a computational strategy to calculate from first principles the coefficient of thermal
expansion and elastic constants of a material over meaningful intervals of temperature and pressure. This computational strategy relies on a novel implementation of the quasi-harmonic approximation (QHA) to calculate isothermal-isochoric linear and nonlinear elastic constants of a material in a reference state, followed by the use of elementary equations of nonlinear continuum mechanics to extrapolate values of lattice parameters and elastic constants of the material in an arbitrary deformed state. Our implementation of QHA relies on finite deformations, the use of non-primitive supercells to describe a material, a recently proposed technique to calculate generalized mode Grüneisen parameters, and the numerical differentiation of the second Piola-Kirchhoff (thermal) stress tensor to calculate both second-order elastic constants (SOECs) and third-order elastic constants (TOECs) (at finite temperature). We remark that our implementation of QHA involves a manageable computational workflow that, measured in terms of number of deformed configurations, requires only 4, 6, and 10 configurations (including reference state) to calculate the isothermal SOECs of a material with the cubic, hexagonal, and orthorhombic symmetry, respectively. In this paper, we first focus on conceptual and technical details of our methods, then we present the results of selected applications, and we conclude with a discussion of the advantages and limits of our methods. Overall, we envision that the methods presented in
this paper have the potential to be used for the following purposes. One, the calculation from first principles
of nonlinear elastic constants (TOECs and potentially fourth-order elastic constants) of materials at finite
temperature. TOECs are important coefficients characterizing the non-linear mechanical response of a material subjected to a deformation, and thereby related to properties such as sound attenuation and yield strength. Our QHA method can be used to calculate these nonlinear elastic coefficients at finite temperature for a variety of materials, for which experimental data are still missing or difficult to obtain. Two, the calculation from first principles of isothermal SOECs of materials with the orthorhombic, monoclinic, or triclinic symmetry, i.e. classes of materials that are within the reach of our QHA approach, which is suitable to be applied to study thermoelastic properties of low-symmetry materials. Three, the "rapid" calculation from first principles of the thermal expansion coefficient and SOECs of a material over finite intervals of temperature and pressure (by
using our strategy combining QHA calculations and nonlinear continuum mechanics). We remark that our computational strategy is applicable to materials of arbitrary symmetry and complexity, and therefore it could be used to build databases of materials properties at finite temperature, or to investigate the thermoelastic and mechanical properties of, for example, minerals of geological relevance or metal alloys for structural applications.

Microscopic View of Heat Capacity of Matter Jaeyun Moon[1], Lucas Lindsay[1] and Takeshi Egami[2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

In contrast to thermodynamic properties of solids and gases that are often described by phonon quasi-particles and real particles, respectively, our microscopic understanding of thermodynamics in liquids is lacking due to strong atomic interactions and lack of symmetry. Recent prior works have initiated efforts to understand heat capacity of liquids based on phonon quasi-particles similar to that of solids but often rely on free fitting parameters and questionable assumptions. In this work, we perform instantaneous normal mode and velocity autocorrelation analysis on single element systems under various conditions up to 10^7 K and 1 TPa. Our results suggest that heat capacity of liquids can be expressed by a combination of both quasi-particles and real-particles, leading to a unified framework to describe heat capacity of all three phases of matter: solid, liquid, and gas.

High Thermal Conductivity and Ultrahigh Thermal Boundary Conductance of Homoepitaxial AlN Thin Films Gustavo Alvarez, Ryan Page, Renjiu Hu, Huili G. Xing, Debdeep Jena and Zhiting Tian; Cornell University, United States

Wurtzite aluminum nitride (AlN) has attracted increasing attention for high-power and high-temperature operations due to its high piezoelectricity, ultrawide-bandgap, and large thermal conductivity k. The k of epitaxially grown AlN on foreign substrates has been investigated; however, no thermal studies have been conducted on homoepitaxially grown AlN. In this study, the thickness dependent k and thermal boundary conductance G of homoepitaxial AlN thin films were systematically studied using the optical pump–probe method of frequency-domain thermoreflectance. Our results show that k increases with the thickness and k values are among the highest reported for film thicknesses of 200 nm, 500 nm, and 1 μm, with values of 71.95, 152.04, and 195.71 W/(mK), respectively. Our first-principles calculations show good agreement with our measured data. Remarkably, the G between the epilayer and the substrate reported high values of 328, 477, 1180, and 2590 MW/(m2K) for sample thicknesses of 200 nm, 500 nm, 1 μm, and 3 μm, respectively. The high k and ultrahigh G of homoepitaxially grown AlN are very promising for efficient heat dissipation, which helps in device design and has advanced applications in micro-electromechanical systems, ultraviolet photonics, and high-power electronics.

11:00 AM DS01.06.06
Extension of Transport-Derived Electronic Entropies to the Thermochemistry of High-Temperature Solid Solutions Jonathan Paras and Antoine

Allanore; Massachusetts Institute of Technology, United States

High-temperature quantification of the entropy of mixing in binary alloys through simulations remains an open challenge in materials thermodynamics. Recent success in using transport-property measurements to rationalize the total entropy of order-disorder and metal-insulator phase transitions in Cu_3Au and VO_2 suggest an empirical link between electronic transport properties and the electronic entropy. Measurements of the Seebeck coefficient and conductivity were conducted in solid-solution and intermetallic forming systems such as Cu-Ni and Fe-Ni at high temperature to assess the extensibility of the transport electronic entropy formalism to binary alloys. Under unipolar transport assumptions, large measured electronic entropy of mixing is reported in Cu-Ni. Similar trends were systematically observed in other high-temperature solid-solutions and their melts.

Zentropy—A Theory for Prediction of Observables Zi-Kui Liu; The Pennsylvania State University, United States

An emergent property appears when a number of simple entities interact in an environment to form more complex behaviors collectively that any single entity does not exhibit. Emergent properties are hard to predict because the number of interactions between a system's components increases exponentially with the number of components. In principle, the elegant Schrödinger equation in quantum mechanics could address the multibody interactions, resulting in the standard statistical mechanics where the individual entities are pure quantum states with zero entropy and their partition functions related to their internal energies. The applications of the Schrödinger equation to complex systems are made possible by the density functional theory (DFT) that postulates the existence of a unique electron density for the ground state of a system at 0 K. Using the ground and non-ground states as the building entities of complex systems, we propose that the entropy of a complex system is composed of the weighted sum of entropies of its building entities plus the classical statistical entropy among the entities. This new theory, termed as Zentropy theory, stacks up the entropic contributions from electrons to the scale of complex system of interest and result in the partition functions of building entities related to their free energies instead of their internal energies. With the properties of ground and non-ground states obtained from DFT, we show that the emergent properties in some magnetic and ferroelectric systems, previously thought to be explainable exclusively by strongly correlated physics, can be predicted, including singularity at critical points. This further provides a theoretical framework to predict emergent cross phenomena, including thermoelectricity, thermodiffusion, electrocaloric effect, and thermal expansion of material systems (https://doi.org/10.1080/21663831.2022.2054668).

Modeling Local Structure and Configurational Free Energy of Multi-Component Alloys Below the High-Temperature Limit Andrew Novick[1], Eric S. Toberer[1] and Vladan Stevanovic[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

We present a method for modeling alloys as a statistical ensemble of randomly sampled ordered configurations on a given lattice. Accurately modeling the structure of alloys can require using large supercells to accommodate atomic disorder. However, with increasing supercell size, the set of possible configurations quickly becomes too large to exhaustively simulate; this is especially true for high-entropy compositions. In this work, we show that randomly sampling from the set of all possible configurations allows for the efficient modeling of alloy systems. This is done while still capturing the structural and energetic complexities found in exhaustive sampling. Furthermore, the statistical treatment naturally produces configurational free energy and local atomic structure as a function of the synthesis temperature. The high-temperature limit, implying perfect configurational disorder, is not assumed; neither is the final structure of the alloy. Thus, our method is particularly useful for studying the relationships between the synthesis temperature, short-range order, and local structure. The high-entropy pseudohexnary system, PbTe-PbSe-PbS-GeTe-GeSe-GeS, will be studied as a case example. Trends in both the miscibility and structural deviation from the rocksalt structure-type will be discussed, as well as their agreement with experiment.

2:15 PM DS01.07.03
First Principles Calculation of Phase Diagrams of Alloys of Technological Interest Including Configurational and Vibrational Entropic Contributions Wei Shao[1,2], Sha Liu[2,3] and Javier Llorca[1,2]; [1]Technical University of Madrid, Spain; [2]IMDEA Materials Institute, Spain; [3]Yanshan University, China

The phase diagram of different alloys of technological interest is predicted from first principles calculations and statistical mechanics including the effect of configurational and vibrational entropy. The formation enthalpy of different configurations was accurately predicted as a function of temperature by means of cluster expansions that were fitted from first principles calculations. The vibrational entropic contribution of each configuration was determined from the bond length vs. bond stiffness relationships for each type of bond and the Gibbs free energy of the different phases was obtained as a function of temperature from Monte Carlo simulations.

The strategy was applied to determine the phase diagram of Al-Cu, Al-Li, Al-Cu-Li alloys and the computed phase diagrams were compared with the current experimental phase diagrams in the literature. Overall, the calculated phase diagrams were in good agreement with the currently accepted experimental phase diagrams and, moreover, they provided new insights and information that is sometimes missing in the experimental phase diagrams due to the limitations imposed by the kinetics of phase changes. This additional information can be very important to optimize the microstructure of these alloys by means of heat treatments.

Configurational Entropy in Complex Multi-Component Oxides Gerbrand Ceder; University of California, Berkeley/Lawrence Berkeley National Laboratory, United States

Configurational entropy embodies the composition complexity that materials can exhibit. Ab-initio methods such as the cluster expansion (CE) technique can be used to develop coarse-grained Hamiltonians that parameterize the energy dependence on configurational state but have rarely been used beyond simple binary or ternary metallic alloys. In this presentation, I will demonstrate the application of cluster expansion techniques to complex oxides with a

high number of cation and anion components. The extension of the cluster expansion is non-trivial due to the combinatorial scaling of basis functions, the inability to sample all characteristic cation configurations leading to unavoidable degeneracy in the ab-initio to CE mapping, and the charge neutrality constrain in systems with charged ions. I will show how modern compressive sensing techniques, combined with physical constraints, can be used to build accurate and stable cluster expansions which can be used with Monte Carlo simulations to determine the state of order in complex oxides. These complex expansions have been used to develop DRX cathode materials, which are an exciting earth abundant replacement for current Ni and Co-based cathodes, but often have a high number of cations present, making their thermodynamic assessment difficult.

High-Component Ionic Cluster Expansions for Exploring Disordered Spaces Tina Chen[1,2], Julia Yang[1], Peichen Zhong[1,2], Luis Barroso-Luque[1] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Cluster expansions coarse-grain the free energy of multi-component systems based on the possible configurations of species on a disordered crystal lattice. The modeling of configurational energetics in conjunction with Monte-Carlo methods enables finite temperature voltage curve calculations and the computation of phase diagrams. While cluster expansions can in theory be used for systems of any dimensionality, their application has generally been limited to binary or ternary alloys. When applied to high-component ionic systems, a number of practical challenges emerge, including charge-state assignment, atomic relaxations from the fixed lattice, and the fitting of predictive models from a large feature space. We demonstrate techniques to overcome these challenges in the fitting of a cluster expansion to the space of cation-disordered Mn-based spinel, a Li-ion cathode materials space within which the high energy density, high-rate partially disordered spinels lie. We then show how the cluster expansion can evaluate how the level of disorder between the 16d TM sites and vacant 16c octahedral sites affects the electrochemical properties of the disordered spinel. Through this thermodynamic analysis, we illustrate how cluster expansions can be applied to isolate and understand the effects of specific types of disorder.

High Entropy Alloys as Glasses and Solid Solutions—Configurational Entropy and Alloy Properties MIkko Alava[1,2], Rene Alvarez-Donado[1], Amin Esfandiarpour[1] and Stefanos Papanikolaou[1]; [1]NOMATEN Center of Excellence, Poland; [2]Aalto University, Finland

High entropy alloys (HEAs) represent highly promising multicomponent crystals that form concentrated solid solutions (CSS) and may violate traditional thermodynamic rules of mixing, ultimately leading to excellent physical properties. Here, we report on simulations on seven CSS, including Co-Cr-Ni-Fe-Mn elements and we use 1-1 comparisons to corresponding glass phase characteristics, attained through rapid cooling protocols. We determine the behavior of various structural features, including the configurational entropy for a set of CSS in their crystalline and vitreous states numerically using swap Monte Carlo and show that the entropic rule of mixing is not always adequate for predicting alloy formation. We study the stability and formability of crystalline solid solutions, as well as glasses, while following the configurational entropy. An apparent entropic similarity between CSSs and corresponding glasses, leads us to use a Kauzmann-like ansatz, relating the CSS with the emergence of a order/disorder transition, at a composition-dependnet temperature. In the context of glasses, a comparison between kinetic and thermodynamic fragilities allows to associate the sluggish diffusion onset to a drop in configurational entropy at the Kauzmann temperature. In analogy to glasses, we classify CSS as strong or fragile in the sense of their ability to migrate across CSS crystal configurations at high temperatures. We argue that the magnitude of the order/disorder transition temperature may predictf CSS single-phase stability, as it appears to scale with well known predictors, such as the valence electron concentration (VEC).

Short-Range Order in High-Entropy Superalloys—First Principles Theory and Atomistic Modelling Christopher D. Woodgate and Julie Staunton; University of Warwick, United Kingdom

Short-Range order (SRO) can be either beneficial or detrimental to the properties of novel superalloys. An understanding of phase behaviour and underlying physical mechanisms driving ordering is therefore essential. We present results from an all-electron, first principles, Landau-type theory which enables us to obtain SRO directly, and also to obtain parameters suitable for atomistic modelling to understand incipient order in these materials. Following successful earlier work on the Ni-based superalloys[1], I will present new results on the refractory-based superalloys, which are being studied as candidate materials for components in fusion reactors, due to their exceptional strength, high melting points, and high levels of resistance to radiation. We present a complete description of SRO in the five-component VNbMoTaW and its derivatives. Further, we elucidate the origins of this order and describe the underlying physical mechanisms by which it is driven.

Short Range Order Corrections to Alloy-Free Energies within the CALPHAD Framework Using the Cluster Variation Method Formalism. Sayan Samanta and Axel van de Walle; Brown University, United States

The CALPHAD method, traditionally used to model experimental thermodynamic data, also provides an effective way to parametrize alloy free energies computed from first-principles. While the Special Quasirandom Structure (SQS) formalism offers a natural and efficient tool to generate input data for disordered solid solution phases, accounting for short range order (SRO) effects in a computationally efficient way presents a challenge. In this work we utilize the Cluster Variation Method (CVM) method in tandem with the SQS formalism to determine closed-form nonlinear expressions for temperature-dependent SRO corrections to the formation free energies. Our approach, which implements the CVM to any level of accuracy, has been integrated into the sqs2tdb software pipeline. As a proof of concept, we perform a thermodynamic assessment of the Ir-Ru binary alloy with SRO correction and show that under the tetrahedron approximation, the SRO correction to the hcp phase is sufficient to accurately reproduce the known experimental phase diagram.

9:00 AM DS01.08.01
Direct *Ab Initio* Calculation of Solid-Liquid Interfacial Energies Anirudh Appachar and Wenhao Sun; University of Michigan–Ann Arbor, United

States

Solid-liquid interfacial energies are notoriously difficult to measure experimentally. This has led to a dearth of values in the scientific literature, despite their centrality to nucleation and crystal-growth phenomena. Computational approaches can successfully calculate the interfacial energy for isolated systems, but are not easily generalizable across materials spaces: most models rely on material-specific interatomic potentials, calling into question their transferability, or are simply too resource-intensive to scale practically across thousands of materials. Here, we present a slab-based DFT methodology to calculate the oriented solid-liquid interfacial energy of a material and demonstrate its application to four pure-metal systems. We discuss crucial model considerations, including slab dimensions, molecular dynamics simulation parameters, effects of periodic boundary conditions, and quantification of amorphous character. Our methodology will enable systematic investigations of trends in interfacial energy across materials spaces and serve as a source of first-principles data upon which to train future interatomic potentials.

9:15 AM DS01.08.02
Interfacial Free Energies from MD Simulations—Application to $CaSO_4 \bullet xH_2O$ Stephen Yeandel, Colin Freeman and John Harding; The University of Sheffield, United Kingdom

Surfaces are a ubiquitous feature of crystals and play an important role in both nucleation and crystal growth. At the nanoscale surface effects play a large role in the stability of different nanocrystal polymorphs and so can influence the selection of which polymorph is grown. Additionally, surfaces themselves can be sites for heterogeneous nucleation. It is therefore important to fully understand the energetics of crystal surfaces.

The calculation of surface Enthalpies is now routine using Molecular Dynamics simulations. But when the crystal surface is in contact with a liquid it may induce ordering of the liquid, making Entropy an important factor which must also be considered. Thus, what is required is a method for calculating Interfacial Free Energies (IFEs), which include both Enthalpic and Entropic contributions.

A general method for calculating IFEs is difficult to construct as it must be able to deal with multiple materials in different physical phases. Previous methods for calculating IFEs often rely on particular properties of the system under study, such as being able to reform bulk material by bring two surfaces together[1], which may in general not be possible.

We present a new, general, method for calculating IFEs which can easily deal with multiple phases as well as complex surfaces. Our method relies on transforming the solid component of the interface into bulk material via an Einstein Crystal; avoiding the need to define an explicit real-space path for the transformation. Furthermore, the efficiency of the calculation is improved as intermediary values may be computed once and re-used for multiple different interfaces.

We have applied our method to the calculation of water interfaces with different members of the $CaSO_4 \bullet xH_2O$ group of materials. This is a particularly challenging system to study due to strong binding between the Ca^{2+} ion and water[2], the inclusion of water molecules which formally belong to the bulk material but may behave as liquids at the interface, and the presence of surface dipoles for the hemihydrate phase (Bassanite, $CaSO_4 \bullet 0.5H_2O$).

Our results indicate that Entropy accounts for between 55-85% of the IFE in these materials depending on surface cut, in contrast to NaCl where Entropy accounts for approximately only 20%. We also find that in general the IFEs of Bassanite interfaces ($CaSO_4 \bullet 0.5H_2O$) are lower than that of Gypsum ($CaSO_4 \bullet 2H_2O$), indicating a possible reason why Bassanite is often observed first in solution[3]. Predicted equilibrium morphologies also show good agreement with experimental studies.

Effect of Solvent on Chemistry at the Electrochemical Interfaces Oskar Cheong[1,2], Michael Eikerling[1,2] and Piotr Kowalski[1]; [1]FZ Juelich, Germany; [2]RWTH Aachen University, Germany

Thermodynamics of chemical reactions at the electrochemical interfaces is a driver of performance of electrocatalyst materials. Computational electrochemistry usually neglects effect of solvent on derived thermodynamic, or model these with simple approximations. The reaction free energies depend on the enthalpy and entropy of the reactant species. Usually only enthalpy effects, computed directly by quantum chemistry computational method such as density functional theory (DFT) is taken into consideration. If accounted for, entropy is usually computed as vibrational, translational and rotational parts using gas phase formulas. In the presence of solvent, the cavitation entropy, which results from the rearrangement of the solvents around the solute, can play a fundamental role in determining the reaction free energy. We will present adaptation of existing models for entropy of the solvent phase derived for the bulk solvent (e.g. [1]) to the description of thermodynamics at an interface, using some hints from the *ab initio* simulation studies [2]. The implication for the surface chemistry thermodynamics will be discussed.

A Novel Application of Metastable Photoacid Molecules in Liquid-State Light-Electricity Energy Transformation Jaehyeong Bae, Haeseong Lim, Jaewan Ahn, Yoon Hwa Kim and Il-Doo Kim; Korea Advanced Institute of Science & Technology, Korea (the Republic of)

Tuning the metastability of a functional chemical can overcome its own functional limitations, including stimuli sources, sensitivity, and reversibility, which determine its ability to design and utilize in practical applications. Compared to its preceding generation of chemical i.e., irreversible photoacid generators, photoacid can release protons upon light irradiation and recombines with them in the dark through a fully reversible reaction. In this presentation, we utilize this reversible and visible-light responsive photoacid to build a novel liquid-state light-electricity energy harvester. Asymmetric light exposure on a photoacid solution contained in a transparent tube generates a pH gradient ($\Delta pH = 2$) along the exposed and dark regions, which charges the Nernst potential up to 0.7 V across the two electrodes embedded at each end, as if a capacitor. Owing to the reversibility of photoacids, a

photoacid-driven liquid-state photoenergy harvester (PLPH) generates capacitive currents up to 0.72 mA m^{-2} on irradiation. Notably, the transparent nature of the PLPH enables vertical stacking up to 25 units, which multiplies the light-harvesting efficiencies by over 1000%. This unique approach provides a new route to harness solar energy with a form-factor-free design that maximizes spatial and light-use efficiencies.

10:30 AM DS01.08.05
Self-Assembly in Supercritical Fluids—Thermodynamics and Fluid Mechanics Loren G. Kaake; Simon Fraser University, Canada

Photolithography and solution phase self-assembly are the two primary approaches to creating nanostructures. The former is the powerhouse of computing, the latter is the manufacturing method of living organisms; the two share very little common ground. Photolithography is a subtractive process, employed with staggering precision, but typically used with monolithic materials. Solution phase self-assembly is an additive process that can be employed with systems of arbitrary complexity. However, entropy places limits on the precision of the technique, especially over large length scales. In an effort to bridge these non-intersecting methods of manufacturing, we have developed a materials deposition technique that leverages the unique properties of supercritical, near-critical, and/or subcritical fluids. We deposited polymer thin films with high precision on photolithographically patterned substrates allowing us to control the process of self-assembly with photolithography. The technique relies on a solubility behavior contrary to typical polymer solutions which show a monotonic increase in saturation solubility with temperature. Instead, the saturation solubility of a solid solute first increases, and then decreases with increasing temperature as a solution is heated near its critical point. The typical Flory-Huggins approach to polymer solubility fails to model this behavior, as solvent compressibility is a key factor in supercritical media. Alternatively, the Sanchez-Lacombe model can be used to describe solubility behavior in supercritical media, however, it is too complicated to be practical use. We have developed a simple model based on classical thermodynamics which is adequate to describe our observations while still being simple enough to provide qualitative insight into the key factors important in the process. This non-monotonic solubility behavior enables us to precipitate thin films onto heated substrates. The resulting films have a complex micro and nanoscale structure which depends upon pressure, the nature of the substrate, and the presence of solvent additives. We attribute the behavior to the influence of the fluid mechanics as parameterized by the Rayliegh number as well as the influence of surface energy and surface diffusion immediately following deposition. The development of a fuller understanding this process will allow us to more finely control the formation of nanoscale structures with the precision and scalability of photolithography.

Ising and Dissipative Particle Dynamics Models of Network Connections Between Engineered Nanoparticles Xingfei Wei and Rigoberto Hernandez; Johns Hopkins University, United States

Complex engineered nanoparticle (ENP) networks are emergent materials that have a variety of applications, such as drug delivery, flexible electronics, and computing devices. Uncovering the fundamental physics of network connections between ENPs is critical to developing new networked materials. In this work, we use an Ising model to resolve the network connections in regular arrays of ENPs by Monte-Carlo (MC) simulations and mean-field theory (MFT). We compare the theoretical predictions from the Ising model with dissipative particle dynamics (DPD) simulation results. We report the network connections inside four different types of ENP regular arrays, *viz.* 2D square, 2D hexagonal, 3D cubic and 3D close-packed hexagonal packings. We found that MFT and MC simulations are in good agreement in describing the thermodynamics of the network connections. We also found that the DPD simulations and Ising model MC simulations agree in predicting the resulting network connections at varying temperatures under a range of external E-field strengths.

11:00 AM DS01.08.07
Picowatt Resolution Calorimetry for High-Throughput Screening of Metabolic Rates in Single Cells Juanjuan Zheng and Joost J. Vlassak; Harvard University, United States

Calorimetry, which measures the heat generated from a sample, is the only technique that provides a direct measure of metabolic rates. However, calorimetry is rarely used in cell and developmental biology due to limitations in sensitivity and throughput. Here, we describe a sensor that has a near order-of-magnitude increase in sensitivity above current state-of-the-art calorimeters and has orders-of-magnitude higher throughput than existing calorimeters. These improvements will push calorimetry into a regime where it can be used for high-throughput screens of single-cell measurements on a broad range of cell types.
These advances are enabled through use of a novel micromachined sensor design that incorporates several key innovations: The first innovation critical to achieving 30-pW sensitivity of our sensor is the use of low-noise thermopiles embedded in a membrane with negligible thermal mass, allowing measurement of minute temperature differences. Second, the use of a differential measurement setup based on multiple references eliminates the effect of thermal gradients due to environmental drift. The key innovations enabling the increased throughput are 1) effective thermal coupling of the capillaries that contain sample and reference(s) to a very sensitive thermometer using capillary forces, and 2) the design of a micromachined sensor with minimal thermal mass, allowing fast (within 30 seconds) thermal equilibration. The combination of high sensitivity and extremely short equilibration times allows for quick signal integration to measure changes in metabolic rate and therefore a high overall sample throughput.
The extraordinary sensitivity combined with the high throughput makes the sensor ideally suited for the direct measurement of metabolic rates and for the study of non-equilibrium processes in a range of materials systems. Calorimetric based screens for small molecules that alter the metabolic rates of cancer cells and bacteria may help identify compounds that are both useful for scientifical research and medically beneficial.

SESSION DS01.09: Defect Thermodynamics
Session Chairs: Jason Calvin, Alexandra Navrotsky, Richard Otis and Wenhao Sun
Thursday Afternoon, December 1, 2022
Hynes, Level 2, Room 204

1:45 PM *DS01.09.01
Constructing Defect Phase Diagrams from *Ab Initio* Calculations Tilmann Hickel[1,2], Ali zendegani[1], Ali Tehranchi[1], Omkar Hegde[1], Prince Mathews[1] and Jorg U. Neugebauer[1]; [1]Max-Planck-Institut für Eisenforschung, Germany; [2]Federal Institut for Materials Research and Testing, Germany

Recent progress in experimental atomic-scale characterization techniques allows one to study the local chemical composition at individual defects such as interfaces, grain boundaries, dislocations and surfaces. These experiments show a surprizingly rich set of structural and chemical phenomena, going well beyond simple Gibbs isotherms. To understand and eventually utilize the large number of possible defect structures, phases and phase transitions, the construction of defect phase diagrams becomes mandatory. In analogy to the well-established concept of thermodynamical bulk phase diagrams they provide direct insight into the themodynamically most stable defect state as a function of state variables such as temperature, composition, stresses etc. The power and performance of this concept are demonstrated using the example of nonstoichiometric stacking faults in metallic alloys. Our ab initio computed defect phase diagrams provide an accurate tool to correctly predict the rich set of experimentally observed defect structures. Based on these insights we will discuss a conceptual framework of how to generalize these findings and to construct defect phase diagrams on a routine basis.

2:15 PM DS01.09.02
A Probabilistic Model for Oxygen Vacancies at the Surface to Explain Oxidation Kinetics of Metals with Protective Oxide Layer Mehdi Pishahang, Nicolas Hadjiconstantinou, Dionysios Sema, Mathew Swisher, Julien Luzzatto, Qingzi Zhu, Youssef Marzouk and Asegun Henry; MIT, United States

This work presents a novel approach towards the oxidation kinetics of metals that form almost perfectly stoichiometric oxide layer upon oxidation. We have developed a model that relates the oxidation kinetics to the probabilistic availability of oxygen vacancies at the surface of the oxide layer. The rate and energy at which oxygen collides to the oxide surface is explained by the Boltzmann-Maxwell distribution. Given than Hf cannot readily possess 3+ valence, the produced undoped HfO2 has a very small intrinsic concentration of oxygen vacancies. The concentration of oxygen vacancies, as well as the transport rate of the oxygen vacancies at each temperature is calculated from defect formation and barrier gap energetics. Our model demonstrates that it is the probability of gaseous oxygen colliding with oxygen vacancies at the surface of oxide layer which defines the rate of oxidation. Our model studies the Hf oxidation in 3 phases, the first phase is for when fresh Hf is exposed to O2 for the first time. The very first gaseous oxygens that hit the surface almost all get fully absorbed, until a very thin (1nm) HfO2 oxide layer is formed. Our calculations estimate phase 1 to take up to 1 microsecond. As soon as the oxide layer is formed the availability of oxygen vacancies at the surface determines the rate of oxidation, as only gaseous oxygens that happen to collide with the oxygen vacancies get absorbed and join the solid. In the third phase, the oxide layer is so thick that the diffusion of oxygen vacancies from bulk to the surface slows down significantly, and therefore becomes the kinetics rate-definer. A set of TGA (thermogravimetric analysis) experiments are performed to analyze and quantify the oxidation kinetics of Hf. These experiments are performed at different isothermal and isobaric conditions with different surface-to-bulk ratios for the solid. The model satisfactorily reproduces the validation experiments.

2:30 PM DS01.09.04
Heterogeneous Melt-Initiation Mechanisms at Interface Junctions and Vertices in Solids Wenkai Pan, Bonan Shen, Nikita Lisenko, Ruobing Song, Jayoung Park and James S. Im; Columbia University, United States

Melting of elemental solids can be identified and appreciated as a particularly simple example of discontinuous phase transitions involving condensed phases. Driven by (1) the need to decipher and understand laser-irradiation-induced melt-mediated microstructure evolution observed in oxide-capped columnar-grained polycrystalline Si films [1], [2], (2) an opportunity to better incorporate the often-overlooked phenomenon of negative-solid/liquid-interface-curvature-stabilized premelting (or “pretransition”) [3], [4] into the field of discontinuous phase transformations in condensed systems, and (3) the interest in identifying and analyzing previously under-recognized and under-analyzed mechanisms and behaviors of phase initiation and propagation in general, we examine in this paper the nature and mechanisms of melt-initiation transpiring heterogeneously at the interfaces, junctions, and vertices that are present within the precursor solids.

Our analysis employs an important thermodynamic element in the classical nucleation theory that pertains to the mechanical-equilibrium-satisfying shapes of the melt; specifically, this requirement dictates that the solid-liquid interfaces predominantly manifested at the interfaces, junctions, and vertices must comply with the contact angle conditions at the involved interfaces while also satisfying the property of constant mean curvature. Simple and idealized Bi-crystal and tri-crystal models are examined to capture the aforementioned microstructural features present in columnar-grained polycrystalline thin films sandwiched by inert oxide layers. Our shape analysis reveals that, at least for the “isomorphic” cases in which the shape of the melt is preserved, there are three distinct cases of melting behavior at these junctions and vertices as a function of the involved liquid wetting angles. Two phase-initiating scenarios involving (1) negative-curvature-induced premelting and stabilized coexistence of solid and liquid phases in thermodynamic equilibrium, and (2) the well- and long-recognized mechanism of site-localized heterogeneous nucleation at junctions and vertices involving unstable equilibrium, are identified [5]. As well, we identify the existence of a wetting-angle parameter space domain within which localized melting at the junctions and/or vertices is specifically prohibited due to the absence of the existence of mechanical equilibrium shape containing these sites. Note that this behavior actually goes against the conventional view that considers vertices and junctions to always be thermodynamically more favorable sites for nucleation due to the presence of additional interfaces than planar interfacial areas.

We will present melt-initiation mechanism diagrams that identify these domains in the contact angle parameter space, and also discuss (1) how our analysis may also be relevant to understanding melt-mediated processing of bulk materials, (2) how localized premelting at junctions and vertices is not sufficient for inducing efficient microstructure evolution of the polycrystalline materials, and accomplishing this at below the bulk melting temperature further requires attaining a local free-growth condition via interface-curvature reducing shape transitions, and (3) trivial extension of our analysis to address the phase-initiation taking place heterogeneously at the edges and corners of embedded single crystals with three distinct wetting interfaces.

2:45 PM DS01.09.05
Identifying and Analyzing Contact-induced Nucleation of Solids in Supercooled Liquid Thin Films Bonan Shen, Nikita Lisenko, Wenkai Pan, Ruobing Song, Jayoung Park and James S. Im; Columbia University, United States

Motivated, on the one hand, by the need to understand laser-induced melt-mediated crystallization of thin Si films for realizing advanced high-resolution displays, and on the other hand, by the opportunity to investigate discontinuous phase transformations in condensed systems, we are in the process of examining various mechanisms and behaviors that are manifested at the onset of transformations (i.e., new phase initiation and evolution), particularly as

they are encountered in small, confined, and embedded systems.

In this paper, we focus on identifying and thermodynamically describing a new nucleation mechanism, which we refer to as transmorphic nucleation, as can for instance be revealed in considering nucleation of solids transpiring in supercooled and encapsulated liquid thin films. Following the basic framework of classical nucleation theory, we investigate heterogeneous nucleation of solids as the thickness of the film decreases. When the film thickness becomes slightly less than the critical height of the spherical-cap nuclei on one interface, some of the evolving embryos must come in contact with the other interface. When this occurs, we suggest based on thermodynamic and kinetic considerations that these clusters will undergo a sudden and irreversible local-interface-curvature-driven shape transition starting from the point of contact, leading to the formation of clusters with two-interface-defined shapes. Subsequently, some of these clusters will become supercritical and grow (i.e., "nucleated"), while others may still evolve to stay subcritical and dissolve. Note that, in contrast to the well-established thermal mechanism of heterogeneous nucleation in which fluctuation over the energy barrier associated with the critical nucleus corresponds to the point at which supercritical clusters are generated, in transmorphic nucleation, the point at which the embryos come in contact with the interface is explicitly identified as the critical moment for the nucleating clusters to become supercritical (i.e., the free energy change due to the formation of the contacting clusters is argued as being the effective energy barrier of nucleation).

Using a simplified example of a uniform thin film consisting of two interfaces with identical wetting angles, we explicitly and quantitatively identify the conditions under which transmorphic nucleation is encountered, and evaluate the free energy changes associated with the process. We will also discuss (1) how transmorphic nucleation can be manifested in melting of all polycrystalline materials as well as in melting of confined and embedded solids, (2) how our transmorphic nucleation model is distinct from previously suggested transformation pathways, (3) certain analytical and numerical treatments for dealing with complex cluster shapes and interface geometries, (4) the implications on calculating both steady-state and transient rates of transmorphic nucleation, and (5) a more general category of transmorphic transitions that can affect phase initiation and evolution in discontinuous phase transformations.

3:00 PM BREAK

3:30 PM DS01.09.06
Observation of Negative Surface and Interface Energies of Quantum Dots Jason J. Calvin, Amanda Brewer, Michelle Crook, Tierni Kaufman and Paul Alivisatos; University of California, Berkeley, United States

Surface energy is a fundamental property of materials and is particularly important in describing nanomaterials where atoms or molecules at the surface constitute a large fraction of the material. Traditionally, surface energy is considered to be a positive quantity, where atoms or molecules at the surface are less thermodynamically stable than their counterparts in the interior of the material because they have fewer bonds or interactions at the surface. Using calorimetric methods, we show that the surface energy is negative in some colloidal semiconductor nanocrystals, or quantum dots with organic ligand coatings. This implies that the surface atoms are more thermodynamically stable than those on the interior due to the strong bonds between these atoms and surfactant molecules, or ligands, that coat their surface. In addition, we extend this work to core/shell indium phosphide/zinc sulfide nanocrystals and show that the interfacial energy between these materials is highly thermodynamically favorable in spite of their large lattice mismatch. This work challenges many of the assumptions that have guided thinking about colloidal nanomaterial thermodynamics, illustrates the fundamental stability of many technologically relevant colloidal nanomaterials, and paves the way for future experimental and theoretical work on nanocrystal thermodynamics.

3:45 PM DS01.09.07
Significant Entropic Effects Driving Dislocation Nucleation Kinetics at Surfaces Soumendu Bagchi and Danny Perez; Los Alamos National Laboratory, United States

A wide range of kinetics of material defects are very successfully predicted by harmonic transition state theory (HTST). It is however worth recalling that the accuracy of HTST relies on a set of assumptions whose validity should be assessed on a case-by-case basis. We discuss a key scenario concerning crystal plasticity i.e., the nucleation of dislocations from surface steps, where HTST dramatically fails to reproduce the transition rates observed in direct MD. We show that a simple and efficient procedure to estimate the changes in vibrational entropy along the minimum energy pathway can resolve the discrepancy with HTST and provide quantitatively accurate predictions of the anharmonic kinetics which is otherwise intractable with the existing HTST approaches ubiquitous in describing reactions in materials.

4:00 PM DS01.09.08
Free-Growth-Initiating Shape Transition from Curvature-Stabilized Premelting in Polycrystalline Materials Nikita Lisenko, Wenkai Pan, Bonan Shen, Jayoung Park, Ruobing Song and James S. Im; Columbia University, United States

This work focuses on investigating phase transformation mechanisms in condensed and confined systems, encountered, for instance, in pulsed-laser-induced melting and solidification of columnar-grained polycrystalline Si films [1]. We start by recognizing that, in addition to nucleation and growth [2], interface-curvature-stabilized premelting can also be relevant for initiating the melting transition. This phenomenon involves equilibrium coexistence of liquid regions confined to grain junctions and vertices within the solid matrix. Isolated premelting clusters or interconnected channels can form and be stabilized below the bulk melting point by adopting negative constant mean curvature (CMC) of the solid-liquid interface, as defined by the Gibbs-Thomson equation [3].
We suggest that consideration of the transition from stable coexistence to free growth is important, as it represents an alternative pathway to nucleation and growth for discontinuous phase transformations. For example, during melt-mediated pulsed-laser processing, complete melting of the grain boundary was established [1] as a necessary condition for microstructure evolution, implying that localized premelting alone is insufficient. In this case, the free growth condition can be realized even below the bulk melting point if the temperature is increased enough to allow the premelting regions to expand until isolated regions meet or connected channels completely envelop and eliminate the grain boundary. We argue that a sudden and spontaneous shape transition must occur at this point of change, necessarily leading to an abrupt reduction of the solid-liquid interface curvature below the premelt-stabilizing CMC value. Consequently, the liquid region is now at least locally in the state of free growth with finite velocity, even without any further increase in temperature. Due to the abrupt shape change that initiates free growth, we call this phenomenon *transmorphic free growth* (TFG); this is in contrast to other examples of free growth starting with infinitesimal drift velocity after thermal nucleation or continuous shape evolution discussed previously in literature [4,5].
In this work we capture the conditions necessary for TFG analytically and numerically, and assess the transition rate through direct cluster dynamics calculation [6]. Although presented here in the context of laser-induced melting of columnar-grained polycrystalline thin films, this mechanism of shape-change-induced transformation below the equilibrium temperature is also applicable to broader classes of phase transitions in condensed and confined systems.

Mimicking the Sustainable Anionic Redox Features for Advanced Lithium-Ion Batteries Jaewoon Lee[1], Kyeongjae Cho[2] and Duho Kim[1]; [1]Kyung Hee University, Korea (the Republic of); [2]The University of Texas at Dallas, United States

The practical capacity of lithium-ion batteries based on the cationic redox mechanism of transition metals (Ni, Mn, and Co) has almost approached the theoretical capacity. As a breakthrough, anionic redox from oxygen in the oxide frameworks has been highlighted, recently, as it demonstrates additional capacity in high voltage regions. For this reason, the representative oxygen redox activating cathode, Li_2MnO_3, got attention since it demonstrates over 300 mAh/g at ~4.5 V versus Li^+/Li. However, it usually suffers from various concomitant electrochemical fast degradations such as a very large irreversible capacity and drastic voltage-fading upon cycling. Doping and coating are commonly used to improve the shortcomings of the cathodes. A lot of experiments and computational calculations have reported the influences of the results to elucidate the electrochemical performances and redox mechanisms to suggest new ways of maintaining the first charge capacity/voltage in Li_2MnO_3. It is not known yet how to practically utilize the pure anion redox capacity of Li_2MnO_3. In addition, a lot of theories coexist, and some experimental results indicate discrepancies with each other. However, the fast degradation is generally acknowledged from the undesirable transition metal migration which transforms the pristine structure into a spinel-like sequence and oxygen dimerization causing O_2 gas to evolve. However, 5*d* contained lithium-excess cathode (Li_2IrO_3) does not exhibit similar degradation even though the crystal structure is the same as Li_2MnO_3. However, it is lack of realistic to utilize the Li-excess 5*d* cathode since it is not feasible due to economic reasons. This motivates us to reinvestigate the critical features of Li_2IrO_3 that contribute to reversible anionic redox without hysteretic features and mimic the sustainable redox characteristics for harnessing the pure anionic redox in Li_2MnO_3.

By computational calculations, we figure out the thermodynamic feature of Li_2IrO_3 that there is an unrevealed stacking sequence during (de)intercalation which was not highlighted sufficiently. The calculated voltage behavior concurs with the experimental results when we reflect on the stacking sequence while the normal Li/vacancy mode demonstrates the difference from the experimental result. Since the atomic configuration was not shown in the Li-excess 3*d* metal compound, we did an intensive investigation of the influences of how the stacking sequence can contribute to sustainable oxygen redox in Li_2IrO_3 without structural deformation. From the same point of view, we reinvestigate the Li_2MnO_3 and investigate that the same stacking sequence state is hidden in the (de)lithiation of Li_2MnO_3 so it was not observed from experimental methods. From the exhaustive computational calculations, we verify why the phase does not have a preference in terms of thermodynamics and concentrate that revealing the stacking sequence is significant to rationally utilize the anionic redox in Li_2MnO_3 sustainably. By controlling the anion in Li_2MnO_3, we elucidate how we can mimic the sustainable redox mechanism in 3*d* metal by suppressing the structural transformation and undesirable oxygen dimerization during (de)intercalation. It has not been reported yet how we can mimic the sustainable oxygen redox characteristics of Li_2IrO_3 in 3*d* metal Li-excess cathode for practical utilization. For these reasons, it has the possibility to extend the battery research area by applying the concept for advanced lithium-ion batteries.

10:30 AM DS01.10.01
Thermodynamic Analysis of High-Strength Al-Cu-Mg-Si Alloys at High Temperatures Designed by Using Bayesian Learning for Neural Networks Takeshi Kaneshita[1], Shimpei Takemoto[1], Hattori Ayami[1], Yoshishige Okuno[1], Kenji Nagata[2], Junya Inoue[3] and Manabu Enoki[3]; [1]SHOWA DENKO K.K., Japan; [2]National Institute for Materials Science, Japan; [3]The University of Tokyo, Japan

We discuss the design of 2000 series high-strength aluminum alloys at high temperatures using Bayesian learning for neural networks and thermodynamic analysis. It is known that the strength of aluminum alloys decreases rapidly above 150°C, so improving the strength at high temperatures is essential for industrial applications. In order to design high-strength alloys, it is necessary to optimize the additive element compositions and the heat treatment conditions such as temperature and time for homogenization, solution processing, and aging. A data science approach using neural networks is suitable for handling such multi-dimensional problems and exploring the optimal process conditions from the vast design space. This study focuses on the thermodynamic calculations of the behavior of the size and dispersion of precipitates affecting the high-temperature strengthening mechanism of designed alloys by the neural network.

Toward a More Accurate But Still Efficient Density Functional Theory for Materials Prediction John P. Perdew; Temple University, United States

Kohn-Sham density functional theory is the workhorse of materials computation. Whether human-designed or machine-learned, approximate density functionals for the exchange-correlation energy become more predictive [1] as they are constrained to satisfy more of the mathematical properties of the exact functional. Meta-generalized gradient approximations (meta-GGAs) that satisfy 17 (SCAN [2]) or 16 (r^2SCAN [3], with reduced grid sensitivity) exact constraints can be remarkably accurate for molecules and non-metallic materials, including some that are strongly-correlated [4]. Further improvements for those systems are possible, including self-interaction corrections [5] re-designed to work accurately and efficiently with SCAN-like functionals. Metallic *sp* and *sd* solids and liquids, however, have perfect screening of long-range exchange and can be better treated by more local approximations that employ only the local electron density and its low-order derivatives [6].

Studies on the Electrochemical Thermodynamics and Safety Behavior of Advanced Batteries and Their Materials Hans-Jurgen Seifert; Karlsruhe Institute of Technology, Germany

Layered oxides NMC ($LiNi_xMn_yCo_zO_2$) and spinel phases ($LiMn_2O_4$) are commercially most relevant cathode materials for lithium-ion battery design. However, there is still lack of fundamental knowledge on electrochemical-thermodynamic properties and related safety behavior of these materials and the batteries assembled thereof. The presented work focuses on the investigation of such properties to provide quantitative data for better understanding the performances of lithium-ion batteries in their regular and irregular operational use and during accidents. Experimental electrochemical, thermodynamic and safety studies are combined with computational methods (CALPHAD). We use various calorimetric methods (DSC, Tian-Calvet) for studies of the energetics of battery active materials as well as electrochemical cells. Such data are input for the thermodynamic modeling and calculation. The results are then used to derive fundamental electrochemical and thermal properties. Accelerating Rate Calorimetry (ARC) is used to quantitatively measure the thermal runaway behavior of self-made and commercial coin cells, cylindrical cells and pouch cells, respectively.

Computational Prediction of Ligand Curvature-Selectivity Ability on Gold Nanoparticle Surface Amanda A. Chen, Yufei Wang, Krista Balto, Andrea Tao, Joshua Figueroa and Tod Pascal; University of California, San Diego, United States

Organic ligands are foundational in determining the properties and assembly of inorganic nanoparticles. Recent works have focused on ligands that passivate the nanocrystal surface to enable the supramolecular structure to be formed. However, precise nanoparticle surface modification, as a means of controlling the nanoparticle assembly structure, is difficult. Therefore, in this work, we devised a ligand ($CNAr^{Mes2}$) that can achieve site selective binding on gold nanoparticle (AuNP) surfaces, based on curvature. We adopted a variety of computational approaches, namely quantum mechanical electronic structure theory calculations and molecular dynamics (MD) simulations, to obtain microscopic insights into the AnNP/ligand interaction energies, dynamics, solvation properties, and spectroscopy. We were able to compute the ligand adsorption characteristic and further predict the ligand adsorption sites on AuNPs, as quantified by four unique descriptors: the site binding ratio, the edge-binding factor, and the ligand solubility and solvent partition factors. We verified our predictions experimentally using liquid-liquid extraction, transmission electron microscopy, zeta potential measurements and surface-enhanced Raman spectroscopy. Together, our investigations indicate that $CNAr^{Mes2}$ provided good selectivity for AuNPs based on their average sizes, with a separation resolution of ± 5Å that is competitive with the state of the art in industry. Our study demonstrates how first-principles based computations can guide experimental design at the nanoscale, to enable novel material physics and commercial processes.

11:40 AM *DS01.10.05
Computational Tools for the Generation and Visualization of High-Dimensional Phase Diagrams Axel van de Walle; Brown University, United States

We present an array of software tools enabling the construction of high-dimensional Calphad databases from first-principles calculations. These tools span the full spectrum of the accuracy vs. computational requirements trade-off, thus fulfilling the needs of both high-throughput efforts and more targeted high-precision modeling. This is accomplished through a generalization of the Special Quasirandom Structure formalism to include short-range order effects and its integration into the Calphad-type compound energy formalism. Another key element is the generalization of the lattice dynamics calculations to allow for a rigorous handling of mechanical instabilities that is consistent with the Calphad formalism. We finally showcase a new visualization tool enabling interactive exploration of 3D cross-section of higher-dimensional phase diagrams and propose a novel way to represent tie-lines in these settings. Applications to high-entropy refractory alloy design are presented.

Phonon Entropy and Thermal Expansion from Inelastic Neutron Scattering and Computation Brent Fultz and Camille Bernal-Choban; California Institute of Technology, United States

Entropy comes from atomic-scale degrees of freedom. Most of the entropy in materials comes from the vibrations of atoms, which increase in amplitude with increasing temperature. This is "phonon entropy" (or "vibrational entropy"). The important question is usually how the entropy differs, sometimes slightly, between different states of a material (such as a crystal with chemical order or with disorder). Today both ab initio computation and inelastic neutron scattering can provide accurate entropies over a wide range of temperatures. High temperatures are where entropy is most thermodynamically significant, but is also where degrees of freedom become coupled. Normal modes of vibration are no longer independent, and interactions between vibrations and electrons become important. I will describe how such couplings are sorted out and how they alter thermal expansion and other thermophysical properties.

The phonon entropy can be obtained by inelastic neutron scattering in two ways. Most common for thermodynamics are measurements of phonon densities of states (DOS) using polycrystalline samples. Measurements of single crystal dispersions can also be performed. Some principles of the conversion of raw spectra into phonon DOS curves will be described for data from the chopper spectrometer, ARCS, at Oak Ridge National Laboratory. Calculations of phonon dispersions based on density functional theory (DFT) were also performed with both quasiharmonic and anharmonic methods, and compared to the measured phonons at different temperatures.

Three examples of thermodynamic measurements by inelastic neutron scattering will be presented. 1) The first is bcc Cr, which was measured from 6 to 1493 K. Here, the interest was in reconciling the entropy from phonons and electrons with the entropy assessed from calorimetry. This was successful to better than 2% at 1500 K, showing that magnetic contributions to the entropy are negligible at high temperatures. 2) The second is fcc Pd and Pt, which were also accurate to within 2% of calorimetric results. In both cases, this good agreement required accounting for the effects of the electron-phonon interaction on the electronic entropy. 3) The third is diamond-cubic silicon, where the phonon entropy agreed with the calorimetric entropy to about 1%.

For Cr and Si, the change in free energy with temperature and volume was used to calculate the thermal expansion by both quasiharmonic (QH) and anharmonic (AH) methods. The thermal expansion was calculated successfully by both methods. Curiously, the temperature dependence of the phonons was not calculated successfully by QH theory. The QH model predicted the wrong sign for the thermal shifts of many phonon energies. Some cancellations of errors in thermal shifts of different phonons evidently allow for the success of the QH method for calculating the thermal expansion of Cr and Si. This is not always the case, however. For NaBr, the thermal expansion from the quasi-harmonic method is too small by a factor of four [4], and AH calculations are necessary. It is possible to calculate bulk thermophysical properties with an unreliable microscopic theory, so more incisive measurements of individual phonons are important for our basic understanding of the underlying physics.

Phase-Field Simulation of Spinodal Decomposition in Fe-Cr-Co Alloys After Ultra-Rapid Cooling in Powder Bed Fusion Additive Manufacturing Yuheng Liu, Daichi Izumikawa, Masayuki Okugawa and Yuichiro Koizumi; Osaka University, Japan

[Introduction] Fe-Cr-Co permanent magnetic alloys are attractive because of the combination of good ductility and tunable magnetic properties. The mechanical and magnetic properties of these alloys are strongly affected by the microstructures of ferromagnetic and paramagnetic phases originating from spinodal decomposition. Lots of experimental investigations and theoretical simulations of the microstructure evolutions in Fe-Cr-Co alloys have been made, and in general, precise multiple-step aging is indispensable to optimize the coercivity and remanence. Recently, the additive manufacturing of the Fe-Cr-Co alloys using powder bed fusion (PBF) has been reported, significantly improving the fabrication efficiency. However, although the segregation of brittle phases can be suppressed commonly in many alloys fabricated by PBF, solidification cellular structures and inter-cellular boundary segregation in stainless steels were observed occasionally [1]. Moreover, supersaturated vacancies can be introduced by the ultra-rapid cooling conditions of the PBF process. These characteristics of PBF may affect the spinodal decomposition reaction [2]. Therefore, the objective of this study is to investigate the influences of vacancies on spinodal decomposition by the phase-field simulation and to optimize the aging conditions using the machine learning method.
[Methods] Phase-Field models considering the concentration of vacancies were used to simulate the spinodal decomposition for the Fe-25Cr-12Co mass% alloy. The diffusivity of vacancies was assumed to decay with time. Besides, the influence of the dimension of the simulation model (the 2D or 3D) was also examined. The simulation results under various aging temperatures, aging times, and cooling speeds were analyzed quantitatively, which was used for machine learning.
[Results] Although the microstructures were qualitatively like the experimental ones, some discrepancies were found. The discrepancy was reduced by using 3D model. The discrepancy in the initial kinetics can be partly attributed to the supersaturated vacancies. However, it was suggested that the inaccuracy of the thermodynamic parameters is also responsible. Therefore, the thermodynamic parameters were modified. The optimization of aging conditions for the PBF process by phase-field simulation will also be discussed.

Phase-Controlled Preparation and Structural Characterization of Five-Cationic High-Entropy Oxides Daehyeon Hong and Yun-Hyuk Choi; Daegu Catholic University, Korea (the Republic of)

In 2015, the first high-entropy oxide (HEO), equimolar $(Co_{0.2}Cu_{0.2}Mg_{0.2}Ni_{0.2}Zn)O$ was successfully synthesized in a bulk ceramic form by Rost et al. using the conventional solid-state reaction method. The authors synthesized the single-phase rocksalt solid solution by sintering the pellet of the five-component mixed powder (MgO-CoO-NiO-CuO-ZnO) at sufficiently high temperatures. The HEO is a new-type inorganic material composed of multiple metal ions with a single-phase structure, and it reveals unexpected properties of high structural stability and superionic conductivity. In this study, the five-cationic HEOs consisting of new compositions are prepared with changes in crystal structure using the solid-state reaction. As a result, rocksalt, spinel, or their mixed phase were obtained in the HEOs depending on sintering temperature. The structure and composition of the synthesized HEOs have been characterized using various methods such as scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD) method, and X-ray photoelectron spectroscopy (XPS).

***Ab Initio* Thermodynamics for Adsorption of MoO_2Cl_2 on SiO_2 Surface** Hyun-Kyu Kim, Na-Young Lee and Yeong-Cheol Kim; KoreaTech, Korea (the Republic of)

As the semiconductor device technology node decreases down below 5 nm, Cu metal resistivity increases due to the increase of diffusion barrier metal portion. Mo or Co metals that require no or less barrier metal have been studied to suppress the resistivity increase with the technology node. MoO_2Cl_2 is a potential precursor for atomic layer deposition of Mo on SiO_2 surface. Density functional theory is applied to calculate its adsorption energy on the surface. Entropy and enthalpy changes with temperature are taken into account to improve the accuracy of its adsorption behavior. Ab-initio thermodynamics is also employed to consider the partial pressure of gas in the reaction chamber.

9:55 PM DS01.11.06
***Ab Initio* Thermodynamics Study for Phase Separation of $Ce_{0.75}Zr_{0.25}O_2$ Solid Solution** Hyun-Kyu Kim[1], Seol Hee Oh[2], Jong-Ho Lee[2] and Yeong-Cheol Kim[1]; [1]KoreaTech, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Since CeO_2 shows high oxygen storage/release capacity and this capacity can be further improved by adding ZrO_2, $Ce_{0.75}Zr_{0.25}O_2$ (CZO) has been studied for catalyst support of vehicles’ catalytic converter and fuel electrode of solid oxide fuel cells. Phase separation, however, of CZO under reducing atmosphere at elevated temperatures has been observed experimentally. TEM with EDS shows oxygen-poor and pyro-like phases as intermediates before

being completely separated to almost pure CeO_2 and ZrO_2; CeO_2 and ZrO_2 contain less than 1 % Zr and Ce, respectively. Ab-initio thermodynamics with density functional theory is employed to analyse the phase separation behavior of CZO.

Improving Materials Modelling with Differentiable Physics Samuel Schoenholz; Google Brain, United States

The last decade has seen explosive progress in machine learning. This rapid growth has been powered by expressive automatic differentiation frameworks that can execute programs efficiently on accelerators (like GPUs and TPUs) and can be orchestrated from high-level languages like Python. Rewriting traditional tools, such as molecular dynamics, in these frameworks can substantially improve workflows in Materials Science, allow us to seamlessly integrate machine learning models into simulations, and open qualitatively new research directions. This talk will describe, and give an update on, JAX MD which is an end-to-end differentiable molecular dynamics simulation library. We will focus on discussing the creative and unique ways in which automatic differentiation has been combined with traditional physics simulation to enable significant improvements in our ability to model and design materials.

8:30 AM *DS02.01.02
Machine Learning for Accelerated Defect Dynamics in Multicomponent Alloys Ghanshyam Pilania, Anjana Talapatra, Anup Pandey, Danny Perez and Blas Uberuaga; Los Alamos National Laboratory, United States

Understanding defect thermodynamics and transport is essential for predicting materials behavior at elevated temperatures. However, despite the exponential increase in computing power, the extreme disparity between atomistic, meso and macro scales prohibits direct brute-force simulations for most materials problems of practical interest. Going forward, realizing the full potential of multiscale modeling of increasingly complex materials through large-scale computing would require effective use of automation and artificial intelligence-based methods. Using defects transport in complex alloys as an example, this talk would provide an overview of the ongoing efforts at the Los Alamos National Laboratory that aim at addressing these challenges through the development of an integrated and automated multiscale simulation capability driven by exascale computing, rigorous uncertainty quantification, and machine learning.

9:00 AM DS02.01.03
Accelerated Convergence of Machine Learning Potentials for the Prediction of Bimetallic Material Properties Christopher M. Andolina and Wissam A. Saidi; University of Pittsburgh, United States

Machine learning potentials (MLPs) for atomistic simulations have an enormous prospective impact on materials modeling, offering orders of magnitude speedup over density functional theory (DFT) calculations without appreciably sacrificing accuracy in predicting material properties. We show that MLP-based material property predictions converge faster with respect to precision for Brillouin zone integrations than DFT-based property predictions for elemental systems. Further, we explore statistical error metrics to accurately determine *a prior* the precision level required of DFT training datasets for MLPs to ensure accelerated convergence of material property predictions, thus significantly reducing the computational expense of MLP development. We apply this approach to bimetallic systems where the generation of the DFT training data is substantially larger and thereby incurs higher computational

costs. MLPs for the Al-Mg bimetallic system were generated based on this convergence acceleration MLP approach and validated with DFT reference values. The resulting MLPs reproduce elemental and intermetallic Al-Mg systems' general bulk properties such as point defects and non-ground state lattice configurations, mechanical properties, and various surface terminations for miller indices <4 with high fidelity. We use a hybrid Monte Carlo and molecular dynamics (MC/MD) from 200 to 800 K to model Mg surface segregation enthalpies in Al-Mg slabs (Mg = 0 to 20%). The Mg surface segregation enthalpies increase from (111) < (100) < (110), consistent with existing literature. Furthermore, we model the segregation tendencies obtained from the MC/MD simulations by adapting a recently introduced isotherm model for grain boundary segregation, which provides a more accurate model for Mg segregation behavior on surfaces. Our accelerated convergence approach yields accurate and robust material predictions with lower precision DFT training data, providing a more efficient workflow for training MLP atomistic potentials.

9:15 AM DS02.01.04
Machine-Learned Electronegativity Equalization Trained with Chemical Potential and Hardness of Atoms in Molecules Alexander Davis and Alex Voznyy; University of Toronto, Canada

The electronegativity equalization method relates the energy of systems to two empirically determined parameters of each atom: the chemical potential and hardness. In its original form, these parameters are functions only of atomic number, and can be determined from ionization energies of free atoms or by empirical fitting to computed partial charges. More recently, machine learning has been used to model the dependence of these parameters on an atom's chemical environment. Although the machine learning method makes predictions of these parameters directly, it is trained using a loss function that depends only on the partial charges calculated from them. To our knowledge, accuracy of the predicted chemical potentials and hardness has not been measured directly, since these parameters are presumed unknown for an atom within a molecule.

We performed first-principles calculations of chemical potential and hardness of atoms within molecules using Bader analysis. A series of differently substituted molecules provided a finely sampled curve of energy as a function of charge for each atom, and the parameters were defined as its first and second derivatives. The theoretically calculated chemical potential and hardness serve as a basis for evaluating the performance of a graph neural network model for the dependence of these parameters on chemical environment. They can also be used for training the model, as an alternative to training with partial charges. Electronegativity equalization using these parameters can serve as the basis of a force field, which can be used for relaxing geometries of molecules bound to catalytic surfaces. In the future, similar methods may also be useful in machine-learned versions of semiempirical quantum methods such as Hückel theory, by enabling predictions of the machine learning model to be compared to theory on an atomic rather than molecular level.

9:30 AM DS02.01.05
Learning a Reactive Potential for Silica-Water Through Uncertainty Attribution. Swagata Roy[1], Johannes P. Duerholt[2], Federico Zipoli[3], Thomas Asche[2], Leonid Kahle[3], Teodoro Laino[3] and Rafael Gomez-Bombarelli[1]; [1]Massachusetts Institute of Technology, United States; [2]Evonik Industries AG, Germany; [3]IBM Research-Zurich, Switzerland

Silica has various polymorphs with different properties, leading to its application in various industries including windowpanes, catalysts, aerogels, rubber and plastic. Despite much progress involving atomistic simulations of different forms of silica, small amorphous silica clusters are still a challenge. Quantum mechanical (QM) calculations have been employed to study the stability of silicate clusters but are limited to a few atoms, often extrapolating to trimers only and cannot deal with reactions involving silicate polymerization in water solvent under different environmental conditions of different temperatures, pH of solutions and different concentration ratio of reactants. Classical reactive force fields can scale up to a large number of atoms but lack in accuracy compared to first principle calculations. Recently, the advent of machine-learning models in materials science has enabled replicating QM accuracy with time and length scale compared to empirical potentials.
Neural network-based interatomic potentials (NNIPs) on condensed phase silica and porous crystalline zeolites trained on QM data have proved to be more accurate than classical potentials and have opened doors to large-scale simulations with high-level QM accuracy. We aim to train a reactive NNIP for silicate polymerization reactions in a water solvent. These reactions are significant to understand the formation of precipitated silica as well as the preliminary stage in zeolite crystallization. Our NNIP is based on a rotationally equivariant message passing neural network known as polarizable atom interaction neural network (PAiNN). Our current dataset comprises 210K molecular clusters with forces and energies calculated using a long-range corrected hybrid functional ωB97XD3. Despite training on molecular clusters, we can perform periodic molecular dynamics (MD) simulations and predict the properties of condensed phases.
Hereon, we also propose a new active learning method based on per-atom attribution of model uncertainty to enlarge our dataset with robust and diverse set of molecular configurations. With this method, we can quantitatively identify inter-atomic interactions with high inaccuracy; carve out an atomic environment within a cut-off on which the potential performs poorly, and thus save QM calculation cost. The method involves taking the derivative of the uncertainty of NNIP ensemble with respect to atomic positions and marks highly uncertain inter-atomic interactions. We then select a molecular cluster environment with a high attributed atom at its center for QM calculations and add to training data. Upon running this automated active learning loop for a few generations, we visualize consecutive improvement of attributions on atoms and thus proving the efficiency of this proposed method.
The current NNIP after eight generations of active learning is successful to predict the properties of liquid water as well as reactions involving deprotonation of water and silicate dimerization in a dilute water solvent. The radial density functions (RDFs) of O-O, O-H and H-H in water obtained from molecular dynamics simulations using our NNIP are comparable to experimental and reported results. The self-diffusivity of water at 300K is predicted as 2.26+-0.06 x 10^{-9} m^2/s, close to the experimental one (2.41 x 10^{-9} m^2/s) and the density is predicted as 1.08g/cc. The reaction involving deprotonation of water molecule is replicated accurately with enhanced sampling based MD and the pK_w of water is predicted as 17.4, which is close to expected value of 17 (higher than experimental due to quantum nuclear effect). The NNIP further predicts the relative energy of siliceous zeolites with respect to quartz with error of only 1.2 KJ/mol compared to experimental results. This robust NNIP can replicate the reaction path of silicate dimerization and will be further used to replicate deprotonation of orthosilicic acid and then silicate condensation and hydrolysis reactions.

Large-Scale Screening of Hypothetical Metal-Organic Frameworks for Thermal Conductivity Meiirbek Islamov[1], Hasan Babaei[2], Jeffrey R. Long[2,2,3], Alan McGaughey[4], Diego A. Gomez-Gualdron[5] and Christopher E. Wilmer[1,1]; [1]University of Pittsburgh, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Carnegie Mellon University, United States; [5]Colorado School of Mines, United States

Metal-Organic Frameworks (MOFs) are highly porous, crystalline materials with ultrahigh surface area that are promising for many gas storage, separation, catalysis, and thermoelectric applications. However, their practical utility depends on their ability to rapidly disperse the exothermic heat generated during the gas adsorption process or on their ability to suppress the directed heat flow to maintain the temperature gradient in thermoelectric applications. Despite their significance, the thermal transport properties of MOFs have been mostly overlooked, which resulted in a lack of an in-depth understanding of the universal structure-thermal conductivity relationships for designing MOFs with tailored thermal conductivity. In this work, we performed a high-

throughput screening of hypothetical MOFs for thermal conductivity to establish structure-property relationships. We judiciously selected 10,194 hypothetical MOFs from the *ToBaCCo* database and performed thermal conductivity calculations using classical molecular dynamics simulation and the Green-Kubo method. We included several important structural and compositional characteristics of MOFs such as density, pore size, surface area, void fraction, node-linker mass mismatch, and metal node connectivity in the analysis. We observed that high thermal conductivity favors small pores, high density, small node-linker mass mismatch, and four-connected metal clusters, whereas low thermal conductivity favors large pores and high porosity. Moreover, we discovered six hypothetical MOF structures that exhibited high average thermal conductivity. We also discovered 36 hypothetical MOFs that displayed ultralow thermal conductivity. Interestingly, those six ultrahigh thermal conductivity MOFs share a four-fold coordinated metal nodes, through which the organic linkers are connected in a perpendicular orientation. This suggests that the underlying topology predominantly determines the limits of the thermal conductivity in MOFs.

Gradient-Based Optimization of ReaxFF Parameters Using Pytorch for the Study of Silica Precipitation Yuliia Orlova, Swagata Roy and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Silica precipitation is a subject of big interest since it occurs in a wide variety of environmental and industrial processes: ceramic and catalytic applications, water heater scaling, biomineralization, coating applications to improve adhesion and wetting properties, and so forth. Even though there are many advances in atomistic simulation research of different forms of silica, the mechanism of silica precipitation has not been fully understood. We propose to study the following process using reactive force-field method (ReaxFF). Despite being a classical force field, ReaxFF can achieve quantum chemical accuracy once the optimal potential coefficients are found. However, the fitting of ReaxFF parameters is a challenge due to the complex functional form of the potential. Several techniques have been proposed to solve this problem, such as genetic algorithms and Monte-Carlo methods. The stochastic nature of these methods requires millions of error evaluations to fit the parameters, which results in excessive optimization times. Recent advances in machine learning made it possible to drastically speed up the process by utilizing the gradient of the potential. In this work, the gradient-based optimization of reactive force-field parameters is performed using Pytorch to apply the method to study silicate polymerization reactions in a water solvent. We have implemented the current ReaxFF potential as a Pytorch model. The model's parameters were fitted to the dataset, which comprises 210K molecular clusters with forces and energies calculated using a long-range corrected hybrid functional ωB97XD3. We have validated the obtained parameters against the kinetic and thermodynamic properties of water and solid silica systems. The optimized potential will be further used to gain insights into the mechanism of silica precipitation.

10:45 AM DS02.01.08
Structure-Property Relation in LiF-NaF-ZrF_4 Molten Salts Using Transferable Deep Learning Potentials Rajni Chahal[1], Santanu Roy[2], Shubhojit Banerjee[1], Vyacheslav Bryantsev[2] and Stephen Lam[1]; [1]University of Massachusetts Lowell, United States; [2]Oak Ridge National Laboratory, United States

Multicomponent molten salts have been identified as promising candidate coolants in thermal solar energy storage, advanced batteries, and next-generation nuclear reactors due to their desirable heat transfer properties. In many systems, molten salts with multivalent cations have been proposed, which can exhibit intermediate-range ordering that can drive important transport and thermal properties. However, accurately simulating the structure and properties of these systems is challenging due to size limitations in ab-initio molecular dynamics (AIMD), and inaccuracies in classical molecular dynamics (CMD). In this work, we circumvent these limitations using neural network interatomic potentials (NNIP) and show that NNIP-based simulations can predict extended-range structures inaccessible to ab initio molecular dynamics, and thermal properties with higher accuracy than classical potentials. Specifically, the system LiF-NaF-ZrF_4 is studied, which is known as a promising salt candidate for advanced nuclear systems due to its low melting point (operability), and low cost. The transferability of computationally efficient and accurate neural network interatomic potential across a wide phase-space of LiF– NaF–ZrF_4 molten salts is reported. We found that the NNIP trained on only two salt compositions involving 29% and 37% ZrF_4 (eutectics) can accurately simulate a wide range of compositions where ZrF_4 mole fractions (determinant of intermediate-range structure and property) was varied between 11% to 40%. At short range, we found that neural network molecular dynamics (NNMD) agrees well with AIMD, CMD, and Raman spectra observations in predicting the existence of 6, 7, and 8-coordinated fluorozirconate complexes in the melt. In addition, NNMD can accurately predict the changes in the first coordination shell (coordination number, and bond angles) with the variation in multivalent Zr content, which is also supported by Raman spectra data. At intermediate range, NNMD predicts the structural ordering increases with Zr content due to Zr-F clusters/network formation for compositions with greater than 23% ZrF_4. These observations are directly validated by the excellent agreement in theoretical and experimental data. Moreover, we found that in order to capture structure ordering and hence, accurately predict the properties of compositions with higher ZrF_4 content, cell sizes of at least 17 Å need to be simulated, exceeding the size of most AIMD-based simulations that are typically performed. In addition to accurate structure prediction, when evaluating diffusion coefficients, density, and viscosities, NNIP outperforms both AIMD and CMD in predicting the values close to the experimental data. NNIP accurately matches the salt density with the experimental value of 2.79 g/cc at 700°C for a salt composition containing 37 ZrF_4 mole%. For the same composition and temperature, the viscosity value evaluated from NNMD is 4.45 ± 0.16 cP compared to 6.9 cP as reported from experimental measurements. For composition with ~11 mole% ZrF_4 content at ~750°C, the Zr diffusion coefficient calculated by NNMD simulations is 2.03 ± 0.3 cm^2/s compared to the experimental value of 2.92 ± 0.3 cm^2/s, while CMD predicted value is 0.73 ± 0.1 cm^2/s. Overall, this work explored the existence of structural ordering in molten salts that is often overlooked in understanding thermal property trends. New data is generated for a promising salt system, which will inform materials selection in advanced nuclear systems. Further, NNIP's ability to provide a deeper understanding of structure-property relations in multicomponent molten salts containing multivalent cations is systematically demonstrated. NNIP's transferability across a wide range of compositions and thermodynamics conditions opens the possibility of the development of robust and reliable neural network potentials to advance the study of many structurally-complex liquids.

Using Density Functional Theory and Machine Learning to Predict the Binding Energies of Metal-Organics to Organic Functional Groups for Hybrid Material Creation Yifan Liu, Emily K. McGuinness, Mark Losego and Rampi Ramprasad; Georgia Institute of Technology, United States

Understanding chemical interactions between organic and metal-organic molecules has wide-ranging interest to the vapor deposition community for creating hybrid organic-inorganic materials via techniques such as molecular layer deposition and vapor phase infiltration (VPI). In the case of VPI, a vapor-phase metal-organic precursor is infused into the bulk of a polymer and becomes incorporated at the nanoscale through either chemical interaction with the polymer or the formation of a non-volatile species via the introduction of a co-reactant. VPI has applicability in a number of industrially relevant fields including the creation of novel organic-inorganic hybrid membranes which have shown enhanced stability in organic solvents, while retaining high permeance and selectivity. Motivated by this application, this work uses density functional theory (DFT) to explore chemical interactions occurring during the VPI of polymer of intrinsic microporosity (PIM-1, a polymeric membrane material) with trimethylaluminum (TMA) and its co-reaction with water. These computations revealed that the coordination between the polymer and metal-organic is a critical mechanism for the formation of the hybrid and its resultant solvent stability. To expand understanding of this critical characteristic and accelerate the design of organic-inorganic hybrid materials, a DFT dataset of computed binding energies was generated from suitable and representative atomic-level models of several common polymer functional groups and over 100 metal-organic precursors. From this dataset, a predictive machine learning model for the binding energy of metal-organic molecules to

polymers has been developed. This predictive model, along with the chemical guidelines obtained from feature analysis, will aid the selection of potential candidates for novel organic-inorganic hybrid membranes as well as hybrid material creation as a whole.

Machine Learned Potentials for Reaction Simulations Patrick Reiser[1], Jingbai Li[2], Steven Lopez[2] and Pascal Friederich[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Northeastern University, United States

Machine learned potentials are widely used to describe the potential energy surface of near-equilibrium systems. To accurately explore and predict potential energy surfaces in the region of transition states requires active learning methods. In Li el al. [1], we show how machine-learned potentials can be used to simulate photochemical reactions, which are widely used by academic and industrial researchers to construct complex molecular compounds via mechanisms that often require harsh reaction conditions. Photodynamics simulations provide time-resolved insight into atomistic processes which are required to understand and predict reactivities and chemoselectivities. However, such simulations require thousands of costly quantum mechanical calculations per trajectory, which limits simulations to a picosecond time scale for most organic photochemical reactions. Westermayr et al. introduced a neural network-based method to accelerate the predictions of electronic properties and pushed the simulation limit to 1 ns for a methylammonium cation model system. We have adapted this methodology to develop two software tools, the Python Rapid Artificial Intelligence Ab Initio Molecular Dynamics (PyRAI2MD) tool for active learning-based molecular dynamics simulations, and the NNs4MD library which implements a single interface to a wide range of machine learning methods to be used in molecular dynamics simulations. Using these tools, we studied the cis-trans isomerization of trans-hexafluoro-2-butene and the 4pi-electrocyclic ring-closing of a norbornyl hexacyclodiene. We performed a 10 ns simulation for trans-hexafluoro-2-butene in just 2 days and discovered unknown reaction pathways in the ring-closing reaction. The same simulation would take approximately 58 years with traditional multiconfigurational photodynamics simulations. We are currently implementing graph neural networks in NNs4MD, in order to move from molecule-specific models to generalizable potentials.

11:30 AM DS02.01.11
High-Dimensional Neural Network Potential for Liquid Electrolyte Simulations Garvit Agarwal[1], Steven Dajnowicz[1], James M. Stevenson[1], Leif D. Jacobson[1], Farhad Ramezanghorbani[1], Karl Leswing[1], Richard A. Friesner[1,2], Mathew D. Halls[1] and Robert Abel[1]; [1]Schrodinger Inc., United States; [2]Columbia University, United States

The development of rechargeable Li-ion batteries (LIBs) has revolutionized electric vehicles and portable electronic devices. Yet, further advancements are needed to improve the power, safety, reliability, and lifetime of LIBs. Existing classical force fields are not accurate enough to predict bulk properties of LIB materials without time-consuming and customized parametrization. To move towards accurate and reliable modeling of Li-ion battery chemistries, we developed a machine-learned force field for liquid electrolyte simulations. This force field was constructed using the charge recursive neural network (QRNN) architecture, which includes both long-range interactions and global charge redistribution. The force field was trained using only non-periodic (cluster) DFT data, allowing the practical use of more accurate functionals, like the range-separated hybrid ωB97X-D3BJ functional used here, which would be prohibitively expensive for generating large datasets with periodic DFT. In this work we focus on seven commonly used carbonate solvents and LiPF6 salt in the Li-ion battery technology, but this methodology is generalizable and can be applied to any liquid electrolyte system. Despite only training to cluster DFT data, the predicted bulk thermodynamic properties and transport properties (such as self-diffusivity and viscosity) are in excellent agreement with experimental data. The force field also reproduces the concentration and temperature dependence for viscosity and diffusivity of ions and solvent. Furthermore, we demonstrate the capability of the model to accurately predict the solvation structure of ions in the liquid electrolyte using a comparison of the radial distribution functions with experimental data. This provides a promising path forward for atomistic modeling of challenging battery chemistries.

11:45 AM DS02.01.12
AuTopology—End to End Force Field Parametrization Workflow for Polymer Electrolytes Using Machine Learning Pablo A. Leon and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Solid polymer electrolytes (SPEs) are seen as promising alternatives to conventional liquid electrolytes in lithium battery systems due to their low density, mechanical compliance, and low flammability but are challenged by lower ionic conductivity. Molecular dynamics (MD) simulations can be used to guide the design of novel SPEs by allowing quantitative determination of separable anion and cation diffusions as well as local solvation environments and correlated ion motions. Classical potential MD simulations update molecular conformations by the net force on each atom due to covalent and nonbonded interactions. However, these classical potentials are often not well defined for novel systems as they require materials- and local environment-specific parameters such as unique bond stiffnesses which are either meticulously hand-tuned across decades or unchangeable due to proprietary licenses.

In this work, we explore the effects of anharmonic bonded interactions on ionic solvation and conductivity mechanisms in polymer and liquid electrolyte systems. An in-house, machine learning-based workflow, named AuTopology, was used to autonomously learn the interatomic potential parameters for prototypical solid and liquid electrolyte systems at experimentally-relevant concentrations with both harmonic OPLS-based and anharmonic PCFF+-based models from DFT forces as training data. These simulations of tens-of-thousands of atoms were allowed to run for hundreds of nanoseconds to determine the individual anion and cation diffusivities and resulting conductivities. Using this framework and an in-house database of molecular conformations, we have been able to reproduce wB97XD3-level DFT forces from trained OPLS force fields to within 5.5 kcal/mol-A. Correlation-based conductivities between the OPLS and PCFF+ models for polyethylene oxide (PEO) and liquid carbonate systems with different lithium salts were found to match legacy parameterizations to the same order of magnitude while matching or improving conductivity predictions relative to experiments.

12:00 PM DS02.01.13
Cement Clinker Microstructure Segmentation Using Machine Learning Mohd Zaki, Sunil K. Gurjar, Siddhant Sharma, Jayadeva Jayadeva and N M Anoop Krishnan; Indian Institute of Technology Delhi, India

Cement is one of the most consumed construction materials. The quality of cement depends upon the clinker which is manufactured using limestone and aluminosilicate sources. The clinker microstructure comprises four phases: alite, belite, tricalcium aluminate, and aluminoferrite. Identifying different components of microstructures is a challenging task which in turn helps the researchers to control the quality of cement. In this work, we first create a dataset by segmenting alite and belite particles in cement clinker microstructure and use supervised machine learning methods to train models for identifying alite and belite regions in the microstructure image. We demonstrate the capability of machine learning models to accurately segment alite and belite regions. Further, we propose the methodology and guidelines to be taken care of while creating the datasets and training machine learning models for clinker microstructure segmentation tasks.

Learning from 2D—Machine Learning Models for Effective Properties of Heterogeneous Materials Based on 2D Microstructure Sections Guangyu Hu and Marat Latypov; University of Arizona, United States

Microstructure--property relationships are key to effective design of structural materials for advanced applications. Advances in computational methods enabled modeling microstructure-sensitive properties using 3D models (e.g., finite elements) based on microstructure representative volumes. 3D microstructure data required as input to these models are typically obtained from either 3D characterization experiments or digital reconstruction based on statistics from 2D microstructure images. In this work, we present machine learning (ML) approaches to modeling effective properties of heterogeneous materials directly from 2D microstructure sections. To this end, we consider statistical learning models based on spatial correlations and multi-view convolutional neural networks as two distinct ML strategies. In both scenarios, models are trained on a dataset of synthetically generated 3D microstructures and their properties obtained from micromechanical 3D simulations. Upon training, the models predict properties from 2D microstructure sections. The advantage of the presented models is that they only need 2D sections, whose experimental acquisition is more accessible compared to 3D characterization. Furthermore, the present models do not require digital reconstruction of 3D microstructures.

8:30 AM *DS02.02.02
Machine Learning Based Surrogate Model for Bioinspired Gradient Composites Shu-Wei Chang, Meng-Lin Tsai and Wei-Han Hui; National Taiwan University, Taiwan

Biological materials evolve extraordinary protective systems to survive the competitive environment, thus having outstanding mechanical properties and multifunctionality. For instance, bone and bamboo are both structural bio-composites with superior mechanical properties. In recent decades, understanding the properties of bio-inspired composites has been a popular subdiscipline of material science. The idea of bioinspiration is to learn from biological structural materials and apply novel structural design strategies for the development of composites with superior mechanical properties. In this research, the composite structures are inspired by the topology of bone and the density distribution of bamboo. In order to explore the extreme huge design space of structural materials, we developed a machine learning based surrogate model by using a combination of principal component analysis (PCA) and deep neural networks (DNN) for predicting the entire stress-strain behavior of the bone- and bamboo-inspired composite structures. Our results show that the surrogate model is accurate and efficient for investigating the design space and the proposed approach in this work can be extended to other composite structures to further accelerate material design and optimization.

9:00 AM DS02.02.03
Learning Local Equivariant Interatomic Potentials for Large-Scale Atomistic Dynamics Simon L. Batzner[1], Albert Musaelian[1], Anders Johansson[1], Lixin Sun[1], Cameron J. Owen[1], Mordechai Kornbluth[2] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch LLC Research and Technology Center, United States

E(3)-Equivariance — the property of a function to transform with the actions of the Euclidean group — has recently emerged as a key design principle in machine learning interatomic potentials. Starting with the high accuracy, sample efficiency, and generalization properties of the NequIP potential [1], a series of other equivariant message passing interatomic potentials has since been proposed. However, all current methods share the message passing paradigm, in which information is iteratively propagated along an atomistic graph. This propagation mechanics, however, severely hinders the time- and length-scales that can be studied with message passing approaches. Here, we introduce Allegro, a strictly local, E(3)-equivariant deep learning interatomic potential that combines the high accuracy of equivariant neural networks with the scalability of local methods. We demonstrate that Allegro not only obtains state-of-the-art accuracy on a variety of benchmarks, but also displays remarkable generalization to out-of-distribution data. We then show how molecular dynamics simulations driven by Allegro predict structure and kinetic of a Lithium phosphate electrolyte with high fidelity. Finally, we demonstrate how the locality of the proposed method enables a simulation of 100 million atoms on reasonable compute resources, enabling a previously impossible combination of accuracy, scale, and computational efficiency.

9:15 AM DS02.02.04
Phase Transformation Prediction by Machine Learning-Crystal Plasticity Finite Element Model (ML-CPFEM) Mehrzad Soltani, Sanjida Ferdousi, Ravi S. Haridas, Rajiv Mishra and Yijie Jiang; University of North Texas, United States

The mechanical properties of alloy are affected significantly by its microstructure. Efforts to touch white area in Ashby's chart for desired material indices to enhance alloy properties have been investigated for the past decades. This target is coming true through improvement in recognizing microstructure of materials and synergy between microstructure and its effect in bulk materials. Plastic deformation originating from defects in materials mingles with microstructural phenomena, including transformation induced plasticity (TRIP), slip, and twining. It is observed that active microstructural phenomena make materials harder and increase their strength. To understand the mechanism, development of crystal plasticity finite element models (CPFEM) enables us to solve deformation field with the given crystallographic orientation and loading conditions. Over the past few years, emerging research in various fields has been growing in using machine learning (ML) to investigate fundamental constitutive relationships and to accelerate classic numerical modeling. In this study, we leverage a ML model on local crystallography and CPFEM for FCC to HCP phase transformation prediction in a high entropy alloy (HEA). The training data of the ML uses electron backscatter diffraction (EBSD) experimental data before and after deformation and CPFEM simulation results of localized stress and texture evolution during deformation. We use an extreme gradient boosting (XGBoost) ML approach, which repeatedly builds new models and combine them into an ensemble model based on a decision tree. This approach effectively enhances performance for finding optimum model and accelerates searching process. We implement this predictive model in multiple experimental measurements to validate our model. To further understand the driving force for phase transformation, we harness the ML model prediction accuracy to evaluate several different forms of proposed driving force.

9:30 AM DS02.02.05
Formula Graph Self-Attention Network for Representation-Domain Independent Materials Discovery Achintha A. Ihalage and Yang Hao; Queen Mary University of London, United Kingdom

Material representation is vital in determining the performance of machine learning (ML) models in predicting the properties of materials. There are two main types of materials descriptors, one that encodes crystal structure details and the other that only uses chemical composition with the hope of discovering new materials. Graph neural networks (GNNs) have dominated materials property prediction tasks outperforming their classical ML counterparts given sufficient data. However, current GNNs are limited to only one of the above two avenues due to the lack of a general graph-based material descriptor. In this study, we propose formula graph that unifies composition-only and structure-based materials descriptors for GNNs. We develop a self-attention integrated GNN that assimilates a formula graph and show that the proposed architecture produces material embeddings transferrable between the two domains, opening further research opportunities in crystal structure prediction. The proposed model can outperform some previously reported structure-agnostic models and their structure-based counterparts while exhibiting better sample efficiency and faster convergence. Finally, the model is applied in a challenging exemplar to predict the complex dielectric function of materials and nominate new substances that potentially exhibit epsilon-near-zero (ENZ) phenomena.

Automated Artificial-intelligence Inverse Design of Polymer Membranes for CO_2 Capture and Separation Ronaldo Giro, Hsianghan Hsu, Akihiro Kishimoto, Rodrigo F. Neumann, Binquan Luan, Seiji Takeda and Mathias Steiner; IBM Research, Brazil

Climate change is mainly due to CO_2 emissions occurring in energy production and transportation. A set of technologies are being developed to separate and sequester CO_2 emitted by point sources. Polymer membranes show certain advantages with regards to their storage and disposal properties, they allow for passive operation, have high tolerance to SO_x and NO_x content and can be integrated within an existing power plant steam cycle, i.e., post combustion application.

Candidate materials for application in polymer separation membranes must fulfill two key requirements: high CO_2 permeability and high CO_2/N_2 selectivity. However, there is a tradeoff between these two requirements: increasing a material's permeability decreases its selectivity, and vice-versa. Screening the large number of candidate materials for molecular properties requires an automated design and validation process which does not yet exist.

Here, we report our progress in automated discovery of membrane polymers through inverse molecular design. We have computationally generated and validated hundreds of polymer candidates designed for application in post-combustion carbon dioxide filtration. Specifically, we have validated each discovery step, from training dataset creation, via graph-based generative design of optimized monomer units, to molecular dynamics simulation of gas permeation through the polymer membranes. We compare the permeability predictions obtained by AI models and molecular dynamics simulations with experimental results and discuss future extensions of the discovery approach.

10:30 AM DS02.02.07
Lagrangian and Hamiltonian Graph Neural Networks for Molecular Dynamics Simulations Ravinder Bhattoo, Sayan Ranu and N M Anoop Krishnan; Indian Institute of Technology Delhi, India

Molecular dynamics simulations are used to realistically simulate the material properties. The interatomic potential energy function (PEF) is critical in determining the validity of the results. Such interatomic PEFs are parameterized using density functional theory (DFT). Usually, interatomic PEF is a multi-body function whose functional form is non-trivial to determine. Therefore, estimating the functional form is critical in determining the interatomic PEF and hence the material properties. Herein, we use Lagrangian Graph Neural Network (LGNN) to learn such interatomic PEF in silica glass system. We show that the LGNN model can learn silica interatomic potential for Si-O, O-O and Si-Si interactions. The inductive bias present in the LGNN makes training easier where it can learn from a significantly small dataset as compared to other ML methods. Thanks to the graph architecture, the size of LGNN model is agnostic to the size of system used and hence, learned LGNN model is scalable. We show the zero-shot generalizability of the LGNN model by simulating systems one orders of magnitude larger than the trained one. Further, LGNN architecture is also capable of incorporating the dissipative force due to connected thermostat. Finally, we show the interpretability of LGNN, which directly provides physical insights on the learned model.

10:45 AM DS02.02.08
Examining Graph Neural Networks for Inorganic Crystalline Structures Sheng Gong[1], Tian Xie[1,2], Rafael Gomez-Bombarelli[1] and Jeffrey Grossman[1]; [1]Massachusetts Institute of Technology, United States; [2]Microsoft Research, United Kingdom

Graph neural networks (GNNs) are widely used to learn the representations of crystal structures from the data. However, there lacks a systematic scheme to analyze and understand the limits of GNNs for capturing crystal structures. In this work, we propose to use human-designed descriptors as a bank of human knowledge to test whether GNNs can capture knowledge about crystal structures behind descriptors. We find that CGCNN and ALIGNN cannot learn primitive cell-level information well. Then, we suggest that, for learning extensive properties, the frequently used average pooling is not a proper choice. Finally, we propose an initial solution, hybridizing descriptors with GNNs, to improve the prediction performance of GNNs for materials properties, especially phonon internal energy and heat capacity with 90% lower errors. All the analysis can be easily extended to other deep representation learning models and human-designed descriptors. This study shows that the fields of deep representation learning and human-designed descriptors can be developed synergically.

11:00 AM DS02.02.09
Predict Microstructure-Property Relationship of Steels and High Entropy Alloy Formation Using Machine Learning Michael Gao[1], Zongrui Pei[1], Junqi Yin[2], Elizabeth Holm[3], Nan Gao[3], Kyle Rozman[1], Ömer Doğan[1], Youhai Wen[1], Jeff Hawk[1] and David Alman[1]; [1]National Energy Technology Laboratory, United States; [2]Oak Ridge National Laboratory, United States; [3]Carnegie Mellon University, United States

Metallurgy and material design have thousands of years' history and have played a critical role in the civilization process of humankind. Composition, processing, microstructure, and materials properties are the four cornerstones in materials research. The traditional trial-and-error method has been unprecedentedly challenged in the modern era when the number of components and phases in novel alloys keeps increasing, with high-entropy alloys as the representative. New opportunities emerge for alloy design in the artificial intelligence era. For the first part of the talk, we will present a successful machine-learning (ML) study using variational autoencoder and a regression model to identify the microstructure images with eye-challenging morphology for a number of martensitic and ferritic steels. The challenge in differentiating performance with respect to microstructure lies in the extreme similarity of

these steel images, where differences seem insignificant to the viewer. The success of the approach is a result of highly optimized neural network structures and fine-tuned parameters therein. The model clearly identified the key role of several elements in the prototypical 9% Cr steel through the formation of the different features of the martensite steels. As such, a new inverse alloy design method is proposed based on neural networks. It demonstrates a systematic approach to design new alloys.

For the second part of the talk, we will present our research progress in predicting solid solution formation to accelerate high entropy alloys research. In the literature various empirical rules are proposed to predict the formation of single-phase solid solution, but many are based on very small datasets and hence are of very limited predictability. In this project, we perform a machine-learning study on a large dataset consisting of 1252 alloys, including binary and high-entropy alloys, and we achieve a success rate of 93% in predicting single-phase solid solution. The present ML results suggest that the molar volume and bulk modulus are the most important features, and accordingly, a new physics-based thermodynamic rule is constructed. The new rule is nonetheless slightly less accurate (73%) than the ML algorithm but employs only the elemental properties and is thus convenient in applications. Finally, the advantages and pitfalls in applying high-throughput screening and ML versus CALPHAD calculations will be discussed.

11:15 AM DS02.02.10
Predictions of Plasmonic Hot Carrier Energies Using Machine Learning Adela Habib, Benjamin Nebgen, Nicholas Lubbers and Sergei Tretiak; Los Alamos National Laboratory, United States

Atomistic simulation of electron dynamics using machine learning provides a pathway to scale computational studies from a few 10s of atoms to device levels with 1000s of atoms, thereby facilitating efficient device design. For example, studies of plasmonic hot carrier-based devices for efficient energy-harvesting has been limited to small scale systems because of the prohibitively expensive quantum-mechanical simulation methods such as nonadiabatic molecular dynamics (NAMD) or real-time time-dependent density functional theory (rt-TDDFT). On the other hand, we have shown that atomistic neural networks (NN) architectures can estimate a time dependent electron density capable of capturing plasmon formation and its subsequent decay into hot carriers, in nanostructures of 500+ atoms, at fractions of the quantum-mechanical simulation time and with minimal quantum-mechanical input data. In this talk, I will present the extension of this work, showing machine-learned hot carriers' distributions evolving over time as functions of their energy. For this purpose, unlike most NN architectures that focus on scalar predictions, we will introduce a network architecture that predicts orbital occupations transforming with tensor algebra. These ML predictions will enable extraction of useful quantities such as electron-phonon scattering lifetimes that are directly comparable with the experimental measurements. Our goal is to explore the transferability of our workflow in pursuit of a scheme for affordable modeling of hot carrier dynamics in systems with thousands of atoms.

Tough Materials by Design—Autonomous Experimentation for Extreme Mechanics Keith A. Brown; Boston University, United States

Energy-absorbing structures are critical to everyday life and span a wide range of design parameters and use cases. For example, some structures – like those in shoes and sporting equipment – must repeatedly absorb energy without permanent damage while others – such as packaging material and the crumple zones of cars – are designed to protect against singular catastrophic events. Despite their ubiquity, developing new energy-absorbing structures is a time consuming and difficult process that requires iterative experimentation. This is in part because energy-absorbing structures are designed to operate under extreme conditions that feature large deformations, high strain rates, and complex self-self interactions that are collectively very difficult if not impossible to accurately capture using simulation alone. Further, the advent of additive manufacturing has meant that the number of potential structures is now effectively innumerable, compounding the slow pace at which structures or components can be optimized for energy absorption.

Our work is based on the hypothesis that autonomous experimentation can accelerate the discovery of novel structures for extreme mechanical properties. At its core, this combines (1) incorporating automation to increase the speed and consistency of experiments and (2) using active learning – a type of machine learning – to iteratively select experiments using all available knowledge. Together, these comprise an autonomous system that iteratively selects and performs physical experiments to efficiently move towards a target goal, namely the discovery of polymeric structures tailored for efficient energy absorption. This system, which we term a Bayesian Experimental Autonomous Researcher (BEAR), can identify high performing structures in ~60 times fewer experiments relative to conventional grid-based searching.[1] Further, we systematically include prior knowledge in the form of finite element analysis and show that even in cases when the property of interest cannot be directly simulated, it is possible to further accelerate optimization using the principles of transfer learning.[2] Extending this concept of transfer learning for mechanical design, we find that experimental data can be used to predict comparatively hard to obtain experimental performance metrics. Specifically, we identify a process for using behavior during quasi-static testing to predict impact performance and use this procedure to identify additively manufactured lattice structures that have optimized impact performance. Using these principles, our present work focuses on combining the BEAR with a novel algorithm for parametrically generating diverse structures known as generalized cylindrical shells in a manner that allows for components to be highly tuned for efficient energy absorption across a wide range of stress thresholds. This database of >10,000 experiments can be used to select parts tailored for specific applications. By expanding the structural and materials palette available to the BEAR, it is possible to vastly shorten the design loop for developing components for extreme mechanics performance.

Predicting Aggregate Morphology of Sequence-Defined Macromolecules with Machine Learning Debjyoti Bhattacharya; The Pennsylvania State University, United States

Self-assembly of dilute sequence-defined macromolecules is a complex phenomenon in which the local arrangement of chemical moieties can lead to the formation of long-range structures. Predicting the aggregation behavior of these macromolecules is challenging due to the lack of effective order parameters, a vast design space, inherent variability, and high computational costs associated with currently available simulation techniques. Here, I present a workflow that can accurately predict the morphology of aggregates self-assembled from sequence-defined macromolecules using supervised machine

learning. I find that regression models with implicit representation learning perform significantly better than those based on engineered features and a Recurrent-Neural-Network-based regressor performs the best out of nine model architectures we tested. Furthermore, I demonstrate the high-throughput screening of monomer sequences using the regression model to identify candidates for self-assembly into selected morphologies. We further investigate training these models by active learning to perform high-throughput screening from an even smaller number of simulation data on the aggregation process for other increasingly complex design scenarios, such as the design of sequences under polydispersity and at varying environmental conditions. Our strategy is shown to successfully identify multiple suitable sequences in every test we performed.

Encoding Dynamic Information from Normal Mode Analysis in Graph Representation Learning for Protein Function Prediction Yuan Chiang[1,2], Yen-Lin Chen[2], Wei-Han Hui[2] and Shu-Wei Chang[2]; [1]University of California, Berkeley, United States; [2]National Taiwan University, Taiwan

The relationship between protein structure and molecular function has fundamental importance for biological science and pharmaceutical application but remains challenging to probe in by experimental approaches. Recent advances in protein function prediction exploit graph-based deep learning approaches to correlate the structural and topological features of proteins with their molecular functions. However, proteins *in vivo* are not static but dynamic molecules that alter conformation for functional purposes. We recently applied normal mode analysis to native protein conformations and augment protein graphs by connecting edges between dynamically correlated residue pairs. In the multilabel function classification task, our method secures a remarkable performance gain based on the dynamics-informed representation. The proposed graph neural network, ProDAR, increases the interpretability and generalizability of residue-level annotations and robustly reflects structural nuance in proteins. We elucidate the importance of dynamic information in graph representation by comparing gradient-weighted class activation maps with and without dynamic information as inputs. Our model learns the dynamic fingerprints of proteins and pinpoints the residues of functional impacts that hold potential interests for protein and drug design.

Structure Determination from Theory and Experiment Maria K. Chan; Argonne National Laboratory, United States

Atomistic modeling has been an invaluable tool for determining structure property relationships and materials design. The relevance of the predicted properties, however, relies on the accuracy of the underlying structure. In many cases of scientific and technological interest, such as nanoparticles, grain boundaries and other interfaces, molecular complexes, and materials with short range order, the determination of the underlying structure is nontrivial. We will discuss approaches to combine information computational modeling and forward simulations of experimental data, driven by AI/ML, to determine structures. Examples include FANTASTX (Fully Automated Nanoscale To Atomistic Structures from Theory and eXperiment) and Ingrained [1]. We will discuss how these tools have successfully determined nanoscale structures from x-ray, electron microscopy, and scanning probe microscopy experimental data.

3:30 PM DS02.03.05
Feature Blending—An Approach Toward Generalized Machine Learning Models for Property Prediction of MXene Swanti Satsangi, Avanish Mishra and Abhishek K. Singh; Indian Institute of Science, India

From studying the atomic structure and chemical behavior to the discovery of new materials and investigating properties of existing materials, machine learning (ML) has been employed in realms that are arduous to probe experimentally. While numerous highly accurate models, specifically for property prediction, have been reported in the literature, there has been a lack of a generalized framework. Herein we propose a novel feature selection approach that enables the development of a unified ML model for property prediction for several classes of materials. It involves an ingenious blending of selected features from various classes of data such that the resultant feature set equips the model with global data descriptors capturing both class-specific as well as global traits. We took accurate band gaps of three distinct classes of 2D materials as our target property to develop the proposed feature blending approach. Using Gaussian process regression (GPR) with the blended features, the ML model developed here resulted in an average root-mean-squared error of 0.12 eV for unseen data belonging to any of the participating classes. The feature blending approach proposed here can be extended to additional classes of materials and also to predict other properties.

Machine Learning Coarse Grained Bond Order Models for Characterizing Mesoscale Aggregation in Liquid Mixtures Anirban Chandra[1,2], Troy D. Loeffler[1], Micheal Servis[2], Srikanth Nayak[2], Pubudu Wimalasiri[2], Dina Sheyfer[2], Jyotsana Lal[2], Gregory B. Stephenson[2], Maria K. Chan[2] and Subramanian Sankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

All-atom molecular dynamics simulations provide crucial insights into a variety of physical phenomena. Despite its numerous successes, all-atom models can be extremely computationally intensive for mesoscale systems. Coarse grained models have been able to overcome the computation bottleneck, but the description of interaction between organic molecules, aqueous media, and inorganic ions is often non-trivial. In this work, we present a coarse grained model for accurately capturing the phase behavior of multicomponent liquid-liquid mixtures. We use TrappE-UA model as a stencil and develop a bond-order based description of interactions between the components. Using the developed model we explore phase behavior and critical phenomena in mixtures consisting of organic solvents, surfactants, and water. Furthermore, aided by the reduced computational cost of our CG model we investigate mesoscale structuring in our systems, for e.g., formation of reverse micellar structures. Insights obtained from our simulations are utilized to interpret experiments performed on such systems.

4:00 PM DS02.03.07
Neural-Network Based Atomistic Modeling of Plastic Deformation Mechanisms of Crystalline Molybdenum Stefanos Papanikolaou[1], Franco Pellegrini[2], Emine Kucukbenli[3,4], Javier Dominguez[1], MIkko Alava[1,5], Efthimios Kaxiras[3] and Amirhossein Naghdi Dorabati[1]; [1]NOMATEN CoE, National Centre for Nuclear Research, Poland; [2]International School for Advanced Studies (SISSA), Italy; [3]Harvard University, Lyman Laboratory 339, United States; [4]Department of Information Systems, Questrom School of Business, Boston University, United States; [5]Department of Applied Physics, Aalto University, Finland

Numerical investigations of nano-mechanical testing for metals and alloys require accurate inter-atomic potentials that may predict configurational energies and interatomic forces, consistent with ab initio calculations. In this work, we investigate crystalline molybdenum (Mo), a viable candidate for extreme environments such as fusion reactors [1]. Mechanical properties of Mo, such as nanoin-dentation hardness, display non-trivial temperature dependence that requires further validation and deeper understanding, beyond classical force fields methods [2]. In this work, we create a Neural-network interatomic potential (NNIP) for nanoindentation and uniaxial tension of pure crystalline Mo to investigate mechanisms of dislocation nucleation and evolution at multiple temperatures, up to 1000K. Elastic constants, dislocation densities, strain maps and slip traces as a function of inden-tation depth of the system are compared with embedded atom method (EAM) potentials and the advantages and limitations of NNIPs over traditional potentials are reported [3].

Multi-Scale Neural Network Quantum Molecular Dynamics Simulations for Computational Ferroelectric Topotronics Thomas M. Linker[1], Ken-ichi Nomura[1], Aiichiro Nakano[1], Rajiv Kalia[1], Fuyuki Shimojo[2], Kohei Shimamura[2] and Priya Vashishta[1]; [1]University of Southern California, United States; [2]Kumamoto University, Japan

Recent discoveries of polar topological structures (*e.g*., skyrmions and merons) in ferroelectric/paraelectric heterostructures have opened a new field of polar topotronics. However, how complex interplay of photoexcitation, electric field and mechanical strain controls these topological structures remains elusive. To address this challenge , we have developed multi-scale neural network quantum molecular dynamics simulation approaches. Our approaches incorporate excited-state neural network quantum molecular dynamics simulations that integrate quantum-mechanical description of electronic excitation and billion-atom machine learning molecular dynamics to investigate far-from equilibrium optical excitation in ferroelectric materials, as well as imbedding of neural-network(NN) force fields for ferroelectric materials within molecular mechanics (MM) based force-fields to provide accurate mechanical properties and stress/strain controls of ferroelectric/paraelectric heterostructures in a novel NN/MM approach. Our multiscale quantum simulations and machine learning methods will boost not only the emerging field of ferroelectric topotronics but also broader opto-mecho-electronic applications

Exploring the Structure-Energy Landscape of Oxidic Structures on Copper Surfaces with Machine Learning Potentials and Global Optimization Methods Hyun Jun Kim, Giyeok Lee, Seung-Hyun Victor Oh and Aloysius Soon; Yonsei University, Korea (the Republic of)

Copper has established itself as a transcending material in many key technologies [1]. Despite its long history as an essential metal, there are still uncharted areas of research that have not been systematically conducted. The full-scale structure determination of thin film Cu_xO/Cu(111) surfaces is one such example. The Cu(111) surface is the most stable surface of copper. Therefore, it will be essential to clarify the most relevant surface structure of its oxidized thin film state under targeted synthesis/technical conditions. Although, there have been many articles from both experimental and theoretical investigations that have discovered the most representative surface oxidic structures such as the “8”, “29”, and “44” surface oxides (which covers 8, 29, and 44 times the area of *p*(1 x 1) Cu(111) surface unit cell, respectively) [2,3], it is still unclear whether these “well-known” thin film structures capture the full family of surface oxides on Cu(111). The objective of this work is to provide a systematic and through survey of the potential energy landscape of O/Cu(111) by utilizing with global optimization technique (such as the Global Optimization with First-principles Energy Expression, GOFEE) [4] coupled to a Gaussian Approximation Potential (GAP) [5] which utilizes descriptors that distinguish local atomic environments within a structure. Through this work, we hope to guide experiments in characterizing new (meta)stable surface oxides on Cu(111) and provide accurate atomistic models for further studies in niche applications such as corrosion and energy-related catalysis.

Tuesday Morning, November 29, 2022
Hynes, Level 2, Room 210

8:00 AM *DS02.04.01
Topology-Optimized Porous Cellular Material Architectures with Maximized Energy Absorption Josephine V. Carstensen[1], Reza Lotfi[2], Wen Chen[3], Stefan Szyniszewski[4], Stavros Gaitanaros[2], Jan Schroers[5] and James K. Guest[2]; [1]MIT, United States; [2]Johns Hopkins University, United States; [3]University of Massachusetts Amherst, United States; [4]Durham University, United Kingdom; [5]Yale University, United States

With the recent rapid development of manufacturing technologies, there is a growing need for design methods that can leverage the new fabrication possibilities. This includes design methods that can identify novel low-weight porous cellular material architectures. Topology optimization is a free-form generative design method that does not require the designer to have a preconceived notion of the final design layout. It only requires the definition of a design domain (or unit cell of the cellular material architecture) with applied loads and boundary conditions and will seek to efficiently distribute material within this domain. The design problem is traditionally formulated as a formal optimization problem and solved using a rigorous mathematical program, resulting in solutions that typically outperform conventional low-weight designs.

However, most topology optimization used to design the architecture of porous cellular materials focus on extremizing one or more of the elastic properties. Herein, we look to extend the design problem to the nonlinear regime and aim to maximize the energy absorption capacity until failure of the base solid occurs locally. This results in a problem formulation where the nonlinear properties are estimated using a finitely periodic structure. An interesting base material choice for energy absorption is bulk metallic glasses for which we optimize the designs and fabricate them through a thermoplastic processing method. Testing to full densification reveals that the governing mechanisms for these topologically-optimized structures are combinations of buckling and yielding at the strut level. As a consequence, they offer superior total energy absorption over the traditional honeycomb topologies. Investigations of the same topologies made of polyether ether ketone suggest future directions on how to improve the post-peak response of the topology-optimized cellular materials.

A significant challenge in moving beyond the design of extreme elastic properties is the significant increase in nonlinearity of the design space. Considering nonlinear mechanics such as yielding and large deformations makes it difficult for conventional gradient-based optimizers to navigate the design possibilities and identify quality solutions. With the aim of decreasing the current notable requirement for parameter tuning, we initiate an investigation of how machine learning techniques can be leveraged to increase the robustness of the design framework.

8:30 AM DS02.04.02
Development and Validation of Versatile Deep Atomistic Potentials for Metal Oxides Pandu Wisesa, Christopher M. Andolina and Wissam A. Saidi; University of Pittsburgh, United States

Metal oxide systems are of great interest for various technologies such as coatings and thin film applications. Simulating these materials at larger timescales and system sizes remain a challenge for materials modeling. Calculations based on standard density functional theory while accurate are computationally expensive. On the other hand, methods based on atomistic potentials that can be extended to large system sizes and time scales often fail to describe the different oxidation states of metal oxides. Herein we focus on creating machine learning deep neural-network potentials for different metal oxide systems in a systematic and replicable manner using recently introduced method for convergence acceleration of the training set. Each of these potentials are trained on experimentally verified structures without limitations on the selection of their oxidation states. We validate these interatomic potentials by matching various computed material properties with density functional theory. We demonstrate how these interatomic potentials and their associated training data can be used for further studies to reduce the gap between atomistic simulation and experiments, such as polymorphism, interfaces between different phases, crystalline growth, and other transformations that might include changes in composition. Our study, in addition to our previous studies of metals and binary metallic alloys, demonstrates that machine learning potentials are effective in describing systems with mixed levels of ionic/covalent bonding.

8:45 AM DS02.04.03
Machine Learning Based Prediction of Cation Distribution in Complex Spinel Oxides Guofeng Wang and Ying Fang; University of Pittsburgh, United States

Spinel ferrites with a general chemical formula of AB2O4 (A, B = Fe, Mg, Co, Ni, Cu, or Al) have interesting and technologically relevant magnetic and electrical properties. The crystal structure of spinel AB2O4 can be viewed as a superlattice consisting of eight (2x2x2) face-centered cubic unit cells with the lattice sites occupied by oxygen ions. In addition, one eighth of the tetrahedral and one half of the octahedral sites of the lattice are occupied by the A and B cations. In a normal spinel structure, all A ions will lie at the tetrahedral sites whereas all B ions at the octahedral sites. By contrast, half of the B ions will lie at the tetrahedral sites, whereas the octahedral sites are occupied by both A and B ions in an inverse spinel structure. Varying from the normal to inverse structures, the cation distribution in spinel AB2O4 could be quantified using degree of inversion which is the fraction of the tetrahedral sites occupied by B ions.

It has been found that both cation chemistry and degree of inversion play an important role in technically relevant properties of spinel oxides. In this study, we have developed and applied a machine learning based computational approach to predict the equilibrium cation distribution in multi-cation spinel oxides at high temperatures. The database was constructed to contain the density functional theory calculated energies of the spinel oxides with various cation distributions. We applied the machine learning techniques (i.e., linear regression and neural network) to find the relation between the system energy and structural features of the spinel oxides and performed the atomistic Monte Carlo simulations to predict the equilibrium cation distribution as a function of temperature for single spinel AB_2O_4 and double spinel $AB_{2-x}C_xO_4$. Our predicted cation distributions for material systems of $CoFe_2O_4$, $NiFe_2O_4$, $MgAl_2O_4$, $CuAl_2O_4$, and $MgAl_{2-x}Fe_xO_4$ are found to agree well with available experimental results.

9:15 AM DS02.04.05
Chracterization of Recrystallization Microstructure of Steel Alloys by Multi Phase Field Model Assisted by Data Assimilation Technique. Nam Hoon Goo; Postech, Korea (the Republic of)

Recrystallization is a fundamental phenomenon in steel metallurgy. Through recrystallization, we can complete the creation of the desired microstructure. The critical aspects of the microstructure are grain size distribution, grain orientation texture, and precipitated particles.
The John-Mehl-Avrami equation can describe the kinetics: however, we can not yet make a quantitative prediction related to the recrystallization. In this study, we carry out the ICME approach combined with CPFEM and phase field approach. The CPFEM simulation prepares the initial state of recrystallization for cold-rolled steel sheets, and we implemented the phase field calculation with the data assimilation technique. Data assimilation is required to determine the phase field model parameters such as grain boundary energy and mobility. We validate the modelling results with the annealing experiments for various Fe-C alloys. With the framework, we can characterize the recrystallized microstructure. The characterization contains grain size distrubtion, orientation texture, and the effect of initial conditions, including plastic deformation and precipitates.

9:30 AM DS02.04.06
Dislocations Shape and Dynamics in BCC Medium Entropy Alloys—Classical Modelling with Machine Learning Potentials Ivan Lobzenko[1], Yoshinori Shiihara[2] and Tomohito Tsuru[1]; [1]Japan Atomic Energy Agency, Japan; [2]Toyota Technological Institute, Japan

High-entropy alloys (HEA) are excellent structural materials due to their promising mechanical properties. Works on body-centered cubic (BCC) HEAs show increased ductility if group 4 elements are present in the composition [1,2,3]. Theoretical studies of that effect by first-principles modeling are complicated by the essential randomness of HEA atomic structure, which requires large systems. To achieve high accuracy in classical molecular dynamics we have developed interatomic potentials using machine learning of artificial neural networks (we refer to them as ANN potentials).
We present in the current work results for two medium-entropy alloys (MEA): MoNbTa and ZrNbTa. Comparison of basic mechanical properties show

decrease of bulk modulus and elastic constants if Mo is substituted with group 4 element Zr.
Edge and screw dislocations are studied. Classical modelling allows construction of big calculation cells, that prevents self-interaction of the dislocation core due to long-range stress field. Moreover, big cells ensures better randomness of alloys, which is vital in simulations of HEA and MEA mechanical properties. Screw dislocation movement is induced by applying shear strain. In case of edge dislocation the shape and energy is studied in the process of migration of the dislocation core between two adjacent easy core configurations. In this way the Peierls barrier is calculated. Results for two MEA are compared to elucidate the role of group 4 element.
Finally, to understand the stress field of dislocations we employ atomic stress calculation scheme in the framework of ANN potentials. Atomic stress calculations is possible based on virial stress definition due to the fact that atomic energy in the ANN scheme ultimately depends on pair distances between atoms.

9:45 AM BREAK

10:15 AM DS02.04.07
Efficient Implementation of Machine Learning-Based Nonlocal Functionals for Molecules and Solids Kyle W. Bystrom and Boris Kozinsky; Harvard University, United States

Machine Learning (ML) has recently gained attention as a means to develop more accurate exchange-correlation (XC) functionals, and in particular could be used to improve XC functionals for solids without using the computationally expensive exact exchange energy. Feature design is one of the main challenges of this approach because the features must include enough nonlocality to capture the complex nonlocal nature of the exact XC functional while also allowing for computationally efficient and scalable implementations. To address this challenge, the CIDER model for designing nonlocal ML functionals is introduced and used to design a nonlocal exchange functional that obeys the uniform scaling rule for exchange. In addition, two efficient methods for evaluating CIDER features are implemented: A quadratic-scaling algorithm for all-electron, molecular density functional theory (DFT) and a quasi-linear-scaling algorithm for plane-wave DFT with the PAW method. Preliminary efficiency and accuracy benchmarks for periodic systems are presented.

10:30 AM DS02.04.09
Molecular Dynamics Simulations of Lattice Thermal Conductivity with Machine-Learning Anharmonic Interaction Jing Wang[1], Jie-Cheng Chen[2] and Mei-Yin Chou[2]; [1]Georgia Institute of Technology, United States; [2]Academia Sinica, Taiwan

The lattice thermal conductivity of crystals with strong anharmonic interaction is of particular interest, which cannot be adequately evaluated by linearized Boltzmann transport equation. In this work, we adopt compressive sensing, a machine learning technique to obtain high-order force constants from a small amount of training data. By considering strong heredity effects, we show that the dominant anharmonic interactions are short ranged. This largely shrinks the number of force constants needed in the expansion. To calculate the lattice thermal conductivity, molecular dynamics simulations that include anharmonic interactions up to the sixth order are performed. Test results for Si and NaCl will be presented. The anharmonic interaction in NaCl is found to be more significant than that in Si, which is consistent with the fact that NaCl exhibits a smaller thermal conductivity at above 100 K. Simulation results for highly anharmonic thermoelectric materials SnSe and GeSe that exhibit very low thermal conductivity will also be discussed.

10:45 AM DS02.04.10
Predicting the Dynamics of Atoms in Liquids by a Surrogate Machine-Learned Simulator Han Liu and Mathieu Bauchy; University of California, Los Angeles, United States

Molecular dynamics (MD) is a workhorse of computational material science. However, the inner-loop algorithm of MD (i.e., numerically solving the Newton's law of motion) is computationally expensive. Here, we introduce a surrogate machine learning simulator that is able to predict the dynamics of liquid systems with no prior knowledge of the interatomic potential or nature of the Newton's law of motion. The surrogate model consists of a graph neural network (GNN) engine that is trained by observing existing MD-generated trajectories. We demonstrate that the surrogate simulator properly predicts the dynamics of a variety of systems featuring very different interatomic interactions, namely, model binary Lennard-Jones system, silica (which features long-term coulombic interactions), silicon (which comprises three-body interactions), and copper-zirconium alloy (which is governed by many-body interactions). The development of machine-learned surrogate simulators that can effectively replace costly MD simulations could expand the range of space and time scales that are typically accessible to MD simulations.

11:00 AM DS02.04.11
Charge-Density Based Convolutional Neural Networks for Stacking Fault Energy Prediction in Concentrated Alloys Gaurav Arora, Serveh Kamrava, Pejman Tahmasebi, Dilpuneet S. Aidhy and Nathan Linton; University of Wyoming, United States

A descriptor-less machine learning (ML) model based on charge density extracted from density functional theory (DFT) is developed to predict stacking fault energies (SFE) in concentrated alloys. Often, in most ML models, textbook physical descriptors such as atomic radius, valence charge and electronegativity are used as descriptors which have limitations because these properties change in concentrated alloys when multiple elements are mixed to form a solid solution. We illustrate that, within the scope of DFT, the search for descriptors can be circumvented by electronic charge density, which is the backbone of the Kohn-Sham DFT and describes the system completely. The model is based on convolutional neural networks (CNNs) as one of the promising ML techniques for dealing with complex images and data. The performance of our model is evaluated by predicting SFE of concentrated alloys with an RMSE and R2 of 6.18 mJ/m2 and 0.87, respectively, validating the accuracy of the proposed approach.

11:15 AM DS02.04.12
Accelerated Development of ReaxFF Forcefields Using Machine Learning Ankit Mishra, Ken-ichi Nomura, Aiichiro Nakano, Rajiv Kalia and Priya Vashishta; University of Southern California, United States

ReaxFF based reactive force field approach has increased the application of reactive molecular dynamics simulation for studying complex material properties and processes. However, complex simulations require careful tuning of model parameters to high quality ground truth data obtained from accurate quantum mechanical methods. Also, a parameter set tuned for a particular system can be extended through optimization to other applications for similar systems since ReaxFF uses fixed functional form representation of all chemical systems. This optimization process is challenging due to large parameter space, especially for multi component chemical systems and therefore, is extremely challenging to achieve. Currently popular local (parabolic interpolation methods, gradient based methods) and global black box optimization methods (Genetic Algorithms, Monte Carlo Methods, Covariance Matrix Adaptation evolution strategy, Particle Swarm Optimization) require hundreds of thousands of error evaluations for complex training tasks and subsequent error evaluation through energy minimization of many several molecules in the training set. Therefore, an efficient optimization scheme is needed for sampling this high dimensional parameter space with many local minima. Here, we demonstrate various machine learning based parameter

optimization scheme, that use a parallel MD agent for environment sampling and utilizing various machine learning methods to efficiently optimize high dimensional parameter sets. These parameter sets can be further fine-tuned by using gradient based gradient approached near local minima to yield high quality parameter sets suitable for a particular problem at hand

1:30 PM *DS02.05.01
Towards Out of Distribution Generalization in Mechanics Lingxiao Yuan, Harold S. Park and Emma Lejeune; Boston University, United States

There has been an explosion of recent work in applying data driven methods to problems in mechanics, with particular emphasis on designing materials with novel functionality and predicting their properties. While traditional machine learning (ML) methods have enabled such breakthroughs, they rely on the assumption that the training (observed) data and testing (unseen) data are independent and identically distributed (i.i.d). However, when applied to real world mechanics problems with unknown test environments, a well-trained ML model is very sensitive to data distribution shifts and can break down when evaluated on the shifted test dataset. In contrast, out-of-distribution (OOD) problems assume that the data in test environments is allowed to shift, and many methods both within and outside the mechanics community, have been proposed to improve the out-of-distribution (OOD) generalization for ML methods. However, because most of these OOD methods have been developed for classification problems, and further because of the lack of benchmark datasets for OOD regression problems, the efficiency of these methods on regression problems, which are more important than classification for mechanics, is unknown. Therefore, in this work, we perform a fundamental study of OOD generalization methods for regression problems in mechanics. Specifically, we identify three OOD generalization problems: covariate shift, mechanism shift, and sampling bias, and develop two benchmark datasets for each problem based on the well-known MNIST and EMNIST-Letters datasets to investigate the performance of the OOD generalization methods. Our experiments show that for most cases, while the OOD algorithms perform better compared to traditional ML methods on OOD generalization problems in mechanics, there is a compelling need to develop more robust OOD methods that can generalize notions of invariance across multiple OOD scenarios. Overall, we expect that the combination of this study, as well as the benchmark datasets we developed, will enable further development of OOD methods for regression problems.

2:00 PM *DS02.05.02
A Framework for Variational Embedding of Data in Physics-Based Models Arif Masud and Shoaib Goraya; University of Illinois at Urbana-Champaign, United States

This talk presents a physics-constrained data driven method that variationally embeds measured data in the modeling and analysis framework. The physics-based model is augmented with sparse but high-fidelity data through a variationally derived loss function. The structure of the loss function is analyzed in the context of variational correction to the model predictions wherein loss function penalizes the difference in the modeled response from the measured data that represents the local response of the system. The Variationally Embedded Measured Data (VEMD) method results in forward simulations that are not only driven by boundary and initial conditions but are also augmented by real measurements taken at only a small number of observation points. In the context of forward simulations, the proposed approach can be seen as inducing inductive biases that exploit the difference between the computed and measured quantities in the parametric space. With the help of a model problem from elasticity, we show that the proposed method learns from the sparse high-fidelity datasets while preserving conservation properties of the balance laws. Method is applied to a non-smooth model problem and the mathematical attributes of the formulation are investigated in the context of high-fidelity sparse datasets.

Transferable Coarse Grained Potentials Enabled by Gaussian Process Regression and Active Learning Blake Duschatko, Jonathan Vandermause, Nicola Molinari and Boris Kozinsky; Harvard University, United States

Despite continuing advances in the development of interatomic potentials, biologically relevant long length- and time-scales remain inaccessible. Recently, machine learning has shown promise in developing sophisticated “bottom-up” coarse grained potentials, wherein the thermodynamic properties of the all-atom system are preserved. Despite the implications of successfully developing these models, a number of roadblocks remain.

In this work, we demonstrate the use of Gaussian process (GP) regression in designing an on-the-fly active learning framework for coarse grained modeling. In particular, we show that the inherent uncertainty of GP’s allow these models to more seamlessly be transferred across chemically adjacent systems, addressing a persistent problem in the field. Moreover, we examine the applicability of this method to a variety of systems and explore ways in which uncertainty can serve as a probe to the fidelity of system property predictions in ways that traditional diagnostics, such as mean force errors, cannot.

Acceleration of Simulations of Complex Compounds by Dimensionality Reduction of Atomic Cluster Expansion Features Yu Xie, Anders Johansson and Boris Kozinsky; Harvard University, United States

Machine learning interatomic potentials have shown promising accuracy and efficiency with equivariant features. Among those, atomic cluster expansion [1] is proposed recently as a systematic method to expand body orders of the features. However, the dimension of atomic cluster expansion features grows quickly with the number of chemical elements, which limits its performance for complex materials. In this work, we investigate embedding strategies for dealing with multiple chemical elements and basis functions of atomic cluster expansion. Our theoretical and numerical results illustrate that the embedding

method is able to reduce the dimension of the features with almost no loss of accuracy, yielding significant acceleration of machine learning molecular dynamics of complex materials.

3:30 PM DS02.05.05
Learning the Short- and Medium-Range Enthalpic Structural Manifolds of Disordered Materials Thomas J. Hardin[1], Mark Wilson[1], Michael Chandross[1], Michael L. Falk[2] and Michael Shields[2]; [1]Sandia National Laboratories, United States; [2]Johns Hopkins University, United States

Enthalpy minimization pulls the local atomic configurations in materials onto a manifold; by parameterizing that enthalpic structural manifold for a particular material, we can obtain a minimal set of structural descriptors that describe the important degrees of freedom in the local atomic configurations in that material. We sampled local atomic configurations from a variety of experimental and simulated glassy materials, compared those configurations using the Gaussian Integral Inner Product distance, and applied hierarchical clustering and diffusion maps to extract low-dimensional discrete and continuous parameterizations of the materials' enthalpic structural manifolds. We used nonlinear regression to interpret these learned parameters in terms of physically meaningful quantities. This presentation will focus on our structure parameterization methodology and physical interpretation of that parameterization, and will also include physical insights gleaned in the process. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525 (SAND2022-8094 A).

3:45 PM DS02.05.06
Specialized Neural Network Interpolant for Accelerated Pair Interaction in Systems of Rigid Bodies Gusten Isfeldt, Jakob Wohlert and Fredrik Lundell; KTH Royal Institute of Technology, Sweden

Motivated by the limitations of conventional coarse-grained molecular dynamics for simulation of large systems of nanoparticles, an approach to enable the use of complex iteraction models for nanoparticles derived from molecular dynamics simulation data in large scale simulation through the use of a class of specialized deep neural networks for interpolation in the relative coordinate space of rigid bodies has been developed.

The first layer of the network transforms the relative position and orientation with a flexibly parametrized geometric representation to a form more suitable to conventional fully connected layers, which, folowed by a weighted sum can be used to approximate a potential. Through backpropagation of the gradient of the potential, the force and torque on the particles can then be calculated through the geometric representation. Compared to training a more general network on the components of the force and torque vectors, this method has the advantage of being guranteed to produce an energy conserving interaction, and due to only being trained on a scalar value, requires fewer internal parameters to be trained. Furthermore since the training data is a scalar potential, the network can be trained to replicate models with no obvious gradient. As the parameters of the geometric transformation are trained along with the other weights in the network, the representation becomes optimized for the geometry of the potential.

The network is fitted to a variety of interaction potentials, investigating training and convergence characteristiscs and noise sensitivity, to demonstrate both the utility and limitations of the method. Additionally, further generalization to use on soft bodies and polydisperse systems is discussed.

4:00 PM DS02.05.07
Neural Network Models of Phase Field Simulations Haiying Yang and Michael J. Demkowicz; Texas A&M University, United States

We explore the potential for neural networks (NNs) to predict two aspects of microstructure evolution, as represented in simple phase field simulations. First, we train NNs to predict the evolution of microstructures under pre-specified, spatially and temporally varying temperature and bias fields. This problem is amenable to solution by existing NN training methods because each input maps to a unique output. Next, we train NNs to solve the inverse problem, namely: what externally applied temperature and bias fields are required to guide microstructure evolution to a pre-specified target state? In this problem, inputs do not map to unique outputs, necessitating an innovative approach to NN training. Our work suggests that NNs may be useful for finding optimal processing parameters for achieving a desired microstructure.

4:15 PM DS02.05.08
A Representation-Independent Electronic Charge Density Database for Crystalline Materials Jimmy-Xuan Shen[1], Jason M. Munro[2], Matthew K. Horton[2] and Kristin A. Persson[2,3]; [1]Lawrence Livermore National Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States

In addition to being the core quantity in density functional theory, the charge density can be used in many tertiary analyses in materials sciences from bonding to assigning charge to specific atoms. The charge density is data-rich since it contains information about all the electrons in the system. With the increasing prevalence of machine-learning tools in materials sciences, a data-rich object like the charge density can be utilized in a wide range of applications. The database presented here provides a modern and user-friendly interface for a large and continuously updated collection of charge densities as part of the Materials Project. In addition to the charge density data, we provide the theory and code for changing the representation of the charge density which should enable more advanced machine-learning studies for the broader community.

4:30 PM DS02.05.09
Structure-Property Relationships for Grain Boundaries Using Strain Functional Descriptors and Supervised Machine Learning Avanish Mishra, Sumit Suresh, Khanh Dang, Saryu Fensin, Edward Kober and Nithin Mathew; Los Alamos National Laboratory, United States

Properties of grain boundaries (GBs) are controlled by the types and arrangement of local atomic environments at the boundary. Although it is possible to estimate GB properties by characterizing minimum energy or well-defined GBs, extrapolating these understanding to real GBs is a formidable task. The increased complexity in metastable states of GBs, with variations in atomic arrangement, provides a remarkable opportunity to utilize data-driven methods to establish the structure-property relationships for GBs. A significant challenge in establishing such relationships is the absence of physically meaningful set of descriptors to represent structural arrangement at GBs. Existing descriptor sets can estimate selected properties; however, they fail to provide any physical insights. Strain functional descriptors (SFD), a complete and symmetry-adapted set of descriptors, are ideal for characterizing the local atomic environment at GBs and provides the capability to decompose the atomic arrangement in terms of physically meaningful descriptions such as strains, strain-gradients, and higher order deformations. The presentation will show the application of SFDs for predicting various properties, such as grain boundary energy, atomic energy density, and elastic stiffness tensor on a large (~5000) database of metastable GBs in Cu, using supervised machine learning models. The developed regression models accurately estimate various properties with unprecedented accuracy and exhibit an exceptional performance even for atomic environments in polycrystalline samples.

Global Optimization of Atomic Structures with Machine Learning Karsten W. Jacobsen; Technical University-Denmark, Denmark

Artifical intelligence is paving the way for new approaches to the understanding and design of materials at the atomic and electronic level. Machine learning can provide guidance for high-throughput computational searches and in some situations effectively replace computer intensive electronic structure calculations.

In the talk I shall focus on one particular application of machine learning: the global optimization of atomic structures. The methodology is based on Gaussian processes and uses the calculated model uncertainties to guide the search [1,2]. Furthermore, the machine learning approach allows for an extension of the configuration space to consider atoms, which are not pure elements, but combinations of several elements (for example an atom which is a combination of gold and copper) [3]. This circumvents barriers in the potential energy surface and makes structure determination much more efficient. The approach is illustrated with applications to clusters, surfaces, and bulk systems.

8:45 AM DS02.06.02
A Deep Learning Model for Formation Energy and Synthesizability of Crystalline Materials Ali Davariashtiyani[1], Zahra Kadkhodaie[2] and Sara Kadkhodaei[1]; [1]University of Illinois at Chicago, United States; [2]New York University, United States

Predicting the stability, synthesizability, and physical properties of hypothetical crystal structures are essential for developing novel materials for different applications. We present a neural network model that predicts the synthesizability and the formation energy of crystals. We created a novel technique to represent crystals by 3D voxel images, which has advantages over the widely used graph representation technique. The advantage of our approach is that the translation and rotation invariance as well as the long-range ordering of crystals naturally arise in the image representation, whereas both are absent in a graph representation. Visual features embedded in these images are learned by convolutional neural networks and are used to predict the synthesizability and formation energy of never-seen-before crystalline materials. We compare the predictions of our model with other available models.

9:00 AM DS02.06.03
Elastic Constants in Ni Based High Entropy Alloys from DFT and Machine Learning Nathan Linton and Dilpuneet S. Aidhy; University of Wyoming, United States

High entropy alloys (HEAs) present a paradigm shift in materials design. These alloys consist of multiple principal elements randomly distributed on a crystal lattice resulting in enormously large phase space which on the one hand presents large opportunities to unravel novel properties whereas on the other presents an equally large challenge to survey the phase space thereby presenting a data-science challenge. We present a machine learning framework coupled with electronic structure methods whereby properties in complex alloys could be predicted by learning from simpler alloys. The mechanical properties in complex alloys are predicted from the database of the constituent's binary alloys. Specifically, we demonstrate predictions of stiffness constants, Young's modulus, bulk and shear moduli, and Poisson's ratio in ternary, quaternary, and quinary Ni-based alloys with a high-level of accuracy. A major benefit of this approach is that for every new composition discovered, the mechanical properties can be computed using only the existing binary alloy database thereby completely bypassing the computationally expensive calculations.

9:15 AM DS02.06.05
Neuroevolution Guided Discovery of Pathways for Materials Synthesis Anirban Chandra[1,2], Amanda Dufek[3], Suvo Banik[1,2], Rohit Batra[2], Isaac Tamblyn[4,5], Pierre Darancet[2], Stephen Whitelam[3] and Subramanian Sankaranarayanan[1,2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]University of Ottawa, Canada; [5]Vector Institute of Artificial Intelligence, Canada

Discovery and synthesis of materials with tailored properties is an overarching goal of material scientists. Thermodynamic phase diagrams are often a good starting point for designing synthesis protocols, but in typical experimental settings, kinetic effects are often more prominent and therefore determine the feasibility of such protocols. Selective synthesis of polymorphs of a material can also be limited by such kinetic barriers. Here using molecular simulations we investigate how neural networks trained by evolutionary reinforcement learning can generate feasible synthesis pathways for materials. These previously unknown pathways can enable us to optimally synthesize a particular material and simultaneously provide physical insight into the kinetics of phase transitions. Moreover, we also show how our neural networks learn to change thermodynamic variables in order to promote generation of a particular phase, i.e. perform polymorph selection. Transformation pathways in several materials, such as Carbon and Silicon, are discussed here. The presented evolutionary scheme can be applied to investigate a broad range of problems (such as self-assembly, experimental design, and additive manufacturing) wherein transition pathways from one state to another are unknown.

9:30 AM DS02.06.06
Adaptive Learning From Scarce And Multi-Fidelity Materials Data Sanaz Zanjani, Mehdi Shishehbor, Amin Yousefpour and Ramin Bostanabad; University of California, Irvine, United States

Materials modeling and design is typically hampered by two major uncertainty sources: lack of data and model form discrepancies. In this talk, we will present a novel approach based on nonlinear manifold learning that addresses these (and more) uncertainty sources. Our approach is based on latent map Gaussian processes (LMGPs) and aims to leverage multiple data sources to quantify uncertainty sources and, more importantly, provide visually interpretable diagnostic measures that indicate the extent to which different data sources (e.g., experiments, simulations, etc.) agree with one another. We will introduce our approach in both Bayesian and frequentist settings and demonstrate that both perform well in a wide range of applications.

Conditional Generation of Liquid Solidification by Manipulating the Degrees of Supercooling Using Deep Generative Model Bor-Yann Tseng, Yu-Chen Chien and Chi Hua Yu; National Cheng Kung University, Taiwan

We propose a deep generative model on the learning of physics behind the dendritic solidification development process.Dendritic structure is commonly seen in many different casting processes, which also plays an important role and affectsthe properties of the final product for freezing casting. However, there is no efficient tool for the researcher to examine the end product with desired properties. In this study, we developed a time-dependent deep generative model to learn to predict the phase change under different cooling conditions. Our model successfully predicts the morphology of different water ices, proving that our model is capable of reproducing the solidification for a complete growth process. Our results also suggest that by controlling the degree of supercooling, we can successfully manipulate the porosity after freeze casting. Our research opens a new avenue for inverse design of casting processes with the desired porosity. This model can be easily extended to different physics systems, such as cell mechanics, metal recrystallization, and two-phase flow.

Utilizing AI and TD-DFT Calculated Raman Response to Optimize CVD Synthesis Parameters of K_2CoS_2 John P. Ferrier and Swastik Kar; Northeastern University, United States

With new materials being theoretically devised using computational techniques, such as Density Functional Theory (DFT), new experimental tactics must be devised to ease the complexities of synthesizing new 2D materials. Given the large parameter control space for experimental synthesis of 2D materials, we propose utilizing an AI model that correlates experimental growth parameters to their resultant sample Raman spectra measurements. Time-Dependent DFT (TD-DFT) is utilized to calculate an approximation for the expected Raman spectra of the desired 2D material using a wavelength-dependent Placzek approximative method [1], allowing the AI model to propose expected growth parameters.
In this presentation we will discuss our preliminary results of ultrathin, possibly monolayer growth of K_2CoS_2, an in-plane antiferromagnetic insulator [2], using these TD-DFT simulations and AI to optimize CVD growth parameters.

Permutation-Invariant Deep Neural Networks for Predicting the Mechanical Properties of Random Cellular Composites Yuan Chiang[1,2], Grace Gu[1] and Shu-Wei Chang[2]; [1]University of California, Berkeley, United States; [2]National Taiwan University, Taiwan

Composite materials hold exciting key to many extraordinary mechanical properties such as reduced weight, high specific strength and toughness, and progressive fracture behavior. Recent advances in additive manufacturing have facilitated the fabrication of complex composite designs. However, searching for the optimal structures and combinations of composite materials has never been a trivial task. Previous machine learning models usually take structured design features (*e.g.* fixed-size vectors, images, graphs, *etc.*) as inputs, which usually confines and discretizes the design space. Here we adopt permutation-invariant neural networks to learn the unordered point distributions in a continuous space. We embed the cell centroid distributions of random cellular composites as high-dimensional representation vectors to predict the stress-strain curves obtained from lattice spring model (LSM) simulations. By learning randomly shuffled and reflected cell centroids, our model obeys permutation invariance and reflection symmetry of cellular composite designs. Without discretization in formulation, the model also learns the continuous mapping of spatial coordinates and can embed arbitrary number of cells. Our model could enable high-throughput and flexible composite design and apply to gradient-based optimization.

11:00 AM DS02.06.10
Inverse Design of Architected Metamaterials Using Isogeometric Analysis and Machine Learning Deepak Kumar Pokkalla[1], Raja Biswas[2], Seokpum Kim[1] and Vlastimil Kunc[1]; [1]Oak Ridge National Laboratory, United States; [2]Evonik Digital Labs, Singapore

Architected materials with prescribed mechanical properties are beneficial for diverse engineering applications. With the advent of additive manufacturing, the fabrication of new lattice metamaterials across multiple length scales with unforeseen properties became feasible. However, rapidly identifying complex architectures with prescribed mechanical properties remains a challenge as the present design paradigm relies on traditional finite element analysis and time-consuming topology optimization. Recently, machine learning techniques are explored for the inverse design of metamaterials, albeit only for infinitesimal deformations. We introduce an efficient machine learning approach for rapid inverse design of lattice metamaterials with tailorable nonlinear stress-strain curves and Poisson's ratios. The structure-property map exploring topological design space with distinct lattice structure types, sizes, and shapes generated using isogeometric analysis serves as the training data. With the prescribed nonlinear stress-strain curve and/or Poisson's ratio profile as input, the machine learning framework rapidly identifies the architecture that, when additively manufactured and mechanically tested, replicates the prescribed mechanical response. We rapidly generate soft network metamaterial architectures that mimic human and cat's skin mechanical behavior for biomimetic applications.

11:15 AM DS02.06.11
Representing Polymers as Periodic Graphs with Learned Descriptors for Accurate Polymer Property Predictions Evan Antoniuk, Peggy Li, Bhavya Kailkhura and Anna Hiszpanski; Lawrence Livermore National Laboratory, United States

One of the grand challenges of utilizing machine learning for the discovery of innovative new polymers lies in the difficulty of accurately representing the complex, multi-scale structures of polymeric materials. Although a wide array of hand-designed polymer representations have been explored, there has yet to be an ideal solution for the problems of how to capture the periodicity of polymer structures, as well as how to automatically develop polymer

descriptors without the need for human feature design. In this talk, I will show how we have tackled these problems through the development of our periodic polymer graph representation. Specifically, our pipeline for polymer property predictions is comprised of our polymer graph representation that naturally accounts for the periodicity of polymers, followed by a message-passing neural network (MPNN) that leverages the power of graph deep learning to automatically learn chemically-relevant polymer descriptors. Across a diverse dataset of 10 polymer properties, we find that this polymer graph representation consistently outperforms previous hand-designed representations with a sizable 20% average reduction in prediction error. Our results illustrate how the incorporation of chemical intuition through directly encoding periodicity into our polymer graph representation is responsible for a considerable improvement in the accuracy and reliability of polymer property predictions. We also demonstrate how combining polymer graph representations with message-passing neural network architectures can automatically extract meaningful polymer features that are consistent with human intuition, while achieving better predictive performance than human-derived features. Whereas previous polymer informatics approaches have typically utilized hand-designed descriptors that have been optimized for representing molecules, this work highlights the advancement in predictive capability that is possible if using chemical descriptors that are specifically optimized for capturing the unique chemical structure of polymers.

SESSION DS02.07: Machine Learning for Materials Structure and Properties VI
Session Chairs: Grace Gu and N M Anoop Krishnan
Wednesday Afternoon, November 30, 2022
Hynes, Level 2, Room 210

2:00 PM DS02.07.02
CEGAN—Crystal Edge Graph Attention Network for Multiscale Classification of Materials Environment Suvo Banik[1], Debdas Dhabal[2], Henry Chan[3], Sukriti Manna[1], Mathew J. Cherukara[3], Valeria Molinero[2] and Subramanian Sankaranarayanan[3]; [1]University of Illinois at Chicago, United States; [2]The University of Utah, United States; [3]Argonne National Laboratory, United States

Material characterization plays a crucial role in data-intensive and Artificial intelligence (AI)-driven materials design. In machine learning (ML) applications, the characterization task typically involves the use of fingerprints which is followed by a learning algorithm that maps the fingerprint to a user-desired property of interest. Fingerprints or"descriptors" can be of diverse types and scales ranging from atomic to micro-scale as demanded by the application domain. It is highly desirable that a representation of material in feature space should not only be able to differentiate between different structures but also should be simple, unique, complete, and sensitive to the locality of application. Most popular mathematical formulation-based descriptors are often not unique across the systems or suffer from transferability issues across the different application domains. Crystal graphs in this regard are unique and carry a global signature of a crystal network. In this work, we introduce a workflow called CEGAN - Crystal Edge Graph Attention Network - that uses graph attention-based architecture to combine simple edge and angle features of a crystal edge graph to learn unique feature representation and perform multiscale classification of materials belonging to different classes. We first demonstrate a case study where classification is based on their global (Structure-level) representation such as space group and structural dimensionality (e.g., Bulk, Clusters, 2D, etc.). Using representative materials such as carbon and zeolites, we next demonstrate the transferability of our network in successfully performing local atom level classification tasks, such as grain boundary identification and studying nucleation and growth of polymorph in synthesis mixtures. Overall, our approach is agnostic to the material type and allows for multiscale classification of features ranging from atomic-scale crystal structures to heterointerfaces to microscale grain boundaries.

2:15 PM DS02.07.03
CG-RNN—A Recurrent Neural Network for Coarse-Grained Force Field Prediction Eshan C. Singhal[1], Ziji Zhang[2], Miriam Rafailovich[2], Peng Zhang[2] and Yuefan Deng[2]; [1]The Oakridge School, United States; [2]Stony Brook University, United States

Simulating proteins in silico using Molecular Dynamics (MD) provides highly precise physics insights allowing experimentation without the need for laboratory procedure [1]. These simulations, however, require heavy computational workload with atomic level computations which is the major challenge for large proteins at long time scales. Thus, coarse graining (CG) algorithms have been studied which attempt to reduce the problem dimensions of the target allowing for longer simulations and more protein observations with a limited cost of accuracy [1]. Previous methods employed neural networks and graph neural networks with features calculated from the atomic simulation data to predict the energies and forces on each CG atom [2].
We propose a novel architecture by using unidirectional Recurrent Neural Network (RNN) layers to improve accuracy of the algorithm. The intuition of using RNN is natural as it specializes in time series as input data which applies directly to the MD trajectories whereas the existing approach [2] simply utilizes a dense network of linear layers ignoring the time dependency in the inputs. We deploy an RNN layer with 128 input nodes and 100 hidden nodes with 1 layer of Rectified Linear Unit activation. Outputs are passed to a single Dense layer with 100-dimensional inputs and 1-dimensional output. Because of the RNN model's reliance on our data, training batches are made variably sized, allowing for one trajectory per batch instead of a constant size. A 3e-4 learning rate with 0.3 decay rate and 4.0 lipschitz strength is utilized along with a predetermined Bead Embedding Layer and Gaussian RBF Layer. After learning, the derived CG simulations are compared to the all-atomic (AA) simulations using the non-infinite energy values in the time-lagged Independent Component Analysis (tICA) free energy distributions, with Jensen-Shannon (JS) Divergence and Mean Squared Error (MSE) as evaluation metrics. Preliminary experiments with 1,000-frame Alanine Dipeptide data demonstrate higher model accuracy for the RNN compared to the baseline CGNet model. Followup experiments are conducted with 50 epoch training on Chignolin data with 1.8 million frames to generate 200 simulated CG trajectories with 200 frames each. CG Trajectories are then processed by assigning unit cell angle and lengths corresponding to Chignolin with a distribution range adjusted from the AA domain in the tICA plot. The loss of the baseline model converges at 847.4 while the loss of the CG-RNN model converges at 304.0. For tICA distributions compared with AA simulations, the baseline model produces a JS divergence of 0.20 and MSE of 3.19, and the CG-RNN model has a JS divergence of 0.14 and MSE of 3.17, which indicates that the CG simulations derived from the CG-RNN model produce closer energy distribution with the AA simulations than the baseline model.
Although experimenting on Chignolin demonstrates merit for the CG-RNN approach, validation with larger proteins will be conducted to further verify the benefit of RNN for coarse graining. Additionally, more variations of the RNN types such as GRU or LSTM with variations in hyperparameters will be tested to further improve the accuracy of the CG-RNN approach.

Adaptive Sampling and Variability—Machine Learning for Optimizing Additive Manufacturing Processes Maher Alghalayini[1], Surya R. Kalidindi[2], Christiaan J. Paredis[1] and Fadi Abdeljawad[1]; [1]Clemson University, United States; [2]Georgia Institute of Technology, United States

Additive Manufacturing (AM) has been the subject of active research in recent years due to its potential use in many applications and the flexibility in designs it offers. However, the sensitivity of AM printed materials and their net properties to the processing conditions remains a challenge to the widespread adoption of these emerging techniques. A need, therefore, exists to optimize AM processes to identify the best printing conditions and unlock the true potential of this manufacturing capability. Recent studies show that traditional optimization approaches are inapplicable as AM materials possess significantly high variability in their net properties when the printing is repeated with the same processing parameters. In terms of optimization, sequential designs can be used to explore the high-dimensional AM processing parameter spaces efficiently. In such approaches, the optimization algorithm learns from previously collected data and adaptively proposes new experiments to selectively sample the space where needed the most to optimize the AM process. Sequential designs usually rely on optimizing a given metric in the design space to choose the experiment in the next iteration. However, the AM costs associated with performing one experiment per iteration are typically high, and an efficient novel optimization algorithm that can identify several experiments per a given iteration is needed to lower the costs associated with the optimization.

Herein, we develop an adaptive optimization method that implements machine learning and integrates the variability in the properties of AM materials. Our approach learns from previous experiments and adaptively proposes new locations in the input domain that maximize expected information gain. Gaussian Process Regression and probability calculus are used to explicitly account for variability in the analysis and optimization. In addition to variability, the novelty of our approach lies in the use of utility theory to define the optimization criteria upon which the new experiments are chosen and the flexibility in identifying the number of new design sites and their respective AM samples to be tested during each optimization iteration. The proposed method is tested on simulated data to showcase its performance. More specifically, multimodal response surfaces for both the mean and variability of AM process parameters are used to benchmark our optimization approach. This study is expected to result in an efficient, variability-embracing adaptive optimization method.

3:45 PM DS02.07.05
Uncertainty Quantification of Coarse-Grained Metal Models Using Bayesian Sampling Methods Abhishek T. Sose[1], Troy Gustke[1], Fangxi Wang[1], Aditya Savara[2], Sanket A. Deshmukh[1] and Soumil Y. Joshi[1]; [1]Virginia Tech, United States; [2]Oak Ridge National Laboratory, United States

A fundamental understanding of large and complex systems through coarse-grained (CG) molecular dynamics (MD) has become increasingly popular. Due to its lower resolution and faster dynamics, CG MD has become an efficient and economical way to perform MD simulations. However, the accuracy of the parameters used in interatomic potentials significantly affects the simulation performance. In this study, we present the development of new CG embedded atom method (EAM) potentials to describe the interatomic interactions of face-centered cubic (FCC) metals: Gold (Au), Palladium (Pd), Nickel (Ni), Copper (Cu), Aluminum (Al) and Platinum (Pt). Particularly, a CG MD integrated particle-swarm optimization (PSO) method was used to explore the 14 parameter space defined by EAM potential in order to reproduce the physical, mechanical, and thermodynamic properties of their respective metals. These developed models may contain several sources of uncertainty, including errors in numerical and modeling calculations. Hence, to develop a fundamental understanding of the sensitivity of the output to these errors, we describe the uncertainty of input parameters through the learning of output. The following framework was developed to evaluate the uncertainty and accuracy of these developed FF parameters: (i) Using data obtained from simulations of the CG model and various parameter options, a sensitivity analysis using Sobol sampling was performed. (ii) From the sobol data, a Gaussian Process Regression (GPR) model was developed and used as a surrogate model for MD simulations. (iii) By integrating PEUQSE, a Bayesian tool for parameter estimation, and the GP model, further uncertainty quantification (UQ) was accomplished. The stochastic way of identifying high confidence level parameter sets was a more efficient way, rather than a traditional deterministic approach. Specifically, we performed three sampling techniques: Ensemble slice sampling (ESS), Metropolis-Hastings (MH), and the Grid search approach to sample and identify the most probable parameter set. Our results suggest that the convergence and accuracy of the ESS method was faster and computationally cheaper compared to other two methods. With this robust computational framework, hard- and soft-material interatomic potentials can be developed with excellent reliability and accuracy.

This material is based upon work supported by the National Science Foundation under Grant No. DMR-2047743

4:00 PM DS02.07.07
Quantifying Disorder One Atom at a Time Using an Interpretable Graph Neural Network Paradigm James Chapman[1,2], Yu-Ting Hsu[1], Xiao Chen[1], Tae Wook Heo[1] and Brandon Wood[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Boston University, United States

At the center of the structure-property paradigm is the fact that macroscopic materials behavior begins at the atomic scale, with local atomic arrangements ultimately coming together to form structural features observed at larger length scales. Characterizing the nature and propagation of these local environments is therefore vital to understanding macroscale structure-property relationships and their evolution. Complicating this endeavor is the fact that the long-range features often depend on structurally disordered atomic environments, which tend to dictate materials functionality. Quantifying the level of atomic disorder within materials is therefore critical to understanding how evolving local structural environments dictate performance and durability. Here, we leverage graph neural networks to define a physically interpretable metric for local disorder. This metric encodes the diversity of the local atomic configurations as a continuous spectrum between the solid and liquid phases, quantified against a distribution of thermal perturbations. We apply this novel methodology to three prototypical examples with varying levels of disorder: (1) solid-liquid interfaces, (2) polycrystalline microstructures, and (3) grain boundaries. Using elemental aluminum as a case study, we show how our paradigm can track the spatio-temporal evolution of interfaces, incorporating a mathematically defined description of the spatial boundary between order and disorder. We further show how to extract physics-preserved gradients from our continuous disorder fields, which may be used to understand and predict materials performance and failure. Overall, our framework provides an intuitive and generalizable pathway to quantify the relationship between complex local atomic structure and coarse-grained materials phenomena.

Development of Machine Learned Force Fields for Transition Metals and an Application to Surface Reconstruction Cameron J. Owen[1], Steven B. Torrisi[1,2], Yu Xie[1], Simon L. Batzner[1], Albert Musaelian[1], Lixin Sun[1] and Boris Kozinsky[1,3]; [1]Harvard University, United States; [2]Toyota Research Institute, United States; [3]Bosch, United States

The development of accurate and efficient machine-learned force fields is a crucial step in an overall materials discovery workflow that complements experiments with theoretical simulations. In order to facilitate the ongoing development of automated machine learned force fields using tools like

FLARE,[1] Nequip,[2] and Allegro,[3] we have generated a benchmarking dataset of single-element bulk structures with a vacancy defect in order to study the interplay between many body behavior and model performance. This dataset contains ab initio molecular dynamics simulations capturing low-temperature crystalline and melted phases. We investigate the difference in model performance across model architectures, levels of descriptor fidelity, and elements. These results reveal the interplay between elemental properties and model accuracy revealed by differences in performance.

The fidelity of these methods is further assessed by considering the reconstruction of low-index Au surfaces. The workflow results in a MLFF that is able to directly observe these low-index reconstructions, which were previously inaccessible using classical techniques.

Flat Magnetic Bands of Full-Heusler Crystals—Analysis and Prediction with a First Principle Deep Learning Model Xiuying Zhang[1], Lei Shen[1] and Tong Yang[2]; [1]National University of Singapore, Singapore; [2]The Hong Kong Polytechnic University, China

Materials with flat bands near or at the Fermi level are a promising route towards strongly correlated states, but the properties demonstration has been severely hindered due to the lack of materials for realization of flat bands. Machine learning is a promising way to speed up the unearthing of the flat band materials. Here, we propose a convolutional neural network classification model, which only have the periodic table as the input and thus is called periodic table classifier (PTC), to explore flat bands along the high-symmetry paths around the Fermi level and search for the physics behind it. The full-Heusler crystals are chosen as targets because of its abundance in dataset and its much high symmetry with the space group of 225. The PTC model is trained with the full-Heusler crystals in the AFLOW database and then it can accurately classify the flat bands with the AUC of 0.91 for the test set and 0.88 for the full-Heusler crystals in the materials project (MP) dataset. Visualizing the model also gets some interesting phenomimes. For example, the model regards the number of valence electrons of the crystal as important for the flat band prediction: crystals have a high probability to have flat band around the Fermi level if they have valence electrons of about $12\times n$ (n=1,2,3…); crystals have a probability as high as 0.8 to possesses flat bands if their number of unfilled *d*-orbital electrons is around 6, and the larger number of unfilled *p*-orbital electrons, the smaller flat band probability. The full-Heusler crystals is reach in magnetic crystals and the PTC can also predict both the flat bands and the ferromagnetic full-Heusler compounds with the accuracy of 0.76. Our work not only provide a quick way to enrich the flat band database but also provide the specific direction for searing for the flat bands.

DS02.08.02
Machine Learning Gamma Phonons from Atomic Coordinates Ryotaro Okabe, Zhantao Chen and Mingda Li; Massachusetts Institute of Technology, United States

The phonon[1] of a material describes the dynamics of its constituent atoms in the harmonic approximation, in the framework of the theory of lattice vibrations. The details of the lattice dynamics are of key importance. Especially, phonon at the Gamma point of the reciprocal space gives us important properties such as dielectric constant and the stability of materials.

In this work, we present a machine-learning model that directly predicts phonon band structure only with simple input like atomic coordinates. At the beginning of the machine learning model, the input feature vectors are passed to an embedding layer for dimensionality reduction. In the next part, the Euclidean neural network (E(3)NN)[2] is then applied to the resulting hidden state and consists of alternating convolution and gated block operations. Here, a convolutional layer operates on the radial distance vectors between atoms in a neighborhood up to a radial cutoff. E(3)NN has made it possible to include 3D rotation, inversion, and translation symmetry in the atomic structures so that high accuracy is reached without data augmentation.

The method we present this time will give us insights about the materials' dynamics. In addition, it is expected that we can expand the tool to predict properties that are difficult to predict, such as the magnetic structures[3].

DS02.08.04
Accelerated Computation of Lattice Thermal Conductivity Using Neural Network Interatomic Potentials JeongMin Choi[1], Kyeongpung Lee[1], Wonseok Jeong[2] and Seungwu Han[1]; [1]Seoul National University, Korea (the Republic of); [2]Lawrence Livermore National Laboratory, United States

With the development of the density functional theory (DFT) and ever-increasing computational capacity, an accurate prediction of lattice thermal conductivity based on the Boltzmann transport theory becomes computationally feasible, contributing to a fundamental understanding of thermal conductivity as well as a choice of the optimal materials for specific applications. However, calculation of the anharmonic force constant by DFT is computationally demanding, and the cost steeply increases as the symmetry of the crystal lowers and the number of atoms in the unit cell gets larger. This difficulty has been a bottleneck in theoretical investigation of lattice thermal conductivity of vast materials. Currently, machine learning potentials are garnering attention as a computationally efficient high-fidelity model of DFT, and several studies have demonstrated that the lattice thermal conductivity could be computed accurately via the machine learning potentials. However, test materials were mostly crystals with high symmetries, and the applicability of machine learning potentials to a wide range of materials has yet to be demonstrated. Furthermore, establishing a standard training set that provides

consistent accuracy and computational efficiencies across a wide range of materials would be useful. Our study here addresses these issues by computing lattice thermal conductivities at 300 K using neural network interatomic potentials. Firstly, to select an optimal approach to generate training sets preliminary tests are conducted, and we find that molecular dynamics trajectories at 50–700 K consistently provide results at par with DFT for the test materials. Next, we increase the benchmark cases to 25 materials with diverse symmetries and a wide range of lattice thermal conductivities between 10^{-1} and 10^{3} $Wm^{-1}K^{-1}$. In contrast to pure DFT approaches, the computational cost in the present approach is uniform over the test materials, yielding a speed gain of 2–10 folds. When a smaller training set is used, the relative efficiency increases by up to ~50 folds without sacrificing accuracy significantly. The current work will broaden the application scope of machine learning potentials by establishing a robust framework for accurately computing lattice thermal conductivity with machine learning potentials.

DS02.08.05
Towards Standardized Polymer Solubility Measurements Using a Parallel Crystallizer Mona Amrihesari, Amari Murry and Blair Brettmann; Georgia Institute of Technology, United States

Recently developed machine learning approaches to understanding material properties provide new opportunities for studying and developing new knowledge about polymers. The vast application of polymers and their sensitivity to many parameters like molecular weight, temperature, morphology, etc. requires developing high throughput experimentation methods that lead to accurate results. It will be vital for developing any prediction model in data science analysis. Although polymer informatics has significantly improved in recent years, using artificial intelligence and machine learning techniques, a significant hurdle in the polymer informatics area is the lack of complete and sufficiently detailed databases. One example where this is a challenge is in developing a dataset for polymer solubility and dissolution, where the classification of "soluble" or "insoluble" is sensitive to molecular weight, concentration, temperature, heating/cooling rate, and other factors that are not always reported or well-controlled. To overcome the challenges with the current dataset on polymer solubility, in this work, we will focus on applying turbidity measurements with precise temperature control technique using a Crystal16 parallel crystallizer. With this method, the experiments are possible to do in reproducible and time-effective ways with minimal human error while also collecting time-resolved dissolution data continuously throughout the experiment. This approach with detailed results in a controllable manner allows us to develop a more information-rich data set for predicting the polymer solubility using machine learning techniques.

DS02.08.06
Hotplate Temperature Studies—On the Need to Characterize the Variability and Reproducibility of Thermal Sources Kyle Williamson, Daniel Herr and Hemali Rathnayake; University of North Carolina at Greensboro, United States

This poster reports the impact of hotplate position on observed temperature and temperature variability. Reaction temperature and variability drive the observed rates and outcomes of many syntheses, such as small-scale reactions on hotplates. Yet, few studies consider whether the hotplate surface consistently and uniformly delivers a targeted reaction temperature. Control charts of five positions on two commercially available hotplates demonstrate significant temperature sensitivity and reproducibility as a function of sample placement position. These results suggest a need for the screening, characterization, and calibration of thermal sources to enhance the reproducibility and credibility of syntheses and mechanistic studies.

DS02.08.07
Development of Coarse Grained Polymer Models by Iterative Boltzmann Inversion and Cross-Entropy Optimization Methods Wei Han Hui and Shu-Wei Chang; National Taiwan University, Taiwan

Bottom-up computational modeling has been widely used to investigate the material properties of polymer matrix in present years. Molecular dynamics (MD) simulations is the powerful simulation method which could accurately describes the molecular interactions between molecules and thus provide an accurate prediction on the performance of materials. Furthermore, by trainning coarse grained (CG) models based on full atomistic information, an accurate CG can be developmed and used for the study of larger molecular weights to bridge the scales between nanoscale and mesoscale. The CG simulations reduce the degree of freedom of MD and thus increase the time scale and length scale in simulations. To develop a CG force field of a polymer system, the Iterative Boltzmann inversion method (IBIm) is widely used. Recently, many studies have shown that machine learning and deep learning methods (ML/DL) are useful for the development of force fields. In this study, we develop a novel workflow for trainning CG force field by the integration of IBIm and Cross-entropy optimizer. Our results show that the structural distribution and properties of a full atomistic system are both converged in optimization. The cross-entropy optimizer is able to optimize the loss of polymer conformation and molecular properties and thus provide a suitable CG force field for polymer materials.

DS02.08.08
An Adaptive Optimization System in Multi-Scale and Multi-Objective Wing Structure Using Deep Learning Algorithms Zilan Zhang[1], Zixiao Wei[1], Francesco Di Caprio[2] and Grace Gu[1]; [1]University of California, Berkeley, United States; [2]Italian Aerospace Research Center, Italy

In the aerospace industry, wing design involves multidisciplinary considerations such as material science, aerodynamics, structural architecture, and manufacturing feasibility. The balance between these primary issues and corresponding design parameters is usually hard to achieve. Optimization is hence an essential procedure to assure maximum design efficiency. The conventional optimization method relies heavily on iterative modeling, testing, analysis, and improvement cycle. This process can be time-consuming, costly, and imprecise due to the complexity of the operative conditions. Here we propose an adaptive optimization system built upon a digitized wing structure database and machine learning algorithms, which enable the rapid formulation of multi-scale wing designs for specific performance demands. This system unfolds as two stages of work. The first stage is oriented toward aerodynamic optimization, where Computational Fluid Dynamics (CFD) simulation is exploited to attain performance outputs corresponding to an extensive collection of geometric inputs. A neural network is subsequently utilized for parametric study and finding the optimal wing configuration. The optimization has successfully improved the aerodynamic efficiency of a fixed-wing aircraft by over 4% compared to the average performance of initial geometric inputs when cruising at 0.48 Mach. The second stage work concentrates on the definition of best stacking sequences with composite materials adopted and on the wing box layout. The multi-objective optimization adapts a deep learning schema that lies upon a series of critical structural requirements, such as specific strength, shear flow, cost, margins of safety, etc. To this end, the proposed methodology aims to significantly reduce the computational cost and contribute to better flight performance. With all the merits addressed, the proposed approach will possess great potential for optimizing several aircraft's wing-like sub-components when concerned with different mission environments and load conditions.

DS02.08.09
Machine-Learning Based Prediction of First-Principles XANES Spectra for Amorphous Materials Haruki Hirai, Tomoyuki Tamura, Masayuki

Karasuyama and Ryo Kobayashi; Nagoya Institute of Technology, Japan

In recent years, x-ray absorption spectroscopy (XAS) has become increasingly important for structural characterization of materials. Especially, x-ray absorption near edge structure (XANES) can provide sensitive information on chemical bonds, valence states, and coordination. Conventional interpretation of XANES spectra is based on the so-called “fingerprint” approach in which an experimental spectrum of interest is compared with that of a reference crystalline material. When there are not enough reference spectra, reliable simulations of XANES spectra are necessary. We have already added the computational code of XANES [1] to Quantum Materials Simulator (QMAS) code [2] based on the density functional theory (DFT) within the projector augmented-wave (PAW) method, and applied it to the elucidations of amorphous structures [1] and chemical reactions at interfaces [3]. However, the computational cost of XANES simulation becomes an important issue when we deal with amorphous materials.
In this study, we developed an efficient scheme based on machine learning to predict the theoretical XANES spectra obtained by DFT calculations using only the information of atomic configurations. Our scheme was based on the linear regression model of the structural descriptor.We present a comprehensive prediction of XANES spectra based on atom-centered symmetry functions (ACSF), smooth overlap of atomic positions (SOAP), local many-body tensor representation (LMBTR) and spectral neighbor analysis potential (SNAP). As a test case, we chose amorphous SiO material used as the negative electrode of rechargeable lithium-ion batteries (LIBs), in which the valence states of Si are distributed between 0 and +4. As a result, we could achieve enough prediction accuracy for Si K-edge XANES spectra. Furthermore, we proposed an efficient scheme for the compression of XANES spectral data and the efficient sampling of training data with the active learning approach.

DS02.08.11
Design of Showerheads Using Machine Learning for Optimizing Semiconductor Manufacturing Processes Daniel D. Lim[1], Zeqing Jin[1], Meenakshi Mamunuru[2], Sassan Roham[2], Xueying Zhao[2] and Grace Gu[1]; [1]University of California, Berkeley, United States; [2]LAM Research Corporation, United States

Distribution of uniform gas to the wafer through showerhead is a key technique to fabricate thin film structures for various semiconductor applications. Film thickness uniformity is a critical factor to evaluate the quality of film growth as a non-uniform film may cause a non-functioning die and hence reduce fabrication yields. During the deposition process, film uniformity is largely influenced by flow distribution, where the showerhead is one of the major components that affect the distribution. In this work, we utilize machine learning based optimization algorithms combined with computational fluid dynamics (CFD) simulations to optimize the showerhead design for uniformity of flow by varying the porosity of the faceplate component and inlet pipe structures. Our machine learning model achieves high accuracy on predictions against ground truth with an R-squared value over 99% and a speedup of orders-of-magnitude compared to CFD simulations. The performance difference of various optimization methods such as genetic algorithm, stochastic gradient descent, and Bayesian optimization are presented. Results show that our optimized showerhead design achieves over 10% improvement in film uniformity compared to a conventional showerhead design. Furthermore, sensitivity analysis is conducted to probe fundamentally the most important features that lead to high-performing showerhead designs. It is envisioned that our proposed framework is adaptive to optimize other manufacturing systems and devices that utilize fluid flow mechanisms.

DS02.08.12
CASTING – (A Continuous Action Space Tree Search for INverse desiGn) in Materials Applications Suvo Banik[1], Srilok Srinivasan[2], Sukriti Manna[1], Troy D. Loeffler[2], Henry Chan[2], Pierre Darancet[2] and Subramanian Sankaranarayanan[2]; [1]University of Illinois at Chicago, United States; [2]Argonne National Laboratory, United States

The most common and popular methods for structure search and optimization are based on evolutionary design. This can often be cumbersome, limited to a few tens of parameters, and fails for large structural configurations or design problems with high degrees of freedom. Reinforcement learning approaches mostly operate in discrete action space such as in the Go game but the applications of that to inverse problems are limited since most inverse problems deal with continuous action space. There are many inverse structural search problems ranging from crystal structure search in material sciences to topology design in Quantum information, where it is highly desirable to optimize structure/configuration to target desired properties or functionalities. We develop CASTING as a scalable framework platform for molecular, crystal structure, defects, topology, device, and component design. We demonstrate the ability of our modified cMCTS algorithm on traditional trial functions. The predicational capability of the CASTING on crystals of 0D, 2D, 3D, polymorphs of carbon and complex system such as perovskite Nickelates. We also compare the cost and prediction performance of our CASTING framework with traditional Evolutionary algorithm-based approaches.

Quantum Materials Research at the Nexus of Exascale Simulation, Artificial Intelligence and Quantum Computing Aiichiro Nakano; University of Southern California, United States

Computing landscape is evolving rapidly. Exascale computers have arrived, and quantum supremacy has been demonstrated for several problems, while artificial intelligence (AI) is transforming every aspect of science and engineering. Atomistic simulations at the exa-quantum-AI nexus are revolutionizing quantum materials research. I will describe research on atomically thin two-dimensional and other materials under National Science Foundation (NSF) cybermanufacturing and cybertraining projects using our AI and quantum-computing enabled exascale materials simulator (AIQ-XMaS). Specifically, I will describe excited-state neural-network quantum molecular dynamics (NNQMD) simulations trained by first-principles nonadiabatic quantum molecular dynamics (NAQMD) to prove the exciting concept of picosecond optical, electrical and mechanical control of symmetric breaking in topological ferroelectric skyrmion, skyrmionium and meron for emerging ultralow-power polar topotronics. This research was supported by NSF Future Manufacturing Program, Award 2036359, and NSF Cybertraining Program, Award 2118061. Simulations were performed at Argonne Leadership Computing Facility under DOE INCITE and Aurora Early Science programs and at Center for Advanced Research Computing of the University of Southern California.

Billions of Atoms with Machine Learning Interatomic Potentials—Performance Portability of FLARE Anders Johansson, Yu Xie, Cameron J. Owen, Jin Soo Lim, Lixin Sun, Jonathan Vandermause and Boris Kozinsky; Harvard University, United States

Machine learning interatomic potentials (MLIPs) have become a prevalent approach to bridging the gap between slow-but-accurate ab initio calculations and fast-but-inaccurate empirical potentials for molecular dynamics. Among MLIPs, there is a pareto front of models with different tradeoffs between accuracy and speed. The FLARE interatomic potential aims to push the boundary of scalability and performance, while maintaining sufficient accuracy to study complex, reactive systems.

FLARE combines the atomic cluster expansion with a sparse Gaussian process. Bayesian uncertainties enable efficient training with active learning and uncertainty-aware, large-scale molecular dynamics simulations. We implement FLARE in LAMMPS with the Kokkos performance portability library, enabling efficient molecular dynamics simulations on GPUs across a wide range of system sizes. Using 27336 GPUs, we demonstrate state-of-the-art scaling and performance in micrometer-scale heterogeneous catalysis simulations with up to half a trillion atoms [1].

9:00 AM DS02.09.03
Effect of Paired Aluminum Sites on the Diffusion of $[Cu(NH_3)_2]^+$ in Cu-CHA Predicted by Machine Learning Accelerated Molecular Dynamics Reisel Millan[1,2] and Rafael Gomez-Bombarelli[1]; [1]Massachussets Institute of Technology, United States; [2]Polytechnic University of Valencia, Spain

The selective catalytic reduction (SCR) in which ammonia is used as reducing agent (NH3-SCR-NOx) is the current state-of-the-art technology to cope with nitrogen oxides (NOx) emissions from stationary power plants and diesel vehicles[1,2]. The materials currently employed as catalysts in transport applications are copper-exchanged zeolites, in particular those possessing small-pore structures such as the CHA [3,4]. Operando X-ray absorption and emission (XAS/XES) spectroscopic studies have shown that at low temperature ($T < 473$ K) ammonia liberates the Cu^+ ions from its coordination with the zeolite framework forming mobile $[Cu(NH_3)_2]^+$ species. These mobile amino-copper complexes are responsible for the activation of O_2 through the formation of the transient dimeric species $Cu(NH_3)_2$ -O_2 -$Cu(NH_3)_2$ [5-7]. The diffusion of the monomeric $[Cu(NH_3)_2]^+$ species to the adjacent cavity through the 8r window is the rate-determining step at low Cu loading. Previous works have shown that the reacting molecules can have a significant impact in the activation free energy and that the diffusion of such species is limited to neighboring cavities[7,8]. The aluminum distribution is another factor that possibly affects the reaction rate but so far remains unexplored[9].
The diffusion of $[Cu(NH_3)_2]^+$ complexes through the 8r windows of the CHA is an activated process and therefore the theoretical study of such diffusion requires the use of enhanced sampling techniques. However, the construction of free energy profiles based on DFT is limited to the most relevant cases because of the significant computational cost of umbrella sampling simulations. Machine learning (ML) techniques have already taken special relevance in the area of materials science and heterogeneous catalysis.These techniques provide an opportunity to speed up the costly Born-Oppenheimer molecular dynamics (BOMD) simulations by several orders of magnitude [10]. NN-based interatomic potentials (NNIPs) retain the accuracy of the ab initio training data and can be executed at a computational cost comparable with that of classical force fields.
In this work, we applied NNIPs-based enhanced umbrella sampling (US) simulations to obtain Gibbs free energy profiles for the diffusion of $[Cu(NH_3)_2]^+$ complexes through the 8-ring windows of SSZ-13 zeolite for different Al distributions at 423 K representative of the low temperature regime. All interatomic potentials converted to sub-kcal mol^{-1} accuracy for the energies on the corresponding validation set, with a mean absolute error of 0.34 kcal/mol, respectively. The NNIPs are able to reproduce the free energy profiles with an error of 0.4 kcal/mol relative to the DFT counterpart (see Figure 1), at least 400 times faster. The calculated free energy of activation for the diffusion of an isolated $[Cu(NH_3)_2]^+$ complex through the 8-ring windows of the chabazite structure is relatively low, 4.3 kcal/mol, showing that this process is fast. An increase in the free energy of activation to 6.7 kcal/mol is observed when a second complex and therefore a second Al are placed in the adjacent cavity (Figure 2). However, when the two Al atoms are placed in the same 8r, through which the diffusion takes place, the free energy of activation decreases by ~1.7 kcal/mol (Figure 2), with which the reaction would proceed ~10 times faster. Our results show that a fine tuning of the Cu-CHA catalyst can be achieved by controlling the Al distribution, that is, the selective positioning of Al pairs in the same 8-ring window.

9:15 AM DS02.09.05
Going Beyond High Throughput Screening Towards AI in Accelerated Electrolyte Discovery Vidushi Sharma, Maxwell Giammona, Dmitry Zubarev, Tim Erdmann, Andy Tek, Khanh Nguyen and Young-Hye Na; IBM, United States

Discovery of new materials is the key to bringing timely advancements and major breakthrough in the developing technologies. Development of sustainable next generation fast charging batteries for electric vehicles (EV) need a step-forward towards the discovery of non-flammable liquid battery electrolytes. Primary electrolyte systems commonly used for lithium metal batteries are based on ether solvents comprising of 1,2-dimethoxyethane (DME) and a cosolvent 1,3-dioxolane (DOL), both of which are highly flammable. The search and development of sustainable electrolyte formulations for the batteries require collaborative efforts from the disciplines of chemistry, material science and computational simulations. Widely adopted high-throughput screening process for electrolyte discovery involves computational simulations of large set of molecules and screening based on domain intuitive properties. This process manages to accelerate the discovery of new compounds for electrolytes but, the high performance of an electrolyte in a battery goes beyond the sum of the individual compounds. It relies on the complex interactions of those constituent compounds that lead to new, immerging properties of the whole, i.e. the electrolyte *formulation.* There remain significant questions as to how to relate the properties of the individual electrolyte compounds to that of whole; finding the right formulation based on those screened new compounds; and predicting performance of the formulation that contains those compounds as well as their stability over versus the electrodes in a full cell. Artificial Intelligence (AI) methodologies built upon high throughput screening process can expedite the discovery and optimization of both new electrolytes molecules *and* electrolyte formulations which contain them. In this talk, we discuss the synergy of high throughput screening and AI methodologies based on graph theory and inverse design in accelerating the process of electrolyte discovery and formulation optimization. To do this, we apply automated simulation workflows capable of simulating multiple molecular properties such as redox potential and stability, and provide in-silico characterization of the interface chemistries at the electrodes on the fly. Post this, surrogate models built on graph theories establish a structure-composition-performance relationship for the new-found electrolyte formulations and enable the search for electrolyte systems with highest capacity retention and long cycle life.

9:30 AM DS02.09.06
Enzeptional—Enzyme Optimization via a Generative Language Modeling-Based Evolutionary Algorithm Yves Gaetan Nana Teukam[1,2], Matteo Manica[1], Francesca Grisoni[2] and Teodoro Laino[1]; [1]IBM Research Europe - Zurich, Switzerland; [2]Technische Universiteit Eindhoven, Netherlands

Enzymes are molecular machines optimized by nature to allow otherwise impossible chemical processes to occur. Besides the increased reaction rates, they present remarkable characteristics to enable more sustainable reactions: mild conditions, less toxic solvents, and reduced waste. Billion years of evolution have made enzymes extremely efficient. However wide adoption in industrial processes requires faster design using in-silico methodologies, a daunting

task far from being solved. The majority of methods operate by introducing mutations in an existing amino acid (AA) sequence using a variety of assumptions and strategies to introduce variants in the original sequence. More recently, machine learning and deep generative networks have gained popularity in the field of protein engineering by leveraging prior knowledge on protein binders, their physicochemical properties, or the 3D structure. Here, we cast the problem of enzyme optimization as an evolutionary algorithm where mutations are modeled via a generalized autoregressive language model trained on fragments of AA sequences from UniProtKB. Relying on a pre-trained language model, we apply transfer learning and train a Random Forest as the scoring model on a dataset of biocatalysed chemical reactions to drive the optimization process. With our approach, using the least amount of assumptions, we can adapt active sites to perform new reactions. Our methodology allows designing enzymes with higher predicted biocatalytic activity, emulating the evolutionary process occurring in nature by sampling optimal sequences modeling the underlying proteomic language.

Determining the Phase Diagram of a Machine-Learned Carbon Potential via Nested Sampling George A. Marchant and Livia Bartok-Partay; University of Warwick, United Kingdom

We detail how the many-body potential energy landscape of a machine-learned (ML) interatomic potential for carbon [1] can be explored by utilising the nested sampling algorithm,[2] allowing for the determination of carbon's phase diagram up to high pressures. The ML potential in question is the GAP-20 model, which was developed in recent years using the gaussian approximation potential methodology to describe the properties of bulk crystalline and amorphous carbon phases with the accuracy of electronic structure methods. With the nested sampling algorithm the 3N-dimensional potential energy surface of the GAP-20 potential can be automatically (and efficiently) sampled at constant pressure, providing a set of configurations with which to test the potential's thermodynamic capabilities. As a point of comparison the phase diagrams of other interatomic potentials - including the ReaxFF, EDIP and Tersoff potentials - are also studied. Despite having been trained on optimised structures at only zero pressure, GAP-20 provides an accurate description of carbon's macroscopic properties up to approximately 200 GPa. Our results also highlight areas for future improvement of the potential.

Htpmd—A Cloud Platform for Automated Analysis of Raw Simulation Data for Polymer Electrolytes Tian Xie[1], Ha-Kyung Kwon[2], Daniel Schweigert[2], Sheng Gong[1], Arthur France-Lanord[3], Arash Khajeh[2], Emily J. Crabb[1], Michael Puzon[2], Chris Fajardo[2], Will Powelson[2], Yang Shao-Horn[1] and Jeffrey Grossman[1]; [1]Massachusetts Institute of Technology, United States; [2]Toyota Research Institute, United States; [3]Sorbonne Université, France

Open material databases storing hundreds of thousands of material structures and their corresponding properties have become the cornerstone of modern computational materials science. Yet, the raw outputs of the simulations, such as the trajectories from molecular dynamics simulations and charge densities from density functional theory calculations, are generally not shared due to their huge size. In this work, we provide a cloud-based platform to facilitate sharing of raw data and enable fast post-processing in the cloud to extract new properties defined by the user. As an initial demonstration, our current database includes 6286 molecular dynamics trajectories for amorphous polymer electrolytes and 5.7 terabytes of data. We create a public analysis library at https://github.com/TRI-AMDD/htp_md to extract multiple properties from the raw data, using both expert-designed functions and machine learning models. The analysis is run automatically with computation in the cloud, and results then populate a database that can be accessed publicly. Our platform encourages users to contribute both new trajectory data and analysis functions via public interfaces, and newly analyzed properties will be incorporated into the database. Finally, we create a front-end user interface at https://www.htpmd.matr.io for browsing and visualization of our data. We hope the platform provides a new way of raw data sharing for the computational materials science community.

11:00 AM DS02.09.09
Identifying Symmetries with Deep Learning Model Yichen Guo[1], Shuyu Qin[1], Xinqiao Zhang[2] and Joshua Agar[2]; [1]Lehigh University, United States; [2]Drexel University, United States

Scientific discoveries rely on extracting understanding from experiment results; however, data collected regularly outpaces human analysis capabilities. In turn, it is common to use computational methods to extract actionable information from scientific data. A fundamental problem with computational methods are that they are bounded by logical rules and thus cannot apply generalized concepts and sentiment. In materials physics, symmetry is one of the most pervasive predictors of structure-property relations. Human identification of symmetry can be time-consuming, inaccurate, and cannot be done at scale. It is essential to create models that can understand this concept. Here, we develop datasets, benchmarks, and DL workflow to classify wallpaper group symmetry.
First, we developed three image datasets based on the 17 wallpaper group symmetries. These datasets are generated by forming symmetry operations on sections of images from the ImageNet dataset, randomly generated noise and artificial atomically resolved images. We apply a Gaussian noise to mimic real data. These datasets with generation metadata provide a predictable benchmark to validate the efficacy of machine learning models.
We benchmarked the performance of the deep learning model to identify the symmetries of our three datasets. We trained the ResNet34 model and VGG-19 model with two training strategies: transfer learning and training from random initialization. Results show that current deep learning models can classify images with different symmetry classes with 99.38% accuracy (ResNet34 transfer learning). While, at first pass, it might seem that these models are learning a generalized concept for symmetry, this is a farce. If we cross-validate the performance of a model with a dataset of a different type, the accuracy is only slightly better than a random guess. This highlights challenges in deploying generalized machine learning models for scientific inference, particularly when limited access to training data. As a first step, we demonstrate few-shot learning using neural networks that have symmetry awareness by being pre-trained on symmetry datasets of other forms. The model achieves a 7.55% error rate when trained on 50 images per class dataset, as accurate as models trained on 1000 images per class dataset.
While adding transformations such as Fast Fourier and Radon does not significantly improve the model performance, we achieved marked improvements by adding symmetry-constrained layers. We developed a customized preprocess layer with the ability to detect 2-, 3-, and 4-folds rotation, mirror, and glide transformation. To better test the performance and limitation of this transformation layer, we designed stepwise training experiments to classify the 2-, 3-, and 4-folds rotation and mirror transformed 2D images. The training accuracy improved compared benchmark result only when we preprocess manually defined image region. Compared to the 47.6% accuracy for the P1, P2, and Pm symmetry dataset trained from scratch with the ResNet34 model, the preprocessed dataset gives 85% accuracy. Improvement in cross-entropy accuracy proves that the preprocessing layer can detect the 2-folds and mirror transformation. Still, more effort is required to parsimoniously learn symmetry with neural networks.
All told, we demonstrate the nuanced challenges of designing and benchmarking machine learning models for detecting symmetry. We show that machine learning models can readily give the illusion of solving a benchmark task without actually learning any physically relevant concepts. This work

demonstrates the importance of including physics constraints in machine learning models to improve performance. Developing a model capable of parsimoniously detecting symmetry in the image will tremendously impact crystallographic and microstructural analysis – and could be pipelined into other machine learning models for materials discovery and design.

Synthetic Scanning Electron Micrographs Created by Generative Adversarial Networks (GANs) from Artificial Height Maps Jonas Bals[1] and Matthias Epple[1,2]; [1]University of Duisburg-Essen, Germany; [2]CeNIDE - Center for Nanointegration Duisburg-Essen, Germany

Scanning electron microscopy (SEM) is a standard method in the morphological analysis of materials, from the nanometer to the centimeter scale. An automated analysis of SEM images helps to save time and also reduces the operator bias when it comes to extract sample parameters like average particle size, particle size distribution, and diversity of particle shapes.
Deep learning and especially deep convolutional neural networks (CNNs) have entered materials science, contributing to image segmentation [1], image classification [2], and object detection [3]. However, a successful training of such machine learning approaches requires a large number of manually annotated training images. Their manual analysis can be extremely time consuming as human evaluators are needed.
The 3D graphics software Blender 3.1.2 [4] was used for artificial image creation, assembling several thousand objects to obtain heightmaps and error-free binary annotation maps. In a second step, we trained a generative adversarial network (GAN) [5] to create a variety of photorealistic SEM images of nanoparticles from these heightmaps.
We have prepared synthetic SEM images as training data by a combination of Blender and GANs. We have first created artificial heightmaps by simulating the dropping of several thousand objects ("nanoparticles") onto a planar surface with Blender. These objects were typical nanoparticles like spheres, deformed spheres, cubes and truncated cubes, hexagonal plates, rods, or star-shaped particles. The hereby created annotation maps as well as height maps have been used to train two networks. First a GAN to create artificial SEM images, and second a UNet model trained completely on artificial SEM images and binary annotation maps [1]. UNet was then validated against human labelled real data reaching an IoU of 81.7%. This still underperforms human labelled data by 11.76 points. Our method builds on the previously published GAN of [6] and outperforms they annotation map approach by 0.69 points. Notably, we found that a major obstacle to obtain better training data is the addition of the "right amount" of noise to an image created by the GAN. This will require further refinements of the method.
In conclusion, synthetic SEM images prepared by Blender and GANs can be used to create large training data sets for automated analysis of SEM images by machine learning.

Tailoring Molecular Topology to Control the Mechanical Properties of Polymer-Grafted Nanoparticle Assemblies Sinan Keten; Northwestern University, United States

In this talk, I will summarize recent advances in computational design of new polymeric materials that make use of nanoscale topologies, namely brushes and folded loops, that result in exceptional mechanical properties. I will first present systematic coarse-graining and machine-learning approaches that we developed describe molecular and mesoscale mechanics of polymer-grafted nanoparticle systems. Following this, I will present strategies for achieving impact tolerance in soft materials. The first strategy involves the use of star polymers and polymer grafted nanoparticles to improve diametric mechanical properties such as modulus and toughness, while also changing the time-dependence of the mechanical response. The second strategy involves creating nanoparticle interfaces with looped tethers that take inspiration from catch bonds in biological adhesion proteins, which results in molecular seat-belt type interfaces that self-strengthen at high strain rates like shear-thickening fluids. I will conclude with some thoughts on how to translate these theoretical findings to new material concepts that could be explored further with synergistic experiments and simulations.

2:00 PM *DS02.10.02
A Free Energy-Based Framework for Scale Bridging in Crystalline Solids—With Some Use of Machine Learning Methods Krishna R. Garikipati; University of Michigan, United States

The free energy plays a fundamental role in theories of phase transformations and microstructural evolution in crystalline solids. It encodes the thermodynamic coupling between mechanics andchemistry within continuum descriptions of non-equilibrium materials phenomena. In mechano-chemically interacting materials systems, consideration of compositions, order parameters and strains results in a high-dimensional free energy density function. Since its origins lie in the electronic structure, a rigorous representation of the free energy presents a framework for scale bridging in solids. In this study we have been exploring such a framework, while developing practical machine learning methods to contend with high dimensionality and efficient sampling. We have developed integrable deep neural networks (IDNNs) that are trained to free energy derivative data generated by statistical mechanics simulations. The latter are based on cluster Hamiltonians, themselves trained on density functional theory calculations. The IDNNs can be analytically integrated to recover a free energy density function. We combine the IDNNs with active learning workflows for well-distributed sampling of the free energy derivative data in high-dimensional input spaces. This enables scale bridging between first-principles statistical mechanics and continuum phase field models. As prototypical material systems we focus on applications in Ni-Al alloys and in the battery cathode material: Li_xCoO2.

2:30 PM DS02.10.04
Graph Recommender System for Ionic Substitution—Discovering New Materials Elton Ogoshi de Melo and Gustavo Dalpian; UFABC, Brazil

Traditional chemical heuristics have been very important for discovering new inorganic compounds in the past, but as they are usually based on patterns observed on a limited or specific set of materials, they are not generalizable as once thought. Today, as the material scientist can access the data of hundreds of thousands of inorganic materials present in databases, it has become frequent that many Material Science projects have become data-driven, i.e., they use large amounts of materials data and statistical methods, such as Machine Learning, to uncover new patterns and explore the phase space of compounds. In the ML context, recommender systems are widely used in various scientific and nonscientific fields. For instance, in the e-commerce area, these systems recommend users new products by analyzing their past purchased products or by collaborative filtering: a system where a heterogeneous network/graph composed of users and items and their interactions is used as input to recommend new products to users. By using this same principle framework and OQMD's database, we were able to build an analogous graph with the elements in the periodic table together with the set of all described crystal structures' sites as two classes of entities. The relationships between the two classes are given by the occupancy of a site by an element and it is weighted by the compound's thermodynamic stability. The heterogeneous graph is used to build an embedding space with a vector representation for each entity (elements and sites). These vector representations were then used as input to model a recommender system. In addition to finding new materials by uncovering new element-site occupancies, we were also able to analyze the embedding space and find interesting patterns on chemical similarities between elements and the local geometry of sites.

Machine Learning for Metal Processing Dierk R. Raabe, Jaber Mianroodi and Nima Siboni; Max Planck Institute for Iron Research, Germany

We propose applications based on the use of a deep neural network as fast surrogate models for local stress calculations in inhomogeneous non-linear materials. We show that deep neural networks can predict the local stresses with <4% mean absolute error for the case of heterogeneous elastic media and a mechanical contrast of up to factor of 1.5 among neighboring material domains, while performing 2 orders of times faster than spectral solvers or finite element solvers. Deep neural network models prove suited for reproducing the stress distribution in geometries different from those used for training. In the case of elasto-plastic materials with up to 4 times mechanical contrast in yield stress among adjacent regions, the trained model simulates the micromechanics with an error <7% in one single forward evaluation of the network, without any iteration. The results reveal an efficient approach to solve non-linear mechanical problems, with an acceleration up to a factor of nearly four orders of magnitude for elastic-plastic materials compared to conventional solvers (1). We also show similar applications of the case of heat treatment of metals.

3:30 PM DS02.10.06
Improving the Robustness of Deep Learning Interatomic Potentials for Molecular Dynamics Albert Musaelian[1], Simon L. Batzner[1], Nicola Molinari[1] and Boris Kozinsky[1,2]; [1]Harvard University, United States; [2]Robert Bosch LLC Research and Technology Center, United States

Machine learning interatomic potentials promise to make large length- and time-scales accessible to atomistic simulations by approximating the potential energy surface from expensive quantum chemical methods. As in other machine learning problems, the central task is to develop models that learn to generalize in a robust manner beyond the data they were trained on. This challenge is even more pressing for molecular dynamics: incorrect force predictions on even a very small number of atoms in an equally small percentage of time steps can lead the system into unphysical configurations and result in unfaithful dynamics and simulation failure. The recent development of *E*(3)-equivariant models, exemplified by our NequIP [1] and Allegro [2] architectures, has led to significant demonstrated improvements in accuracy and generalization even with small training sets. In this talk, we will discuss recent efforts to improve the robustness of the accurate simulations NequIP and Allegro can drive at scale.

Voxelized Atomic Structure Framework for Developing Structure-Property Relationships from Density Functional Theory Calculations Matthew C. Barry[1], Michael Chandross[2], Kristopher E. Wise[3], Surya R. Kalidindi[1] and Satish Kumar[1]; [1]Georgia Institute of Technology, United States; [2]Sandia National Laboratories, United States; [3]NASA Langley Research Center, United States

The behavior of material systems is governed by complex physical phenomena taking place over a hierarchy of length scales, making it computationally infeasible to model the full material response with physics-driven simulation methods alone. Machine learning approaches offer new opportunities to efficiently learn the underlying structure-property relationships in material systems using low-computational cost surrogate models trained on expensive physics-based computations. In this talk, we present a comprehensive framework for formulating physics-based, high-fidelity reduced-order material structure-property relationships using density functional theory computations. In this framework, the charge density field is directly utilized as the definition of atomic structure. This provides a complete, purely physics-based definition of the atomic structure that does not require any *ad hoc* feature engineering or idealizations beyond those of the first-principles computations. The spatial features underlying the atomic structure that dictate the physics underlying the material response are then captured by the directionally resolved two-point spatial correlations of the charge density field, projected to a salient low-dimensional feature-space using principal component analysis and correlated to physical properties using Gaussian process regression (GPR). An active learning strategy based on Bayesian experiment design is implemented using the uncertainty quantification provided by GPR to minimize the number of computationally expensive physics simulations required for model training. We utilize this framework to elucidate physical insight into the relationship between chemical composition and bulk modulus in high entropy alloys.

4:00 PM DS02.10.08
DyFraNet—Predicting Fracture Dynamics in Crystalline Solids Using a 2D to 3D Deep Neural Network Yu-Chuan Hsu and Markus J. Buehler; Massachusetts Institute of Technology, United States

We present a novel deep neural network, DyFraNet, to learn from dynamic fracture behaviors in crystalline solids to identify a complete history of fracture propagation. This model can not only forecast future fracture processes but also backcast to elucidate the past fracture history by providing the outcome of a fracture event, from which the model will show what will happen or has happened that led to this failure state. We also show that DyFraNet can capture dynamic fracture mechanics by accurately predicting how cracks develop over time and implying when cracks become unstable. Furthermore, we then use GradCAM to interpret how DyFraNet perceives the relationship between geometric conditions and fracture mechanics and we find DyFraNet pays attention to different areas at different stages during a fracture event. Overall, this approach has great potential to accelerate the exploration of material

design against fracture failures and can be beneficially adapted for different kinds of dynamical engineering problems.

4:15 PM DS02.10.09
A Molecular Dynamics and Machine Learning Approach to Predicting SARS-CoV-2 Spike Protein Denaturation at Varying Temperature and pH Levels Evan Xie[1], Ayush S. Arora[2], Anya Vaish[3], Ziyuan Niu[4], Peng Zhang[4], Miriam Rafailovich[4] and Yuefan Deng[4]; [1]The Pingry School, United States; [2]Munster High School, United States; [3]Tesla STEM High School, United States; [4]Stony Brook University, The State University of New York, United States

The SARS-CoV-2 virus has spread globally, causing rapid technological innovation and research on the virus's spike protein (S-protein)[1]. The viral infection is initiated when the S-protein binds to the human ACE2 receptor[2]. Understanding the denaturation of the S-protein under various environmental conditions is essential to understanding the virus's infectivity and developing more effective methods of combatting it. Molecular dynamics (MD) simulations can precisely model the S-protein and its structural changes. Previously, these simulations examined only the effect of temperature on S-protein structure[3]. This project examines both temperature (3°C, 20°C, and 37°C) and pH (pH1, pH2, pH3, pH4, and pH5) and utilizes a novel neural network component to analyze their effects on the protein's root mean squared deviation (RMSD).

The MD simulation is achieved on the open-source Gromacs and the AiMOS supercomputer configured with IBM POWER9 processors and NVIDIA Volta V100 GPUs. The initial structure of the S-protein is 6VXX.pdb, and the force field is the CHARMM27. The TIP3P water box is $21\times21\times21$ nm^3 with periodic boundary conditions in all three Carstensen dimensions, and simulations are controlled by the canonical (NVT). The pH values are controlled by the protonation states of the residues in the S-protein following the PROPKA. Charge neutralization and the protonation state accuracy are achieved by adding the Na^+ or Cl^- ions to the solvent.

A weighted K-Nearest Neighbors model, a random forest model, and a neural network were optimized to predict the S-protein RMSD at any temperature and pH. The simulation outputs were processed into training data through averaging, truncating, denoising, and sampling. With this training data, the model predicted the RMSD at each timestep and combined these predictions to predict the entire RMSD vs. time curve. Each model was evaluated with the root mean squared error (RMSE) metric and five-fold cross-validation.

The S-protein conformational changes were measured by the backbone RMSD. (1) The RMSDs of pH3-pH5 were around 0.4 nm at all three temperatures. (2) The pH2 RMSD, as a transition, showed a gap between 37°C and 20°C. The RMSD of 3°C and 20°C increased slightly, while the RMSD of 37°C increased significantly to 0.58 nm. (3) For pH1, the RMSDs of all three temperatures reached around 0.58nm.

The neural network achieved an RMSE of 0.041nm, which was lower than the KNN's RMSE of 0.048nm and the random forest's RMSE of 0.070nm. Another advantage of the neural network was its ability to model a fully continuous function, whereas the KNN and random forest had clusters of input values where they predicted the same RMSD. As the best model, the neural network was used to predict the S-protein's RMSD from 3°C to 37°C and pH 1 to 5, and it illustrated a clear trend that structural change increases as temperature increases and pH decreases.

Further research will involve the adaptation of the MD simulation and machine learning model to other structural metrics for additional insight into S-protein denaturation.

The project is supported by the Stony Brook Garcia Center for Materials Research, the Garcia High School Program, and the Morin Charitable Trust.

Atomic Structure Generation from Structural Fingerprints Victor Fung[1,2]; [1]Georgia Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States

Data-driven machine learning methods have the potential to dramatically accelerate the rate materials design over conventional human-guided approaches. These methods would help identify or, in the case of generative models, even create novel crystal structures of materials with a set of specified functional properties to then be synthesized or isolated in the laboratory. For crystal structure generation, a key bottleneck lies in developing suitable atomic structure fingerprints or representations for the machine learning model, analogous to the graph-based or SMILES representations used in molecular generation. However, finding data-efficient representations invariant to translations, rotations, and permutations, while remaining invertible to the Cartesian atomic coordinates remains an ongoing challenge. Here, we propose an alternative approach to this problem by taking existing non-invertible representations with the desired invariances and developing a method to reconstruct the atomic coordinates through a global optimization scheme. This can then be coupled to a generative machine learning model which generates new materials within the representation space, rather than in the data-inefficient Cartesian space. In this work, we demonstrate this approach by using conditional variational autoencoders to generate representations from atom-centered symmetry functions, which are then reconstructed to their corresponding atomic positions using the developed optimization method. We are able to successfully generate novel and valid atomic structures of sub-nanometer Pt nanoparticles as a proof of concept. Furthermore, this method can be extended to any suitable structural representation, thereby providing a powerful, generalizable approach towards structure-based generation.

8:45 AM DS02.11.02
Predicting Stable Electron-Exact Clathrate Superstructures via Convolutional Nerual Network Frank T. Cerasoli[1], Philip Yox[2], Kirill Kovnir[2] and Davide Donadio[1]; [1]University of California, Davis, United States; [2]Iowa State University of Science and Technology, United States

Clathrate structures consist of nanometer-size polyhedral cages encapsulating guest atoms or molecules that are not directionally bonded to the framework. Compounds in this class of crystal structure have already demonstrated many unique properties, such as ultra-low thermal conductivity and superconductivity. Enforcing electron-balanced compositions, with an average of four electrons per framework site, results in a semiconducting electronic structure and offers utility in electronic devices. To date, only a handful of stable electroneutral tetrel-free clathrates are known, most as ordered superstructures up to eight times larger in volume than the type-I clathrate unit. In this work, new clathrate compounds are predicted computationally and experimentally verified through synthesis. The group III-V A8T27Pn19 clathrate family (A={Na, K, Cs, Rb}, T={Al, Ga, In}, Pn={P, As, Sb, Bi}) is studied comprehensively with density functional theory (DFT). A crystal graph convolutional neural network (CGCNN) model is trained on the computed clathrates and roughly 500 compounds of similar composition. The model is refined by the results of experimental synthesis and employed to discover other electron-exact superstructures composed from group III-V or II-VI elements.

9:00 AM DS02.11.03
A Physics-Informed Machine Learning Model for Polymer Melt Viscosity Ayush Jain, Arunkumar Rajan and Rampi Ramprasad; Georgia Institute of Technology, United States

Polymer-melt processing is highly dependent on the rheological properties of a given polymer, including melt viscosity. For novel polymers and processes to be industrially viable, the in-situ viscosity must be appropriate for the given application. This viscosity is dependent not only on the polymer identity, but also on the molecular weight (or polydispersity), induced shear rate, and processing temperature. Though phenomenological relationships, motivated by known underlying physics are commonly used to relate these environmental factors to the viscosity, such relationships involve empirical constants obtained by fitting measurements to the phenomenological equations. Predictions of viscosity for new cases are thus generally difficult due to the unavailability of the empirical parameters. Here, we adopt a data-driven approach, with or without physical equation augmentation to predict a set of machine learned models to predict the melt viscosity of polymers as a function of molecular weight, shear rate, and temperature. Our ML models were trained on a data set of 1903 melt-viscosity values pertaining to 93 distinct polymers. Two models, one based on Gaussian-Process Regression (GPR) and the second on Artificial Neural Network (ANN) were first employed, devoid of any physical equation, and trained on the melt-viscosity dataset. Next, we created a HyperNetwork architecture that encodes the known viscosity equations. All three models are critically evaluated to determine the limits of the models with no encoded physics and the extrapolative capabilities of the physics-informed model.

9:15 AM DS02.11.04
Sampling the Thermodynamics of Material Interfaces with Markov Chain Monte Carlo and Machine Learning Xiaochen Du, James K. Damewood, Jaclyn Lunger and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Material surfaces often differ significantly from the bulk in both structure and composition. Surface structures depend on temperature, the presence of external chemical potentials (oxygen, hydrogen, water) and applied electrical potential. These surface reconstructions are key because they control the performance of the surface in processes like electrochemistry in batteries, electrocatalysis in fuel cells, adsorption on sensors, etc. While electronic structure simulations can accurately predict the energy of a single surface configuration, they are too expensive to investigate all the possible geometrical and compositional transformations that surfaces can undergo. In order to create accurate models of surfaces that can relate surface composition and structure to external conditions, it is necessary to efficiently sample the thermodynamic distributions of states the surface can access. To this end, we propose integrating Markov Chain Monte Carlo (MCMC) sampling with neural network potentials (NNP) trained on electronic simulations data. We demonstrate the validity of our MCMC model with discrete adsorption sites on the well-known Au(110) missing-row reconstruction. Next, as we show in the GaN(0001) surface reconstruction, adding in continuous relaxation leads to better sampling when the atomic spacing changes near the surface. Finally, we evaluated the effectiveness of our combined MCMC-NNP approach on complex oxide surfaces of the $SrTiO_3$ perovskite.

9:30 AM DS02.11.05
Fast and Accurate Prediction of Polymer Rheology: Multi-Scale Simulation and Physics-Inspired Machine Learning Umi Yamamoto[1], Heyi Liang[2], Kenji Yoshimoto[1], Masahiro Kitabata[1] and Juan J. de Pablo[2]; [1]Toray Industries, Inc., Japan; [2]The University of Chicago, United States

We report two latest advances in enabling fast and accurate prediction of polymer rheology using a bottom-up multi-scale simulation method and a top-down machine-learning approach.
First, a multi-scale simulation method is presented for the prediction of the viscoelastic properties of entangled homopolymer melts. Starting from an atomistic model of a polymer, and introducing two coarser representations (a bead-spring model and a slip-spring model) that successively operate at longer time and length scales, we demonstrate that linear rheology of syndiotactic and atactic polystyrene melts is predicted in good agreement with experiments without requiring experimental parameters as input. Very recently, the same method is applied to another industrial polymer, Nylon 6, leading to reasonable agreement for the molecular-weight dependence of the melt viscosity.
Second, we present a machine-learning framework to construct a predictive model for the dynamic moduli of linear entangled homopolymer. As an initial attempt, using computationally generated data based on Likhtman-McLeish model as a training dataset, it is shown that a straightforward supervised learning with standard algorithms (support vector machine, kernel ridge regression, etc.) provides not-too-bad prediction when an input parameter, the number of entanglements in the present case, is extrapolated. However, the predictive power is non-trivially improved by introducing a polymer physics idea into the learning procedure. Namely, by constructing individual predictive models that specialize in the prediction of distinct relaxation behavior at short, intermediate and long-time scale, and merging them into a single model using a frequency-dependent ensemble method, we are able to predict the storage and loss modulus in quantitative agreement with the training data. This approach is expected to be applicable to more complicated cases where a wider variety of input parameters, e.g. monomer chemical structures, polymer architectures, molecular weight distributions, etc. enter.
Finally, integration of the above two approaches, i.e. generation of polymer rheology data using the multi-scale simulation and construction of accurate predictive models by machine-learning the simulation data, leads to an "ideal" framework where a fast and accurate predictive model for the polymer dynamic modulii can be established via purely in-silico techniques. We will discuss an outlook and latest progress on this front.

9:45 AM BREAK

10:15 AM DS02.11.06
Discovery of Multi-Functional Polyimides through High-Throughput Screening Using Explainable Machine Learning Lei Tao[1], Jinlong He[1], Vikas Varshney[2], Wei Chen[3] and Ying Li[4]; [1]University of Connecticut, United States; [2]Air Force Research Laboratory, United States; [3]Northwestern University, United States; [4]University of Wisconsin–Madison, United States

Polyimides have been widely used in modern industries because of their excellent mechanical and thermal properties, e.g., high-temperature fuel cells, displays, and aerospace composites. However, it usually takes decades of experimental efforts to develop a successful product. Aiming to expedite the discovery of high-performance polyimides, we utilize computational methods of machine learning (ML) techniques and molecular dynamics (MD)

simulations. We first build a comprehensive library of more than 8 million hypothetical polyimides based on the polycondensation of existing dianhydride and diamine/diisocyanate molecules. Then we establish multiple ML models for thermal and mechanical properties of polyimides based on their experimentally reported values, including glass transition temperature, Young's modulus, and tensile yield strength. The obtained ML models demonstrate excellent predictive performance to identify the key chemical substructures influencing the thermal and mechanical properties of polyimides. The use of explainable machine learning describes the effect of chemical substructures on individual properties, from which human experts can understand the cause of the ML model decision. Applying the well-trained ML models, we obtain property predictions of the 8 million hypothetical polyimides. In such way, we search the whole hypothetical dataset and identify three (3) best-performing novel polyimides that have better combined properties than existing ones through Pareto frontier analysis. For an easy query of the discovered high-performing polyimides, we develop an online platform http://polyimide.herokuapp.com that embeds the developed ML model with interactive visualization. Furthermore, we validate the ML predictions through all-atom MD simulations and examine their synthesizability. The MD simulations are in good agreement with the ML predictions, and the three novel polyimides are predicted to be easy to synthesize via Schuffenhauer's synthetic accessibility score. Our study demonstrates an efficient way to expedite the discovery of novel polymers using ML prediction and MD validation. The high-throughput screening of a large computational dataset can serve as a general approach for new material discovery in other polymeric material exploration problems, such as organic photovoltaics, polymer membranes, and dielectrics.

10:30 AM DS02.11.07
Alloy Informatics Using Charge Profiles For Energy and Hydrogen Storage Applications Dario Massa[1], Stefanos Papanikolaou[1] and Efthimios Kaxiras[2]; [1]NOMATEN Center of Excellence in Multifunctional Materials, (NCBJ), Poland; [2]Harvard University, United States

Studies have confirmed the crucial role of solid-state based solutions in hydrogen storage, with respect to liquid or gas states which cannot ensure comparably high amounts of storage per unit volume [1]. The empirical approach is not an option when it comes to the complexity of the quest for hydrogen storage materials, as well as to the strict urgency of a transition to clean and sustainable energy solutions. Here, we pursue machine learning approaches to composition searches for hydrogen storage materials. The compositional space to be explored is extremely vast, and still its vastness is not defined due to the on-going explorations, not only spanning the chemical compositions, but also the dimensionalities of the possible candidate systems [2]. Therefore, there is the need of finding a general predictive approach based on first-principles.
Electron charge profiles shall be illuminating for identifying and classifying local defect properties, thus characterizing alloying, and this is why our machine learning approach is based on the ab-initio analysis of the charge profiles of interstitial hydrogen in pure FCC bulk metallic crystals. Our descriptors are constructed by differential electron charge profiles for a large variety of crystals and also, after analysis of their characterizing local quantities, such as radii and extrema, as well as consider the full profile properties and their integrals. The integration of the profiles and the distinctive features of the effects of hydrogen are discussed, and can be exploited to infer hydrogen mobility in the surrounding matrix, as well as electron clouds motions around hydrogen. After the building of a density dataset, we perform unsupervised machine learning. Basing on preliminary tests we discuss interesting trends between the profile features and the properties of the embedding pure crystals (atomic number, valence electrons, lattice constant, bulk modulus), uncovering compositional relationships (among different crystals) and non-compositional ones (among different hydrogen interstitial equilibrium positions in the same crystals). The results also shed light over the influence that the compressibility of the systems have upon the radii of the hydrogen electron density profiles, which finds interesting connections with the complementary problem of systematically changing an impurity in a same crystal [3].
The results of this study might pave the way to novel material informatics methods for prediction of hydrogen storage behaviours by interpretation of the differential charge density profiles around the defect. Our goals are to understand up to which extent such charge profiles method can be exploited to predict diffusive, as well as the adsorption and desorption properties, overcoming the limited predictive capacity of empirical and thermodynamic based methods.

Machine Learning Accelerated Lattice Boltzmann Simulation for Multiscale Platelet Modeling Amit Saha[1], Yicong Zhu[2], Miriam Rafailovich[2], Peng Zhang[2] and Yuefan Deng[2]; [1]Great Neck South High School, United States; [2]Stony Brook University, United States

Background: Cardiovascular disease (CVD) is responsible for upwards of 17.9 million deaths globally per year. CVD-related death commonly occurs on account of platelet-mediated thrombosis. Modeling platelet dynamics is necessary to develop a mechanistic understanding of platelet-mediated thrombosis at multiple scales. Multiscale modeling (MSM) links microscale, mesoscale, and macroscale simulations to speed up computation while maintaining desired accuracy. Previous simulations model platelet aggregation using a MSM model that uses dissipative particle dynamics (DPD) for the shear flow and coarse-grained molecular dynamics (CGMD) for the platelet dynamics. However, the resolution of the fluid particles in the DPD simulation occupies unnecessary computational resources. In contrast, the lattice-Boltzmann method (LBM) may be up to 20-50x faster than DPD while still resolving the relevant fluid phenomena. In this work, we present a machine learning (ML) accelerated LBM for platelet dynamics.

Methods: We evaluate two methods for LBM: the conventional LB algorithm and the ML-LBM model. The conventional LBM solves the discrete Boltzmann equation for velocity distribution functions to predict flow dynamics. An in-silico model of the system was developed for LAMMPs using CGMD for platelets and LBM for fluid dynamics. We initially predicted future dynamics with this framework. The ML-LBM model trains based on existing data to accelerate computation. First, input data is preprocessed by normalization into a series of tensors indicating velocity distributions. The proposed architecture consists of an encoding layer, utilizing a ConvLSTM architecture to effectively resolve system dynamics in both space and time, and a decoding layer, utilizing the ResNet CNN architecture to map these inputs back to the original space. The training process minimizes the Mean Square Error (MSE) loss to iteratively improve predictive accuracy. The model outputs a series of tensors representing the final velocity distribution based on the LB dynamics. Our workflow exports data from LAMMPs, predicts the flow dynamics with the ML model, and then sends these predicted velocity distributions back into LAMMPs. Accuracy was computed by comparison of flow velocity and platelet stresses from our model to CGMD-DPD simulations. Simulations were performed with a total of 4 aggregated platelets and 3 flowing platelets within a box of 16x16x39.1 micrometers, for a total of 1,148,441 particles in the simulation.

Results: The conventional LB algorithm was 9x faster than DPD while maintaining 96.4% and 96.2% accuracy for flow velocity and platelet stress respectively. Evaluation of the ML-LBMyielded a 26x speedup with a 96.1% and 95.8% accuracy for flow velocity and platelet stress respectively. Both algorithms were able to capture major flow dynamics and platelet stresses while evaluating significantly faster than DPD. We attribute the lower accuracy of the machine learning LB model to the inability to effectively learn the dynamics of the platelet-fluid boundary, where lowest accuracy was observed.

Discussion and Future Work: We assessed the relative performance of LB methods in recreating the dynamics of DPD. Both the conventional LB

algorithm and the novel ML-LBM captured the system dynamics of blood flow and platelet stresses. Due to the inherent limitations of LBM, both models used in this study were less accurate near the platelet-fluid interfaces, since LBM cells are much larger than CGMD particles with the added resolution. This added resolution, albeit rather costly, has not caused errors in the platelet dynamics. Future work should implement and assess the efficiency of the ML-LBM method for studying larger and more complex platelet clusters for platelet dynamics modeling.

Coarse Graining to Expedite Molecular Dynamics Simulations of Solvated Fibrinogen Eric Chen[1], Ziji Zhang[2], Miriam Rafailovich[2], Peng Zhang[2] and Yuefan Deng[2]; [1]Wayzata High School, United States; [2]Stony Brook University, The State University of New York, United States

Accurate molecular dynamics (MD) simulations often require massive computing resources to simulate millions to billions of individual atoms. These all-atomic (AA) simulations are computationally intensive, and often fail to reach long simulation time scales [1]. Coarse graining (CG) alleviates these limitations by reducing an all-atomic model to a skeleton with fewer particles while preserving accuracy by ensuring that the interparticle forces closely resemble those of the all-atomic model [1]. Fibrinogen is especially important in modern biology due to its ability to form fibrin, a protein central to blood clotting and controlling bleeding in vascular injury. A CG model of Fibrinogen with alpha C domains in a vacuum was created by [2] in 2021 using machine learning methods. Our research builds upon the CG model of [2] by solvating it with water to more accurately emulate Fibrinogen's naturally solvated form. Such a solvated model would greatly boost pharmaceutical research in several important areas including thrombosis prevention.

To ensure that our CG model of solvated Fibrinogen accurately emulates an all-atomic model (AA model), we create a control system with the all-atomic 3GHG PDB file. We utilize the structure and force files from [2] for the CG Fibrinogen model. VMD's water box creation tool is employed to solvate both systems. The AA model is solvated with TIP3 water, whereas the CG model is solvated with MARTINI water with the same water box dimensions. We undertake NVT simulations at 310K with Langevin dynamics. To get comparable analyses from the AA model, we group atoms of the resultant AA trajectory into CG beads in the same way the original CG model was formed in [2], referred to as the "mapped all atomic" (MAA) model. For accuracy analysis, we measure the MAA and CG models' root-mean-squared deviation (RMSD), free energy distributions as a function of dihedral angles, and radial distribution functions (RDF).

Our prototyping CG system possesses 85,861 atoms including 15 atoms for Fibrinogen, whereas the AA system consists of 1,186,598 atoms including 42,003 atoms for Fibrinogen in atomistic resolution. On a 2GHz Quad-Core Intel Core i5, the CG model took 41 seconds of wall clock time to complete a 1 picosecond simulated time, while the AA model took 7028 seconds—the CG simulation achieving 172x speedup. After conducting 14.16 nanoseconds of CG simulation with 10 femtoseconds as the time step size and 249 picoseconds AA simulation with 1 femtosecond as the time step size, we conduct our accuracy analyses. The RMSD plot of the MAA model is steeply increasing, matching almost exactly with the CG plot. Because the CG simulation is significantly less computationally expensive, we could continue it beyond the results of the AA simulation until it plateaus at an RMSD value of around 0.37 Å. The dihedral plots of the MAA and CG models all appear very similar, with higher concentrations in similar areas. Likewise, the RDF plots demonstrate highly similar distributions between the two models.

We conclude that our CG model of solvated Fibrinogen utilizes much less CPU time than the AA model while emulating most of the structure properties, meaning that our CG model will feasibly and accurately achieve significantly longer simulation times than the AA model. This will boost future research on Fibrinogen in essential pharmaceuticals and other essential biological fields.

Use of Machine Learning and Graph Neural Networks for Predicting Hardness Solely Based on the Grain Boundary Microstructure—An Experimental Case Study of Nanoindented Polycrystalline Steel Kamran Karimi and Stefanos Papanikolaou; NOMATEN CoE, Poland

There has been a long-standing notion that alloys' micro/nano hardness is strongly tied to the underlying microstructure. Polycrystals, for instance, consist of multitudes of disoriented grains within a complex polycrystalline network that dictate the mechanical response (i.e. hardness) across nano and micro scales. Nevertheless, the nature of such inherent microstructure-property correlations remains elusive and debated to this date. Conventional physics-based frameworks such as the Hall–Petch relationship empirically describe grain boundary strengthening effects by a single (mean) grain size parameter ignoring inherent grain scale hierarchies and intricate topology of the grain boundary network at micro/nano-structural levels. Here we use a data-driven approach based on the state-of-the-art machine learning (ML) and Graph Neural Net (GNN) model to infer grain-scale hardness from the (initial) grain boundary microstructural information. We trained our GNN model using an Electron backscatter diffraction (EBSD) map containing local lattice orientation information which was supplemented by a nano-mechanical dataset corresponding to a nanoindented polycrystalline steel. The trained ML model was able to make robust predictions of the load-depth curves over a broad range of grain scales. We further investigated that the model performance strongly depends on some certain set of grain-level (topological) attributes such as individual grain size, number of (nearest) neighbors, and grain-grain misorientation angles. On top of mechanical properties (such as hardness), our model can accurately forecast intermittent displacement bursts (i.e. pop-ins) and associated size and statistical distributions solely based on microstructural metrics.

Learning the Stress-Strain Fields in Digital Composites Using Fourier Neural Operator Meer Mehran Rashid, Tanu Pittie, Souvik Chakraborty and N M Anoop Krishnan; Indian Institute of Technology Delhi, India

The search for high-performance materials has led to advanced composite materials with hierarchical designs. However, designing a superior material with targeted properties and performance is challenging due to the vast design combinations and computational limitations imposed by conventional physics-based solvers. In this study, we use a neural operator-based framework, namely, Fourier Neural Operator (FNO) to learn the mechanical response of 2D digital composites. By just providing the material microstructure to the FNO it predicts the complete stress and strain tensor fields. The model exhibits

zero-shot generalization to unseen arbitrary geometries. Besides, the model demonstrates zero-shot super-resolution capabilities by predicting high-resolution stress and strain fields from low-resolution input configuration images. We show that FNO works for generalized boundary conditions (BCs) by testing the model for different unseen BCs. Furthermore, FNO provides high-accuracy predictions of equivalent stress and von-mises stresses thereby allowing upscaling of the results.

Accelerating Calculations of Leonard-Jones Potentials using Physics-Informed Neural Network Yuhe Wei[1], Ziji Zhang[2], Yicong Zhu[2], Miriam Rafailovich[2], Peng Zhang[2] and Yuefan Deng[2]; [1]Rutgers Preparatory School, United States; [2]Stony Brook University, The State University of New York, United States

Computing Leonard-Jones potentials dominates the computational costs in many simulations involving molecular dynamics (MD), for example, in platelet dynamics that plays an essential role in understanding the mechanisms of blood clotting. The extreme computational workload demand of MD simulations often hinders the study of bioprocess with large spatial and temporal scales. In the recent decades, the rise of machine learning (ML) techniques allows for a significant reduction of computational workload while maintaining the accuracy, by utilizing the ML predictions for MD calculations. Our work aims to simplify the computation of Lennard-Jones (LJ) potentials, which is the intermolecular force fields between interacting platelets, by proposing a generalized equation for theoretically similar ellipsoid models.

Problem Statement: The study considers the two interacting platelets, B_1 and B_2, to be modeled as ellipsoids, r as the distance between B_1 and B_2, Φ, Ψ, and θ and as the relative rotation angle of B_1 and B_2, respectively. Numerical experiments are conducted to generate training samples. We caculated the LJ potential for each 300 thousand random distrubuted points for each ellipsoid and used Monte Carlo Integration to estimate the double summation over each particle in a fixed form. The length, angle, and distance from center for x, y, z directions are measured to be the independent variables. By using the massive training set with 208,000 samples and 10 independent variables, we train our models to describe the predicted equation that governs the integrated potentials between interacting ellipsoids while significantly reducing the computation time.

The Results: With the numerical training set, we designed a physics-informed neural network (PINN) [1] guided by the proposed equation for LJ potentials with variables of relative distance and orientation (λ_2) between platelets and their respective correction parameters, $\lambda_1$and λ_3, presented in the equation as $LJP= \lambda_1\lambda_2[\lambda_3(\sigma/r)^7-(\sigma/r)]$. We used 10 neural network hidden layers each with 20 nerons and employed the Adam optimizer with a learning rate of 0.001.We splited the data to training and testing sets into 1:1 ratio to avoid potential overfitting issues. We then trained the data for 15K iterations with the relative orientation (λ_2) as the target output in the neural net framwor and use the results to calculate the predicted LJ potential value using the aformentioned equation. Finally, we assess the PINN training with a loss function of root mean square error (RMSE) to penalize the difference between predicted LJ potential and the true LJ potential value. In the range of LJ potential value less than 0, we got a RMSE error of 0.01568. Our learned force-field parameters for orientation (λ_1) and distance (λ_3) are -1.526 and -1.915, repectively.

We learned the paramaters for relative orientation and distance for the generalized LJ potential equation to describe the large-scale biophysics systems. The leveraged PINN effectively accelerates the learning process and improve the overall approximation accuracy of the model prediction by embedding the governed physics principles. Our work contributes to thrombosis simulation which could help us better understand the complex risk of blood clotting, providing promising applications to learn the generalized equations of other similar biophysics systems. Future work can investigate other neural network model architectures to improve performance.

Multi-Fidelity Scale Bridging Using AI and Machine Learning Subramanian Sankaranarayanan; Argonne National Laboratory, United States

Reinforcement learning (RL) approaches that combine a tree search with deep learning have found remarkable success in searching exorbitantly large, albeit discrete action spaces, as in chess, Shogi and Go. Many real-world materials discovery and design applications, however, involve multi-dimensional search problems and learning domains that have continuous action spaces. Exploring high-dimensional potential energy models of materials is an example. Traditionally, these searches are time consuming (often several years for a single bulk system) and driven by human intuition and/or expertise and more recently by global/local optimization searches that have issues with convergence and/or do not scale well with the search dimensionality. In this talk, we present our recent efforts on the use of RL for parameterization and development of interatomic potential functions. In a departure from discrete action and other gradient-based approaches, we introduce a RL strategy based on decision trees that incorporates modified rewards for improved exploration, efficient sampling during playouts and a “window scaling scheme" for enhanced exploitation, to enable efficient and scalable search for continuous action space problems. We will demonstrate a set of use cases to highlight the efficacy of our RL approach in interatomic potential development for a broad class of materials.

Machine Learning Based Strategies for Materials Discovery and Design Gowoon Cheon; Google Research, United States

With the rapid increase in computational resources and the large-scale datasets of materials, data-driven methods for materials discovery and design are rising to prominence. I will talk about our work on combining high-throughput calculations, data mining and machine learning-based modeling to discover new materials.

3:30 PM DS02.12.04
Accelerated Discovery of Aerospace Materials via Graph Neural Networks and Multiscale Modeling Mark Polking, Lin Li, Kevin Tibbetts, Charles Epstein and Nathan Frey; Lincoln Laboratory, Massachusetts Institute of Technology, United States

The extreme aerothermal conditions encountered in space vehicle re-entry and supersonic flight pose severe challenges for material survivability. Window materials, which must maintain high optical transparency in addition to high mechanical strength, thermal stability, and chemical resistance, pose particular challenges. Here, we demonstrate high-throughput discovery of new high-temperature aerospace window materials using a combination of machine learning-guided materials screening, first-principles materials theory, macroscale modeling with custom thermo-mechanical-optical models, and high-fidelity computational fluid dynamics (CFD) simulations. Our machine learning models, powered by a novel integrated graph neural network (I-GNN) architecture, enable accurate predictions of key thermo-mechanical properties, including thermal conductivity, coefficient of thermal expansion, melting temperature, and other properties. Importantly, by integration of materials physics with GNN models, we demonstrate accurate, temperature-dependent predictions of these properties. Use of these fundamental property predictions as inputs to high-fidelity CFD simulations enables, for the first time, rapid and accurate predictions of macroscale material behavior under realistic aerothermal flow conditions for many thousands of previously unexplored materials. With this approach, several new candidate materials have been identified with combinations of thermal, mechanical, and optical properties that may enable superior performance compared with conventional sapphire windows in the mid-wave and long-wave IR spectral ranges, such as AlReSi and $CaZrN_2$. Property predictions for these and other top candidate materials have been validated using first-principles calculations with density functional theory and density functional perturbation theory.

3:45 PM DS02.12.05
Exploring Interface Structure Between Perovskite Oxides Using Evolutionary Structure Search and Automated Design of Deep Learning Potentials via Neural Architecture Search Hong Sun[1], Amit Samanta[1], Vincenzo Lordi[1] and Yayoi Takamura[2]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Davis, United States

Perovskite oxides have attracted enormous interest in producing next-generation magnetic and ferroelectric devices. Interfaces between perovskite oxides warrant particular attention as they present distinctive charge transfer reactions and magnetic properties that are often absent in the constituent materials. To harvest the special functionality of perovskite oxide multilayers, developing a mechanistic understanding of their interface phases is imperative to establish materials design principles. In this study, we leveraged evolutionary algorithm and neural architecture search methods to design deep learning potentials and first principles simulations to systematically examine interface structures of $La_{1-x}Sr_xCoO_{3-\delta}/La_{1-x}Sr_xMnO_{3-\delta}$ (LSCO/LSMO) bilayer system as a function of oxygen deficiency (δ) and strontium concentration (x). Neural network potentials proposed in the literature are typically designed based on intuition and a particular neural network architecture can induce systematic errors into the potential. To overcome this problem, we use a state-of-the-art neural architecture search method to design potentials by optimizing network architectures and hyperparameters over a variety of neural network ensembles. The end products are a set of optimized potentials that then are used to search for interface structures using evolutionary structure search. Since total energies are calculated using an ensemble of potentials, our framework naturally allows us to incorporate uncertainty quantification. To generate our potentials, we use a set of about 800 training structures generated with first principles calculations by using evolutionary structure search. Next, we use these potentials to explore interface structures for different δ and x – this combination of evolutionary structure search and automated design of potentials allowed us to explore over 50,000 interface structures corresponding to 25 distinct δ and x at LSCO/LSMO interfaces. We validate the predictions made using our potentials by (a) performing first principles calculations of energetically favorable structures and comparing them with total energies predicted using our potentials, and (b) comparing predictions with a structure search performed using evolutionary algorithms with first principles calculations (i.e., without potentials). By statistically analyzing the spatial distribution of oxygen vacancies, Sr atoms, and the distortion of Co-/Mn-centered octahedral units, we determine the complex interplay of oxygen vacancy concentration, valence states of transition metal ions, and electronic properties at perovskite oxide interfaces. The fundamental understanding provides useful insights in designing perovskite oxide multilayers with tailored properties for device applications.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory (LLNL) under Contract DE-AC52-07NA27344. This work was funded by the Laboratory Directed Research and Development (LDRD) Program at LLNL (project tracking code 21-ERD-005). Computing support for this work came from the LLNL institutional computing facility.

Early Prediction of Ion Transport Properties in Molecular Dynamics Simulations of Solid Polymer Electrolytes Using Machine Learning Arash Khajeh[1], Daniel Schweigert[1], Steven B. Torrisi[1], Tian Xie[2] and Ha-Kyung Kwon[1]; [1]Toyota Research Institute, United States; [2]Massachusetts Institute of Technology, United States

Solid polymer electrolytes have received much interest for developing a new generation of safe, high-performance Li-ion batteries. To this end, Molecular Dynamics (MD) simulations have been widely used to quickly screen polymer candidates for desirable properties, such as high ionic conductivity and mechanical robustness. Unfortunately, these simulations can be time-consuming, and accurate predictions of these properties can require MD simulation lengths of 20ns or more which correspond to wall clock times on the order of hundreds of hours using conventional computational resources. Therefore, accelerating MD simulations is critical to expedite the screening process, and subsequently, the design of new polymers. In this study, we show that with the correct choice of descriptors, we can make predictions of equilibrated transport properties at 10% of the total simulation time. The new set of descriptors used in the current study combines the configuration of ion clusters with the early time evolution of transport properties. Specifically, we find that descriptors that include information about anion-cation interactions and dynamics of ion transport in the polymer environment outperform features extracted from the molecular structure of the polymers. We show that these descriptors have several advantages over polymer structure-only descriptors, as features can be extracted and predictions made at any time point, increasing the applicability of this method to a wide range of polymer systems, simulation times, and conditions such as different temperatures and concentrations.

4:15 PM DS02.12.07
Combining Density Functional Theory and Machine Learning for Compositional Optimization of Alloyed Perovskite Electrocatalysts Jessica Karaguesian, James K. Damewood, Jaclyn Lunger, Daniel Zheng, Jiayu Peng, Daniel Schwalbe Koda, Yang Shao-Horn and Rafael Gomez-Bombarelli; Massachusetts Institute of Technology, United States

Multicomponent metal oxides, such as perovskite oxides, hold promise for use as sustainable alternatives to Ir-, Ru-, and Pt-based electrocatalysts at scale. Perovskites can accommodate a wide variety of elements in their A- and B-sites, enabling tuning of their structural and electronic properties through compositional alloying. These properties, which are obtainable from density functional theory (DFT) calculations, can be used as low-dimensional descriptors that correlate with experimental stability and activity in, for example, the oxygen evolution reaction (OER). Established descriptors of stability include energy above convex hull and energy above Pourbaix hull, while those for catalytic activity include the difference between oxygen 2p-band center and the Fermi level, the difference between the metal 3d- and oxygen 2p-band centers, as well as oxygen vacancy formation energy. We are therefore presented with a combinatorial problem of determining which A- and B-site compositions optimize such descriptors. The compositional search space for $A_xA'_{1-x}B_yB'_{1-y}O_3$ perovskites with up to two different elements in their A- and B-sites is $O(10^6)$, making it intractable to calculate descriptors exhaustively using DFT. Here, we thus combine high-throughput DFT calculations with crystal graph convolutional neural networks (GCNs) to screen for stability and activity descriptors.

Previous high-throughput screening efforts have largely focused on ABO_3 perovskites, without alloying of the A- and B-sites, or narrow compositional ranges of perovskites with A- and/or B-site alloying. To predict descriptors of highly-alloyed perovskites over a wide cation space, we have used our high-throughput virtual screening platform to generate a dataset of over 10,000 perovskites. Notably, the presented dataset includes over 4,000 $(AA')(BB')O_3$ perovskites with varied A- and B-site alloying ratios and with over 2,000 unique cationic combinations. This significantly increases the amount of available highly-alloyed perovskite DFT data, with previous alloying studies including only a few hundred unique combinations of cations. Moreover, we have generated a dataset of over 2,000 $(AA')(BB')O_3$ perovskites with oxygen vacancies; to our knowledge, the only available high-throughput dataset studying vacancy formation in alloyed perovskites. Using our datasets in combination with data available in the literature, we have trained GCNs to predict the aforementioned descriptors from unrelaxed cubic perovskite structures and used these models to predict descriptors for $O(10^6)$ perovskites containing over 20 different A- and B-site cations, respectively. Leveraging these predictions, we describe trends in the structural and electronic properties of alloyed perovskites across a vast compositional space and work to establish improved structure-property relationships between computed descriptors and experimental catalytic performance. The presented work provides the community with a benchmark dataset for further study of alloyed perovskites and analyses of compositional trends, laying the groundwork for improved design of perovskite electrocatalysts.

4:30 PM DS02.12.08
Deep Learning-Based Prediction of Interfacial Surface Tension of Pendant Droplets Kazi Zihan Hossain, Sharif Amit Kamran, Alireza Tavakkoli and M. Rashed Khan; University of Nevada, Reno, United States

Pendant drops of oxide-coated high-surface tension fluids frequently produce perturbed and distorted shapes that impede surface tension measurements. Eutectic Gallium Indium (eGaIn), a high surface tension fluid coated with a 5nm Gallium Oxide film, falls under this fluid classification, and the recent emergence of eGaIn-based applications often cannot proceed without analyzing interfacial energetics in different environments. The low viscosity, chemical reactivity, and the passive surface oxide have also contributed to the accelerated materials discovery where eGaIn is alloyed with other elements for novel catalysts, bioreactors, and sensor discovery. In this study, for the first time, we are using a regression-based Deep Learning (DL) technique to predict the surface tension of eGaIn that can be extended to analyze any pendant drop. Time and resource-consuming image analysis software with manual intervention is generally used to analyze interfacial surface tension of different fluids. Here, we address the challenges associated with physics-based interfacial energy measurements of eGaIn and introduce a deep convolutional neural network architecture that can be deployed without using Goniometers (interfacial energy measurement instruments). A set of 13081 images were acquired and further analyzed to measure the surface tension. The dataset was split into 10594 training, 1178 validation, and 1309 test samples. We trained various convolutional neural networks on this regression task to accurately predict and compare the pendant drop shape properties. Our best-performing model, ResNet-50v2, achieved a mean absolute error of 0.995 and an R2 value of 99.97%, which signifies a high correlation, and our architecture can predict 99% of the variance in outcome. eGaIn droplets can create a non-axisymmetric shape due to their oxide layer, which cannot be solved with presently available software but can easily be handled with our presented DL technique. In limited-resource settings, our approach can also be deployed with a cell phone, and this deep learning model can be further leveraged to harness the influence of the external environment.

Hybrid Density Functional based Tight Binding-Molecular Mechanics Approach with Machine Learned Potentials for Large-Scale Materials Modeling Gekko P. Budiutama, Sergei Manzhos and Manabu Ihara; Tokyo Institute of Technology, Japan

Density Functional based Tight Binding method (DFTB) has seen a rise in adoption in recent years as it offers both DFT-like accuracy and access to electronic structure as well as scalability for systems where appropriate parameters are available. DFTB is based on the parameterization of interatomic interactions that reduce the cost of calculation when compared to DFT. In DFTB, all interatomic interactions for all atoms of the model have to be pre-parameterized. Conventionally, these parameterizations are performed to multiple DFT calculations and or reference data. This approach, however, requires a significant number of comparatively high-cost DFT calculations and specific knowledge and skillsets to be performed appropriately, therefore reducing the applicability of DFTB for many heteroatomic materials. In this study, we propose a hybrid approach where interatomic interactions which have little influence on electronic properties are modeled with pairwise interatomic potentials while other interactions are modeled with the conventional Slater-Koster approximation. We demonstrate the usefulness of this method by modeling a large-scale silica-titania interface where the Si-Ti interactions are modeled at the force field level while other interactions are modeled at the DFTB level. The most appropriate functional representation of the potential and its parameters are obtained with a combination of machine learning and gradient-based fitting. The validity of the approximation is verified against DFT on small-scale models. The approach allows the expansion of DFTB application to new materials where Slater-Koster parameters are not yet available.

Disconnection Aware Steering of Retrosynthesis Transformer to Facilitate Materials Design Amol Thakkar, Andrea Byekwaso, Alain Vaucher, Philippe Schwaller, Alessandra Toniato and Teodoro Laino; IBM Research-Zurich, Switzerland

Retrosynthetic analysis is the task of breaking down a target molecule into its constituent precursors until a set of commercially available building blocks is reached. At each single step in the sequence, the bonds to be changed and/or functional group interconversions are identified, and the molecule broken into hypothetical precursors. Several deep-learning-based approaches to single-step retrosynthesis treat the prediction of possible disconnections as a translation task, relying on the use of the Transformer architecture [1] and the simplified molecular-input line-entry system (SMILES) [2,3] notation [4-7]. Given a target molecule, these approaches suggest the best set of precursors (i.e. reactants, and possibly other reagents) as the translation's outcome, with the possibility to generate multiple such sets.

However, in their current form, retrosynthetic prediction systems offer the chemist little control over the site at which disconnections are made. As such, this work serves to enable user-defined disconnections for single-step retrosynthetic analysis, enabling steering of transformer models for retrosynthetic prediction. Whereas previous models offer no opportunity to steer the model and remain limited in the disconnections they propose. Thus, paving the ground for a 'human-in-the-loop' component harnessing both expert knowledge and deep learning. To this end, we have investigated methods to enhance user interaction from tagging input molecules, through to dataset augmentation. We additionally introduce and examine the predictions using several metrics beyond topN accuracy, which serves to build an understanding of how the predictions made align with those expected by chemists. Thus, we take a step towards improving decision-making strategies that statistical and machine learning algorithms cannot yet encode due to a lack of relevant training data. Ultimately this serves to enhance a chemist's experience by facilitating user engagement.

Accelerating Material Design with the Generative Toolkit for Scientific Discovery (GT4SD) Matteo Manica[1], Joris Cadow[1], Dimitrios Christofidellis[1], Ashish Dave[1], Jannis Born[1], Dean Clarke[1], Yves Gaetan Nana Teukam[1], Samuel C. Hoffman[2], Matthew Buchan[1], Vijil Chenthamarakshan[2], Timothy Donovan[1], Hsianghan Hsu[3], Federico Zipoli[1], Oliver Schilter[1], Giorgio Giannone[1], Akihiro Kishimoto[3], Lisa Hamada[3], Inkit Padhi[2], Karl Wehden[2], Lauren McHugh[2], Alexy Khrabrov[2], Payel Das[2], Seiji Takeda[3] and John Smith[2]; [1]IBM Research Europe, Switzerland; [2]IBM T.J. Watson Research Center, United States; [3]IBM Research Tokyo, Japan

The GT4SD (https://github.com/GT4SD/gt4sd-core) is an open-source library to accelerate hypothesis generation in the scientific discovery process that eases the adoption of state-of-the-art generative AI.
GT4SD includes models that can generate new molecule designs based on properties such as target proteins, target omics profiles, scaffolds distances, binding energies, and additional targets relevant for materials and drug discovery.

The library provides an effective environment for the generation of new hypotheses (inference) and for fine-tuning the models to specific domains using custom data sets (models retraining). It is compatible with the majority of popular deep learning frameworks: PyTorch, PyTorch Lightning, HuggingFace Transformers, GuacaMol, Moses, Torchdrug, and serves a wide range of applications ranging from materials science to drug discovery.

GT4SD's common framework makes models easily accessible to a broader community, like AI/ML practitioners developing new generative models who want to deploy with just a few lines of code. GT4SD provides a centralized environment for scientists and students interested in using generative models in their scientific research, allowing them to access and explore a variety of different models — all of which are pretrained. Consistent commands and interfaces for inference or retraining with customizable parameters harmonize the use across the different models.

The development of problem-specific intelligence is made possible thanks to the automatic workflows enabling retraining with users' own data covering molecular structures and properties. The replacement of manual processes and human bias in the discovery process has important effects on downstream applications that rely on the use of AI models, leading to an acceleration of expert knowledge.

In this talk, we will present GT4SD and its main functionalities, ranging from model inference to training and using live applications demos in the context of material science and chemistry.
The session is designed to provide a deep dive for developers and research scientists who want to accelerate their discovery pipelines with generative modeling capabilities.

8:45 AM DS02.13.05
Development of a Machine Learning Interatomic Potential for High-Entropy Alloys Akash A. Deshmukh[1], Manish Sahoo[2] and Raghavan Ranganathan[1]; [1]Indian Institute of Technology Gandhinagar, India; [2]Indian Institute of Technology Indore, India

High-Entropy Alloys (HEAs) are alloys of multiple components (usually 5 or more) in nearly equiatomic composition, forming simple solid solutions. Four core effects namely, the high-entropy effect, sluggish diffusion, lattice distortion, and the cocktail effect have enabled HEAs to exhibit excellent mechanical properties such as high hardness, high strength, good corrosion, and wear resistance, unlike traditional alloys. Due to the large compositional space, it is exceptionally difficult to predict promising HEA compositions. Atomistic simulations such as molecular dynamics (MD), Monte Carlo (MC), and first principles (DFT) calculations have provided an alternative to accelerate materials research manyfold, thereby reducing the experimental cost, labor, and time involved in the traditional trial-error approach.
Interatomic potentials (IPs) or force fields (FF), are the heart of such simulations and are used for predicting characteristics, describing interatomic interaction, physical, and mechanical properties at varying conditions such as temperature, pressure, and strain rate via molecular simulations. The selection of the appropriate FF is very important for accurate structure-property predictions in HEAs. Although first-principles calculations are the most accurate, small system sizes and small-time scales limit their applicability. Besides, semi-empirical models such as EAM/MEAM are capable of simulating large systems at long time scales with the compromise of accuracy. Being nonparametric in nature, the accuracy of machine learning-based interatomic potentials (MLIP) can be improved by fitting them to different atomic environments and simulation conditions. MLIPs not only combine the advantages of

both first-principles calculations and semi-empirical models but also address the limitations without compromising accuracy. The objective of the work is two-fold: first, we develop an MLIP for the unary molybdenum (Mo) system as a benchmark for testing the efficacy of the potential. This is achieved by training a moment tensor potential (MTP) from the training set that consists of various atomistic configurations during DFT simulations and configurations chosen on the fly during MD simulations, by means of an active learning approach. Specifically, to ensure a reasonable sampling of the phase space, the training set consists of atomic configurations picked up during NVT simulations at 300, 600, and 900 K, with defects such as vacancy and edge dislocation. The accuracy of the MLIP was validated periodically with improved training set by calculating the intrinsic properties such as lattice constant, melting point, and strength. Secondly, this protocol was extended to the CONiCrFeMn HEA. Initially, a defect-free unit cell of the HEA was designed at 300 K using the Special Quasirandom Structure (SQS) approach. Subsequently, defects such as stacking fault, edge dislocation, and vacancy were introduced. Atomic configurations obtained from the defects and at different temperatures (300, 600, and 900 K) form the training set. Again, the accuracy of the MTP was validated against experimental measurements of the lattice constant, melting point, and mechanical properties. We believe that this work will serve as a strong basis for the rapid development of machine learning-based force fields for the exploration of promising HEAs.

9:00 AM *DS02.13.06
Machine Learning Based Design of Composite Structures Seunghwa Ryu; KAIST, Korea (the Republic of)

Despite the technical importance of composite materials and structures, systematic design frameworks for them are limited because conventional optimization techniques face difficulties in handling the high-dimensional design space consisting of an astronomical number of material combinations and configurations as well as a complex nonlinear response beyond the linear response regime. With the advancement of machine learning (ML) techniques, extensive efforts are underway to establish alternative data-driven design frameworks for finding the optimal microstructure, external shape, and processing condition of composite materials and structures. In this talk, I would like to propose systematic composite structure design strategies using machine learning by accounting for the size of design space, dataset size, and the fidelity of the dataset. I will then introduce a few case studies concerning the optimization of nonlinear characteristics such as strength and toughness, design of a composite microstructure with very small dataset which limits the usage of the deep neural network, and the development of composite analysis model with less accurate but large homogenization model dataset with the aid of accurate but small experimental dataset. Additionally, the data-driven optimization of injection modeling process parameters will be discussed.

1:00 PM *DS02.14.01
Graph Neural Networks for Learning System Dynamics Wei Wang; UCLA, United States

Learning multi-agent system dynamics is important yet challenging. The complex interplay among agents is often explained with a one-step discrete model in existing work, which predicts the next observations for all agents given the current observations and their interaction graph. In reality, the interaction graph among agents may evolve over time and not always be observable. Moreover, many real-world systems are continuous in nature and using discretized modeling may significantly impair the precision of nonlinear dynamics. In this talk, I will present our recent work on modeling dynamic interactions using graph neural networks. Our models can jointly learn the latent representations of agent trajectories and the interaction graph in an unsupervised manner over time. Experiments show that they can accurately predict system dynamics especially in the long range and generalize well to low-resource systems that have only few training samples.

1:30 PM DS02.14.02
Combined Machine Learning and Density Functional Theory Approach to Predict Element Distribution of High-Entropy Alloys in Scanning Transmission Electron Microscopy Images Marco Ragone, Abhijit H. Phakatkar, Reza Shahbazian-Yassar, Farzad Mashayek and Vitaliy R. Yurkiv; University of Illinois at Chicago, United States

In comparison to their binary counterparts, high entropy alloys (HEAs) possess many unique properties that make them of high interest for applications in energy storage, bio/plasmonic imaging, catalysis, etc. The information about the element's distribution in columns of HEAs is imperative for a fundamental understanding and to reveal their structure-properties relation. We present a machine learning (ML) framework for the estimation of the element distribution in the atomic columns of HEAs nanoparticles (NPs), using semantic segmentation of high angle annular dark-field (HAADF) scanning transmission electron microscopy (STEM) images. NPs of two distinguished compositions, specifically, PtNiPdCoFe and $(MnFeNiCuZn)_3O_4$ serve as examples. The ML model is built upon a fully convolutional neural network (FCN), to learn the non-linear correlations between the columns' pixels' intensities in STEM images and the number of atoms of different constituent elements in the atomic columns to resolve the random elements distribution in chemically-complex NPs.[1] The elements motive in NPs with structural characteristics in agreement with the samples observed in the experimental measurements, is obtained using the density functional theory (DFT) calculation. The DFT calculations have been performed using the Vienna Ab Initio Simulation Package (VASP)[2] and Atomistic Tool Kit (ATK)[3], while an FCN has been built using the Tensorflow 2.2[4].
In order to generate a training dataset of simulated STEM images representing the aforementioned NPs for ML, the multislice algorithm and Gaussian filtering, implemented in the PyQSTEM[5] Python library, are used. Statistical analysis of the simulated STEM images revealed that the correlation between the columns' pixel intensities and the column heights (CHs) of the constituent elements is highly nonlinear, because of the random distribution, the different electronegativity of the constituent elements, and the crosstalk effect.
After proper training, we illustrate that in the simulated HAADF STEM images, our FCN predicts the majority of the columns correctly with an error of just one atom and with a maximum error of three atoms in 10 nm-sized NPs. Applying the trained network to the experimental HAADF STEM images revealed an overall even distribution of the five constituent elements (i.e., no local clusters of single element rich columns), with inhomogeneous fluctuations with local aggregations at a column level. The mapping of the HEAs element distribution via ML presented in this work allows for a more accurate characterization and engineering of the physical properties of HEAs. Moreover, in addition to the estimation of the number of atoms in the atomic columns of HEAs, our work represents an advancement to the development of computer vision techniques based on statistical learning methods for microscopy analysis, which could be beneficial to a broad area of nanoscience applications.

Polycrystal Graph Neural Network Minyi Dai, Mehmet Demirel, Xuanhan Liu, Yingyu Liang and Jiamian Hu; University of Wisconsin-Madison, United States

Graph Neural Network (GNN) has recently emerged as a powerful machine learning model for predicting the properties of molecular and crystal structures, but its application to 3D, topologically complex polycrystalline microstructures still remains scarce. Here, we develop a Polycrystal Graph Neural Network (PGNN) model that permits an accurate prediction of the properties of polycrystalline microstructures by considering the physical features and interactions of both grain and grain boundaries. Trained with 4000 data points, our PGNN model achieves a property prediction error of ~1.5%, which is significantly lower than baseline machine learning models such as ResNet (error ~4%). We also show that such trained PGNN model can be transferred to accelerate and improve the prediction of other physical properties with smaller available data. Our accurate, and transferable PGNN model is well suited for harnessing large-scale datasets of 3D polycrystalline microstructures, which is crucial for realizing accelerated design of polycrystalline materials.

Are Symmetries All We Need? Machine Learning Directions Beyond Equivariance Jonathan W. Godwin; DeepMind, United Kingdom

Machine Learning research for molecular and material simulation has often concentrated on embedding symmetries into the network architecture. A common argument is that embedding such symmetries allows the model to generalise from small amounts of data, and so removes the need to train large models as we do in Natural Language Processing and Computer Vision. In this talk I will argue that this is only partially correct, and that we need to move beyond symmetric architectural improvements.

I'll present evidence that symmetries are not sufficient on their own for learning representations across the periodic table. I'll then show promising evidence that taking inspiration techniques for representation learning and more stable training from other machine learning areas can provide significant performance increases at scale, indicating that we may see an inflection point as we increase the amount of data and compute. Finally, I'll finish by outlining some promising reaerch areas in this direction.

2:30 PM DS02.14.06
Linking Local Atomic Environments to Interfacial Co-Segregation Behavior in NbMoTaW Complex Concentrated Alloy Using Machine Learning Methods Doruk Aksoy and Timothy J. Rupert; University of California, Irvine, United States

Discovery of complex concentrated alloys unveiled a new generation of materials accommodating intricate local atomic environments. Linking these local atomic environments to the co-segregation behavior is instrumental in predicting the interfacial segregation behavior to assess chemical and thermodynamic stability of polycrystals. In this work, the co-segregation landscape of NbMoTaW refractory complex concentrated alloy is studied by employing atomistic simulations coupled with machine learning methods. First, the site availability of every possible combination of interactions (binary, ternary, and quaternary) is obtained at the dilute limit via molecular statics simulations at 0 K. Then, for the same interactions, hybrid Monte Carlo and molecular dynamics simulations are utilized to study chemically complex environments at different compositions. Finally, data-driven methods are employed to create structure property maps, through vectorized local atomic environments and segregation energies. The goal of this work is to gain insights on the effect of interfacial structure on co-segregation behavior rapidly, without the necessity of running costly atomistic simulations. A potential application of this method is to facilitate interfacial design of complex concentrated alloys by using these maps as building blocks.

Accelerated Prediction of Vickers Hardness of Cobalt and Nickel Based Superalloys from Microstructure and Composition Using Advanced Image Processing Techniques and Machine Learning Nikhil Khatavkar, Sucheta Swetlana and Abhishek Kumar Singh; Indian Institute of Science, India

Superalloys are an important class of material that are employed heavily in energy and defence sectors of economy. The high temperature properties of superalloys is the backbone of the aerospace industry due to its applicability in combustion zones of turbine. Vickers hardness is an important property for the selection of this material. In this work, a new approach is developed to establish the structure-property linkages for nickel and cobalt based superalloys. This approach utilizes advanced image processing techniques coupled with machine learning (ML) to estimate the Vickers hardness of the superalloys with unprecedented accuracy. Initially, highly accurate phase separation is achieved for the gamma and gamma-prime phases followed by evaluation of statistical 2-point correlations on the SEM micrographs. These 2-point correlations are an obvious improvement over the conventional microstructure quantification techniques. The correlations are then transformed and ranked according to their variance using principal component analysis (PCA). These transformed correlation along with the composition of the superalloys are then utilized to develop the ML models. The ML models trained using the

Gaussian process regression (GPR) shows unprecedented accuracy with the root mean squared error (RMSE) of 0.14 and R^2 of 0.98. The ML models are unparalleled in the literature and can be of direct applicability to the industry for performance and safety optimization of several important components of aircraft turbines. Further analysis of the model presents numerous trends for increasing the hardness of superalloys. For instance, addition of iron and titanium lead to increase of hardness, while aluminium and tantalum affect the hardness negatively. The ML models developed in this work are trained on the experimental data directly, as opposed to the works on simulated data found commonly. This gives an insurmountable advantage to our ML models in the applicability and transferability. The ML models developed can be generalized for any mechanical property of interest with minimal efforts and can be utilized for accelerated development of new generation of high temperature superalloys.

Data-Driven Discovery and Design of Thermoelectric Materials Christopher Wolverton; Northwestern University, United States

Thermoelectrics have potentially significant energy applications, but only if high efficiency materials can be found. However, discovery and design of novel thermoelectrics is particularly challenging, due to the complex set of materials properties that must be simultaneously optimized. Data-driven approaches to discovery and design of materials are a research area that has the potential to significantly accelerate discovery of these energy materials. Here we discuss our efforts at developing and applying data-driven computational techniques that enable an accelerated discovery of novel thermoelectrics. These techniques involve a combination of high-throughput density functional theory (DFT) calculations, inverse design approaches, and machine learning and artificial intelligence based methods. We discuss several recent examples of these methods: (i) inverse design strategies based on a materials database screening to design a solid with a desired band structure, specifically both flat and dispersive components with respect to crystal momentum, (ii) inverse design strategies to identify compounds with ultralow thermal conductivity (iii) an effective strategy of weakening interatomic interactions and therefore suppressing lattice thermal conductivity based on chemical bonding principles, and (iv) the development of crystal graph based neural network techniques to accelerate high-throughput computational screening for materials with ultralow thermal conductivity.

11:00 AM DS03.01.02
A Reinforcement Learning Guided Search for Stable and Functional Inorganic Crystal Structures Jeffrey Law[1], Shubham Pandey[2], Prashun Gorai[2,1] and Peter St. John[1]; [1]National Renewable Energy Lab, United States; [2]Colorado School of Mines, United States

Solid-state batteries (SSBs) are safer, more efficient, and potentially more recyclable than traditional batteries. However, major challenges such as interfacial instabilities remain to be overcome. Well-known solid electrolytes are unstable at the interface with metal anodes (e.g. Li metal) as well as with a high-voltage cathode. While large-scale DFT calculations has enabled functional materials discovery, only a small fraction of the plausible compositions (10^6-10^9) can be explored with these relatively expensive computations.

A central problem in using AI to accelerate the search for novel crystalline materials is finding thermodynamically stable structures. Composition-only models lack the accuracy required for assessing stability, especially for polymorphic structures (*1*). Graph neural network (GNN) models can achieve

impressive accuracy, on the order of 1 kcal/mol, in predicting formation enthalpy and energy above the hull; however, the exact input structure is known only after performing expensive DFT relaxation (*2*, *3*). Some progress has been made in predicting stability directly from the unrelaxed structures (*4*), but the accuracy of these approaches is limited by the degree to which the crystal structure changes during DFT relaxation. In developing models intended to rank the stability of potentially unstable crystal structures, including high-energy hypothetical structures in the training data is critical to achieving reasonable performance (*5*). In an analogous fashion, training only on fully relaxed energies may bias GNN models to predict lower energies for unrelaxed inputs in high-energy configurations.

Here we develop a reinforcement learning (RL) framework for designing new crystal structures and apply it to the challenge of discovering stable SSB materials. For the surrogate model, we trained a crystal-graph convolutional neural network (CGCNN) on a carefully designed dataset of close to 150,000 final geometries and total energies of three main structure types: ground-state (ICSD), hypothetical battery structures fully relaxed with DFT, and example hypothetical battery structures where only the cell volume is optimized. In this manner, our surrogate model learns to predict a scale-invariant formation energy of the crystal structure in its given coordination, which we subsequently minimize with RL. Validating our top-performing candidates with full DFT relaxations confirms a high percentage of them to be stable while exhibiting large electrochemical stability windows.

11:15 AM DS03.01.03
Comparing Forward and Inverse Modeling Paradigms—A Case Study on High-Entropy Alloys Arindam Debnath and Wesley Reinhart; The Pennsylvania State University, United States

Refractory High-Entropy Alloys (HEAs) are a promising class of materials for ultra-high-temperature applications including energy generation from gas turbines. In addition to having exceptional mechanical properties at elevated temperatures, these materials can be highly tailored to individual applications by selection of the constituent elements. The relationship between elemental composition and function is challenging to understand and even harder to predict because it is nonlinear, high-dimensional, and results from physical phenomena at many scales. As a result, machine learning is an attractive tool for the empirical design of these materials. While conventional materials design has utilized predictive models to rapidly test hypothesized material compositions in a search for improved ones, more recent generative modeling approaches provide for the possibility of "inverse modeling."

We have recently developed deep-learning-based generative models including variants on the Generative Adversarial Network (GAN) architecture to perform inverse modeling of refractory HEAs with tailored properties. Generative modeling offers an attractive solution to materials design problems due to its ability to approximate the inverse function directly (i.e., properties to composition) without the need to search the design space. However, we have also faced challenges in training our models on sparse and uncertain experimental data gathered from literature. Here we compare the design of HEAs using these generative models (the "inverse" paradigm) and surrogate regression models (the "forward" paradigm). We discuss the lessons learned from our preliminary work and strategies we are developing to measure the effectiveness of each approach in designing new HEAs for ultra-high-temperature applications.

11:30 AM DS03.01.04
A Unified Active Learning Framework for Designing Energy-Relevant Molecules Shomik Verma[1], Jiali Li[2], Kevin Greenman[1], Rafael Gomez-Bombarelli[1], Xiaonan Wang[2,3] and Aron Walsh[4]; [1]Massachusetts Institute of Technology, United States; [2]National University of Singapore, Singapore; [3]Tsinghua University, China; [4]Imperial College London, United Kingdom

Solar photovoltaic (PV) technology has received immense, global interest in recent years. Many novel devices have been created beyond conventional silicon solar cells, such as thin film PV, organic PV, and perovskites. Unfortunately, all such single-junction solar cells suffer from an efficiency cap known as the detailed-balance limit, which limits solar cell efficiency to 33.7%. This limit is primarily due to solar cells unable to absorb light below their bandgap, and inefficiently absorbing light above their bandgap.

One strategy to improve PV efficiency is to use certain organic molecules that up- or down-convert photon energies using interplays between their excited states. Two common types of photon conversion processes are triplet-triplet annihilation (TTA) up-conversion and singlet fission (SF) down-conversion. However, designing efficient TTA and SF molecules comes with several challenges. Namely, the design space of organic photon conversion molecules is massive; for example, 166 billion organic molecules exist with less than 17 atoms. Further, experiments or first-principles simulations to evaluate the excited state energies of these molecules are time- and resource-consuming.

Fortunately, large scale virtual screening and inverse design with machine learning are promising solutions, as they allow accelerated evaluation of properties and efficient exploration of chemical space. Supervised machine learning comes with its own challenges, however. As a primarily data-driven method, it is limited by slow acquisition of labeled data for model training. Further, the chemical design space is diverse, so a large amount of labeled data is required for training to ensure sufficient coverage. Finally, tasks may be very different or require non-overlapping data. For these reasons, a model with high accuracy for desired properties is difficult to obtain.

Therefore, it is useful to develop an efficient, unified strategy for generating training sets and suggesting candidate molecules under different conditions. Active learning is one promising strategy for achieving this, as it efficiently explores chemical space. This study presents an active learning framework for designing energy-relevant molecules, where molecules suitable for TTA up-conversion and SF down-conversion are taken as a case study.

First, an ultra-fast chemical simulation method based on machine-learned calibrations to tight binding is developed for accelerating the labeling process. The calibration training set is carefully curated to ensure both breadth of chemical space and depth in space of molecules of interest, namely large aromatic molecules with pi-conjugated bonds.

Next, we use this accelerated labeling to generate a large molecular database and benchmark various active learning strategies with different priorities over this database. Namely, we implement different acquisition functions for both pool-based and generative-based active learning approaches, based on suitability terms developed for target tasks, uncertainty terms derived from surrogate models, and domain knowledge terms for different specific applications.

Finally, a generative machine learning model is developed based on the informative database derived from the unified active learning framework. The

generative model considers both suitability and synthetic accessibility to reduce experimental effort. A pool of molecules suitable for TTA up-conversion and SF down-conversion are proposed, verified with higher-fidelity computational chemistry methods, and finally demonstrated with experiments.

Overall, a unified active learning framework is developed, and molecules suitable for TTA and SF are proposed. The suitability of these materials as photon conversion materials to improve PV efficiency is a promising demonstration of the utility of this approach for designing energy-relevant molecules.

11:45 AM DS03.01.05
Machine-Learning Assisted Discovery of High-Mobility Materials Husna Anwar[1], Hitarth Choubisa[1], Koen Bertens[1] and Edward H. Sargent[1,2]; [1]University of Toronto, Canada; [2]Northwestern University, United States

Machine Learning (ML) models have been shown to accelerate materials discovery by orders of magnitude over traditional computational methods such as density functional theory (DFT)[1]. Optical properties, specifically absorption profiles, are very computationally expensive to calculate for alloys, given the large number of configurations available for a single combination of precursors. Additionally, even ML models trained on simulated data often fail to produce physically realizable predictions. Herein we present a multistep ML model that produces new, high-mobility material compositions by predicting their absorption spectra. This model is the first to use a database of experimentally derived compositional data to predict absorption profiles.
Absorption profiles contain a rich array of information about material characteristics including bandgap and carrier concentration. The capability of predicting absorption spectra without having to fabricate and characterize thin films is of particular interest for the spectroscopy community[2]. Hence, the first step of our model is trained on various material compositions and predicts their absorption spectra. Given that our chosen database also contains conductivity measurements and synthetic parameters, we further develop our model to calculate the carrier mobility for a given composition using the number of free carriers derived from the absorption profile and conductivity. So, in the second step, the model uses the predicted absorption profile together with conductivity data to train a genetic algorithm (GA) that produces new compositions with high mobilities. We demonstrate the effectiveness of our model by combining it with a segmentation algorithm that identifies materials with bandgaps favorable for optoelectronic applications and verify our results using DFT.
For a given set of precursors, we found that our model produces absorption spectra, at a minimum, 1000 times faster than when we tried to predict the same using DFT. Rather than training on optical data, that may introduce bias in our predictions, we train on three experimental parameters that are key to thin-film fabrication and optimization: compositional stoichiometry, film thickness and annealing temperature. By training on these parameters, we produce a well-generalized model with an R2 value of 0.87. The bandgaps derived from the predicted spectra have a mean absolute error (MAE) of 0.1 eV, a significant improvement over 0.33 eV MAE for current state-of-the-art computational bandgap predictions[3].

Polymer Informatics—Recent Advances in Algorithms to Solve Forward and Inverse Problems Rampi Ramprasad; Georgia Institute of Technology, United States

Polymers display extraordinary diversity in their chemistry, structure, and applications. However, finding the ideal polymer possessing the right combination of properties for a given application is non-trivial as the chemical space of polymers is practically infinite. This daunting search problem can be mitigated by surrogate models, trained using machine learning algorithms on available property data, that can make instantaneous predictions of polymer properties. I will present a versatile, interpretable, and scalable scheme to build such predictive models. Our ‘‘multi-task learning’’ approach is used for the first time within materials informatics and efficiently, effectively, and simultaneously learns and predicts multiple polymer properties. It is thus a powerful tool to solve “forward materials problems”, i.e., property predictions. I will also discuss new approaches to solve “inverse materials problems”, i.e., identifying materials that satisfy target property criteria. This discussion will include advances made to the genetic algorithm and graph-to-graph translations for polymers. These forward and inverse method developments are expected to have a significant impact on data-driven materials discovery.

2:00 PM DS03.02.04
Fast Optimization of Needle-in-a-Haystack Energy Problems Using Zooming Memory-Based Initialization (ZoMBI) Alexander E. Siemenn[1], Zekun Ren[2], James Serdy[1], Basita Das[1], Blake H. Hudspeth[1], Marilyn R. Meyers[1], Emre Tekoglu[1], Myles G. Stapelberg[1], Michael Short[1], Ju Li[1], A. John Hart[1] and Tonio Buonassisi[1]; [1]Massachusetts Institute of Technology, United States; [2]Singapore-MIT Alliance for Research & Technology, Singapore

Energy materials innovation challenges can require identifying rare combinations of properties at the extremes of distributions. Standard optimization approaches fare well with largely convex and smooth function spaces, but fail in high dimensions, in non-convex spaces with multiple suboptimal local extrema, and with needle-like global optima with local convexity in only a tiny fraction of total function space. Examples of these kinds of problems are searches for specific compositions of matter with constellations of rare user-defined target properties, for example metal alloys with ultrahigh specific strength. With today’s methods’ limitations, experimental searches for novel rare materials require prohibitively large numbers of experiments, even with machine-learning guided exploration.

We believe that addressing this problem requires a multifaceted approach, bringing together simulation, high-throughput experiment, and machine learning methods. To address the ML portion of this challenge, we propose the Zooming Memory-Based Initialization (ZoMBI) algorithm to augment traditional BO methods by zooming in the search bounds of BO based on the extents of the best-performing data points in memory, and then erasing all other memory to accelerate compute. We demonstrate the performance and compute requirements (dimensional scalability) of ZoMBI on a 5-dimensional Ackley

function, a common algorithm benchmarking function, and a 5-dimensional DFT-derived dataset of a rare materials property (negative Poisson's ratio). The ZoMBI algorithm is demonstrated to achieve computing speed-ups of over 400x compared to traditional BO. We also introduce preliminary results from an automated synthesis tool capable of achieving >2000 materials per minute, to explore alloyed materials in the search for rare properties.

2:15 PM DS03.02.05
Variational Method-Based Operator Neural Network for Dynamic Systems in Energy Materials Governed by Gradient Flows Wei Li[1,2], Avtar Singh[1] and Juner Zhu[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Northeastern University, United States

Variational methods have been well established to derive the governing equations of complex, coupled, and nonlinear systems. One example is the gradient flow that entails finding and constructing an appropriate potential energy and inner product to incorporate the kinetics into a variational framework. Gradient flows can be applied to a large variety of physics, including diffusion, phase separation, microstructure evolution, etc., where the governing partial differential equations (PDEs) can be eventually obtained. The conventional numerical methods, such as the finite element method (FEM), have been proven to be effective in solving PDEs. However, it is still challenging for systems with high dimensionality and nonlinearity. Recently, we have witnessed great successes in machine learning (ML) applications in many scientific disciplines. The concept of scientific machine learning was proposed and widely used by many research groups to solve variational problems. One of such approaches is approximating the solutions with ML models and training them by minimizing the energy functional, instead of solving a large set of non-linear equations. An example is the energy-based neural networks. Recently, another approach started to gain increasing attention, which is referred to as operator learning (OL). OL models the mapping from one functional space to another. It has the potential to incorporate solutions with different initial conditions into one algorithm. In this study, we proposed a general variational method-based operator neural network framework for dynamics systems governed by gradient flows. To validate the proposed framework, we investigated several dynamics systems that commonly exist in energy materials, including the linear relaxation kinetics, Allen-Cahn dynamics, and phase-field dynamic fracture. We compared the prediction of the proposed neural network with the FEM solution and found satisfactory agreements. We expect that the trained neural networks can work as surrogate models for energy materials to provide rapid predictions.

4:00 PM DS03.03.02
A Holistic Multi-Step Retrosynthesis NLP Model for Plausible Synthetic Pathway Planning in Time Efficient Manner. Jin Woo Kim, Youngchun Kwon, Dongseon Lee and Youn-Suk Choi; Samsung Advanced Institute of Technology, Korea (the Republic of)

The plausible synthetic pathway design is critical for accelerating new material discovery. There can be various precursor candidates for a given target molecule. Also, it usually requires investigation of the vast majority of multi-step pathways to find all available (or purchasable) building blocks, which makes it complex and challenging task. Conventionally, highly skilled experts plan multi-step synthesis strategies utilizing their knowledge and intuition. In recent years, a variety of AI-driven pathway suggestion methods have been developed, leveraging extensive synthetic pathway data with emerging machine learning techniques.
The AI-driven methods have three common components: i) AI model for single-step retrosynthesis, ii) Synthetic tree search algorithm, and iii) Pathway scoring functions. The single-step retrosynthesis model takes the structural representation of a target molecule as an input, then it proposes sets of precursor candidates. It is applied recursively for each synthetic step until all available building blocks are figured out. To prevent combinatorial explosion during the recursive enumeration, tree search algorithms such as Monte Carlo Tree search (MCTS) or hyper-graph exploration method have been employed. Also, pathway scoring functions are devised to select probable nodes (i.e. precursor candidates) to be explored during the tree search. In many cases, scoring functions included some simple heuristic terms such as the number of steps. Also, a recent study proposed pathway evaluation method based on tree-LSTM model for considering tactical synthetic strategies which can be recognized by observing the overall multi-step information, not individual single-step data. The results showed that it provided more plausible pathway suggestions.
The previous methods have shown successful results. However, there are two points to be addressed. First, synthetic step-wise tree search algorithm is still time-consuming part for obtaining the results. Second, even though the current stand-alone evaluation model can view the information of entire synthesis steps, the retrosynthesis AI model can only deal with single-step synthesis data yet. To this end, we propose a novel approach to train AI retrosynthesis model which can suggest multi-step pathways more efficiently. Also, we developed it to learn holistic multi-step pathways, which we expect it to suggest more plausible pathways. There are two key differences from the previous studies. The first one is that we designed a new multi-step pathway representation and the training technique for it. Our representation expresses entire synthesis steps as a string format, so that it contains a whole steps information in a single representation. Then, we adopted the several natural language process techniques to train those data. The other one is that our method does not require synthetic step-wise tree search algorithm, which decreases the computational time.
We validate the performance of our method in terms of its accuracy and elapsed time. First, we trained our model on 28 thousand multi-step synthesis data extracted from Reaxys DB with 8:1:1 (=train:valid:test) split ratio. The top-10 accuracy was 59.1 % and it takes approximately 9 minutes for suggesting multi-step pathways of 2.8 thousand test target molecules with a single core AMD EPYC 7413 CPU and a single A100 GPU. Moreover, we compared our method to the previous approach. For comparison, we devised our baseline model combining single-step retrosynthesis model based on the tied two-way architecture invented in our previous research and the MCTS algorithm. We randomly selected 40 target molecule examples from the test set. The top-10 accuracy of new approach was 37.5 % higher than the conventional one with dramatically decreased elapsed time.

4:15 PM DS03.03.03
The Largest Knowledge Graph in Materials Science—Entities, Relations and Link Predictions Through Graph Representation Learning Vineeth Venugopal[1], Sumit Pai[2], Elton Pan[1], Christophe Guéret[2] and Elsa Olivetti[1]; [1]Massachusetts Institute of Technology, United States; [2]Accenture Labs, Ireland

Information on materials is available through several platforms - online computational data repositories such as the Materials Project, OQMD, NOMAD etc, scientific literature databases such as a Elsevier, Arxiv, Web of Science etc, repositories of experiments such as ICSD, NIST databases, published textbooks, handbooks, industrial datasheets, and more recently in high throughput databases. This data can be structured - eg, the indexed, tabular data in online databases - or unstructured, as in textbooks and scientific literature. Further, while some data is available as numerical or categorical attributes ('melting point', 'space group'), most are delocalised within large chunks of text, or available in images. The presence of multiple streams and modes of data along with the sheer amount of information available at present and being continuously generated taxes human cognition and calls for automated systems that identify, catalog, link, and query information on its own.

Recently, Knowledge Graphs (KGs) have emerged as a tool for integrating data and relational ontologies through versatile graph databases. KGs arethe industrial standard for data retrieval and organization as demonstrated by KG use in Google Search, social media sites such as Facebook and LinkedIN, as well as companies with large data inventory such as Ikea and NASA. In the field of materials science as well, several domain specific ontologies and property graphs have been proposed, though the use of knowledge graphs as a relational database tool is not very common at present.

Here we present a knowledge graph in the field of materials science comprising over half a million unique entities and over ten million statements, where each statement is an (entity, relation, entity) triple. The KG covers several topical fields such as inorganic oxides, functional materials, battery materials, metals and alloys, polymers, cements, high entropy alloys, biomaterials, and catalysts. The triples are generated autonomously through data driven natural language processing pipelines and extracted from a corpus of around 6 million published scientific articles. Several informational entities such as materials, properties, application areas, synthesis information, and characterization methods are integrated together with a hierarchical ontological schema, where the base relations are extracted through statistical correlations to which higher level ontologies are appended. Thus the KG is heterogeneous and contains multiple relations between entities. It is shown that a bipartite projection of the base KG leads to comprehensive relational graphs that link materials to their chief attributes and applications and help answer questions such as "what are key attributes of battery materials?" without human intervention.

We use a graph neural network based representational learning method to learn embeddings for entities and their relations which translate the graph data structure to a high dimensional mathematical space in which semantic relations between entities can be formulated as algebraic operations. This can be used not only to query the KG but can also predict new linkages between existing entities, thereby providing a versatile data informed tool for materials development and discovery. Key aspects of the knowledge graph which include entity extraction and link prediction are variously validated and compared with benchmarks where available. Finally, it is shown that the learned embedding representations encrypt physical and chemical information, which lend itself to machine learning in an easy manner.

4:30 PM *DS03.03.04
Natural Language Processing for Data Extraction and Synthesizability Prediction from the Energy Materials Literature Anubhav Jain; Lawrence Berkeley National Laboratory, United States

Historically, both data and knowledge (connections and conclusions based on data) in the materials domain has been recorded mainly as text, figures, or tables in journal articles. Such data is critical to both conventional and machine learning-driven materials discovery. In this talk, I will describe some of our efforts to extract information from the research literature automatically based on natural language processing techniques. For example, data on the dopability of materials is difficult to simulate, but is present either implicitly or explicitly as part of many research studies. Similarly, data on materials synthesis can be difficult or impossible to simulate but can be extracted from the historical research literature. The talk will summarize our most recent progress towards extracting both individual data items as well as "knowledge" (e.g., proposed applications of a chemical composition) in various areas, including extracting materials property data and data pertaining to materials synthesis. Overall, such work may ultimately lead to accelerated energy materials design through access to previously hidden data sets.

5:00 PM DS03.03.05
MOF Synthesis Prediction Enabled by Automatic Data Mining and Machine Learning Yi Luo[1], Saientan Bag[2], Orysia Zaremba[3], Adrian Cierpka[4], Jacopo Andreo[3], Stefan Wuttke[3], Pascal Friederich[4] and Manuel Tsotsalas[1]; [1]Institute of Functional Interfaces, Karlsruhe Institute of Technology, Germany; [2]Institute of Nanotechnology, Karlsruhe Institute of Technology, Germany; [3]Basque Center for Materials, Applications & Nanostructures, Spain; [4]Institute of Theoretical Informatics, Karlsruhe Institute of Technology, Germany

Metal–organic frameworks (MOFs) are porous materials formed via the connection between metal-centered nodes with organic linkers.[1] With the utilization of different metal nodes and linkers, the topology, pore size, and functional groups of MOFs can be adjusted for high specific surface area, numerous active sites, and mass transfer channels.[2] This flexibility in the MOF design allows great potential for MOF-based and MOF-derived material in the application in energy storage and conversion.[3] Computer-assisted methods have been applied in the acceleration for the design of MOF-based materials.[4–6] However, the potential of using machine learning (ML) methods to suggest parameters in MOF synthesis experiments is not well explored. Here, we show an approach of data mining and machine learning (ML) method for rationalization and acceleration of the MOF discovery process by directly predicting the synthesis condition of a new MOF based on its crystal structure.[7] There are three steps in our approach: 1) Creation of a MOF synthesis database (SynMOF) via automatic extraction of synthesis parameters from scientific literature; 2) Training of multiple ML models on the SynMOF database; 3) Prediction of synthesis conditions for new MOF structures by the ML models. These early-stage ML models, exhibit a good prediction performance, surpassing human expert predictions, which was shown through a synthesis survey from 11 MOF experts worldwide.

SESSION DS03.04: Knowledge Extraction and Methods
Session Chairs: Sijia Dong and Arun Kumar Mannodi Kanakkithodi
Tuesday Morning, November 29, 2022
Hynes, Level 2, Room 206

8:00 AM *DS03.04.01
Reinforcement Learning for Crystal Structure Search Subramanian Sankaranarayanan; Argonne National Laboratory, United States

The most common and popular method for structure search and optimization are based on evolutionary design. This can often be cumbersome, limited to few tens of parameters and fails for large structural configurations or design problems with high degrees of freedom. Reinforcement learning approaches mostly operate in discrete action space such as in Go game but the applications of that to inverse problems is limited since most inverse problems deal with continuous action space. There are a large number of inverse structural search problems ranging from crystal structure search in material sciences to topology design in Quantum information, where it is highly desirable to optimize structure/configuration to target desired properties or functionalities. This talk will provide an overview of our current efforts to perform scalable crystal structure and topology search to discover and design metastable or non-equilibrium phases with desired functionality. We will also discuss our efforts on fingerprinting and use of unsupervised learning to identify crystal structures and critical nuclei from amorphous melts, using zeolites as a representative example.

8:30 AM DS03.04.02
Combining Organic and Inorganic Descriptors for Predictions of Volatility Across Vast Chemical Space Anand Chandrasekaran, Alex K. Chew, Simon D. Elliot, Asela Chandrasinghe, Subodh Tiwari, H. Shaun Kwak and Mathew D. Halls; Schrodinger, United States

Many industries are now leveraging machine learning approaches to predict materials properties that are challenging to measure, necessitating descriptors that are capable of characterizing a wide range of materials. Traditional QSAR/QSPR approaches use machine learning to map 2D molecular structures to a materials' property/label of interest. These 2D structures are usually numerically characterized using bit-based fingerprints that count the number of substructures in a molecule. However, fingerprint-based approaches do not generally perform well for inorganic or metal-containing compounds. Recently, materials informatics descriptors have been developed that span the entire periodic table, capturing both chemical and stoichiometric information of inorganic compounds and alloys. In this work, we utilize a combination of bit-based fingerprints and inorganic descriptors to train machine-learning models that can predict volatility across a huge chemical space of organic and organometallic materials (spanning more than 50 elements). We benchmark a number of different machine learning approaches and show that stacking estimators perform better than a single algorithm/model. These highly accurate models for evaporation temperatures (at different pressures) and vapor pressures (at different temperatures) are invaluable in areas, such as thin film deposition, flavors/fragrances, refrigerants, volatile pollutants and toxicity.

8:45 AM DS03.04.03
Multi-Task Machine Learning Predictors to Combat Data Scarcity—The Examples of Gas Diffusivity and Permeability in Polymers Brandon K. Phan, Kuan-Hsuan Shen and Rampi Ramprasad; Georgia Institute of Technology, United States

Gas transport through polymer membranes is critical in current and emerging applications such as carbon capture, hydrogen recovery and fuel cells. Accurate machine learning (ML) prediction of gas diffusivity in polymers allows us to better control membrane transport properties such as selectivity and permeability and opens up the opportunity to discover novel polymer membrane materials with enhanced performance. However, the accuracy of traditional predictive ML models that are trained on one single property is often constrained by the size of the dataset. To overcome this issue, we created multi-task neural network (NN) models that are trained on both gas diffusivity and permeability to take advantage of larger available permeability data in literature. Such multi-task models exploit the correlations in the data corresponding to the different tasks. In our case, gas diffusivity is related to the ratio of the permeability and solubility. Our multi-task model showed significantly improved R^2 and reduced error for gas diffusivity predictions compared to the single-task model, especially at a small training dataset size. This demonstrated the effectiveness of this multi-task approach on improving the model accuracy when not enough data is available for the property of interest. Moreover, a multi-task gaussian process regression (GPR) model was also trained to test against the NN model. We found that the NN model outperformed the GPR counterpart at almost all training dataset sizes, and also benefited from the better scaling of training time. Overall, we created a multi-task neural network model capable of predicting gas diffusivity in various polymers with a high accuracy. With this model, we will screen existing and new polymers to identify promising polymer membrane materials with improved gas properties.

9:00 AM *DS03.04.04
Enhancing Physics-Based Modeling and Extracting Physics from Data Using Machine Learning Alejandro Strachan; Purdue University, United States

The synergy between principles-based modeling and data science is playing an increasingly important role in materials science and engineering. In addition, there is significant interest in using machine learning (ML) tools to extract physical laws as well as symmetries and associated invariants from data. I will discuss recent progress in machine learning applied to multiscale modeling and in the development of interpretable models that balance accuracy with parsimony.
ML for multiscale modeling. ML interatomic potentials have shown near quantum mechanical accuracy at a fraction of the cost, enabling large-scale atomistic simulations. We developed an iterative approach to address the challenge of generating training data and address the stochastic nature of NN training. I will demonstrate the approach with the development of neural network reactive force fields (NNRF) for the phase change material GeSbTe of interest in electronics. MD simulations with these potentials provide new insight into the process of crystallization from the amorphous state.
Discovery of interpretable physical laws from data. I will introduce parsimonious neural networks (PNNs) that combine neural networks with evolutionary optimization to find models that balance accuracy with parsimony. The power and versatility of the approach will be demonstrated by developing models for classical mechanics and for the melting temperature of materials from fundamental properties. In the first example, the resulting PNNs are easily interpretable as Newton's second law, expressed as a non-trivial time integrator that exhibits time-reversibility and conserves energy, where the parsimony is critical to extracting underlying symmetries from the data. In the second case, the PNNs not only find the celebrated Lindemann melting law, but also new relationships that outperform it in the Pareto sense of parsimony vs. accuracy.
Making workflows and data FAIR. Finally, I will also describe recent developments in nanoHUB, an open cyberinfrastructure for cloud scientific computing, towards making simulation workflows and their data findable, accessible, interoperable, and reusable (FAIR). We introduce Sim2Ls (pronounced sim tools) and the Sim2L Python library that allows developers to create and share end-to-end computational workflows with well-defined and verified inputs and outputs. The Sim2L library makes Sim2Ls, their requirements, and their services discoverable, verifies inputs and outputs, and automatically stores results in a globally accessible simulation cache and results database.

9:30 AM DS03.04.05
A Multi-Task Machine Learning Approach to Predict Molecular Interactions and Diffusivity in Polymers Janhavi Nistane, Lihua Chen, Kuan-Hsuan Shen and Rampi Ramprasad; Georgia Institute of Technology, United States

Understanding the diffusion behavior of organic molecules through polymers is critical for many applications, including fuel production, coatings, and drug delivery systems. Experimental methods to measure diffusivity are usually time and cost-intensive. Further, available experimental data on organic molecular interactions and diffusivity is sparse and covers only limited chemical space. Here, we present a multi-task machine learning (ML) approach to instantaneously predict solvent diffusivity in polymers. The multi-task ML model is trained simultaneously on both available experimental and computational data generated by us using high-throughput classical molecular dynamics simulations. The experimental data is regarded as high-fidelity data; however, this data is only available across a limited chemical space. On the other hand, simulations offer the flexibility to obtain diffusivity values across a vast chemical space. Although there is only semi-quantitative agreement between simulations and experimental values, correlations that do exist between the two classes of data is exploited by the multi-task neural network architecture. This approach tackles the problem of data scarcity while offering a scalable scheme for further data augmentation, enabling the model to co-learn and make predictions more effectively.

10:30 AM DS03.05.01
Bayesian Optimization of Perovskite Solar Cells Made by Multiple Short Light Pulses Weijie Xu, Anusha Srivastava, Jessica Grayson and Julia W. Hsu; The University of Texas at Dallas, United States

Photonic curing, a novel processing technique, can promote large-area perovskite crystallization in milliseconds. Photonic curing delivers light pulses from a xenon flash lamp to the sample. The time profile of the pulse can be shaped by utilizing multiple short pulses with custom duty cycles, i.e., micro-pulses. Thus, we can use micro-pulses in photonic curing to design the resulted temperature profiles of perovskite films. Because perovskite films are not exposed to continuous high-intensity light, they can absorb more radiant energy while not being damaged. However, micro-pulse has too many variables—pulse voltage, pulse length, number of micro-pulses, and duty cycles—making it difficult to be optimized by one variable at a time efficiently, which hinders the application of micro-pulses in photonic curing.

In this work, we demonstrate the optimization of micro-pulsed photonic curing with four input variables and aim to achieve the highest PSC power conversion efficiency. Pulse voltage is proportional to the radiant power (W/cm^2) and pulse length is the duration of the pulse (ms). Bayesian optimization (BO) framework is employed to search for the optimal processing conditions in the high-dimensional experimental space. To minimize the optimization time, we perform BO in two steps. Because UV-vis absorbance spectra are quick to measure, we first use UV-vis absorbance to characterize the $MAPbI_3$ film quality by comparing the absorbance step at $MAPbI_3$ bandgap (~ 785 nm) and scattering at longer wavelengths. High-quality $MAPbI_3$ films should have a large absorbance step at 785 nm and little scattering.[1]Utilizing acquisition function and sequential learning ensures that the ratio between the absorbance step at 785 nm and absorbance above 800 nm is maximized. The first step ensures that we do not spend extra time making solar cells using not promising input variables. Within the narrowed-down input space, our second step exploits the input variables with finer spacings based on device performance. Through iterations, we achieve the global maximum device power conversion efficiency in the input parameter. Visualizing 2D contour plots at every iteration allows the learning results to be understandable by a human. We also examine real-time feature importance using the Shapley Additive Explanation (SHAP) method. Our results demonstrate the feasibility of this two-step BO approach, and we believe that a similar approach can be applied to other processing optimization problems at a lower experimental cost.

This work is supported by NSF CMMI-2109554.

Machine Learning Prediction of Perovskite Solar Cell Properties Under High Pressure Minkyung Han[1], Chunjing Jia[2], Yu Lin[2], Cheng Peng[2] and Feng Ke[2,1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Halide perovskites are promising solar cell materials due to their suitable bandgap range and high tunability. However, materials based on the organic-inorganic $(MA)PbI_3$ ($MA = CH_3NH_3^+$) suffer a chemical instability issue to heat and moisture due to the volatile MA cation, while the all-inorganic Cs-based analogs present a phase instability challenge where the functional perovskite phases are unstable at ambient conditions and spontaneously convert into the thermodynamically stable non-perovskite phase. Therefore, stabilizing the perovskite phases at the room condition is crucial to achieving higher efficiency and commercialization. Tuning the structure by applying pressure and strain is an effective way to modify the stability and electrical properties of perovskite phases. In this work, we investigate the leading structural features that determine the material properties of the perovskites upon compression. We use various machine learning models to train the large-scale dataset obtained from first-principles DFT calculations. This study will provide insights into developing general models to predict the relationship between structural and electrical properties of similar perovskite structures using cost-effective machine learning approaches.

11:00 AM DS03.05.03
Process Understanding of Scalable Perovskite Thin-Film Formation Through Unsupervised Machine Learning of *In Situ* Luminescence Data Felix Laufer[1], Sebastian Ziegler[2], Fabian Schackmar[1], Edwin A. Moreno Viteri[1], Markus Götz[1], Charlotte Debus[1], Fabian Isensee[2] and Ulrich W. Paetzold[1];

[1]Karlsruhe Institue of Technology, Germany; [2]German Cancer Research Center, Germany

High performance perovskite solar cells (PSCs) at laboratory scale show that hybrid metal-halide perovskite semiconductors are a promising absorber material class for the next generation thin-film solar cells. However, transferring the processes to scalable methods that enable large-scale processing remains a key challenge hindering the commercialization of the technology. To enable large-scale and high-throughput production of PSCs, the formation and morphology of perovskite thin-films fabricated by scalable deposition methods needs to be optimized. The perovskite formation process includes the entangled process phases of drying, nucleation and crystal growth, which are crucial for the quality of the perovskite thin-film and must be controlled to obtain thin-films of high optoelectronic quality. Consequently, scaling the technology is complex and demands enhanced understanding of the highly intricate formation process. To improve this understanding and the reproducibility of the scalable thin-film formation process, data-driven machine learning (ML) methods can be employed to accelerate research and process control of large-area perovskite thin-films. For this, a unique, labelled *in situ* photoluminescence (PL) dataset was generated. The dataset contains *in situ* PL data of more than 1,100 PSCs captured during the vacuum-assisted annealing of the blade-coated perovskite thin-films with an in-house-built imaging setup. To generate the ML-based in-line process monitoring dataset, all solar cells were fabricated at the exact same conditions, e.g. layer stack and precursor materials.
In this work, we present unsupervised ML for process understanding of perovskite thin-film formation by employing k-means clustering to our unique *in situ* PL dataset. We show the benefit of acquiring *in situ* PL data during the perovskite formation over *ex situ* PL data by demonstrating the correlation between expert-chosen *in situ* PL features and the power conversion efficiency (PCE) of the corresponding PSCs. Next, we show that k-means clustering creates *in situ* PL clusters that correlate with the performance of the final PSC without prior data encoding assumptions made by a human expert. The correlations display that the *in situ* PL data contains information about the quality of the perovskite thin-film and, consequently, about the performance of the solar cell. Furthermore, we identify detrimental process mechanisms during the formation of the perovskite thin-film using the data science approach. Next to the clusters' performance correlation, differences in the spatial distributions of PL data assigned to the different clusters are identified and reveal substrate areas with adverse thin-film properties. Finally, when applying the trained model to previously unseen data, we find that k-means clustering allows for reasonably good prediction of solar cell performance even though clustering is typically used mainly to explore datasets. In summary, we demonstrate that ML-based in-line processing monitoring of the formation of perovskite thin-films holds great potential and can accelerate the successful commercialization of perovskite thin-film PV.

How to Find What is Limiting Your Perovskite Solar Cell Using Bayesian Inference? Basita Das[1,2], Thomas Kirchartz[1,3] and Tonio Buonassisi[2]; [1]Forschungszentrum Jülich GmbH, Germany; [2]Massachusetts Institute of Technology, United States; [3]University of Duisburg-Essen, Germany

In a perovskite solar cell, the root cause for underperformance may originate from a large variety of different phenomena such as bulk or interface recombination, transport limitations in the contact layers or bad energy alignment at interfaces. Traditionally, discriminating between these mechanisms has been done by applying a variety of different characterization methods to the samples and then performing some data analysis that often involves fitting the data with analytical equations or numerical models. Such characterizing techniques can be time consuming and often destructive to the device. Furthermore, for the sake of simplicity and to allow fitting the data with a low number of unknowns, the models used for fitting and analyzing the data are often insufficiently complex to really capture all necessary physical phenomena that are relevant to understand the measurement. Ideally one can try to fit more complex device models to the characterization data, but the sheer number of parameters that usually goes into a device simulator, and the correlation between the parameters make the problem intractable. Also, such rudimentary parameter fitting usually gives just one set of parameters that fits the data reasonably well but does not tell us if that combination of parameters is unique or if there are any correlation between the parameters. Information on correlation between parameters is not only important from a device optimization point of view but can also teach us more about the underlying physics controlling the functionality of the device.
In this presentation, we introduce a fast non−destructive method of parameter estimation using Bayesian inference in combination with data current and photoluminescence-voltage measurements taken on perovskite solar cells. From the inferred parameters we identify which region or which layer in our device stack is limiting the performance of our device. Such information is useful to strategize device optimization for better performance.
Bayesian inference methods have been previously used in the field of solar cells for well-studied solar cell technologies like Si solar cells as well as for material systems like SnS solar cells where the number of unknown parameters is small [1–3]. In cases where the number of unknowns are few, parameter estimation using only temperature and illumination dependent current voltage *JVTi* curves yielded good results.
However, perovskite solar cells have many unknown parameters given it's an emerging PV technology and hence is not as well studied as already established technologies. Perovskite materials are usually intrinsic in nature such the both the electrons and holes matter for carrier transport and recombination and hence increases the number of parameters further. Also, the complex architecture of perovskite solar cell means one requires the knowledge of material parameters of not just the absorber layer but also of the different interfaces and transport layers to fully understand the cause of underperformance. In such scenarios, using only *JVTi* measurements might not be enough to estimate all the desired parameters. In this context we also introduce how combining data from a small number of relatively simple characterization techniques helps in better estimating unknown material parameters.
Also, the Bayesian inference code we developed and the methodology we will introduce is general in nature and can be applied for parameter estimation across fields with just domain expertise of the specific field.

Crystal Structure Prediction of Mixed-Halide Perovskites at Room Temperature Using Machine-Learning Potentials Changho Hong[1], Seungwu Han[1], Yong Youn[2] and Kanghoon Yim[2]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of)

Cesium lead halide perovskites ($CsPbI_3$) have attracted much attention as a potential candidate for an all-inorganic, high-efficiency solar cell. However, they suffer from short lifetimes because the perovskite phase is unstable at room temperature. To overcome this, recent experiments introduced another halogen element such as Br to stabilize the perovskite structure, which has lower power conversion efficiency than the pure phase. Several computational studies investigated the thermodynamic stability of mixed halides with density functional theory (DFT) calculations and confirmed that the mixing can enhance the stability. However, those computational studies are based on known prototype structures of $CsPbI_3$, which risks missing unknown phases in mixed-halide perovskites. The heuristic crystal structure prediction (CSP) based on DFT calculations would be necessary in this respect, but it is computationally too expensive to evaluate the energies of numerous candidates.
In this study, we conduct CSP in mixed-halide perovskites ($CsPbI_xBr_{3-x}$, $CsPbI_xCl_{3-x}$) with SPINNER, a recently developed in-house code for CSP using a neural network potential.[1] Using SPINNER, we can explore structures beyond prototypes, with computational costs far less than with the DFT-based approaches. As a result, we identify the most stable phases at 0 K for each stoichiometry. We also estimate the transition temperatures between phases by

calculating finite-temperature free energy. The computed transition temperatures of $CsPbI_xBr_{3-x}$ are consistent with experimental observations. In case of Cl, the results indicate that γ-phase with a smaller composition than Br is stable at room temperature. We also find that the predicted γ-phases with mixed-halide are expected to have good optical properties as in $CsPbI_3$ perovskites. We anticipate that the present findings can contribute to extending the lifespan of solar cells based on all-inorganic lead halide perovskites.

Autonomous Scanning Probe Microscopy—from Imaging to Learning Physics of Local Bias-Induced Transformations in Functional Materials
Sergei V. Kalinin; University of Tennessee, Knoxville, United States

Machine learning and artificial intelligence (ML/AI) are rapidly becoming an indispensable part of physics research, with domain applications ranging from theory and materials prediction to high-throughput data analysis. However, the constantly emerging question is how to match the correlative nature of classical ML with hypothesis-driven causal nature of physical sciences. In parallel, the recent successes in applying ML/AI methods for autonomous systems from robotics through self-driving cars to organic and inorganic synthesis are generating enthusiasm for the potential of these techniques to enable automated and autonomous experiment (AE) in imaging. Here, I will discuss recent progress in automated experiment in scanning probe microscopy, ranging from feature to physics discovery via active learning. The applications of classical deep learning methods in streaming image analysis are strongly affected by the out of distribution drift effects, and the approaches to minimize though are discussed. I will further illustrate transition from post-experiment data analysis to active learning process, including learning structure-property relationships and materials discovery in composition spread libraries. Here, the strategies based on simple Gaussian Processes often tend to produce sub-optimal results due to the lack of prior knowledge and very simplified (via learned kernel function) representation of spatial complexity of the system. Comparatively, deep kernel learning (DKL) and structured Gaussian Processes methods allow to realize both the exploration of complex systems towards the discovery of structure-property relationship, and enable automated experiment targeting physics (rather than simple spatial feature) discovery. The latter is illustrated via experimental discovery of ferroelectric domain dynamics in piezoresponse force microscopy. For probing physical mechanisms of tip-induced modifications, I will demonstrate the combination of the structured Gaussian process and reinforcement learning, the approach we refer to as hypothesis learning. Here, this approach is used to learn the domain growth laws on a fully autonomous microscope. The future potential of Bayesian active learning for autonomous microscopes is discussed.

2:00 PM *DS03.06.02
Reproducible Sorbent Materials Foundry for Carbon Capture at Scale Austin McDannald; National Institute of Standards and Technology, United States

Direct air capture (DAC) is an emerging technology aiming to mitigate climate change by adsorbing CO2 from ambient air for subsequent use or sequestration. There is a dire need to improve the performance of DAC facilities, as measured by metrics including CO2 captured per unit energy. This work presents our vision and current progress towards an autonomous sorbent materials foundry for rapidly evaluating materials for DAC. Our initial work focused on machine learning models predicting CO2 uptake from the sorbent material structure. However, CO2 uptake alone is not enough to evaluate the fitness of a sorbent for DAC. We subsequently develop more holistic performance metrics for DAC sorbents based on the mixed-gas sorption behavior. For example, knowing the mixed-gas sorption behavior and an choosing a refresh cycle it is possible to calculate intrinsic amount of CO2 captured per unit energy for the sorbent material. We show how this work fits into a hierarchical framework of autonomous systems accelerating the development of DAC.

2:30 PM *DS03.06.03
Humans and Research Robots: Autonomous Experimentation for Materials Science Benji Maruyama; AFRL/RXA, United States

Autonomous Experimentation is changing the way we do research. We explore the role of human researchers and their partnership with Robot Researchers in the fast-growing area. From job security to job satisfaction to workforce development, there are significant questions and opportunities that arise from the autonomous experimentation movement.
The current materials research process is slow and expensive, taking decades from invention to commercialization. The Air Force Research Laboratory pioneered ARES™, the first autonomous research system for materials development. A rapidly growing number of researchers are now exploiting advances in artificial intelligence (AI), autonomy & robotics, along with modeling and simulation to create research robots capable of doing iterative experimentation orders of magnitude faster than today. Far from displacing human researchers, we expect Autonomous Experimentation to free human researchers to do the “fun,” creative & insightful part of research.

In the future, we expect autonomous experimentation to revolutionize the research process, and propose a “Moore’s Law for the Speed of Research,” where the rate of advancement increases exponentially, and the cost of research drops exponentially. We also consider a renaissance in “Citizen Science” where access to online research robots makes science widely available.

3:30 PM *DS01.06.04
Hierarchical Bayesian Data Analysis for Challenging Structural Materials Characterization Problems Brian L. DeCost; National Institute of Standards and Technology, United States

Automated quantitative analysis for structural materials characterization is a challenging task primarily because of the difficulty of physical model specification and optimization. However, potential development of robust online automated quantitative analysis would significantly expand the scope and impact of autonomous platforms for materials development.

Our approach of hierarchical Bayesian analysis of high throughput structural characterization data blurs the lines between machine learning based approaches and conventional nonlinear least squares analysis. This approach allows models to pool information across related samples, and also allows

integration of flexible non-parametric models such as Gaussian Process priors to model functional dependencies between parameters.

We demonstrate how this modeling strategy can provide higher sensitivity for analysis of minority or trace phases in challenging high throughput X-ray diffraction (XRD) data. We will also show how to apply Bayesian modeling workflow to extended X-ray absorption fine structure (EXAFS), a spectroscopic technique that provides insight into local structural and chemistry.

Finally, we will discuss the current limitations of the hierarchical Bayesian modeling approach, and how it may be complemented by other contemporary machine learning based methods.

4:00 PM *DS03.06.05
Autonomous Combinatorial Experimentation Ichiro Takeuchi; University of Maryland, United States

We are incorporating active learning in screening of combinatorial libraries of functional materials. The array format with which samples of different compositions are laid out on combinatorial libraries is particularly conducive to active learning driven autonomous experimentation. For some physical properties, each characterization/measurement requires time/resources long/large enough that true "high"-throughput measurement is not possible. Examples include detection of martensitic transformation and superconducting transitions in thin film libraries. By incorporating active learning into the protocol of combinatorial characterization, we can streamline the measurement and the analysis process substantially. We will discuss some of our latest efforts including real-time autonomous experiment-theory interaction for closed-loop mapping of thin film phase diagrams, and multi-instrument autonomous characterization of library wafers where two different physical properties are simultaneously mapped. Our effort in developing synthesis – measurement closed loops on a combinatorial thin film platform will also be discussed. This work is performed in collaboration with A. Gilad Kusne, H. Liang, A. McDannald, H. Yu, C.-H. Lee, and M. Lippmaa. This work is funded by SRC, ONR, AFOSR, and NIST.

DS03.07.01
DCGANs-Based SOFC Synthetic Image Generation Method Wonjun Lee[1], Sunjong Bong[1], Tae Ho Shin[2] and Suyoung Chi[3]; [1]University of Science and Technology, Korea (the Republic of); [2]Korean Institute of Ceramic Engineering and Technology, Korea (the Republic of); [3]Electronics and Telecommunications Research Institute, Korea (the Republic of)

Solid Oxide Fuel Cell(SOFC) is attracting attention as a next-generation fuel cell for its eco-friendliness and efficiency. However, surface defects may occur during manufacturing, leading to poor quality and material failure. Deep learning has recently become widespread in research and has been implemented in various applications, including surface defect inspection using computer vision. Though, images that show surface defects are limited, making the dataset class imbalanced, and it becomes problematic. Therefore, we propose a method for generating synthetic data based on Deep Convolutional Generative Adversarial Networks(DCGANs) to solve the limited data problem, train with deep learning, and evaluate it.

DS03.07.02
Inverse Design of $BaTiO_3$'s Synthetic Condition via Machine Learning Minjeong Gong[1], Dong-Hwa Seo[1], Young Seog Yoon[2], Hyun-woo Oh[2], Suyoung Chi[2], Seong Hyeok Choi[3], HyeonJin Jeong[3], Moonhee Choi[3] and Sung Beom Cho[3]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Electronics and Telecommunications Research Institute, Moldova (the Republic of); [3]Korea Institute of Ceramic Engineering & Technology, Korea (the Republic of)

Due to its high permittivity, barium titanate ($BaTiO_3$) has attracted attention as a dielectric material for electronic devices. However, the dielectric properties of $BaTiO_3$ are highly affected by factors such as tetragonality, particle size, impurities, and density. Because these dielectric properties are affected by synthetic conditions, optimizing the synthetic process is required to produce $BaTiO_3$ with high permittivity and low dielectric loss. Solid-state reaction is attracting attention among synthesis methods because it allows low-cost mass manufactures by using advance technologies for atomization and dispersion of barium carbonate ($BaCO_3$) and titanium oxide (TiO_2) precursors. However, it is challenging for them to optimize the synthetic processes for targeted permittivity and dielectric loss by a trial-and-error experimental approach due to the large number of combinations of synthetic conditions such as synthetic variables and precursor types affecting their properties. This work suggests a machine learning (ML) approach to find suitable synthesis conditions for achieving target properties of $BaTiO_3$. We first carried out 370 experiments to synthesize $BaTiO_3$ using solid-state reactions with various $BaCO_3$ and TiO_2 precursors of varying purity, particle size, and specific surface area, as well as various synthetic variables for wet mixing, calcination, and sintering, and measured density, permittivity, and dielectric loss. And then, the correlation analysis is performed to figure out the relationship between the synthetic conditions and dielectric properties of $BaTiO_3$ such as the density, permittivity, and dielectric loss. We discovered that density is highly related with sintering temperature, while permittivity and dielectric loss are correlated with total impurity concentration in $BaCO_3$. We conduct regression and classification analyses by three models (Random Forest, Gradient Boost and XG Boost) with independent variables as synthetic conditions and dependent variables as dielectric properties. With excellent accuracy, our ML models can predict dielectric properties from synthetic conditions. After then, the ML models predict all possible synthetic conditions. Based on predicted values, synthetic conditions that satisfied target properties are sorted and we call these processes as inverse design. From additionally conducted experiments with ML-guided synthetic conditions, this inverse design based on our ML models allows us to achieve target dielectric properties of $BaTiO_3$ (density, permittivity, dielectric loss).

DS03.07.03
Development of an Open-Source Adsorption Model for Direct Air Capture Thomas Sadowski[1,2], Mit Patel[1,2], Jeffery G. Weissman[3] and Christine Broadbridge[1,2]; [1]Southern Connecticut State University, United States; [2]CSCU Center for Nanotechnology, United States; [3]Precision Combustion Inc., United States

The continued increase in global energy demand has made it clear the aggressive net-zero targets suggested by the IPCC cannot be attained through conversion to renewables alone. Negative emission technologies such as direct air capture (DAC), are required to remove legacy CO_2 directly from the atmosphere and reduce concentrations back to preindustrial levels. The active element in DAC is a sorbent material that selectively removes CO_2 from the

air stream; however, low atmospheric CO_2 levels severely limit the choice of materials. Physisorbent solids possess the potential to overcome these limitations but can be costly to produce and evaluate, possibly limiting their discovery through traditional trial-and-error physical experimentation and observation. Computational modeling offers a cost-effective alternative approach to rapidly test the efficacy of solid sorbents towards DAC and create optimized models for carbon capture and recovery in an industrial setting. Though such software is commercially available, it can be prohibitively expensive and lacks the ability to model solid-vapor interactions. Hence, there is an acute need to overcome these obstacles to accelerated DAC research efforts. In this study, a computational model was developed to simulate the dynamic adsorption of CO_2 using open-source software supplemented with user-generated code written in Python and implemented as a custom unit operation in the chemical process simulator, DWSIM. To test the accuracy of this model, breakout curves and adsorption isotherms were calculated for activated carbon and compared to experiment, agreeing to within 5%. This framework will provide the basis for a future multivariate sensitivity analysis study to determine the energy duty required for a target sorbent to capture and release a product CO_2 stream with purity from 80 to 98%.

DS03.07.04
High-Throughput Discovery of High-Entropy Alloys Nanocatalysts via Active Learning Approach Zhichu Ren, Ali Abdelhafiz and Zhen Zhang; Massachusetts Institute of Technology, United States

Research solutions aiming to replace existing hydrocarbon fuel technologies with green energy sources have so far been only partially successful. Proton Exchange Membrane Fuel Cells is a very promising candidate for its light weight and high energy density, while its performance and durability are limited by the catalysts used in the cell electrode. Recent studies show that synergistic effects of multiple metals alloyed together yield a material that is even better than noble metal catalysts. Yet, such a very well controlled and precise synthesis of more than tri-metallic nanoparticles is extremely challenging by conventional synthesis techniques at normal/ambient conditions, which are dictated by thermodynamics rules. Ultrafast Joule heating technique is a promising tool to leverage kinetic rules to form meta-stable high entropy alloys by heating and cooling samples within one second. This extreme fast process makes it practical to make the workflow in a high-throughput manner.

The high throughput system consists of a liquid handler, a carbothermal shock setup, and a robotic testing platform. The liquid handling robot allows us to precisely control the composition of each sample, specifically, the ratio between each metal precursor solution. Carbothermal shock is enabled by conducting a large current to a precursor loaded carbon substrate, which can reach above 2000K within hundreds of milliseconds. Once the carbon strips are prepared with the shocking method, a rapid evaluation will be conducted, also in a high-throughput manner. Samples will be cut into pieces and loaded onto testing holders, then a robotic arm will handle sample loading and unloading to the electrocatalytic testing beaker. Testing software is automated using python scripts, as well as data extraction and SQL storage process. The ending step is to run an active learning step, which can analyze the dataset using Bayesian Optimization to generate the suggestion for the next batch of recipes, based on the surrogate model fitted by the Gaussian Process. The newly suggested task will be sent to the liquid handler, forming a closed-feedback optimization loop. Such a high-throughput and autonomous optimization system will greatly enhance the efficiency of finding new high entropy alloy recipes for electrocatalyst application.

DS03.07.05
Trend Analysis and Insight Extractions Using Named Entity Recognition of CO_2RR Literature Jiwoo Choi[1,2], Kihoon Bang[1], Suji Jang[1], Kwang-Ryeol Lee[1], Sang Soo Han[1] and Donghun Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

In recent years, big data and artificial intelligence have penetrated materials science research. Currently, most openly available material databases use results derived from computer simulations and not from experiments. Some examples of materials research projects include the Materials Project, Novel Materials Discovery (NOMAD), and Open Quantum Materials Database (OQMD). Unfortunately, it is still difficult to build a large-scale experimental materials database. In this context, the scientific literature is one of the underutilized potential data sources because it contains well-organized experimental data that is easily accessible. An intensive study of natural language processing (NLP) of a huge volume of literature in materials science is required. Data can be automatically extracted from literature using NLP.
Among various research topics in materials science, CO_2 reduction reaction (CO_2RR) catalysis would be an interesting topic to apply NLP. CO_2RR catalysis, a conversion process from carbon dioxides into valuable compounds, would alleviate today's energy crises and environmental problems. Although a large volume of CO_2RR studies have been performed, however the experimental databases have not yet been built. We aim to build a large scale experimental databases using a variety of NLP techniques, and also aim to utilize them to extract research trends or insights, which would benefit the relevant research community.
In this work, we collected papers related to CO_2RR and conducted a study to extract key entities from the papers based on named entity recognition (NER). We provide a universal method to crawl and screen papers of user's interest (in this example, CO_2 electrochemical reduction research) and excluding noise papers using a combination of Doc2Vec and the Latent Dirichlet Allocation (LDA) model: As a result, we collected approximately 4,800 papers. Then, we developed NER models based on long short term memory (LSTM) or bidirectional encoder representations from transformer (BERT). These models were applied to the abstracts of the collected papers so that ten key entities regarding material names (catalyst, electrolyte etc.) and catalytic performances (Faradaic efficiency, current density etc.) are extracted. The average f1-score of MatBERT-based approach is over 85%, greatly exceeding that of LSTM-based approach, indicating the context-inclusive approach is necessary. Additionally, we also investigated over various BERT models, from BERT_base, SciBERT, MatSciBERT, and MatBERT) and their performance comparisons tell that the more domain knowledge is reflected in BERT model, the better the performance we achieve. Lastly, the trend and knowledge extracted from the NER studies in the CO_2RR research field will be discussed.

DS03.07.06
DenseSSD—A Computer Vision Model for Vial-Positioning Detection to Improve Safety in Autonomous Laboratory Leslie Ching Ow Tiong[1], Hyuk Jun Yoo[1,2], Na Yeon Kim[1,2], Kwan-Young Lee[2], Sang Soo Han[1] and Donghun Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Robot-based automation methods for material synthesis have recently garnered much attention because they can substantially accelerate the material development process. Some recent examples were reported, which involves organic or inorganic material synthesis in energy applications (catalysis and photovoltaics) [1-3]. Despite the substantial promise of these methods, surveillance-free environments may lead to dangerous accidents primarily due to hardware control errors. Object detection techniques can play important roles in addressing these safety issues; however, state-of-the-art detectors, including single-shot detector (SSD) models, suffer from insufficient accuracy in environments involving complex and noisy scenes due to uneven visual environments. With the purpose of improving safety in a surveillance-free laboratory, we developed the deep learning (DL)-based object detector, namely, densely connected single-shot detector (DenseSSD) with a densely connected mechanism. For the foremost and frequent problem of detecting vial positions, DenseSSD achieved a mean average precision (mAP) over 95% based on a complex dataset involving both empty and solution-filled vials, greatly exceeding those of conventional detectors; such high precision is critical to minimizing failure-induced accidents. Additionally, DenseSSD was observed to be highly insensitive to the environmental changes, maintaining its high precision under the variations of solution colors or testing view angles. The roughness of DenseSSD would allow the utilized vision module settings to be more flexible. This study verified that DenseSSD is practical for

enhancing safety in an automated material synthesis environment, and it can be extended to diverse applications where high detection accuracy and speed are both needed.

DS03.07.07
Autonomous Laboratory for Bespoke Synthesis of Nanoparticles Using Parallelized Bayesian Optimization Hyuk Jun Yoo[1,2], Na Yeon Kim[1,2], Leslie Ching Ow Tiong[1], Hee Seung Lee[1], Kwan-Young Lee[2], Donghun Kim[1] and Sang Soo Han[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Autonomous laboratories based on robotics and artificial intelligence (AI) has been recently conducted widely for accelerated search of materials. On the other hand, an inverse design that suggest specific synthesis conditions to achieve various target properties is required for bespoke synthesis of materials. However, because the inverse design needs to solve questions in a high-dimensional parameter space, it is greatly complex, so that researchers need to perform enormous numbers of experiments for the inverse design to find the optimal synthesis condition. It is very difficult to predict the next synthesis condition by understanding the correlations between experimental data via human intelligence. Usually, material properties have been individually explored with a single Bayesian optimization (B.O.) model in recent autonomous laboratories; likely leading to successive problems caused by a number of experiments and a lot of physical time although it is more efficient than the high-throughput screening (HTS) process. The conventional B.O. does not share experimental data simultaneously during the entire optimization process. In other words, the inverse design for bespoke synthesis of materials must be performed in parallel for the B.O. models while sharing experimental data in the single variable space. This parallelization allows to accumulate experimental results in the same parameter space without redundant experiment conditions. We tried to optimize the synthesis of silver nanoparticle (Ag NPs) to demonstrate the efficiency of parallelized B.O., in which a home-made automatic apparatus was used for synthesis of Ag NPs. Our automatic synthesis system and B.O. model were used to identify the optimal synthesis condition for various combinations of optical target properties (e.g., λ_{max}, full width half maximum, intensity, etc.) at the same time. Then, we compared the efficiency of HTS, conventional B.O., and parallelized B.O. with increasing the numbers of input synthesis variables and target properties. Our work provides a strong potential to solve the high-dimensional space issue for bespoke design of materials via an autonomous laboratory. In addition, our demonstration of autonomous nanoparticle synthesis will be useful in energy applications such as catalysis, photovoltaics which are made up of nanoparticles.

DS03.07.08
Machine Learning Based Investigation of Optimal Synthesis Parameters for Epitaxially Grown III–Nitride Semiconductors Andrew S. Messecar, Steven Durbin and Robert Makin; Western Michigan University, United States

Materials informatics has demonstrated immense utility in the design and development of synthesis routes for a wide spectrum of materials, ranging from aluminum alloys for additive manufacturing to lead titanate used in aqueous photocathodes for dye-sensitized solar cells. One synthesis route that can benefit greatly from a materials informatics approach is molecular beam epitaxy (MBE). Molecular beam epitaxy offers purity and control in the synthesis of thin-film materials and devices, but its high purity source materials and ultra–high vacuum environment can make finding the optimal growth conditions for a given material costly and time-intensive. A materials informatics approach to MBE can aid in the determination of the optimal synthesis parameters and help reduce the number of runs needed to achieve high quality samples. Recently, machine learning has been used to assist the design of perovskite oxides to be synthesized via molecular beam epitaxy as well as superconducting titanium nitride. Here, we report on initial results that build upon these reported studies by applying statistical learning to plasma–assisted molecular beam epitaxy (PAMBE) growth data to investigate optimal synthesis parameters of PAMBE-grown nitride thin films.

Utilizing the detailed records of over 600 PAMBE nitride thin films grown in a single Perkin-Elmer 430 system, key synthesis parameters such as substrate temperature, substrate lattice mismatch, growth duration, and RF power applied to the plasma source, are associated with the resulting crystallinity (single crystalline, polycrystalline, or amorphous) of the sample as determined by analyzing in-situ acquired reflection high-energy electron diffraction (RHEED) images. Taking the set of synthesis parameters as the predictors and the crystallinity as the categorical response, machine learning algorithms for classification and inference have been implemented to uncover insights regarding the relationship between synthesis parameters and the quality of the PAMBE–synthesized film. Algorithms were implemented using the R open-source programming language, specifically including the “tree”, “rpart” and “randomForest” packages.

The initial results indicate that the temperature of the Knudsen cell with the cation (gallium or indium) source material was the most significant predictor in whether an epitaxial film developed to be single crystalline, which is consistent with conventional wisdom regarding the importance of growing under metal-rich conditions. The complete data set was also divided into separate, focused data sets for gallium nitride and indium nitride, on which a random forest, classification tree and logistical regression were modeled. For gallium nitride films, agreement was found between the results of the classification tree and the random forest, which both found the gallium Knudsen cell temperature to have the greatest impact on the sample's crystallinity, followed by substrate temperature and initial nitrogen pressure. For indium nitride, the logistical regression and random forest model both indicated that the greatest impact on sample crystallinity was the initial nitrogen pressure, followed by substrate temperature and the forward power on the RF plasma source.

These initial results identify key synthesis parameters for obtaining single crystalline nitride thin films, however the differing results among the various statistical algorithms points to an underlying complexity that is not fully captured by these approaches. These results are helping to inform the development of a neural network architecture to be used in predicting crystallinity of PAMBE grown nitride semiconductors based on provided synthesis parameters, while the size of the data set is also being increased by incorporating synthesis and crystallinity data from the literature.

This work was supported in part by the National Science Foundation (grant number DMR-2003581).

DS03.07.09
Towards an Autonomous Combinatorial Co-Sputtering Reactor Davi M. Febba[1], John Mangum[1], Rebecca Smaha[1], Julian Calder[1], Sage Bauers[1], Kendal Johnson[1], Kevin Talley[2] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory (NREL), United States; [2]Qorvo, Inc., United States

Computational databases can predict novel and promising materials, but those that can be synthesized and subjected to characterization face the challenge of reproducibility. For example, tin-based oxynitride ferroelectric perovskites with band gap in visible, or zinc-based oxynitrides wurtzites with perfect short-range order, have been computationally proposed. However, the oxygen to nitrogen ratio required for these promising properties, such as long-term stability and semiconductor-like charge transport, is difficult to achieve and reproduce.
To answer the question of how to reproducibly synthesize promising computationally predicted materials, a custom-designed co-sputtering reactor “combi-

9” was recently designed and built at NREL. Equipped with four cathodes, this ultra-high vacuum instrument allows the exploration of a wide substrate temperature range, from cryogenic temperatures up to 1000 °C, besides RF and DC substrate biasing. Additional capabilities include real-time deposition data logging of sputtering parameters (such as power, voltage, pressure, gas flow), control of gas distribution to individual targets, time-sequenced shutters, and turbo gate position, all of which enable the user to execute complex programmable synthesis recipes.
However, this automated instrument still requires an expensive and time-consuming trial-and-error approach for synthesis and optimization of novel materials, since the researcher oversees all the sputtering parameters of an experimental campaign to obtain a specific material composition or properties. Therefore, to allow reproducible synthesis of promising materials with minimal human intervention, we are transforming this *automated* instrument into an *autonomous* one, in which a Bayesian algorithm has full control of all sputtering variables, (e.g., plasma powers, gas pressure, substrate temperature, etc.). This algorithm is informed about the process environment by in-situ spectral measurement tools, with the objective to learn how to control the chemical composition of the film, especially it’s mixed-anion content, during the deposition process.
This presentation will describe this state-of-the-art automated sputtering instrument and discuss our progress towards turning it into an autonomous sputtering reactor, such as estimating film composition from in-situ spectral data, integration among many software platforms, data logging and integration with databases.

DS03.07.10
A Robust Neural Network for Extracting Dynamics from Time-Resolved Electrostatic Force Microscopy Data Madeleine Breshears, Rajiv Giridharagopal, Justin Pothoof and David Ginger; University of Washington, United States

Advances in scanning probe microscopy (SPM) methods such as time-resolved electrostatic force microscopy (trEFM) now permit the mapping of fast local dynamic processes with high resolution in both space and time, but such methods can be time consuming to analyze and calibrate. Here, we design and train a regression neural network (NN) that accelerates and simplifies the extraction of local dynamics from SPM data directly in a cantilever-independent manner, allowing the network to process data taken with different cantilevers. We validate the NN’s ability to recover local dynamics with a fidelity equal to or surpassing conventional, more time-consuming calibrations using both simulated and real microscopy data. We apply this method to extract accurate photoinduced carrier dynamics on *n*=1 butylammonium lead iodide, a halide perovskite semiconductor film that is of interest for applications in both solar photovoltaics and quantum light sources. NN extracted dynamics from trEFM measurements confirm previous observations of charging rate heterogeneity across microstructures in the perovskite. Finally, we use SHapley Additive exPlanations (SHAP) to evaluate the robustness of the trained model, confirm its cantilever-independence, and explore which parts of the trEFM signal are important to the network.

DS03.07.11
Deep Learning Models for Predicting the Experimental HOMO and LUMO Orbital Energies Minseok Jeong, Joonyoung Joung, Minhi Han and Sungnam Park; Korea University, Korea (the Republic of)

The highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) energies are fundamental properties of molecules. Accurate predictions of the HOMO and LUMO energies of newly-designed molecules are crucial for the efficient development optoelectronic materials in many research areas such as organic light emitting diodes and organic photovoltaics. Here, we developed a deep learning model to accurately predict the HOMO and LUMO energies of organic molecules based on an experimental database which contains the experimental HOMO and LUMO energies of molecules in solutions, solid states, and the gas phases. Our deep learning model includes the molecule-environment interaction that influences the HOMO and LUMO energies. Our deep learning model based on the experimental database is found to predict the HOMO and LUMO energies within the mean squared error of 0.058 eV. The details and performance of our deep learning model will be presented. In addition, we will demonstrate that our deep learning model can be efficiently used to develop new optoelectronic materials.

DS03.07.12
Development of Machine-Learning Force Fields for Simulating Interfaces in Solid-State Batteries Kwangnam Kim[1], Aniruddha dive[1], Andrew Grieder[2,1,3], Nicole Adelstein[3,1], ShinYoung Kang[1], Liwen Wan[1] and Brandon Wood[1]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Santa Cruz, United States; [3]San Francisco State University, United States

There are increasing interests in using machine-learning force fields (MLFFs) in molecular dynamics (MD) simulations to explore local structure and chemistry at complex interfaces that governs the performance of energy storage devices. A number of methodologies has been developed to train MLFFs using ML algorithms (e.g., artificial neural network) and input features that describe local atomic environments. The training data are often collected from highly accurate ab-initio simulation and therefore the trained and validated ML potentials are capable of performing simulations with quantum-level accuracy while achieving thousands of times faster computational speed than ab-initio calculations. In this talk, we will discuss our recent development of MLFFs based on artificial neural network[1,2] to study ion transport kinetics and structural and chemical features at disordered interfaces between garnet-type LLZO solid-electrolyte and cobalt-oxide LCO cathode. The training data was collected from AIMD simulations at a wide range of temperatures and the MLFF is able to predict atomic forces for LLZO, LCO, and the interfaces between them with a DFT level of accuracy. The predicted radial distribution functions, vibrational characteristics of atoms, and ion diffusivities in each system show excellent agreement with those calculated by ab-initio simulations. Also, we will briefly illustrate how the ML force field can be applied to investigate interdiffusion of ions and chemical degradation at the interfaces.

Finite Element Simulation of Resistive Memory Using Fully Coupled Electrothermal and Phase-Field Models Dongmyung Jung and Kwon Yongwoo; Hongik University, Korea (the Republic of)

Along with phase change memory, resistive memory that utilizes transition metal oxide as switching material can serve as a synapse device in neuromorphic computing systems thanks to its multilevel resistances. In filamentary switching by valence change mechanism, anion vacancies play an important role. When a high electric field is applied inside the insulator, anion vacancies are created and aggregate inside the insulator to form conductive filaments. In existing papers where the finite element analysis of the filament switching was presented, the initial state was the low-resistance state with a

predefined or “assumed” filament shape. Therefore, the forming behavior cannot be predicted for different cell geometry and materials. In this work, we demonstrate our simulation that can predict a full switching cycle of forming, reset, and set operations. The switching material is regarded as a mixture of two phases: high-resistance state (HRS) and low-resistance state (LRS). This mixture is expressed as an order parameter that has 0 and 1 in HRS and LRS phases, respectively. In forming and set operations, new LRS phases are generated, or existing LRS phases are migrated and connected. In reset operation, connected LRS phases are disconnected by dissolution or migration. All these switching behaviors are regarded as the change of the order parameter. At each time step, electrothermal equations are solved to obtain electric field and temperature distributions that determines the driving forces for LRS phase behaviors such as migration, generation, and dissolution. Then, a phase-field equation that is the Cahn-Hilliard equation with migration, sink, and source terms for the LRS phase is solved. Using our simulation, we can reproduce full-cycle current-voltage curves for both unipolar and bipolar switching. We believe that our simulation can serve as an effective tool for the design of cell architecture

Supporting Material Synthesis via Research Data Management, Data Mining from Literature and Machine Learning—Metal-Organic Frameworks as Use-Case Manuel Tsotsalas and Christof Wöll; KIT, Germany

In this conference contribution we will present how Metal-Organic Framework (MOF) synthesis data can be managed, sored, and automatically extracted from literature. In addition, we will show how this synthesis data can be used to support researchers from the field of MOF synthesis via synthesis prediction tools. [1]
The contribution will cover the four aspects (I) electronic lab notebooks (ELN), (II) repositories and archives for material synthesis, (III) automatic data mining using natural language processing (NLP), and (IV) machine learning (ML) to identify patterns from the extracted synthesis data.
In the aspects (I) and (II) we will focus on research data management tools developed / under development by the German National Research Data Infrastructure initiative (NFDI) with a focus on NFDI*4*Chem and FAIRmat. In this context we will introduce the ELN Chemotion and the Repository and Archive NOMAD and demonstrate how these tools can be implemented in MOF synthesis.

Bayesian Optimization of a Scalable Coating Process Using a Self-Driving Laboratory Connor Rupnow, Ben MacLeod, Mehrdad Mokhtari and Curtis Berlinguette; The University of British Columbia, Canada

The commercialization of energy materials can take decades, in part due to the challenge of scaling-up laboratory synthesis techniques for manufacturing. For example, perovskite solar cells were discovered in 2009, but are not yet commercially available. Scaling-up the solution-based fabrication process is widely cited as the major reason for this. To address this challenge, we have designed and built a self-driving laboratory, “Ada”, for autonomously optimizing ultrasonic spray-coating, a scalable coating process. We used this self-driving laboratory to maximize the conductivity of a spray-combustion synthesized Pd coating by optimizing seven experimental variables under the control of a Bayesian optimization algorithm. This optimization yielded coatings with conductivities twice the previous state-of-the-art for spray-combustion synthesis. The best coatings deposited using our vacuum-free process exhibit conductivities comparable to vacuum-sputtered coatings and are directly scalable to larger area substrates with no loss in conductivity. This work shows how self-driving laboratories can contribute to accelerated commercialization of energy materials by rapidly optimizing scalable coating processes.

Data-Driven Prediction of Interphase Reactions for Energy Storage Applications Kristin A. Persson; University of California, Berkeley, United States

Despite decades of work, there is considerable uncertainty regarding the major components of the solid-electrolyte interface (SEI) and its dynamic formation mechanism as a function of electrolyte and anode chemical and structural composition. Here we present a new data-driven first-principles framework using a combination of high-throughput calculations, reaction networks, machine learning and microkinetic modeling. Our automated methodology is based on a systematic generation of relevant species using a general fragmentation/recombination procedure which provides the basis for a vast thermodynamic reaction landscape, calculated with density functional theory. We explore this landscape using stochastic methods and shortest pathfinding algorithms, which yield the most likely reaction pathways which are then refined with transition state calculations and kinetic information. The results of the framework show promise in being able to automatically recover previous insights on single reaction pathways, as well as successfully predicting the early dynamics and competitive nature of the SEI formation. As examples, we present formation mechanisms of major SEI-forming molecules and recover the Peled-like separation of the SEI into inorganic and organic domains resulting from rich reactive competition.

8:30 AM DS03.08.03
Design Flow in Stabilizing Oxygen Redox for Na Layered Oxides—DFT-Assisted Machine Learning Sojung Koo; Kyung Hee University, Korea (the Republic of)

As the demand of electric vehicles grows tremendously for green and sustainable energy environments, the family of Li- and Na-based materials (LIBs and SIBs) have been urged to move toward next generation with remarkable capacities. In particular, Li excess cathode materials exhibit excellent capacity and high potential (>4 V versus Li^+/Li) resulting from not solely by transition metal (TM) redox, and thus anionic redox is necessary for the extra charges beyond TM redox during Li^+ (de)intercalation. The high voltage redox which gives excess capacities originates from the oxygen 2*p* lone pair states in Li^+–O(2*p*)–Li^+ configurations. However, there are serious issues such as the poor cycling stability of anionic redox processes, voltage hysteresis and voltage

fade as a result of the irreversible local structural transformation or lattice oxygen loss. For P2-type $Na_{0.6}[Li_{0.2}Mn_{0.8}]O_2$ (NLMO), these issues in Li-excess materials have been mitigated as promoted stable electron holes on O^{2-} and showed intriguing reversible oxygen redox with the nonhysteretic voltage for SIBs. This has driven comprehensive explorations of Na-based compounds in spite of its less attention than Li-based materials, in view of the prevention of dimerized oxygen gas-release accompanied by structural distortion. Additionally, Al^{3+} incorporated NLMO (Al-NLMO) exhibits significantly improved reversibility of anion redox as well as maintains nonhysteretic voltage behaviors by stabilization of the oxide framework upon cycling. Extending the voltage range to the high voltage region with extra oxidation of oxygen species leads to an easier oxygen mobility, de-coordination of oxygen from the crystal network, and eventually to vacancies at the neighboring cation sites which drive cation disorder and defects in cathodes. Therefore, the stability or reversibility of oxygen redox is correlated closely with the atomic structure or the local oxygen coordination environment, as elaborated by chemical state of redox-active oxygen showed the isolated Na–O–Li or Li–O–Li O-2*p* configuration. In terms of this, although cation doping strategies have offered alternative and similarly promising approach toward reversible high energy density materials, the more systematic and comprehensive study could be required to explore crystal structures and atomic configurations compatible with oxygen redox reaction in Li excess system.
Theoretical and computational understandings have been powerful in understanding the structural changes in Li-based compounds. Machine-learning potentials have attracted considerable attention because they can provide close to DFT-accurate energies at a fraction of cost, which finds applications to structure prediction of crystals. In this work, first principles calculations and machine learning techniques were adopted to evaluate the oxygen redox behavior of various cation ordering with $NaMnO_2$, NLMO and Al-NLMO. First, we propose a probabilistic model assessing the energetically favorable neighboring cation sites for each Li and Al atoms while retaining the crystal structure. Second, the oxygen species formation at the highly charged state of the NLMO and Al-NLMO models, constructed to represent Li-excess and cation-doped, respectively, were evaluated in detail. In addition to the discussion of cation ordering and oxide framework based on atomic-and electronic-level considerations, comprehensive data-driven verification of the structure and thermodynamic energetics with several junction patterns is described. The verification results suggest that the oxygen release from TM intralayer is hindered by Al^{3+}-incorporation with α-Li/Mn ordering, indicating the effectiveness of inactive as a doping element. Via multiple physicochemical and theoretical characterizations, we identify the presence of tailored oxygen species bonds and peculiar morphological structures as the main factors responsible for the improved electrochemical performances of Na layered oxides.

Machine Learning-Aided Strategy to Discover Intermetallic Catalysts for the Hydrogen Evolution and the Oxygen Reduction Reactions Carmen Martínez[1,2], José Manuel Guevara[1] and Javier Llorca[1,3]; [1]IMDEA Materials Institute, Spain; [2]Universidad Complutense de Madrid, Spain; [3]Universidad Politécnica de Madrid, Spain

The efficiency and rate of hydrogen generating by water splitting are determined by the Hydrogen Evolution Reaction (HER). Similarly, the production of energy from hydrogen in fuel cells by the oxidation of hydrogen into water is limited by the Oxygen Reduction Reaction (ORR). The sluggish kinetics of both reactions are usually improved by using platinum-based catalysts. However, the high cost of Platinum hinders the application of this technology and, at the same time, drives the search for efficient and affordable materials to replace it. Theoretical approaches to predict the catalytic activity of new materials are based on the calculation of the adsorption energies of the intermediate species (-H, O, and OH-) for both the HER and the ORR using Density Functional Theory (DFT) simulations. This strategy has been successfully applied to determine the catalytic activity of late transition metals for both HER and ORR, including the influence of the application of elastic strains in the catalytic performance [1,2].

The extension of this strategy to look for new catalysts based on intermetallic compounds is limited by the dimensions of the chemical space as well as by the computational cost of DFT calculations. Machine learning-based approaches can be used to overcome these limitations, and this is the objective of this talk. Thus, DFT simulations were used to determine the adsorption energies of the intermediate species (-H, O, and OH-) for the HER and ORR in 13 transition metals (Pt, Pd, Ni, Au, Ag, Zn, Cd, Rh, Ir, Ru, Os, Co, and Cu) and around 200 intermetallic compounds with AB and A3B stoichiometries and fcc, bcc, and hcp structures. These intermetallic compounds were among those non-toxic, non-radioactive, stable, and environmentally friendly from the Materials Project database. In addition, the effect of elastic strains was assessed in a subset of the intermetallic compounds, which showed the best catalytic performance. This information was used to train a Decision Tree Regression model using geometrical and electronic descriptors, such as the area of the adsorption hole, the applied strain, and the first ionization energy of the catalyst. This model was used to screen the large chemical space of binary intermetallic compounds at a very low computational cost, thus paving the way for the discovery of affordable catalysts for the HER and ORR.

First-Principles-Informed Machine Learning Study of Defects on the Lithium Metal Surface Hao Yu, Sahar Sharifzadeh, Emily Ryan, Brian Kulis, Tianlun Huang, Kubra Cilingir, Madison Morey and Ziqing Zhao; Boston University, United States

Lithium (Li) metal anode can largely improve the energy density of Li batteries but dendrite formation in the metal prevents its practical implementation. Structural defects on the mesoscale are expected to play the role as precursors to dendrite formation. Here, we combine first-principles density functional theory (DFT) results with machine learning (ML) to study the impact of structural defects on a Li surface. We present a comparison of different ML models for predicting the change in surface energy upon defect formation. We consider the accuracy of available structural descriptors (SOAP, ACSF, MBTR) and show that data sampling impacts our conclusions. We then present a possible approach to bridge the micro- and meso-scales.

9:15 AM DS03.08.06
Machine-Learning Assisted Quantum Materials Discovery And Optimization—Metal-Insulator Transition Compounds Alexandru Georgescu and James M. Rondinelli; Northwestern University, United States

Metal–insulator transition (MIT) compounds are materials that may exhibit metallic or insulating behavior, depending on the physical conditions, and are of interest due to their correlated properties as well as due to their potential applications in emerging microelectronics, including neuromorphic computing and Mott Field Effect Transistors. Nonetheless, only around 60 materials with a thermally-driven metal-insulator transition are known, and their computational discovery is difficult due to the non-equilibrium nature of the transition, and the complexity of the many-body problem. To address this issue, we have built the first database of all known thermally-driven metal-insulator transition compounds, as well as stoichiometrically related compounds, and a machine-learning based classifier tool to accelerate their discovery - and provided both to the wider public, with no installation required. Using Bayesian optimization techniques, we have also optimized specific materials families to find compounds which are both stable, and may display strong MIT behavior while minimizing the number of calculations. Time permitting, we will present possible new metal-insulator transition oxide compounds identified through a combination of machine learning and DFT calculations, as well as preliminary experimental results on their experimental validation.

First-Principles and Machine-Learning Assisted High-Throughput Screening for Novel Inorganic Perovskite Solar Cell Kanghoon Yim[1], Jiho Lee[2], Wonzee Jung[1,3], Seungwu Han[2] and Kihwan Kim[1]; [1]Korea Institute of Energy Research, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Chungnam National University, Korea (the Republic of)

In recent years, perovskite-based solar cells have shown a dramatic growth of their efficiency whereas the conventional silicon-based solar cells reached the theoretical limit through decades. However, the hybrid organic-inorganic perovskites (HOIP) which enable the rapid improvement of photovoltaic efficiency suffers from lack of long-term stability. To overcome the instability which originate from their organic components, the development of fully inorganic perovskites with comparable performance could be the solution. In this work, we first investigate the optical and electrical properties of all known ABX_3 inorganic perovskites from the inorganic crystal structure database (ICSD) using density functional theory (DFT) calculations. Though we found several new candidate materials for photovoltaic absorbers, their properties are not expected as promising as reported best materials. To discover new all-inorganic perovskite materials that have good performance and stability simultaneously, we suggest so-called 'double-anion perovskite' as new promising perovskites for solar-cell. While ABB'X-type double perovskite can only replace B-site with element having the same oxidation state, double-anion perovskites can expand possible combinations of A-B metals if chalcogen and halogen elements are mixed in the anion sites. To search the most stable structure of a given combination, we adopt a machine-learning potential based crystal structure prediction method, which is called 'SPINNER'. By combining DFT calculations and machine-learning potential methods, we suggest new all-inorganic double-anion perovskites for photovoltaic absorbers.

Many-Body Materials Graph Networks for Massive-Scale Discovery of Lithium Superionic Conductors Shyue Ping Ong, Chi Chen and Ji Qi; University of California, San Diego, United States

The matterverse is vast and complex. It comprises the infinite combinations of elements of the periodic table in ordered and disordered arrangements. While ab initio techniques can accurately probe the matterverse, the scope of our exploration has been bottlenecked by their high cost and poor scaling. In this talk, I will discuss how graph deep learning models models trained on large materials datasets have revolutionized our ability to explore the matterverse at unprecedented scales and accuracy. I will demonstrate how combining the strengths of graph neural networks with many-body interactions provide the means to access the matterverse in all its chemical diversity and structural complexity. Such universal M3GNet interatomic potentials can be applied to perform massive scale screening for novel lithium superionic conductors, as well as for other technological applications.

11:00 AM DS03.09.02
Bio-Inspired Computational Design of Vascularized Electrodes for High-Performance Fast-Charging Batteries Optimized by Deep Learning Chenxi Sui and Po-Chun Hsu; Duke University, United States

Slow ionic transport and high voltage drop (IR drop) of homogeneous porous electrodes are the critical causes of severe performance degradation of lithium-ion batteries at high charging rates. Nature has already provided plenty of examples like vascular structures to solve this kind of multi-variable transport optimization problem. In this presentation, it is numerically demonstrated that a bio-inspired vascularized porous electrode can simultaneously solve these two problems by introducing low tortuous channels and graded porosity, which can be verified by porous electrode theory. Despite the immense geometrical parameter space of the vascularized electrodes, recent progress in the machine learning algorithm has accelerated the optimization of the complicated topological structures. To optimize the vasculature structural parameters, artificial neural networks are employed to accelerate the computation of possible structures 84 times with high accuracy. Furthermore, an inverse-design searching library is compiled to find the optimal vascular structures under different industrial fabrication and design criteria, based on the structure-property relationships learned by artificial neural networks from the numerical simulation. The prototype delivers a customizable package containing optimal geometric parameters and their uncertainty and sensitivity analysis. Finally, the full-vascularized cell shows a 66% improvement in charging capacity compared to the traditional homogeneous cell under 3.2 C current density in a numerical simulation. This computational research provides an innovative methodology to solve the fast-charging problem in batteries and broaden the applicability of deep learning algorithms informed by numerical simulations to different scientific or engineering areas.

Understanding Proton Dynamics near the Superprotonic Phase Transition of Solid-Acid Electrolytes Using Machine Learning Force Fields Menghang Wang, Cameron J. Owen, Yu Xie, Simon L. Batzner, Albert Musaelian, Anders Johansson and Boris Kozinsky; Harvard University, United States

Solid-acid materials CsH_2PO_4 and $CsHSO_4$ exhibit superprotonic behavior above their phase transition temperatures. Due to the high computational cost of ab initio method, previous studies of proton dynamics were limited to a single phase with constant temperature at the scale of hundreds of atoms. While empirical force fields have been applied to study the phase transition specific systems, their accuracy and transferability are limited for the understanding and discovery of new solid-acid materials.

In this work, we build machine learning potentials for CsH_2PO_4 and $CsHSO_4$ data that combining quantum mechanical accuracy, scalability to large systems, as well as long time-scales. First, we collect training data by the Bayesian active learning framework FLARE [1], which utilizes molecular dynamics and uncertainty quantification to sample the configurational space. Then, we train the Allegro neural network potential [2] on the data set. We use the Allegro potential to study proton dynamics and properties near the phase transition by molecular dynamics. Then, we perform large-scale simulations on solid acids to unravel the mechanism of superprotonic behavior around the phase transition. The work flow is transferable to simulate a

wide range of superionic materials, predict their relevant properties, and propose promising candidates for experimental validation.

Multi-Objective Optimization of Lithium Ion Battery Manufacturing by Using Machine Learning Coupled to Physics-Based Process Modeling
Alejandro A. Franco; Universite de Picardie Jules Verne, France

In this lecture I present a digital twin for the accelerated optimization of the manufacturing process of Lithium Ion Batteries (LIBs). This digital twin is developed within the context of our ARTISTIC project[1] and it is supported on a hybrid computational approach encompassing a physics-based process modeling workflow and machine learning models, validated with in house experimental data acquired in our battery pilot line.[2] This digital twin simulates the different steps along the LIB cells manufacturing process, including the electrode slurry, the coating, the drying, the calendering and the electrolyte infiltration. The physics-based process modeling workflow is supported on the sequential coupling of experimentally-validated Coarse Grained Molecular Dynamics, Discrete Element Method and Lattice Boltzmann simulations which allows predicting the impact of the process parameters on the final electrode microstructures in three dimensions. The predicted electrode microstructures are injected in a continuum performance simulator capturing the influence of the pore networks and spatial location of active material particles and carbon-binder within the electrodes on their electrochemical response. Machine learning models are used to accelerate the physical models' parameterization and to derive surrogate models capturing with high accuracy the predictions of the physics-based modeling workflow. Such surrogate models are incorporated in a Bayesian Optimization-based algortihmic loop which allows to predict which manufacturing parameters to adopt in order to maximize and minimize several electrode properties simultaneously. The predictive and optimization capabilities of our digital twin are illustrated with results for different electrode formulations and manufacturing parameters. Finally, the free online battery manufacturing simulation services offered by the project[3] and designed to support the optimization of battery electrodes manufacturing are illustrated through several examples.

Maximizing Supercapacitor Capacitance Through Adopting Convolutional Neural Network Guided Bayesian Optimization of 3D Printing
JongHyun Kim, Seon Il Kim and WonHyoung Ryu; Yonsei University, Korea (the Republic of)

Supercapacitors are desired in the field of energy harvesting for its high capacitance. Although material properties are the primary factors in determining capacitance, the physical structure is also a dominant factor. 3d printed lattice structures are among preferred structures of supercapacitors as they allow a large surface to volume ratio (SAV). Once the structural rigidity is guaranteed, the printed lines must be narrow to maximize the surface area. Thus, in direct ink writing (DIW) 3d printing, printing parameters are tuned to find an optimal condition under which a uniform and thin line can be printed. However, this process is not only laborious but also costly due to many parameters that can influence printing quality. Recently, there has been a novel trial to implement Bayesian optimization, a technique used in machine learning, to optimize printing parameters [1]. With sample sizes less than 32, the Bayesian optimizer suggested printing conditions of different inks with higher printing resolution. In this work, we introduce a convolution neural network (CNN) guided Bayesian optimization to enhance the performance of supercapacitor through maximizing SAV of 3d-printed lattice electrode. The two optimization goals of high uniformity and narrow width in 3d printed lines are reached through a single scoring method: standard deviation of line widths. Through a camera with 600 x 800 resolution, 800 width measurements are made for each 6.5mm line printed from a 3d printer (Pro4, Nordson) and standard deviation of the measurements are calculated. The Bayesian optimizer attempts to find the global maxima of a surrogate model built from these standard deviation values, fed in negative. Throughout the process, the CNN model guides the Bayesian optimizer to keep its search space within straight line printed regions, preventing costly explorations and reducing total optimization time. The CNN model categorizes the printed lines to discontinuous, straight, coiled, or aggregated and resets the Bayesian optimizer's parameter boundaries when it detects a non-straight line. 7mm x 7mm x 0.72mm lattice structure supercapacitors are made using either graphene oxide (GO) ink or poly(3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT:PSS) ink. Three printing parameters: nozzle speed, nozzle height, and pressure, are optimized. Throughout 50 iterations of Bayesian optimization, the CNN model reset the search space 6 times for GO ink and 7 times for PEDOT:PSS ink. Supercapacitors were 3d printed with the optimized parameters and compared to supercapacitors prepared with conventional DIW printing method [3]. For GO and PEDOT:PSS supercapacitor, ligament widths decreased by 78.3% and 82.5% respectively. While ligament spacing was set to 0.3mm, number of unit cells increased by 158.2% and 156.3%, enhancing the pore architecture of the lattice structures. The capacitance, measured by cyclic voltametric method, increased by 121.5% and 108.4%.

AI Guided Manufacturing for Space Applications Todd M. Muller, Hud Wahab, Jacob Heil, Lars Kotthoff, John Ackerman and Patrick A. Johnson; University of Wyoming, United States

Compact printable devices manufactured from lightweight, versatile, and easily stored materials are of interest for in-space manufacturing due to high transportation costs and limited supply chain. Moreover, automated closed-loop experiments could support production during manned and unmanned missions and further limit waste generation. In this article, we demonstrate the use of advanced manufacturing techniques to produce laser-induced graphene temperature and humidity sensors from Kapton. We explore the techniques used to manufacture these sensors, using Bayesian Optimization for single and batch evaluations to interpolate and optimize future experiment parameters from small amounts of data. We also explore the application of these techniques in the development of capacitors for energy storage.

Data-Driven Discovery of Materials with Tuned Surface Properties for Thermionic Energy Conversion Peter Schindler[1,2], Evan Antoniuk[1], Gowoon Cheon[1], Yanbing Zhu[1] and Evan Reed[1]; [1]Stanford University, United States; [2]Northeastern University, United States

Data-driven approaches based on high-throughput computational methods have emerged as a new paradigm to facilitate the search through vast chemical spaces for new materials with tuned properties or novel behavior. The rapid increase in available computational data structured in open-source material databases has opened an avenue towards material discovery using data mining and statistically driven machine learning approaches. However, most big material databases like the Materials Project, AFLOW, and NOMAD largely lack to report surface properties like the work function and surface energy, as each bulk material typically has dozens of distinct low-index crystalline surfaces and terminations. The discovery of thermally stable materials with surfaces that exhibit an ultra-low work function (less than 1.5 eV) would allow thermionic conversion of heat (>1500C) directly to electricity with efficiencies exceeding 30% (typical thermionic and thermoelectric converters have efficiencies around 10%). Further, the work function is crucial for band alignment in heterostructures and electron emission devices. Here, we report on a recent advance in our high-throughput workflow using density functional theory (DFT) to calculate both the work functions and the cleavage energies of over 30,000 surfaces that we created from ~2,500 bulk materials, including up to ternary compounds. Moreover, we developed a physics-based approach to featurize surfaces and established a surrogate machine learning model to predict the work function. We find that physical choice of features improves prediction performance such that our random forest model achieves a mean absolute test error 4 times lower than the baseline, comparable to the accuracy of DFT. This surrogate model enables rapid predictions of the work function (~10^5 faster than DFT) across a vast chemical space. By identifying the Pareto front of material surfaces that have an ultra-low work function as well as low cleavage energy we are able to discover promising, stable material surfaces for application in thermionic energy conversion.

Finding Thermally Robust Superhard Materials with Machine Learning Jakoah Brgoch; University of Houston, United States

Superhard materials with a Vickers hardness >40 GPa are essential in applications ranging from manufacturing to energy production. Finding new superhard materials has traditionally been guided by empirical design rules derived from classically known materials. However, the ability to quantitatively predict hardness remains a significant barrier in materials design. To address this challenge, we constructed an ensemble machine-learning model capable of directly predicting load-dependent hardness. The predictive power of our model was validated on eight unmeasured metal disilicides and a hold-out set of superhard materials. The trained model was then used to screen compounds in Pearson's Crystal Data (PCD) set and combined with our recently developed machine-learning phase diagram tool to suggest previously unreported superhard compounds. Finally, industrial materials often experience tremendous heat during application; thus, we are building a method for predicting hardness at elevated temperatures.

Elucidating Precipitation in FeCrAl Alloys Through Explainable AI—A Case Study Christopher Reynolds, Andrew Hoffman, Indranil Roy, Sandipp K. Ravi, Subhrajit Roychowdhury, Bojun Feng and Rajnikant V. Umretiya; GE Global Research, United States

One of the primary challenges of using FeCrAl as a nuclear fuel cladding material is the formation of α'-precipitates that can cause brittleness in the alloy. The precipitation causes hardness change during thermal aging which is sensitive to both alloy composition and experimental conditions (i.e., temperature and time of heat treatment). While this behavior is well known for Al free ferritic stainless alloys, in FeCrAl alloys the effects of Al and Mo additions include both influence on kinetics and thermodynamics. To better understand the influence of composition on this age hardening behavior, artificial intelligence and machine learning have been utilized to interpret a large data set of aging experiments. A Gaussian process regression model was built on the hardness data collected at General Electric Research. Subsequently, for the first time, SHapley Additive exPlanations (SHAP) is leveraged as an explainable artificial intelligence (XAI) tool to understand the effect of feature values in driving the hardness change. This new approach broadens the capabilities of machine learning and artificial intelligence. Several key insights are affirmed and obtained from a material science perspective.

Machine-Informed Design of π-Conjugated Molecules with Tuned Optical Properties Parker Sornberger[1], Vinayak Bhat[1], Baskar Ganapathysubramanian[2] and Chad Risko[1]; [1]University of Kentucky, United States; [2]Iowa State University of Science and Technology, United States

While organic π-conjugated materials demonstrate great utility in energy generation and storage, lighting, transistors, sensors, and other optical and electronic devices, designing a new molecular material with precise properties for a specific application requires the exploration of a vast chemical space. Molecular generative models show great efficacy for in silico property prediction and design for drug-like molecules. Given this success, these models can have a natural extension to the design of π-conjugated molecules. Here, we will discuss the development of generative normalizing flow models to tune the optical properties of π-conjugated chromophores. The models are trained on the more than 25,000 chromophores and points of optoelectronic data from the Organic Crystals in Electronic and Light-Oriented Technologies (OCELOT) database. The generative models, with a focus on molecules that can be of

interest for singlet fission or thermally activated delayed fluorescence, can quickly generate structures with the aim of tuning the energy gaps between low-lying singlet and triplet excited states. The model optimizes these gaps through sampling a learned chemical space and predicting the gap between a molecule's low-lying singlet and triplet excited states using pretrained message passing neural networks that were trained on the optoelectronic data from OCELOT. Results from the generative models are verified through density functional theory (DFT) and time-dependent DFT (TDDFT) calculations to obtain their optical transitions and frontier molecular orbital energies. Though the models here are focused on robustly tuning optical transitions, the methods can be transferred to optimize additional electronic properties.

Automating Experiments Using Charged Particle Beam Nanofabrication Tools Michael Titze, Edward Bielejec and Alex Belianinov; Sandia National Laboratories, United States

Imaging methods with electrons, ions, and probes have played a central role in modern science and engineering with applications ranging from condensed matter and quantum physics, materials science, chemistry, biology, and medicine. Despite the variability of these approaches in terms of hardware, interaction mechanisms, and extracted information; the fundamental principles of the imaging process remain largely similar. Practically all methodologies map data on grids, to highlight an area of interest pertinent to the given problem. It is no surprise then, that hardware and software developments in the area of machine vision, AI, and decision-making that focus on consumer problems like driving and feature recognition, are now presenting themselves as opportunities for automating aspects of routine scientific processes. This talk exploits the underlying similarities of imaging experiments to combine probe, electron, and ion-based techniques by a common software thread encapsulating image processing and machine-learning algorithms to help focus researchers' efforts on high quality targets and enhance productivity.
Specifically, a combined, transferrable hardware-software toolset aimed at automating routine aspects of the decision-making process in ion exposure, implantation, milling, and deposition will be presented.

DS03.12.02
Semi-Automatic Scheme for Material Search Projects in Early Stage—Developing Practical Solvent-Solubility Prediction Models of Tetraphenylporphyrin Derivatives Securing Chemical-Space Coverage Raku Shirasawa[1], Ichiro Takemura[1], Shinnosuke Hattori[1] and Yuuya Nagata[2]; [1]Sony Group Corporation, Japan; [2]Hokkaido University, Japan

A semi-automatic molecular exploration scheme to model the solvent-solubility of tetraphenylporphyrin derivatives (TPPs) was designed and implemented. This scheme consisted of the following steps: (1) defining a practical chemical search space, (2) prioritizing molecules in the space using an extended algorithm for submodular function maximization (SFMMOL) without requiring biased variable selection or pre-existing data, (3) synthesis and automatic measurement, and (4) estimating machine-learning (ML) model. The evaluation order of TPPs selected using SFMMOL covered several similar molecules (32% of all targeted molecules, whereas that obtained by random sampling and uncertainty sampling was ~7% and ~4%, respectively) even with a small number of evaluations (10 molecules: 0.13% of all targeted molecules). The top 5 molecules in the order were synthesized, and, in conjunction with commercially available molecules, totally 15 molecules in 16 solvents were evaluated by the automatic measurement of UV-Vis absorption spectra. The derived binary ML classifiers for solute-solvent pair predicted 'good solvents' with an accuracy > 0.8. Consequently, we confirmed the effectivity of the proposed semi-automatic scheme for accelerating the early-stage material search project and expected the scheme applicable to a wider range of material research.

DS03.12.03
Deep-Learning-Based Inkjet Droplet Classification for Jetting Status Evaluation Eunsik Choi[1], Kunsik An[2] and Kyung-Tae Kang[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Konkuk University, Korea (the Republic of)

Inkjet printing is a powerful direct writing process technology of materials, which has been successfully exploited to printed electronics and energy devices including batteries, supercapacitors, fuel cells, and solar cells. Inkjet printing is also an economic and eco-friendly process which deposits microfluidic droplets on a designated area and enables non-contact, additive, maskless patterning in micrometer resolution which reduces materials usage. It can be adopted to print versatile materials into scalable patterns.
Nonetheless, printability or droplet jettability of an ink is not easy to predict owing to the intrinsic complexity of the process depending on ink-nozzle-air interactions. Thus, droplet jetting conditions should be monitored by adept experts to ensure reliability of the process. Moreover, it is unwieldy to predict droplet jetting conditions of multiple nozzles which are the requisite to increase productivity, resulting in incalculable labour costs and application bottleneck.
In this regard, we present a deep learning based method to classify inkjet droplets and evaluate its jetting statuses. MobileNetV2 was used as a pretrained convolutional neural network (CNN) model and its hyperparameters were optimized for the present study. Inkjet droplet frame sets were recorded by an *in situ* CCD camera and each frame was classified by the CNN model. Each classified frame set was accumulated in order of frame time to evaluate the jetting status of the frame set. It was demonstrated for both of single-jet and multi-jet processes.
7,852 frames were used for the single-jet deep learning model and accuracies for training and validation were 0.90 and 0.86, respectively. Jetting statuses were comprehensively evaluated by the accumulated frame classification data. In particular, the jetting status, which is based on frame class-time profile provided complete and perceptive information compared with jetting map, which had been diagnosed from human expert. It was especially valuable for non-expert operators to evaluate the jetting status and to optimize the process based on pulse width (μs) and pulse amplitude (V).
1,463 frames were gathered from 7 different nozzles for the training and validation of multi-jet model. In addition, 693 frames were generated for the test data of multi-jet model. Multi-jet model proved the accuracies of the training and validation to be 0.97 and 0.98, respectively. Broader distribution of data from differences of the droplet jetting environment was trained by the neural network which resulted in the improved accuracies of the multi-jet model compared with the single-jet model.
Runtime of a frame classification was less than a second, which demonstrated feasibility of the deep learning based real-time process monitoring. The deep learning based inkjet frame classifier could be further developed for autonomous process testing system with numerous nozzles. Moreover, it was applicable to long-term process, while saving plenty of data and frame class-time profiles. On top of that, the droplet classification model was able to be

applied for the other microfluidic jetting processes in that the frames were acquired from shadow images of the ejected inks lighted from strobe LED regardless of ink materials.
The strategy was firstly demonstrated to silver nanoparticle ink jetting process and applicable to the other comprehensive inkjet printing process of materials which can be exploited to fabricate electrodes for energy storage devices. This result shed a light on artificial intelligence based material processing research by using overlooked data during process. Furthermore, it is applicable to large scale process for both academia and industry.

DS03.12.04
Predicting Electronic Properties of Organic π-Conjugated Systems with Graph Neural Networks Vinayak Bhat, Parker Sornberger and Chad Risko; University of Kentucky, United States

Organic π-conjugated molecules have widespread applications namely in field-effect transistors, solar cells, (bio)sensors, and dyes. Accurate estimations of molecular electronic and optical properties using state-of-the-art density functional theory are time-consuming for large systems. Using graph neural network (GNN) and data from the OCELOT database, we trained machine learning (ML) models to predict properties, namely frontier molecular orbital energies, reduction and oxidation energies, relaxation energies, and low-lying singlet and triplet excitation energies. The trained GNNs can provide explanations for the predictions, thereby providing insights into the structure-property relationships. Further, we trained ML models to predict material properties, including the intermolecular electronic couplings between molecular dimers and crystal properties including bandgaps and cohesive energies. These models provide distinct connections between molecular and crystal properties, which we aim to build on as we develop and deploy machine-informed materials design for organic semiconductors.

DS03.12.05
Machine Learning-Assisted Models for Understanding and Optimizing Boiling Heat Transfer on Scalable Random Surfaces Hyeongyun Cha, Yang Zhong and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Boiling is a ubiquitous process in numerous applications, including nuclear power plants, water treatment, and thermal management. However, predicting and enhancing boiling heat transfer performance is notoriously difficult due to the complex nature of the boiling process. Here, we develop supervised machine learning (ML) models based on convolutional neural networks (CNN) to elucidate and predict boiling curves using detailed surface profiles as the only inputs. To train and validate the models, we fabricated a large number of statistically distinct random surfaces using sandblasting, a scalable surface engineering technique to enhance boiling heat transfer. The copper surfaces were sandblasted by aluminum oxide abrasives, and the surface morphologies and roughness were characterized by optical profilometry. Furthermore, the effects of multiple process parameters, including sandblasting medium size, pressure, nozzle distance, sweeping speed, and sweeping pitch, were investigated. The pool boiling experiments were conducted with saturated water in an ambient laboratory condition. The supervised ML models were trained by feeding a variety of surface morphologies with their measured boiling behaviors, which later enabled the models to predict boiling performance solely based on surface morphology. As a result, for a given unobserved random surface, the ML algorithms predicted both the heat transfer coefficient (HTC) and the critical heat flux (CHF) values within a deviation of 10% from experimental results. In addition, we developed the inverse design models based on variational autoencoder (VAE) and generative adversarial network (GAN) to create boiling surfaces for the target boiling performance. The VAE and GAN models were trained and validated with the same training datasets containing different surface morphologies with measured boiling behaviors. The ML models generated surface structures as well as the corresponding manufacturing parameters, which highly matched with the real surface features and the boiling experimental results. This work not only provides optimal boiling surface design guidelines without time-consuming experiments, highly inaccurate empirical correlations (up to 90% error), or extensive computational models (~months), but also enables scalable engineering techniques to be more readily adopted in current energy applications, enhancing performance and enabling a shorter payback period for increased deployment.

DS03.12.06
Real-Time 3D Analysis During Tomographic Experiments Using Tomviz Jonathan Schwartz[1], Chris Harris[2], Huihuo Zheng[3], Jacob Pietryga[4,1], Prashant Kumar[1], Anastasia Visheratina[1], Nicholas A. Kotov[1], Brianna Major[2], Patrick Avery[2], Peter Ercius[5], Utkarsh Ayachit[2], Berk Geveci[2], David Muller[6], Yi Jiang[3], Marcus D. Hanwell[7] and Robert Hovden[1]; [1]University of Michigan, United States; [2]Kitware, United States; [3]Argonne National Laboratory, United States; [4]Northwestern University, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]Cornell University, United States; [7]Brookhaven National Laboratory, United States

Three-dimensional (3D) characterization across the nanoscale is now possible using scanning / transmission electron microscopes (S/TEM) [1,2]. Unfortunately, tomographic reconstructions can take one to several days to complete depending upon the dataset size or algorithm(s) employed. Even worse, the reconstruction occurs offline, long after all the data has been collected, preventing immediate interpretation during an ongoing experiment. While advancements in detector hardware have boosted throughput with digital data collection, substantial human effort and computational resources are still required to process the deluge of raw data. It has been a longstanding goal to start 3D analysis of specimens in real-time, enabling the immediate assessment of nanoscale structure. Achieving high-throughput electron tomography requires an integrated pipeline that links the microscope hardware to optimized reconstruction algorithms and efficient 3D volumetric visualization.

Here we present interactive 3D visualization that seamlessly runs while experimental projections are collected in an electron microscope using the tomviz platform (www.tomviz.org). Tomviz provides 3D materials structure to scientists in real-time enabling high-throughput specimen interpretation with immediate tomogram visualization [1]. During the experimental acquisition, tomviz monitors for new projections which are continuously appended into the reconstruction process. After a reconstruction updates, tomviz immediately renders the 3D volume. We demonstrate real-time tomography on a helical nanoparticle comprised of a Cysteine amino-acid coordinated with Cadmium (Cys/Cd). The specimen's left-handed chirality is discerned in the first twenty minutes and a high-resolution volume is available within 50% of the experiment (20-30 minutes).

Real-time tomography demands maximally efficient computational speed to ensure the optimization runs faster than the experimental data acquisition rate. Tomograms are reconstructed in parallel with data acquisition and a high-quality 3D reconstruction is available before the experiment completes. The multithreaded pipeline in tomviz enables interactive 3D analysis of the current reconstruction state with minimal impact on performance. A robust graphical user interface allows 3D objects to be rendered as shaded contours or volumetric projections and these objects can be rotated, cropped, or sliced as the reconstruction evolves. Thus, scientists can go beyond superficial inspection to quantify specimen features or internal structure while simultaneously operating the microscope. This immediate feedback can save researchers days of effort as reconstructions are no longer processed offline.

DS03.12.07
Machine Learning Prediction and Experimental Validation of Novel Materials for Rotating Electrical Machines Shakti P. Padhy[1], Varun Chaudhary[1], Yee-Fun Lim[2], Kedar Hippalgaonkar[1] and Raju V. Ramanujan[1]; [1]Nanyang Technological University, Singapore; [2]Agency for Science, Technology and Research, Singapore

Magnetic alloys play a key role in energy conversion, transmission, and utilization. The urgent need for Net Zero energy technologies demand the development of the next generation of high strength magnetic alloys for high frequency rotating electrical machines operating in extreme environments. Multiple properties need to be optimised in such demanding applications. A data-driven approach to develop new Fe-Co-Ni-based alloys for such applications was utilized. A database consisting of the magnetic, electrical, and mechanical properties of Fe-Co-Ni based alloys was curated from the literature. A machine learning (ML) based imputation methodology was utilized to complete the database. A multi-property regression ML model with the lowest mean absolute error (MAE) was chosen to map the composition to the properties. An inverse design strategy was also developed to predict new alloy compositions. Both the multi-property model and inverse design strategy were validated. Fe-Co-Ni ternary alloy compositions were prepared and characterized *via* a high-throughput methodology. New alloy compositions, e.g., $Fe_{73}Co_{24}Ni_3$ and $Fe_{53.6}Co_{36.4}V_4W_{3.5}Cu_{1.3}Al_1Ti_{0.2}$ with a balanced set of properties for electrical machines applications were identified. This successful strategy can also be deployed for the accelerated development of other classes of materials. This work is supported by the AME Programmatic Fund by the Agency for Science, Technology and Research, Singapore under Grant No. A1898b0043.

DS03.12.08
Data-Driven Approaches to the Electrochemistry of Multi-Component Cathode Materials Peichen Zhong[1,2] and Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The increasing demand in electrical energy storage requires the discovery of high energy density cathode materials for lithium-ion batteries. Disordered rocksalts with Li-excess (DRX) materials are promising candidates as these materials do not require a specific cation chemistry to favor any particular ordering, and can be synthesized with a very wide variety of elements. However, the computational modeling for DRX is difficult as it can be composed from a wide variety of chemistry with site disorder.

In this presentation, we will demonstrate a state-of-art approach to the modeling and prediction of electrochemistry (discharge voltage profile) of DRX materials via a data-driven approach. We applied a deep neural network (DNN) trained directly on a large amount of experimental results. The DNN is trained with an end-to-end learning scheme, that includes the redox information appropriately regularized. The DNN can interpolate and make predictions for compounds that have not yet been tested, which can accelerate the exploration of DRX and other electrode materials.

DS03.12.09
Epitaxial Growth of Silicon Carbide from Molecular Dynamics and Active Learning of Machine Learning Force Field Yu Xie[1], Senja Ramakers[2,3], Maximilian Amsler[2], Thomas Eckl[2], Ralf Drautz[3] and Boris Kozinsky[1]; [1]Harvard University, United States; [2]Corporate Sector Research and Advance Engineering, Robert Bosch GmbH, Germany; [3]Interdisciplinary Centre for Advanced Materials Simulation, Ruhr-Universität Bochum, Germany

The wide-bandgap semiconductor silicon carbide (SiC) has been widely applied to power electronics, nuclear physics, and quantum computing. Epitaxial growth is the primary approach to fabricate high-quality SiC wafers. However, it remains a challenge to understand and control the growth process. Molecular dynamics (MD) provides computational insight on a microscopic scale, but reliability of simulations is often limited by the insufficient accuracy of empirical force fields, whereas ab initio MD is too expensive to scale to large length and time scales. Machine learning force fields are shown to be promising with efficiency comparable to empirical force fields and with quantum accuracy. Our Bayesian active learning method [1] has been used for fast training of force fields from first principles. In this work, we incorporate the deposition process with the active learning to train the force field efficiently on the epitaxial growth. We then validate the force field and run large-scale molecular dynamics of the epitaxial growth process. The simulation helps with the understanding of the deposition growth, and can facilitate the control and improvement of the fabrication of high-quality SiC.

DS03.12.11
Integrated Neural NLP Pipeline for Autonomous Synthesis Database Extraction from Literature Vineeth Venugopal and Elsa Olivetti; Massachusetts Institute of Technology, United States

The heuristic nature of materials synthesis limits researchers' ability to extend materials genome initiative-type approaches to methods to make novel materials or extend existing materials to new, controlled morphologies and microstructures.A number of recent informatics-based approaches have shown that machine learning models are able to learn synthesis conditions given sufficient data. These data-driven methods should save time and energy in the fabrication of new material compositions and structures. However, machine readable databases of inorganic material fabrication and processing are stil limited since the underlying information is present only in unstructured databases such as archives of published scientific literature.

Recent work has shown how Natural Language Processing (NLP) can be used to extract synthesis specific information from texts. Databases for solid state and solution based processing have been made available. The techniques used for these extractions include sequence to sequence tagging algorithms employing recurrent neural networks, large language models, and language dependency parsing using linguistic grammar trees (most often implemented in the popular NLP package, Spacy). While these algorithms are accurate at identifying synthesis specific tokens such as names of the synthesis operations, units, and temperature values, they can be improved when tokens are not proximate in a dependency tree. As a result, the autonomous extraction of synthesis data tends to be error prone and many concurrent data points are required to improve our confidence in a given material -synthesis condition - parameter relation.

We propose a transformer based neural network architecture that directly learns the relations between different entities in a text which is learnt from a custom annotated database of synthesis literature. This approach integrates large language model based named entity recognition systems with neural relational classifiers, thereby creating a unified approach to both entity identification and linkage. Using this approach, the accuracy of extracted synthesis conditions for solid state and solution based processing is greatly increased. This is demonstrated through comparison with extracted public datasets. The results are additionally validated manually. Some reflections on dataset creation and human labeling for NLP tasks is presented as a guideline for the community in extending this approach to non-synthesis datasets.

DS03.12.13
Analysis of Variability in Resistive Memory Originated from Initial Defect Configuration by Fully Coupled Electrothermal and Phase-Field

Models Chanhoo Park, Dongmyung Jung and Kwon Yongwoo; Hongik University, Korea (the Republic of)

Recently, resistive random-access memory (RRAM) has been profoundly studied to apply to neuromorphic computing. So far, it is hard to use the RRAM as a synapse device because its characteristics are sensitively affected by various factors. In other words, the variability is too severe. Therefore, reducing the variability is one of the major challenges in the RRAM device research. In this work, we investigate the factors affecting the device variability in conductive filament behaviors using a multi-physics simulation that integrates the electrothermal and phase-field models. The initial defect configuration is the source of the variability. With the given defects, the cell architecture, both cell geometry and constituent materials, to reduce the variability in the device characteristics are investigated.

Modeling and AI/ML play increasingly important role in the design and understanding of numerous classes of materials. In this talk, we will discuss our work on battery materials including the important question of oxygen redox, and on photovoltaic materials including Cd chalcogenides and perovskite halides.

8:30 AM DS03.13.02
Machine Learning Guided Interrogation of Gas Evolving Electrode Catalyst Activity Simon Rufer[1], John Lake[1], Aristana Scourtas[2,3], Jim James[4], Nathan Pruyne[5], Marcus Schwarting[2], Ben Blaiszik[2,3] and Kripa Varanasi[1]; [1]Massachusetts Institute of Technology, United States; [2]The University of Chicago, United States; [3]Argonne National Laboratory, United States; [4]Georgia Institute of Technology, United States; [5]Northwestern University, United States

Being able to effectively manage gas evolution at electrochemical electrodes is a major challenge in a wide variety of industrial applications. Perhaps the most important activities where electrochemical bubble generation is critical to control are the chlor-alkali (chlorine gas production) and Hall-Héroult (electrochemical aluminum smelting) processes. Significant effort goes towards mitigating the “anode effect” of the Hall-Héroult process, where carbon dioxide gas inactivates the carbon anode, causing catastrophic increases in overpotential. For the chlor-alkali process, the attachment of bubbles to electrode surfaces accounts for approximately 20% of the overpotential at industrially relevant current densities. Similar inefficiencies and problems are caused during water electrolysis when bubbles adhere to or flood electrodes. As a result, the limiting effects of bubbles restrict the adoption of traditional, low-temperature electrochemical methods for hydrogen generation from renewable electricity. In this way, both understanding and mitigating the negative impacts that bubbles have on electrode performance offer a unique path to enable high performance gas evolving electrochemical technologies, which will play a major industrial role in a renewably electrified future.

These problems motivate this work as we investigate the way that bubble inefficiencies manifest on electrodes by fabricating novel electrodes for studying the effects that adhered bubbles have for electrochemical performance using both hydrogen and oxygen evolution reactions. Despite extensive knowledge of the negative impacts adhered gas bubbles cause at a system level, there is limited fundamental understanding of the extent to which specific mechanisms inactivate active electrode materials. By using surface engineering gas evolving electrode for testing, we can manipulate the micro- and nanoscale electrode morphologies to control bubbles nucleation and bubble/electrode interactions. By developing machine vision algorithms for the detection and tracking of bubbles from electrode surface imaging, we obtain empirical results which oppose the prevailing view held in regard to how bubbles inactivate electrodes. The utility of tracking nucleating and growing bubbles on electrodes’ surfaces can also provide important spatiotemporal information about the activity of the electrocatalyst materials used, not only regarding the inactivation that the bubbles cause. As a result, the machine vision methods developed are also proposed and demonstrated as a useful electrocatalyst screening tool for the evaluation of catalyst materials for gas evolving electrochemical reactions. As a result of these findings and the methods developed, we provide a novel framework for designing gas-evolving electrochemical electrodes and for the discovery of highly active electrocatalyst materials for gas evolving reactions.

8:45 AM DS03.13.03
Multi-Instruments Autonomous Discovery of Phase Change Memory Materials for Nonvolatile Memory Devices Chih-Yu Lee[1], Haotong Liang[1], Heshan Yu[1], Austin McDannald[2], A. Gilad Kusne[2] and Ichiro Takeuchi[1]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

Autonomous experimentation enabled by artificial intelligence (AI) facilitates acceleration of materials discovery and design. Investigating materials of complex compositional and structural landscapes requires resource-intensive high-throughput experimentations. Conventionally, we study materials by analyzing data collected from multiple characterization and measurements at different times. However, analyzing these data streams separately cannot exploit shared trends to boost analysis, prediction, and decision making. Herein, a novel approach is proposed to explore structural and functional properties synchronously. The autonomous robot is able to explore phase maps and exploit property optimization simultaneously in the high dimensional space. Multi-instruments run in parallel. The central AI exploits shared trends from the diverse measurement data sources and then employs a multi-objective active learning process to make decisions on the next iteration. The goal is accelerate discovery of optimal materials by learning and utilizing knowledge of composition-structure-property relationships. With this approach, we successfully discover novel materials in the titanium-selenium-tellurium system (TST), which is considered a promising phase change memory (PCM) candidate used in random-access memory. Combining x-ray diffraction and four point probe measurements, structural and functional property maps are established in terms of combinatorial wafer composed of hundreds of various compositions. The algorithm combines active phase mapping of a live x-ray diffraction data stream and multi-objective optimization of functional properties from additional live data streams. We identify a set of materials with identical structural signatures as well as two important features required for nonvolatile memory—large contrast of resistance between amorphous and crystalline states and large resistance in crystalline states. This novel approach again confirms that AI accelerates materials discovery and design.

Generative Materials Informatics—Going Beyond Screening Taylor D. Sparks[1], Sterling Baird[1], Michael Alverson[1,2], Hasan Sayeed[1] and Marianne

Liu[1]; [1]University of Utah, United States; [2]University of Southern California, United States

Machine learning already enables the discovery of new materials by providing rapid predictions of properties to complement slower calculations and experiments. However, a persistent criticism of machine learning enabled materials discovery is that new materials are very similar, both chemically and structurally, to previously known materials. This begs the question "Can machine learning ever learn new chemistries and families of materials that differ from those present in the training data?" In this talk, I will describe two important tools we are developing to truly move beyond screening to actual discovery. First, I will describe new generative machine learning approaches that can be used to generate structures that do not yet exist, but are likely to. I will compare generative models including variational autoencoders, generative adversarial networks, and diffusion models which have become standard in machine learning for images. I will describe the unique challenges that we face when using tools of this nature to generate periodic crystalline structures. Second, I will describe the Descending from Stochastic Clustering Variance Regression (DiSCoVeR) algorithm to bias the discovery of new suggested materials away from known chemistries in a systematic way towards unintuitive and even unlikely yet promising candidates for new materials.

9:30 AM DS03.13.05
Visual Explanations for the Generation of Dislocation Clusters in Multicrystalline Silicon Using Gradient-Based Techniques Kyoka Hara[1], Takuto Kojima[1], Kentaro Kutsukake[2], Hiroaki Kudo[1] and Noritaka Usami[1]; [1]Nagoya University, Japan; [2]RIKEN, Japan

Multicrystalline materials are often the most common choice for various applications because of their affordable processing. As for solar cells based on multicrystalline absorbers, the conversion efficiency has improved over the years, stimulated by the increasing variety of constituent materials such as silicon, CIS, CdTe, and perovskites. However, device performance tends to be limited by a high concentration of defects that provoke recombination and deteriorate conversion efficiency. Thus, it is essential to reveal how these defects are generated and to control them. In particular, we focus on examining and controlling the formation of dislocation clusters (DCs) in multicrystalline silicon. In order to establish a systematic and comprehensive knowledge on the generation of DCs, we have previously developed a machine-learning based model to estimate the existence of DCs from the microstructures of the sample wafers. This model is constructed with a convolutional neural network. It learns the features of optical images taken of the wafer surface and uses photoluminescence images of corresponding wafers as teacher data. The optical images were taken by a house-made apparatus and inherits crystallographic features such as grain boundaries, grain sizes, and crystal orientations. The photoluminescence images display the locations of DCs. We have previously reported on the techniques regarding this model and the results of the estimations. Promising results have indicated the possibility that some key structures responsible for the generation of dislocation clusters have been successfully extracted from the input images. In this study, we present further analysis of the model's estimations using gradient-based interpretability techniques.
While machine learning has become increasingly powerful and successful, the urgency in interpreting the neural network's decisions has escalated. The reasonings the model makes being a black box, building trust and transparency in machine learning techniques has miles to go. In this case, the neural network has indeed displayed correct estimations on whether dislocations exist or not, but the structures that contribute most to those estimations are masked in the layers. To reveal the model's reasoning in this estimation, we have performed calculations of the gradients flowing into the model's layers using Gradient-weighted Class Activation Mapping (Grad-CAM). The results have been integrated into localization maps showing the most important regions in the input images for the model's decision-making. This provides us with some visual explanations on the microstructures responsible for the generation of DCs.

9:45 AM DS03.13.06
Crystal Structure Reconstruction from X-Ray Diffraction Patterns Based on Supervised Contrastive Learning Doosun Hong[1,2], Tian Xie[3], Donghun Kim[2], Jeffrey Grossman[3] and Hyuck Mo Lee[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Massachusetts Institute of Technology, United States

Techniques based on X-ray diffraction (XRD) are the most related to the identification of crystal structures. The latest generation of tools for high-throughput diffraction experiments and simulations has led to collection of a large volume of XRD data. The handling of these large-sized dataset calls for big data and machine learning (ML)-based approaches. Several recent studies were reported, where powder XRD 1D curves were used to classify crystal symmetry such as crystal systems and space groups. However, these studies are limited to identifying crystal symmetry, and not yet extended to the full reconstruction of three dimensional (3D) crystal structure.
In this work, we report a deep learning (DL)-based approach to reconstruct 3D crystal structures from XRD patterns, based on supervised contrastive learning (SupCon). This protocol largely consists of crystallographic prototype classifier and element position assigner. The former process attempts to classify crystallographic prototype, which is one of crystal structure symmetry groups. According to AFLOW, 1,100 prototypes are available today, and each has a unique combination of material composition (stoichiometry), crystal symmetry (Pearson symbol and space group), and Wyckoff position. Using SupCon, we achieved the classification accuracy around 90%, based on the datasets involving 28 prototypes. The latter process is element position assigner, which finds the position of elements as well as lattice parameters for a given prototype. Through our novel protocols leveraging prototype classification, we demonstrate several examples where 3D crystal structures were fully reconstructed from XRD patterns.
We additionally emphasize the importance of SupCon, which is much better in contrasting the subtle differences of similar crystal prototypes than traditional supervised classification methods, which was key to achieving classification accuracy around 90%. This work offers a method to reconstruct 3D crystal structure directly from XRD patterns, which will be useful in understanding the structural information more intuitively.

Using Artificial Intelligence to Transform Data into Actionable Knowledge Jason R. Hattrick-Simpers; University of Toronto, Canada

Materials synthesis and measurements are messy, plagued by irreproducibility, outliers, uncertain labels, and are guided by human decisions, assumptions, and biases made while interpreting data. This is only natural but as the materials science field increasingly moves towards AI driven autonomous workflows, automated decision-making is problematic if the AI is trained on ground truth data and models without a means to automatically interrogate their validity. Here I will discuss our recent work across three major thrusts (1) using machine learning to discover unknown unknowns in experimental

analysis, (2) creating physics-based inference models that challenge the assumptions of scientists, and (3) using statistical methods to extract more information from fewer and less complex measurements. The first part of the talk will focus on the how through random seed perturbation and a modification of Cook's distance we were able to identify a major technical issue in the study of molten salt corrosion of high entropy alloys. In the second thrust, we will illustrate that combining evolutionary algorithms with expert heuristics and Bayesian inference we are able to both generate and (in some cases) justify the acceptance of AI generated models over those made by topical experts. Finally, I will discuss how simple statistical models of cross-sectional SEM images can be used to generate 3-D microstructures of membranes.

11:00 AM DS03.14.02
Artificial Intelligence and Human Collaboration in Human-In-The-Loop Materials Science Autonomous Experimentation Felix Adams[1], A. Gilad Kusne[2] and Ichiro Takeuchi[1]; [1]University of Maryland, United States; [2]National Institute of Standards and Technology, United States

Autonomous experimentation uses machine learning and automation to intelligently choose the order of and perform experiments on the fly to achieve goals specified by a user (for example, finding synthesis parameters which optimize a materials property). Autonomous experimentation reduces the time and cost of materials research by achieving research goals with fewer experiments than exhaustive searching and traditional prototyping. While autonomous experimentation can incorporate many sources of information, qualitative human judgement remains an important part of decision making in some individual experiment tasks, which are difficult to automate. We present a method for integrating human input into an autonomous experimental campaign which maps structural phase regions in a high-throughput combinatorial library, demonstrated on the Fe-Ga-Pd system. X-ray diffraction patterns from the Fe-Ga-Pd library are used to predict potential phase maps. During the campaign, the user can indicate phase regions and boundaries based on their materials science knowledge (e.g., known specific material phases or the phase rule). This user input is integrated as a probabilistic prior into a Gaussian Process classifier, the posterior of which is used to choose the next experiment. We will describe the overall procedure and present the campaign results.

11:15 AM DS03.14.03
RoboMapper—On-Chip Robotic Micro-Experimentation Reveals Quantitative Structure-Property Relations in Hybrid Perovskites Tonghui Wang[1,1], Ruipeng Li[2], Hossein Ardekani[1,1], Mahdi Ramezani[1], Ryan Wilmington[1,1], Robert Epps[1], Kasra Darabi[1,1], Boyu Guo[1,1], Milad Abolhasani[1], Kenan Gundogdu[1,1] and Aram Amassian[1,1]; [1]North Carolina State University, United States; [2]Brookhaven National Laboratory, United States

Solution-processed semiconductors, such as metal halide perovskites (MHPs), have attracted tremendous attention over the past decade, promising to revolutionize the fields of photovoltaics, photonics, and other printed electronic applications. However, given the large compositional and chemical space of modern solution-processed semiconductors, meeting multiple material requirements together with device performance, operational stability, material toxicity and cost, as well as sustainable manufacturing is currently a fundamental challenge that is nearly impossible to overcome using trial-and-error and heuristics approaches. We introduce the RoboMapper, a novel compact robotic laboratory which integrates materials on a chip. We demonstrate end-to-end miniaturized, automated workflow from ink formulation to high-throughput multi-modal characterization for efficient data collection. Compared with traditional manual workflows and existing full-scale serial automation, the RoboMapper is shown to be 5-10 times faster and reduces the material cost, toxic waste, and greenhouse gas emissions by more than an order of magnitude. A state-of-the-art case study on $FA_{1-y}Cs_yPb(I_{1-x}Br_x)_3$ proves the ability of our platform to rapidly establish the quantitative structure-property relationship (QSPR) in a large and complex compositional space and provide accurate and practical guidance for the screening and selection of compositions among a wide range of options with an ideal bandgap as well as improved photo-stability for different target applications. This platform can be universally applied to solution processable materials such as organic semiconductors, quantum dots, and nanoparticles to pave the way towards the fully autonomous experimentation of ink-based semiconductor materials, ink formulations and (opto)electronic devices co-design with the guidance of artificial intelligence (AI).

11:30 AM DS03.14.04
RoboCoater—Automated, Closed-Loop Bayesian Optimization of Hybrid Perovskite Anti-Solvent Drip Nathan Woodward[1], Boyu Guo[1], Mihirsinh Chauhan[1], Kasra Darabi[1], Tonghui Wang[1], Milad Abolhasani[1], Kristofer Reyes[2] and Aram Amassian[1]; [1]North Carolina State University, United States; [2]University at Buffalo, The State University of New York, United States

Hybrid metal-halide perovskites are a promising material for photovoltaics that have made large strides in power conversion efficiency (PCE) in the past decade due to being an affordable, solution-processible, tunable direct bandgap material. Spin coating is a widely adopted technique for the fabrication of perovskite thin films; however, it is a very strenuous, manual process that can vary person-to-person in each lab. In addition, anti-solvent treatment is a crucial step in the fabrication process. Different anti-solvents and drip parameters are required for varying perovskite systems to achieve the optimal thin film for high PCE devices. Optimization of one-step spin coating of a hybrid perovskite system with an anti-solvent drip is a multiparametric problem that requires many human hours and resources.

Here, we present a fully automated spin coating platform, the RoboCoater, which allows precise control of processing conditions like spin speed, anti-solvent drip timing, drip volume, and on-chuck thermal annealing to achieve accurate and reproducible results that are not feasible by humans. In addition, this platform has integrated in-situ absorbance and photoluminescence measurement capabilities that are synchronized with the spin coating experiment to determine film properties. We have utilized Bayesian Optimization to reduce the time spent to optimize the multiple process parameters of perovskite thin-films in a high-throughput, closed-loop manner to reduce the time and material cost to optimize the perovskite active layer to achieve a higher power conversion efficiency perovskite solar cell. This dramatically reduces the number of person-hours needed to optimize a single anti-solvent for a given perovskite system and allows us to more quickly screen various anti-solvents to find the best performing process parameters. Overall, we have built a compact, modular 3D printed scientific platform that is much more affordable than the large, commercial optical characterization platforms that can run autonomous experimentation for a wide range of solution processable materials. The RoboCoater defines standardized processing conditions for different research labs to achieve repeatable, peer-executed experimentation to help the community advance together.

8:00 AM *DS03.15.01
Many-Body Perturbation Theory Meets Machine Learning to Discover Singlet Fission Materials Noa Marom; Carnegie Mellon University, United States

Singlet fission (SF), the conversion of one singlet exciton into two triplet excitons, could significantly enhance solar cell efficiency. Molecular crystals that undergo SF are scarce. Computational exploration may accelerate the discovery of SF materials. We have used many-body perturbation theory (MBPT) within the GW approximation and the Bethe-Salpeter equation (GW+BSE) to identify several potentially promising candidate materials [1-4]. However, GW+BSE calculations of the excitonic properties of molecular crystals are impractical for large-scale materials screening. In recent years, machine learning (ML) algorithms have been used increasingly in conjunction with first-principles simulations to accelerate computational design and discovery of materials. We use the sure-independence-screening-and-sparsifying-operator (SISSO) machine-learning algorithm to generate computationally efficient models that can predict the MBPT thermodynamic driving force for SF for a dataset of 101 polycyclic aromatic hydrocarbons (PAH101) [5]. SISSO generates models by iteratively combining physical primary features. The best models are selected by linear regression with cross validation. The SISSO models successfully predict the SF driving force with errors below 0.2 eV. Based on the cost, accuracy, and classification performance of SISSO models, we propose a hierarchical materials screening workflow. Three potential SF candidates are found in the PAH101 set.

Auto-Generating Databases about Batteries and Solar-Cells for Data-driven Materials Discovery Jacqueline M. Cole[1,2]; [1]University of Cambridge, United Kingdom; [2]ISIS Pulsed Neutron and Muon Source, United Kingdom

This talk will introduce the 'chemistry aware' natural processing tool, ChemDataExtractor,[1,2] and illustrate its ability to auto-generate databases on battery and photovoltaic materials and device information. The battery database contains a total of ¼ million data records and includes chemical names of anodes, cathodes and electrolytes as well as five device properties.[3,4] The photovoltaics database contains ½ million data records and includes chemical names and device properties of perovskite-based and dye-sensitized solar cells.[5] The database auto-generation methods are discussed as is the applicability of these large databases to machine-learning pipelines which enable a design-to-device approach to data-driven materials discovery.[6]

Screening of Next Generation Ni-Rich Cathode Materials with High Electrochemical Properties via Machine Learning Minseon Kim, Seungpyo Kang and Kyoungmin Min; Soongsil University, Korea (the Republic of)

Ni-rich layered cathode materials are promising candidates to satisfy high energy density and high voltage requirements, but they suffer from degradation during cycling. Ni-rich layered cathodes, such as $LiNi_xCo_yMn_zO_2$ (NCM) and $LiNi_xCo_yAl_zO_2$ (NCA), were extensively investigated to minimize the proportion of Co, which caused price volatility and supply chain problems. Recently, $LiNi_xCo_yMn_zAl_wO_2$ (NCMA), with the minimum Co content and maximum Ni content, was studied owing to its advantages of low manufacturing cost and high theoretical capacity and working potential. However, as the Ni content increases in the cathode, its commercialization is challenging owing to (1) performance degradation and (2) safety issues during electrochemical cycling. Therefore, the development of next-generation Ni-rich cathodes is necessary to resolve these problems.
Density functional theory (DFT) calculations are widely implemented in designing electrode materials owing to their remarkable accuracies and reliabilities. However, DFT calculations require significant computational resources to calculate all possible combinations of candidate materials. This limits the scope of the search for novel materials and the possibilities of fundamental research and development. Thus, to efficiently design next-generation battery materials, narrowing the large design space for cathode materials using artificial intelligence (AI) is necessary. And although various battery-material studies aim to yield cathodes with high voltage and small volume changes, few studies focus on developing prediction models of the average voltage and volume changes of novel materials.
In this study, we developed a machine-learning-based surrogate model to predict the average voltage and volume changes of Ni-rich cathodes with various dopants ($LiNi_{0.85}D'_xD''_{(0.15-x)}O_2$) to determine ideal cathode materials with excellent electrochemical properties. To construct the training database, data regarding 4,401 materials were obtained from the Materials Project. Thirty-three elements were implemented as candidate dopants, suggesting 1,617 potential cathode materials.
We improved the accuracy of predictive models through feature engineering including feature addition and data pre-processing. As a result of adjusting the hyperparameters with Bayesian optimization, the performance improved significantly from the initial to the final model (average voltage: R^2 = 0.801 to 0.873, MAE = 0.404 to 0.323 V; volume change: R^2 = 0.241 to 0.561, MAE = 41.030% to 2.890%).
Using the constructed model, we identified 107 candidate materials. The following are the criteria for selecting cathode materials: (1) The gravimetric energy density should be 〉 875 mWh/g based on the capacity of Ni-rich compounds (200-250 mAh/g). (2) Based on the potentials (2.7–4.3 V) of recently proposed Ni-rich layered materials, the average voltage should be 〉 3.5 V. (3) The volume change should be 〈7% based on the Ni-rich compounds (2–9%). 969 materials satisfy criterion (1), 541 satisfy criteria (1) and (2), and 107 satisfy criteria (1)–(3).
The constructed platform may be employed to determine ideal Ni-rich cathode materials with different elemental ratios and compositions, with significantly reduced computational and experimental costs. The model was validated using DFT calculations. We identified 101 Co-free compounds among the candidates and presented a strategy for material selection that could overcome resource limitations. The top ten materials displayed high potentials and capacities and low volume changes without Co, suggesting the potential of developing Co-free cathode materials. The platform used in this study accelerated the screening of unknown materials without extensive calculations. These next-generation cathode candidates may be used in future experimental research regarding cathode material development or predictive models based on constructed databases.

9:15 AM DS03.15.04
Evaluating NMR Chemical Shifts of Ionic Liquids Using Machine Learning Michael O. Ashby[1], Difan Zhang[1], Roger Rousseau[2] and Vassiliki-Alexandra Glezakou[2]; [1]Pacific Northwest National Laboratory, United States; [2]Oak Ridge National Laboratory, United States

Ionic liquids have a wide range of applications in electrochemistry, engineering, and chemical processes as solvents, catalysts, or reagents. To understand the properties of ionic liquids, Nuclear Magnetic Resonance (NMR) is commonly used because it provides a unique set of chemical shifts that can uniquely characterize an ionic liquid compound. However, due to the versatile categories and complex environments of ionic liquids, it is time-consuming and costly to measure the experimental NMR data for ionic liquids. Although computational methods such as density functional theory calculations provide an alternative way to obtain NMR data, they are limited to small molecular models and are computationally expensive, especially for complex systems. Here, we propose a machine learning approach to evaluate the NMR chemical shifts of ionic liquids. A neural network is trained on an ionic liquid dataset established on experiments and ab initio calculations of ionic liquids. The network can help us to evaluate the NMR data of ionic liquids more quickly and efficiently, as well as predict the NMR data of unknown ionic liquids to accelerate the understanding of their structures and properties. We believe such an approach could be applied beyond the scope of ionic liquids as well as other energy materials,such as optimizing electrolyte solutions to extend the life of flow batteries at a cheaper cost.

9:30 AM DS03.15.05
Crystal-Orientation-Based Analysis on Ingot-Scale Structure of Multicrystalline Silicon Takuto Kojima[1], Kyoka Hara[1], Kentaro Kutsukake[2], Tetsuya Matsumoto[1], Hiroaki Kudo[1] and Noritaka Usami[1]; [1]Nagoya University, Japan; [2]RIKEN, Japan

The introduction of defects into multicrystalline silicon during unidirectional solidification growth is expected to be caused by phenomena on various scales, such as microscopic atomic arrangements and macroscopic stress distributions. The crystal orientation of the multicrystalline structure is extensively involved in the occurrence of twinning and the stress distribution around grain boundaries at grain boundaries. In addition, the multicrystalline structure formed by unidirectional solidification grows columnarly from nuclei at the bottom of the crucible, and the interior of the columnar structure contains a variety of grain boundaries due to continuous twinning. While the orientation relationship between individual nuclei is random, the orientation relationship due to twinning is crystallographically determined and thus contains information on the grain generation relationship. Therefore, it is expected that the macroscopic crystal orientation distribution can be used to analyze the dynamics of crystal growth. Since obtaining ingot-scale data using conventional diffraction-based methods is difficult, we have developed a method to estimate crystal orientation with a machine learning model using optical images of the surface textured by anisotropic etching as input data. We have achieved the estimation model with an average estimation error of 3.5° (95th percentile < 9°) trained on the crystal orientation distribution obtained by X-ray diffraction [1-3]. In addition, to extract macroscopic features of the multicrystalline structure, we have developed a method to analyze the crystal orientation distribution by attributing the orientation relationship due to twinning to a network graph [4-7]. We will report an ingot-scale analysis of the development of the polycrystalline structure during crystal growth using these methods.

9:45 AM DS03.15.06
Machine Learning for Anion Exchange Membrane Used by Fuel Cells to Determine the Dominant Factor Controlling Anion Conductivity Yin Kan Phua[1], Tsuyohiko Fujigaya[1,2,3] and Koichiro Kato[1,3,4]; [1]Kyushu University, Japan; [2]The World Premier International Research Center Initiative, International Institute of Carbon Neutral Energy Research (WPI-I2NER), Kyushu University, Japan; [3]Center for Molecular Systems (CMC), Kyushu University, Japan; [4]Research Institute for Information Technology (RIIT), Kyushu University, Japan

Increasing global demand for clean and sustainable energy has increased attraction towards fuel cell for its zero emissive, sustainable and highly efficient properties. Current mainstream proton exchange membrane fuel cell (PEMFC) faces problems such as sluggish Pt-catalyzed oxygen reduction reaction (ORR) kinetics occurring at the cathode due to low pH operating environment of PEMFC, requiring more Pt to improve ORR reaction rate. In contrast, anion exchange membrane fuel cell (AEMFC) has better ORR reaction kinetics when compared to PEMFC due to the high pH operating environment of AEMFC. This potentially allows the reduction of Pt quantity used in AEMFC compared to PEMFC, thereby bringing down the cost of AEMFC. However, AEMFC carries problems such as low durability and low anion conductivity for the anion exchange membrane (AEM) used as electrolyte membrane in AEMFC, inhibiting it from commercialization. To date, AEM materials research and development (R&D) are carried out through experimental research, requiring huge amount of budget, time, and labor, thereby slowing down the progress of R&D. To solve such issues, high hopes are placed on utilizing machine learning (ML) to accelerate AEM R&D. However, readily available database regarding AEM materials, critical for implementing ML, are not available, and complex structure of AEMs made of functional polymers are difficult to represent in terms understandable by ML models. Hence, a database as well as a method to represent the complex structure of AEM polymers needs to be established to implement ML into the AEM materials research field. In this study, we sought to establish a database that contains both homopolymer and copolymer, represent it using descriptors understandable by ML models, and determine the dominant controlling factor of anion conductivity for AEM materials based on the chemical features information provided by the descriptors. AEM database was made by extracting papers listed in several review papers. Extracted polymer structures were converted to numerical form easily understandable by ML models. For machine learning, objective variable was set as anion conductivity, and explanatory variables were set as anion conductivity measuring temperature and polymer structure in numerical form. The models used in this study are chosen based on their ability to provide high prediction accuracy and difficulty in overfitting, which includes Category Boosting (Catboost), eXtreme Gradient Boosting (XGBoost), Gradient Boosting for regression (GBR) and so on. After training and validating the ML models, R^2 value was used to evaluate their prediction accuracy. Then, Shapley values for each model when predicting anion conductivity were calculated to determine the dominant controlling factor of AEM polymers. We successfully built a database containing 60 AEM papers worth of data, with 4,014 data points in it. Among the data points, there are 1,200 anion conductivity data points obtained from 180 types of AEM polymer structures. Machine learning models were trained in Python 3.9 using Intel Core i9-11900K. All trained models gave prediction accuracy exceeding 90%, with Catboost model achieving the highest prediction accuracy of 97.7%. To understand the prediction mechanism behind the machine learning models, Shapley values calculated from each ML models showed that anion conductivity measuring temperature carried the highest impact on predicted value. Others include polarizability of the polymer, meaning the polarizability of AEM polymer affects the anion conductivity of AEM heavily. Hence, during the design of AEM polymers, polarizability of the polymer should be increased to achieve higher anion conductivity. This shows that our model successfully determined the dominant control factor for anion conductivity of AEMs, carrying potential to serve as polymer design guidelines in the future.

10:30 AM *DS03.16.01
Accelerating Battery Research, Development and Deployment Using Machine Learning Kandler Smith; NREL, United States

Batteries are complex multi-physics systems, with weak observabilty into their underlying physical processes. Physics models have made great strides to answer engineering questions and accelerate scale-up of batteries for 100-kWh-scale electric vehicles and MWh-scale grid energy storage. Yet many challenges still exist. First, with 50+ parameters, electrochemical models of conventional Li-ion batteries are still cumbersome to identify, requiring 3+ months of experiments - a pace too slow to keep up with new product development. Developers often compromise with empirical models that do not directly predict operating limits. Second, complex chemo-mechanical-coupled physics are not fully understood or modeled accurately enough. This slows development of next generation emerging electrode/electrolytes and impedes lifetime prediction/optimization for conventional Li-ion. Semi-empirical reduced-order models predict lifetime, but their supporting aging characterization experiments take 9+ months. Third, battery data comes in many forms, ranging from microscopy/spectroscopy to electrochemical. Streamlined approaches are needed to interpret all of these disparate data sources, distill them, and guide research, design, and deployment decisions.

This talk presents recent progress in application of machine learning to electrochemical and microscopy data, as well as storing that data and supporting models in accessible, searchable formats. Super-resolution generative adversarial networks quantify cracking and damage processes from scanning electron microscopy images of polycrystalline cathodes. Machine learning algorithms interpret electrochemical data to indentify physics-based electrochemical models and reduced-order lifetime models. A new battery data hub stores battery R&D data to better coordinate the efforts of researchers and provide uniform access to data and analysis tools.

11:00 AM DS03.16.02
Optimization of Thermoelectric Generators Using Genetic Algorithms Chun-I Wu and Yen-Chen Chu; National Taiwan Ocean University, Taiwan

This research studies optimizing segmented thermoelectric and two-stage thermoelectric generators and using Matlab programming language and Real Number Genetic Algorithm to perform optimization. With different segment lengths and different cross-sectional areas, the material properties of the cold and hot sections can be obtained by calculating the temperature of the material contact surface. The thermal resistivity, electrical resistivity, Seebeck coefficient, and thermoelectric generator output power can also be calculated. After optimization by a genetic algorithm, the output power of the two-stage thermoelectric generator increases by 17.06%, and the output power of the segmented thermoelectric generator increases by 159.32%. Finally, observe the thermoelectric material distribution and temperature changes to make inferences.

Autonomous Colloidal Atomic Layer Deposition Amanda A. Volk[1], Robert Epps[1], Kristofer G. Reyes[2] and Milad Abolhasani[1]; [1]North Carolina State University, United States; [2]University of Buffalo, United States

Colloidal atomic layer deposition (cALD) is a versatile technique for the solution-phase, room temperature, formation of complex heterostructure nanoparticles.[1] In cALD, sequences of independent, self-limiting, half reactions are used to grow multi-compositional shells with monolayer precision. Despite the limited number of existing studies, the versatility of this method has allowed for the formation of a diverse set of complex nanostructures, including Au/CdS, Ag/AlO_X, CeO_2/AlO_X, SiO_2/AlO_X, SiO_2/$AlPO_4$, CdSe/CdS, CdSe/ZnS, PbS/CdS, HgSe/CdSe, HgSe/CdS, HgSe/CdSe, and $CsPbX_3$/AlO_X.[2] However, a detailed study of this powerful synthetic route remains challenging due to a variety of factors. Primarily, the multistep and dynamic nature of cALD creates an exponentially growing parameter space. In cALD processes which routinely require over 50 sequential reaction steps, the range of tunable conditions becomes impractically large ($> 10^{100}$). Furthermore, optimized cALD reaction conditions at each cycle depend on material properties which cannot easily be measured, such as surface ligand coverage. Experimental designs to elucidate the role of such hidden states, because of an extremely large parameter space, are nearly infeasible as well as highly resource intensive.
In response to the presented challenges, in this work, we designed and developed an autonomous robotic experimentation strategy for accelerated studies of cALD by integrating a modular microfluidic platform with machine learning (ML)-assisted experimental planning.[3] Using shelling of cadmium sulfide (CdS) onto cadmium selenide (CdSe) quantum dots (QDs) as a case study, we developed a material-efficient microfluidic platform to automatically investigate cALD cycles in sequence, using only a 10 mL biphasic droplet. The developed autonomous robotic experimentation platform is fully automated and modular in design and is capable of on-demand reagent addition, controlled mixing and reaction, online multimodal spectral monitoring, and in-line phase separation. Using the autonomous cALD platform, reagent addition sequences and purification protocols could be varied without hardware reconfiguration. Reaction progress was monitored through a UV-Vis absorption and photoluminescence flow cell positioned at the end of the reactor. The developed autonomous cALD platform could routinely carry out over 1,000 successful reaction step instructions without user intervention.
To demonstrate machine-driven knowledge discovery of the cALD protocol, we directed the ML algorithms to explore different precursor injection and washing sequences up to 20 total injections per starting reactive precursors. After running an exploratory design space search policy over more than 1,000 total injections, we exploited the ML models to identify the optimized injection sequence. Without any prior knowledge of conventional cALD reaction protocols, the integrated system successfully identified an alternative cycled injection sequence substructure that achieved a larger shift in the first absorption peak wavelength and higher photoluminescence intensity than conventional methods (new knowledge generation). The developed intelligent fluidic robot is the first autonomous system to solve a high-dimensional multi-step material synthesis problem in colloidal nanoscience without user guidance and using only in-house generated data. Further implementation of the technologies developed here can lead to more efficient, machine-driven studies of dynamic, highly complex, multi-step, reactive systems.

Graph Convolutional Neural Network for Projected Density of States Predictions Ihor Neporozhnii, Oleksandr Voznyy and Zhibo Wang; University

of Toronto, Canada

Machine learning models recently demonstrated prominent results in predicting materials properties and accelerating materials discovery [1]. However, they still fail in predicting complex material properties (particularly bandgaps) or maintaining accuracy in the low-data regime.
Graph Convolutional Neural Networks (GCNNs) became the de facto standard for encoding crystal structures of arbitrary size. They showed high accuracy in predicting additive properties of the materials, e.g. total energy, which can be represented as a sum of energies of single atoms. However, we find that they fail to predict atomic interactions that result in delocalized properties, such as molecular orbitals and the resulting electronic bandstructure, even in the simplest 2-level system case.
Here, we developed a material representation that retains the locality of atomic contributions to the final molecular orbitals and band structure. Our GCNN trained on band structure data from the Materials Project database [2] with elements from s, p, d, and f blocks is capable of making accurate predictions of projected densities of states even when training on a dataset with less than 5000 materials.

11:45 AM DS03.16.05
Investigating the Perovskite Solar Cells Layers' Materials Effect on Degradation Curve Shape Using Clustering Algorithms Noor Titan Putri Hartono[1], Hans Köbler[1], Paolo Graniero[1,2], Mark Khenkin[1] and Antonio Abate[1]; [1]Helmholtz-Zentrum Berlin, Germany; [2]Free Universität Berlin, Germany

Despite the high efficiency, addressing the perovskite solar cells (PSCs) degradation issue remains critical for pushing their levelized cost of energy down and making the technology economically feasible to enter the manufacturing stage. Recent studies point out that the most common lifetime metric for solar cells, the T80 lifetime (the time required to reach 80% of initial performance), in PSCs vary due to the difference in degradation curve shape, due to an initial burn-in loss, an initial sharp efficiency increase, and a combination of both. The exact cause of such variations is unknown, which hinders the mitigation efforts for reducing the degradation in PSCs.

In this study, we utilize machine-learning-based clustering algorithms, including dynamic time warping (DTW) and self-organizing map (SOM), to categorize ~1,400 degradation curves of devices degraded under various environmental stressors with different electron- and hole-transport layer, perovskite composition, and contact materials. We also investigate how the various layers affect the shape of the degradation curves, pointing out the layers responsible for specific degradation curve shape. This will be an important step in finding the optimum layer combination, and finally, mitigating the degradation issue in PSCs.

12:00 PM DS03.16.07
Real-Time Parameter Estimation in Electrochemical Systems with Confounding Variables using Neural Network Sarthak Jariwala; PARC, United States

Measuring and estimating parameters of interest in real-time in electrochemical systems remains a challenge. Traditional methods used to characterize the response and estimate parameters of interest are often slow and time-consuming, thus, not applicable for real-time applications. Here, we develop a workflow utilizing physics-based processing and deep learning to estimate parameters and confounding variables with uncertainties in real-time from large amplitude AC Voltammetry (LA-ACV) measurements on electrochemical systems. We demonstrate our approach on a model electrochemical system ($K_3Fe(CN)_6$ in potassium phosphate buffer) to estimate the concentration of redox active species ($K_3Fe(CN)_6$) in the presence of unknown viscosity (confounding variable) with 0.3 mM median absolute error in concentration estimation.

12:15 PM *DS03.16.08
Automated Defect Detection in Electron Microscopy of Radiation Damage in Metals Dane Morgan[1], Ryan Jacobs[1], Mingren Shen[1], Priyam Patki[2], Matthew Lynch[1] and Kevin Field[2]; [1]University of Wisconsin--Madison, United States; [2]University of Michigan, United States

In this talk, we discuss our recent work on automating detection of defects in electron microscopy images of irradiated metals.[1-5] Radiation response of materials is a critical design constraint for future nuclear fission and fusion materials. Electron microscopy is widely used to explore defects in crystal structures, but human tracking of defects can be time-consuming, error prone, unreliable, and is not scalable to large numbers of images or real-time analysis. In this work, we discuss application of machine learning approaches to find the location and geometry of different defects in irradiated alloys, such as dislocation loops, black dot interstitial clusters, and cavities. We explore multiple deep learning methods (Faster Regional Convolutional Neural Networks (Faster R-CNN), Mask R-CNN, and You Only look Once (YOLO)) and generally find performance approaching or equivalent that of human accuracy. We explore multiple avenues of assessment, including precision and recall of specific defect identification (F1[endif]-->0.8), accuracy of microstructurally relevant averages (e.g., average defect areal density and size distribution ([endif]-->10% fractional errors), and accuracy of modeled defect dependent macroscopic properties such as hardening (10-20 MPa errors, or about 10% of total hardening), and swelling ([endif]-->0.3% swelling errors). These results suggest that specific images can have significant errors, but averaging over many images yields quite good results. We explore convergence of the results with number of training samples, finding that certain defect types are significantly less well detected, likely due both to their having reduced sampling and greater variability, as well as model limitations for small size features. In addition, our targeted evaluation tests also suggest the best path toward improving future models is not expanding existing databases with more labeled images but instead data additions that target weak points of the model domain, such as images from different microscopes, imaging conditions, irradiation environments, and alloy types. Finally, we discuss the new types of science enabled by the massive data which can be extracted with these approaches, e.g., detailed defect evolution during in-situ irradiations. We will also point to provided cyberinfrastructure to enable use of our models, including Python notebooks tailored for running on Google Colab and cloud accessible models on the Foundry for data, models and science,[6] which enables inference on new images using only two lines of python code.

7:00 AM DS03.17.01
A Self-Driving Lab Autonomously Learns to Accurately Dispense Samples via Dynamic Experimental Control Martin Seifrid, Riley Hickman, Emre Alca and Alán Aspuru-Guzik; University of Toronto, Canada

Self-driving labs – automated experiments guided by machine learning (ML) algorithms – have the potential to accelerate discovery of new molecules, materials and processes across a range of disciplines. They can enable researchers to think about their experiments in the context of trends, datasets, and other higher level questions rather than individual experiments by minimizing the necessity for manually performing routine or repetitive tasks.

A central challenge of self-driving labs is building robotic systems capable of carrying out the same wide range of actions and experiments as humans. For example, accurately dispensing both large and very small quantities of material. Currently, this requires careful calibration and testing to determine the correct process parameters for each material, and substantially eats into valuable researcher time. It would therefore be desirable for a robotic systems to be able to teach itself the optimal process parameters autonomously. This would reduce the necessity for human involvement in routine tasks, and boost the efficiency of self-driving labs.

In this talk, I will detail our work toward developing a fully autonomous synthesis platform, enabled by a closed loop of Bayesian optimization and automated experiments, that can optimize its own instrument parameter to accurately dose samples, and learn from its previous experience with optimizing the parameters for other samples in order to further speed up its learning rate. Such systems have the potential to significantly improve the capabilities of self-driving labs, the development of which is often limited by the need to adapt them to each new material.

Redox Flow Batteries Trends—Chemistries and Materials Grigorii Soloveichik; ARPA-E, United States

Fast growing grid-scale energy storage requires a portfolio of technologies tuned for intermittent renewable energy sources and capable to provide wide range of discharge times up to seasonal storage. Redox flow batteries (RFBs) can occupy an intermediate position with the storage time from several hours

to tens of hours. The amount of stored energy can be adjusted depending on the customer's need by changing the volume of electrolyte storage tanks for rated power, and the system cost could be competitive with other energy storage technologies.
The cost reduction remains the major driver in current RFB development, which can be achieved by decreasing costs of the stack via increasing power density and using inexpensive stack components, energy storage media via employing inexpensive active materials and electrolytes, storage tanks via increasing solubility of active materials and BOP (separately or in combination). The former approach targets development of high-power cells based on mainstream vanadium chemistry. The least expensive option is the utilization of earth-abundant inorganic salts (e.g., iron or zinc) and water as solvent. These chemistries are limited by competitive reaction of water splitting. Another option is the use of water-soluble organic compounds, which potential and solubility can be tuned by adding functional groups to the core molecule. However, such tuning requires additional synthetic steps that increase the manufacturing cost and may negate the performance advantage. Non-aqueous RFBs have hypothetically higher (above water splitting threshold) cell potential and higher solubility of tunable active materials. However, this potential was not realized yet, and high cost, low conductivity and flammability of solvents render such RFBs not competitive with aqueous RFBs. Current trends, research needs and tradeoffs for RFBs with stationary (hybrid RFB) and liquid (conventional RFB) electrodes will be discussed.
Development of novel ion-selective membranes and chemistries for RFBs was funded by ARPA-E via GRIDS, OPEN, IONICS and DAYS programs.
Important lessons from completed projects will be also discussed.

2:00 PM *EN01.01.02
Recent Progress in Organic-Based Aqueous Flow Batteries Michael J. Aziz; Harvard University, United States

The ability to store large amounts of electrical energy is of increasing importance with the growing fraction of electricity generation from intermittent renewable sources such as wind and solar. Wide-scale utilization of flow batteries is limited by the cost of redox-active metals such as vanadium or precious metal electrocatalysts. We have developed high performance flow batteries based on the aqueous redox behavior of small organic and organometallic molecules, e.g. [1-6]. These redox active materials can be inexpensive and exhibit rapid redox kinetics and high solubilities, potentially enabling massive electrical energy storage at greatly reduced cost. We have developed protocols for measuring capacity fade rates, which are particularly important for establishing very low capacity fade rates, and have discovered that the capacity fade rate is determined by the molecular calendar life, which can depend on state of charge, but is independent of the number of charge-discharge cycles imposed [7,8]. We will report the performance of some of the very few chemistries with long enough calendar life for practical application in stationary storage [8], and on progress in reversing capacity fade by recomposing decomposed molecules [9].

2:30 PM *EN01.01.03
Inroads and Challenges in the Design of Robust, High-Performance Flow Battery Electrolytes Patrick J. Cappillino[1], Shyam K. Pahari[1], Jennifer Bolibok[1], Sara Amin[1], Benjoe Rey B. Visayas[1], Maricris L. Mayes[1], Sundar R. Aravamuthan[2] and Ertan Agar[2]; [1]University of Massachusetts Dartmouth, United States; [2]University of Massachusetts Lowell, United States

Redox flow batteries (RFBs), in which charge-carrying electrolytes are pumped through electrochemical cells, are a promising energy storage technology. In these systems, the energy capacity scales with the volume of electrolyte stored in tanks, and the power scales with the size of the cell. This decoupling gives RFBs potential advantages for long- and medium-duration grid energy storage applications and a favorable safety profile compared with integrated systems like lithium-ion batteries (LIBs).[1] Furthermore, next-generation RFBs, such as those comprising nonaqueous electrolytes with high voltage active-materials, are an exciting research area, because they may find much wider application. For example, a nonaqueous RFB (NFRB) system that meets or exceeds the energy density of LIBs, while maintaining the flexible architecture of a flow system, could impact distributed energy storage markets.

This presentation will provide a progress update on a bio-inspired NRFB system under development in our laboratories that is based on a molecule known as vanadium bis-hydroxyiminodiacetate (VBH).[2] This molecule, biosynthesis of which evolved in mushrooms, owes its extraordinary stability to natural selection pressure.[2] An NRFB system containing a mixed electrolyte of VBH, as catholyte, and an organic anolyte, both at moderate concentration, will be described. This system operates at a current density approaching state-of-the-art aqueous RFB systems and is stable to exhaustive cycling. Capacity fade from crossover can be restored by rebalancing the electrolyte. I will describe how high stability was achieved and how solubility constraints were overcome, by implementing a combined experimental and theoretical approach.[3-4]

Improving RFB energy density by increasing active-material concentration, while solving one problem, creates another. Inefficiencies due to decreased electrochemical performance and pumping losses in so-called “crowded electrolytes” have been recognized as a fundamental obstacle that must be overcome before NRFB technology can mature.[5] In the last portion of this presentation, I will describe inroads and remaining challenges for two strategies we are pursuing to overcome poor transport in high-concentration NRFB electrolytes. First, a combined theoretical and experimental, structure/function study to understand how nanoscale interactions between ions and solvent molecules impact macroscale transport properties. And second, a “redox targeted” flow battery approach, in which VBH-based electrolyte is combined with a solid storage material to boost the energy density while preserving the high-performance we observe at moderate active-material concentration.[6]

Redox flow batteries (RFBs) are proposed to fill the supply-demand gap in the renewable energy market. Nonaqueous RFBs are of special interest due to their wider electrochemical windows compared to aqueous systems and compatibility with redox-active organic molecules (redoxmers). However, engineering stability in these systems is highly dependent on redoxmer, electrolyte salt, and solvent. Here, we examine 2,1,3-benzothiadiazole (BzNSN), a negative charge carrier for nonaqueous RFBs. Our previous work revealed significant solvation effects in acetonitrile depending on the cation of the electrolyte, where lithium cations strongly coordinate the BzNSN radical anion and shift its half-wave potential 150-200 mV positive depending on counter-anion. This shift is accompanied by decreased redoxmer stability as shown by spin resonance and symmetric H-cell cycling experiments. We hypothesized that a solvent with strong lithium binding would alleviate the redoxmer-cation chelation effect. For this task, *N*,*N*-dimethylacetamide (DMA) was explored as preliminary calculations showed that it should interact strongly. Comparing lithium vs. tetraalkylammonium electrolytes showed no shift in half-wave potential in this solvent. Further, there was little change in radical anion stability by spin resonance experiments. Finally, we compared symmetric H-cell cycling of BzNSN in the two solvents in lithium-based electrolyte and found that DMA had successful cycling while the acetonitrile experiment barely cycled. This study reveals the importance of solvation effects in evaluating new materials for nonaqueous RFBs.

4:00 PM *EN01.01.05
Opportunities and Challenges of Organic Redox Flow Batteries Tianbiao Liu; Utah State University, United States

Aqueous redox flow batteries (AORFBs) represent one promising energy storage technology for integration of renewable energy and balancing the electricity grids because of their technical merits of decoupled energy and power, sustainable and tunable redox active materials, and non-flammable and low cost aqueous supporting electrolytes. This presentation will review recent efforts in developing new flow battery chemistries, including viologen (anolyte), quinone (anolyte), TEMPO (catholyte), ferrocene (catholyte), and ferrocyanide (catholyte). The merits and drawbacks of representative acidic, pH neutral, and alkaline AORFBs will be discussed and compared. A number of research strategies will be discussed to develop high-performance redox active electrolytes to enable energy dense, durable, low-cost flow battery technologies. Particularly, this presentation emphasizes that in-depth mechanistic understandings of redox active electrolytes play crucial roles in developing advanced organic redox flow batteries towards sustainable, long-duration energy storage.

Decomposition Mechanisms and Stabilized Organic Catholyte Molecules for Aqueous Redox Flow Batteries Xiaoliang Wei[1], Diqing Yue[1] and Wei

Wang[2]; [1]Indiana University-Purdue University, United States; [2]Pacific Northwest National Laboratory, United States

Redox flow batteries have been widely recognized as promising stationary energy storage solutions for solving the intermittency issue of renewable energies. Owing to the high chemical cost, the state-of-the-art vanadium flow batteries are largely limited in market penetration. Organic redox materials have advantages of structural diversity and tunability, offering an opportunity to harvest exceeding materials properties such as solubility, stability and redox characteristics. In aqueous flow battery systems, organic anolyte molecules are extensively investigated and a variety of promising candidates have been reported such as phenazine, viologen, anthraquinone, etc. However, organic catholyte is an under-addressed area. The major limitation is the often limited chemical stability in aqueous electrolytes, especially for those having high redox potentials. Therefore, a ready urgency lies in understanding the decomposition mechanisms of chosen organic catholyte based on which to develop stable structures.

Here we report the mechanistic analysis of decomposition of TEMPO-based organic catholyte and the resulting development of a highly soluble, highly stable candidate. The unstable TEMPO derivative in the charged cation form is monitored temporally. Based on the evolutions of NMR peaks and pH values in its electrolyte, a decomposition pathway is proposed and a new TEMPO structure is accordingly designed so as to avoid the pathway. The new TEMPO analog exhibits a remarkably high solubility in water and an excellent stability in its charged form. Its solvate structure in water is analyzed and the preferential solvation interactions were suggested. The flow cells using this TEMPO catholyte demonstrate excellent cycling stability under practically relevant conditions. Our result represents a significant advancement in developing soluble, stable organic catholyte molecules to energy-dense, durable aqueous organic flow batteries.

Electrochemical and Rheological Modeling of Suspension-Based Electrolytes for Redox Flow Batteries Madhu Majji, Bertrand Neyhouse, James Swan and Fikile Brushett; Massachusetts Institute of Technology, United States

Electrochemical energy storage is poised to play a key role in enabling society-wide decarbonization by facilitating the deployment of variable electricity generators and enhancing existing grid infrastructure. Redox flow batteries (RFBs) possess several technology features which are favorable for cost-effective, long-duration energy storage, including independent scaling of power and energy, long service life, and simplified manufacturing [1]. In particular, the battery configuration enables a diversity of electrolyte compositions and cell materials to be considered, either at the beginning of life or during the installation lifetime (e.g., chemistry swaps). While conventional RFBs are based on redox couples dissolved in electrolyte solutions, more recently, suspension-based electrolytes containing solid charge storage materials have emerged as an alternative formulation. Flowable suspensions enable higher capacities (and thus cell energy densities) and unlock new operating modes (e.g., dissolution and precipitation on suspended particles) [2,3]. However, such electrolytes also frustrate traditional approaches to cell design and operation as their complex electrochemical and rheological behavior presents multifaceted tradeoffs [4,5]. By exploring the essential features of these tradeoffs, we aim to better understand fluid dynamic and electrochemical engineering criteria for high-performance flow cells that operate with suspension-based electrolytes.

In this presentation, we develop and apply a one-dimensional model to derive scaling relationships for suspension-based electrolytes in RFBs. Specifically, we investigate connections between rheological (i.e., non-Newtonian behavior, shear stress) and electrochemical (i.e., species and charge transport) phenomena for electrolyte flow through a planar channel. We then identify key dimensionless groups which describe the relative magnitudes of relevant processes within the flowing suspension-based electrolyte. Through scaling analyses, we assess the importance of each parameter under different dynamic and geometric constraints to enable the identification of favorable materials sets and operating conditions. Ultimately, these dimensionless quantities offer a compact representation of the design considerations for suspension-based electrolytes, allowing more informed materials selection, cell engineering, and system formats. Finally, we hypothesize that these results can be generalized to describe flowable and stationary solid suspensions of utility in multiple electrochemical systems.

Quantifying Chlorine Gas Evolution from Mixed-Acid Vanadium Redox Flow Batteries Reed Wittman, Cassandria E. Poirier, Harry Pratt, Travis M. Anderson and Yuliya Preger; Sandia National Laboratories, United States

Mixed-Acid (MA) Vanadium Redox Flow Batteries (VRFB) improve on standard VRFBs' energy density via the addition of hydrochloric acid (HCl) to the standard sulfuric acid (H_2SO_4) electrolyte. This improves the stability of the vanadium (V) in the solution, which allows for electrolytes with higher concentrations of V ions and increased operating temperatures. However, the addition of HCl to the system introduces a new safety risk, the evolution of chlorine gas (Cl_2) from the catholyte.
In this study, we cycled an MA VRFB under a range of conditions to understand the fundamental causes of gas evolution. We constructed a single cell MA VRFB using a standard electrolyte composition of 2M H_2SO_4, 5M HCl and 2M V, with a gas analyzer sampling the head space of the catholyte chamber. Cl_2 gas quantity was measured under systematically varied cycling rates and potential holds. The mechanism of gas evolution was determined to be an electrochemical side reaction that occurs when charging the cell beyond 1.5 volts. Depending on the duration the cell was held at high voltage and the

maximum voltage, headspace Cl_2 concentrations between 1 and 4.2% were observed. Overcharging the cell beyond 1.7 volts (the standard VRFB upper limit) generated gas concentrations near 10%. These concentrations represent a significant safety risk that may occur during system operation and need to be mitigated.
Previously it was assumed that the 360 millivolts potential difference between the V^{4+}/V^{5+} (1.00 volts vs SHE) charging reaction in the posolyte and the $2Cl^-/Cl_2$ (1.36 volts vs SHE) gas evolution reaction would prevent Cl_2 gas evolution through electrochemical means. We will discuss how solution chemistry and cell inefficiencies make Cl_2 generation a viable side reaction when charging a cell above 1.5 volts. This new understanding of gas evolution will aid development of safer MA VRFB systems that mitigate Cl_2 formation during operation.

Accelerating High-Throughput Flow Battery Characterization via Temperature-Dependent (Electro) Chemical Kinetics Eric M. Fell and Michael J. Aziz; Harvard University, United States

Aqueous Organic Redox Flow Batteries (AORFBs) have emerged as potentially disruptive technologies for the storage of electrical energy from intermittent renewable sources for use over long discharge durations when the wind isn't blowing, and the sun isn't shining. AORFBs could become preferred solutions for grid-scale storage due to their potentially low-cost active materials, inherent non-flammability, and intrinsic decoupling of energy and power capacities. Our group has previously demonstrated that calendar life, rather than cycle life, limits molecular lifetimes in AORFBs due to various molecular instabilities that lead to side reactions, thus inhibiting performance [1]. To accurately determine molecular fade rates, we utilize potentiostatic holds to avoid artifacts caused by drifts in internal resistance and employ volumetrically unbalanced, compositionally symmetric cell configurations to distinguish molecular fade from membrane crossover. Synthetic efforts have continued to improve molecular design strategies to the point that the most stable molecules degrade at less than 1% per year [2]. With further lifetime increases, the measurement of lower capacity fade rates now necessitates higher precision coulometry methods [3] and the use of thermally accelerated degradation protocols [4,5] to determine which stabilizing approaches are most effective without waiting for multi-month cycling tests to quantify capacity fade.

We have developed a high-throughput setup for cycling AORFBs at elevated temperatures, providing a new dimension in the flow battery characterization space to explore. An in-depth study comparing previously published redox-active organic molecules has been performed using the protocol discussed above. Capacity fade rates as functions of temperature are evaluated in the high-throughput setup using high-precision coulometry, providing the ability to extrapolate fade rates to lower operating temperatures. Collectively, these results highlight the importance of accelerated decomposition protocols to expedite the screening process of candidate molecules for long lifetime AORFBs, which may enable massive grid penetration of intermittent renewable energy.

***In Situ* Reliability Investigation of All-Vanadium Redox Flow Batteries by an Ultra-Stable Reference Electrode** Qian Huang[1], Chaojie Song[2], Alasdair Crawford[1], Zhengming Jiang[2], Alison Platt[2], Khalid Fatih[2], Christina Bock[2] and David Reed[1]; [1]Pacific Northwest National Laboratory, United States; [2]National Research Council Canada, Canada

Redox flow batteries (RFBs) have been investigated over the past several decades as a promising energy storage system (ESS) for grid applications due to their unique features that include the separation of energy and power output, high safety, and long cycle life. It is therefore vital but still in severe deficiency to understand the reliability of RFBs, and the mechanisms that cause degradation with time. One of the primary challenges involves the unseparated contributions from individual electrodes due to the lack of a stable reference electrode (RE). In this work, a long-term stable reference electrode is developed for a scaled all-vanadium redox flow battery (VRFB). The newly developed reference electrode demonstrates its high accuracy and long-term stability that enables *in-situ* monitoring of individual electrode potentials throughout hundreds of cycles. By introducing the RE approach to decouple the cathode and anode, the reliability and degradation mechanism of a VRFB is further investigated. This exploratory work will be beneficial for the insight into the reliability/degradation mechanism of a VRFB and future design and development of a stable reference electrode in the practical application of a scaled ESS.

Understanding the Membrane-Electrolyte System for Designing Aqueous Organic and Metalorganic Flow Batteries Thomas Y. George, Naphtal O. Haya, John P. Deneen, Isabelle C. Thomas, Cliffton Wang and Michael J. Aziz; Harvard University, United States

Redox flow batteries with aqueous electrolytes hold promise for large scale energy storage, offering independent scaling of power from the electrochemical

stack and energy stored in tanks of dissolved reactants. The all-vanadium redox flow battery (VRFB) has been the most developed chemistry to date, although more recently organic and metalorganic redox reactants have been proven viable for batteries with long calendar life. Ion exchange membranes for flow batteries must suppress crossover of redox reactants while enabling conductivity of a charge-carrying ion for efficient battery cycling. Studies on VRFBs have shown that the concentration and composition of the solutions contacting the membrane have crucial influence on transport phenomena through the membrane pores. Building on this understanding, the research presented here contributes an evaluation of the effects of iron(II/III) hexacyanide electrolyte concentration and pH on cation exchange membrane performance, which will inform the design of aqueous organic and metalorganic redox flow batteries (AORFB).

In AORFBs, the size and charge numbers of organic molecules and metalorganic complexes afford them more crossover resistance than metal ions like iron or vanadyl, but many of the most stable chemistries use neutral or alkaline electrolytes where sodium or potassium ions carry charge through the membrane. The widely-used cation exchange membrane Nafion has a factor-of-ten reduction in conductivity in potassium form compared to the proton form available in acidic environments. Therefore in AORFBs, ohmic resistance of the membrane is a substantial limiting factor on practical current densities and power densities for battery operation.

The composition and concentration of the electrolyte contacting the membrane influences the water content of the membrane, which determines the pathways available for transport, and hence the conductivity. Here we describe simple methods for conductivity and electrolyte uptake measurements that can be used to screen a variety of membrane materials and electrolytes. We show the influence of both iron hexacyanide concentration and supporting electrolyte (sodium or potassium hydroxide) on water content and conductivity of both Nafion cation exchange membranes and a non-fluorinated, hydrocarbon-based cation exchange membrane from Fumatech (E-620K). These results emphasize that total ion concentration of the electrolyte affects membrane water content, and therefore supporting electrolyte should be minimized when concentrations of redox active species are high enough to provide ionic conductivity. We also show that maximizing the concentration of iron hexacyanide by using mixed cation electrolytes results in increased membrane resistance, signifying that conductivity and volumetric capacity become a tradeoff. Considering membrane and electrolyte properties as an interrelated system supports the design of battery electrolytes for compatibility with a given membrane, and may also accelerate the creation and selection of new membranes tailored for flow batteries.

Optimization of Redox Flow Battery Carbon Felt Electrode Mesostructures By Applying Lattice Boltzmann Method and Machine Learning Jia Yu[1,2], Marc Duquesnoy[1,2,3], Chaoyue Liu[1,2] and Alejandro A. Franco[1,2,3]; [1]Laboratoire de Réactivité et Chimie des Solides (LRCS), UMR CNRS 7314, France; [2]Réseau sur le Stockage Electrochimique de l'Energie (RS2E), FR CNRS 3459, France; [3]ALISTORE-European Research Institute, FR CNRS 3104, France

Carbon felt electrodes constitute state-of-the-art Redox Flow Batteries (RFBs) components because of their high electronic conductivity, high specific surface area, and high porosity. In order to further improve the electrochemical performance of these electrodes, many researchers have investigated different treatment methods, including plasma treatment, thermal, and chemical modifications [1]. However, the geometrical features of the fibrous electrode, which has a significant influence on mass transport (convection) and the anolyte/catholyte utilization rate, are often left from the discussion. This study presents an innovative computational approach that examines the fluid dynamic properties of the anolyte/catholyte flow separately from the electrochemistry behavior in various carbon felt electrode mesostructures. First, electrode mesostructures were generated stochastically based on realistic tuneable manufacturing parameters, including the fiber diameter, electrode density, amount of in-plane and through-plane fibers, and the compression ratio. Afterward, the Lattice Boltzmann Method (LBM) [2–4] was applied to simulate each electrode permeability and the reactive volume ratio, where the latter quantifies the dead volume due to the slow fluid velocity compared with the diffusion coefficient. Finally, based on the results obtained from the LBM, a Bayesian Optimization Algorithm was applied to analyze the datasets and propose promising parameter values corresponding to the optimized anolyte/catholyte utilization rate. This optimization workflow allows analyzing the impact of different manufacturing parameters on fluid dynamic properties and predicting a theoretical optimized carbon felt electrode mesostructure is also identified and tested by computational simulations for charging and discharging conditions.

MIcroband Electrode Platforms for Identifying Homogeneous and Heterogeneous Factors Limiting Redoxmer Performance for Redox Flow Batteries Michael A. Pence, Oliver Rodriguez Martinez, Inkyu Oh, Nikita Lukhanin, Charles M. Schroeder and Joaquin Rodriguez-Lopez; University of Illinois at Urbana Champaign, United States

Chemical and electrochemical limitations of redox-active species (*redoxmers*) that cause long-term performance losses in redox flow battery devices may not be immediately evident during conventional electroanalytical experimentation. In both aqueous and nonaqueous solutions, effects of uncompensated resistance and non-idealities in the redoxmer response can lead to difficulties in identifying mechanistically complicating factors. Here, we posit that in contrast to ~cm^2 electrodes typically used for the initial screening of redoxmers, ultramicroelectrodes – electrodes with at least one critical dimension in the micron or sub-micron range – can be used directly or integrated into microfabricated devices to reveal such limitations. Complicating factors can present in the form of heterogenous, i.e. related to reactivity at the electrodes, or homogeneous, i.e. related to the behavior of the charged molecules in solution. In this talk, we will present our approaches using microfabricated band electrodes (MBEs) and interdigitated array electrodes (IDAs) to tackle these analytical needs for both aqueous and non-aqueous systems. Emphasis will be made on approaches designed to inform on processes at timescales relevant to the flow battery experiment.

In a first example we will discuss an automated generation-collection experiment with IDAs is used to determine the homogeneous rates of decomposition of redoxmers in highly systematic experiments. Taking advantage of several simplifications afforded by this experiment enables the swift estimation of the impact of interfering species, redoxmer concentration, and other electrolyte conditions on the chemical stability of these systems. In a second example, we will show how MBEs are used to obtain heterogenous kinetics of electron transfer with great versatility, avoiding complications associated with the use of high scan rates in typical cyclic voltammetric experiments at macroelectrodes. We will discuss prospects for integrating these methodologies into systematic experiments similar to those conducted using scanning electrochemical microscopy and associated techniques to promptly identify mechanistic limitations in redoxmer systems.

Minimizing Performance Degradation Due to Crossover in Non-Aqueous Redox Flow Batteries Shelley Minteer; University of Utah, United States

Non-aqueous organic redox flow batteries have been suggested for sustainable grid storage. However, rapid electrolyte crossover between anolyte and catholyte is a problem. Bipolar redox-active molecules are single molecules that undergo both anode and cathode redox reactions and they are an option for addressing this crossover problem. The unique redox chemistry of bipolar redoxmers is commensurate to vanadium species in aqueous redox flow batteries, but enable greater design flexibility and potentially better properties than are otherwise observed. However, there are complex tradeoffs in their properties. Balancing these properties have been incredibly challenging. As such, this talk will discuss the rational design of bipolar redoxmers and the tradeoffs needed to optimize performance. This talk will also discuss ion exchange polymer strategies for minimizing crossover in RFBs.

Eutectic Mixing of Quinones—A Strategy for Engineering Highly-Energy Dense Liquid Electrolytes Emily Penn, Antonio Baclig, Devi Ganapathi and William C. Chueh; Stanford University, United States

To address the low energy density of redox flow batteries, eutectic electrolytes have emerged as an approach to achieving high concentrations of redox-active species. Here we introduce an entropically-driven eutectic mixing approach which, through eutectic mixing of chemically similar redox active species, can be used to engineer highly concentrated liquids composed of nearly all redox active molecules. Demonstrated using quinones, we investigate a ternary benzoquinone eutectic and a binary naphthoquinone eutectic which,if the total charge could be accessed, have a theoretical volumetric capacities of 16.8 and 8.8 M e-, respectively. We quantify melting point, ionic conductivity, and viscosity across multiple states of charge. We also explore application to redox flow batteries using a binary naphthoquinone eutectic electrolyte with a protic ionic liquid supporting salt, achieving a volumetric capacity of 37 Ah/L in symmetric static cell cycling. Though reactivity of the redox active quinones and capacity fade during cycling present challenges for the electrolytes in this study, the entropically-driven eutectic approach presents a general framework which could be used to develop highly concentrated, low viscosity electrolytes using redox-active organic small molecules.

2:15 PM EN01.03.03
Multi-Objective Goal-Directed Optimization of De Novo Stable Organic Radicals for Aqueous Redox Flow Batteries Peter St. John[1], Shree Sowndarya S. V.[2], Jeffrey Law[1], David Biagioni[1] and Robert Paton[2]; [1]National Renewable Energy Laboratory, United States; [2]Colorado State University, United States

Advances in the field of goal-directed molecular optimization offer the promise to find feasible candidates for even the most challenging molecular design applications. One example of a fundamental design challenge is the search for novel stable radical scaffolds for an aqueous redox flow battery that simultaneously satisfy redox requirements at the anode and cathode, as relatively few stable organic radicals are known to exist. To meet this challenge, we develop a new open-source molecular optimization framework coupled with a fast, machine learning-derived surrogate objective trained with nearly 100,000 quantum chemistry simulations. The objective function comprises two graph neural networks: one that predicts adiabatic oxidation and reduction potentials and a second that predicts electron density and local 3D environment, previously shown to be correlated with radical persistence and stability. With no hard-coded knowledge of organic chemistry, the reinforcement learning agent finds molecule candidates that satisfy a precise combination of redox, stability, and synthesizability requirements defined at the quantum chemistry level, many of which have reasonable predicted retrosynthetic pathways. The optimized molecules show that alternative stable radical scaffolds may offer a unique profile of stability and redox potentials to enable low-cost symmetric aqueous redox flow batteries.

2:30 PM EN01.03.04
High Performance Nitrogen-Doped Hierarchical Nanostructured Carbon Electrode for Vanadium Redox Flow Batteries Gerardo M. Pagano[1,2], Simone Fiorini Granieri[1,2], Matteo Zago[1], Andrea Casalegno[1] and Fabio Di Fonzo[2]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy

In recent years, we have seen an impressive progress in the deployment of renewable energy sources, and in particular of photovoltaics and wind turbines. However, renewable energies have some well-known drawbacks due to their intermittent nature and direct usage of the electricity generated would destabilize the grid. To overcome these problems large scale energy storage systems have drawn great attention in the last few years both from the academic and industrial world. Redox flow batteries (RFB) are emerging as one more promising electrochemical energy storage technologies. Notably, the Vanadium redox flow battery (VRFB) is currently the most widespread technology as it allows for the implementation of strategies that permit to recover the capacity decay induced by ion cross-over. Despite the many advantages, VRFBs have long suffered from low power density, mainly caused by the usage of electrodes which are not optimized for this application. The use of heteroatom dopants, such as nitrogen, phosphor, and boron, is currently the most common method to enhance the performance of carbon electrodes. Nitrogen has been extensively studied as a catalyzer for Vanadium redox reactions, showing exceptional boosts in performance in several works. In a previous work we developed a two-step process based on a plasma enhanced nano-aerosol jet deposition source. Starting from a gas precursor we deposited a nanostructured carbonaceous material on a commercially available substrate, this process allows to increase the current density to 400 mAcm-2 with an energy efficiency of 80%, that is, 4 times greater than the commercial reference. The two-steps process permits a fine tuning of the properties and structure of the material leading to an exceptionally high surface area and a defect rich structure. The advantage of this process is that nitrogen can be added easily during the deposition phase without the need for any other processing steps. In this work we aim to further increase the performance of our nanostructured electrode by adding nitrogen functionalities to the carbon nanostructure, thus combining the effects of an incredibly high surface area with the excellent catalytic properties of nitrogen. The morphology and chemistry of the synthesized material is analyzed by different techniques such as SEM-EDX, Raman spectroscopy, XPS, BET analysis. The properties of the material are then correlated to the electrochemical properties by testing the material in increasingly complex setups, starting from a three-electrode setup, then in symmetric cell and finally in a full-cell setup. The kinetic activity of the material is studied by cyclic voltammetry and electrochemical impedance spectroscopy. Cyclic voltammetry showed an impressive activity of the electrodes towards the active species, especially towards the V2+/V3+ couple where a peak-to-peak separation of 65 mV was obtained, which is among the lowest reported in literature. These results were confirmed by EIS, from which the reaction rate constants were calculated following the method proposed by Stimming et al. [1] The addition of nitrogen led to an order of magnitude increase of the reaction rate with respect to the un-doped material. The performance enhancement was then validated by the test in symmetric cell and full cell. Thus, we propose a vertically integrated process, from the synthesis of the material to the final application, which is able to deliver a comprehensive overview on the material properties, its electrochemical performance and the correlation between the two.

Design High Performance Double Layer Ion Selective Membrane with Porous Boron Nitride and Polyetherimide Tongtai Ji, Xiao Sun, Daxian Cao, Ying Wang, Haoze Ren and Hongli Zhu; Northeastern University, United States

Flow batteries is one of the most attractive large-scale energy storage technologies, while the high cost and ion crossover issues of the commercial ion selective membranes limit scale-up of flow batteries. Herein, we designed a double-layer membrane with a unique bifunctional porous boron nitride (PBN) layer coated on a low cost porous polyetherimide (PEI) layer. PBN, synthesized through a one-step template free method from a precursor with boric acid and excess urea, has high nanoporosity and great stability. Through sonicating in isopropanol, PBN obtained hydroxyl and amino groups during the decomposition of the amorphous part, which increased the hydrophilicity and crystallinity simultaneously. PBN was further mixed with Nafion to constitute the ion selective layer, integrating ion selectivity with proton conductivity. The nanoporous PBN structure decorated by sulfonic acid groups from Nafion formed high-speed proton transfer channels. On the other hand, the nano-sized and tortuous channels from PBN effectively prevented the crossover of other ions and increased the ion selectivity. The ultra-thin (5 μm) PBN ion selective layer was coated on the high ion conductive and low-cost porous PEI layer prepared by nonsolvent induced phase separation method to obtain free-standing membranes with both high mechanical strength and ion conductivity. The PBN-PEI double layer membrane achieved superior coulombic efficiency of 97.02%, voltage efficiency of 93.79%, and energy efficiency of 91.18% at 40 mA cm^{-2} in vanadium redox flow battery compared to the Nafion 115 membrane (coulombic efficiency of 95.01%, voltage efficiency of 92.32%, and energy efficiency of 87.71%). Meanwhile, the PBN-PEI displayed long cycling stability with 700 cycles at 100 mA cm^{-2}. This work presents a novel approach to designing ion selective membrane by imparting ion-exchange groups into the PBN inorganic porous structure to break the tradeoff between ion selectivity and ion conductivity and provides a thread for cost reduction by double-layer design.

Efficient Prediction of Redox Potentials of First-Row Transition Metal Complexes for Aqueous Targeting Redox Flow Batteries Using Density Functional Theory. Noura Rahbani[1], Emmanuel Baudrin[1] and Piotr de Silva[2]; [1]Université de Picardie Jules Verne (UPJV), France; [2]Technical University of Denmark, Denmark

Targeting redox flow batteries are an emerging alternative to traditional redox flow battery architecture which offer improved energy density *via* an added solid electroactive 'booster'. For an efficient system, it is imperative that the redox potentials of the soluble redox mediator and the solid match.[1] For this purpose, transition metal complexes are a promising class of redox mediators due to the tunability of their solubility and electrochemical potential, and their safety and sustainability. As such, reliable and time-efficient prediction tools for the redox potentials of transition metal complexes are needed for the discovery of new materials. While density functional theory usually provides a good trade-off between computational cost and accuracy, calculations on organometallic complexes often result in large errors, so they have been used for studying trends of the ligand effect rather than providing accurate predictions.[2,3] In this communication, we compare redox potential predictions from different solvation methods and levels of theory using an initial experimental data set based on aqueous iron complexes with bidentate ligands complexing through oxygen. Good predictions (MAE= 0.23 V) are obtained using the COSMO-RS solvation model; however, this model is only available through a select list of DFT software. When using the more common implicit solvation models, there is a general deviation from experimental results, irrespective of the level of theory used. We propose that these errors are conveniently corrected by using simple linear regression which yields a good prediction of redox potentials (MAE=0.09 V). The predictive power of this method is also demonstrated by cross-validation using complexes with different metal centers and ligand types.

3:45 PM EN01.03.07
A Spin-Crossover Fe Complex for Low-Cost and Long-Life Aqueous Redox Flow Batteries Donghwi Ko, Jantakan Nedsaengtip and Hye Ryung Byon; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

The development of low-cost and long-life energy storage systems (ESSs) is essential to alleviate the growing demands for energy and environmental issues. Redox flow batteries (RFBs) are considered promising grid-scale ESSs thanks to the ensured safety, low cost, and decoupled energy and power density. While vanadium has been commercially utilized as the redox-active material in aqueous RFBs, more economical materials such as Fe-based complexes are necessary. Ferrocyanide and ferrocene are representative Fe complexes showing the stable and reversible redox process in aqueous electrochemical cells. However, they suffered from low solubility and chemical instability under acidic and alkaline conditions.[1,2] Many other Fe complexes even showed unstable nature in the neutral aqueous media due to high sensitivity to water and air.[3,4] Thus, better molecular designs of Fe complexes are required to extend a Fe-based redox molecular library and understand Fe chemistry in aqueous RFBs.
Here we introduced hexadentate Schiff-base ligands to the central Fe ion, which formed the spin-crossover Fe complexes. These spin-crossover Fe complexes showed a correlation between spin state and electrochemical stability. The spin state depended on the strength of the hydrogen bond between the secondary amine group of the ligands and the solvent. The water solvent has a strong hydrogen bonding and increases the electrostatic interaction between the secondary amine group and the Fe metal center. Thus, the percentage of low-spin isomers increases. Besides, the type of functional groups implemented into phenyl rings of the ligands also determined the spin states. We selected the sulfated or hydroxyl groups as representatives of the electron-withdrawing or electron-donating groups, respectively. The electron-withdrawing groups increased the degree of Fe to ligand pi-interaction, thereby increasing the ratio of low spin. This trend was inverse for the electron-donating groups. The Evans method reflected the magnetic moment of these Fe complexes according to the functional groups, supporting the relationship between the ligand functional groups and the spin-state of Fe. In cyclic voltammetry, the low-spin Fe complex showed stable 100 cycles with the redox potential at –0.45 V vs. Ag/AgCl. By contrast, the high-spin Fe complex showed the redox potential at –0.53 V vs. Ag/AgCl with poor cyclability. In the aqueous RFB operation, 0.1 M of the low-spin Fe complex showed ~94.4% capacity utilization and achieved 0.004% capacity decay per cycle over 100 cycles, demonstrating a promising candidate as the stable negolyte in aqueous RFBs.

Ultrathin MoS_2 Membrane with Low Stacking Fault for Vanadium Redox Flow Battery Ji Soo Roh, Kailing Lin, Robert Dryfe and Mark A. Bissett; The University of Manchester, United Kingdom

Vanadium redox flow battery (VRFB) is one of the most promising sustainable large-scale energy storage systems. In VRFB, a membrane with high proton/vanadium ion selectivity and high proton conductivity is essential for improved cycle life, energy efficiency, and power density of the entire cell. Commercial Nafion membranes are commonly used, but they require a high cost even though they have low ion selectivity and swelling issues. In this

study, we applied MoS_2 as a VRFB membrane material due to its excellent chemical stability. The MoS_2 is vacuum-filtered on porous polymer support to prepare ultrathin membranes, but poor dispersion stability of MoS_2 flakes in solvents has resulted in membrane defects during the filtration process. To decrease the stacking fault, we employed graphene oxide as an additive and used a different solvent system to stabilize the MoS_2 dispersion. As a result, the prepared MoS_2 membranes showed lower vanadium crossover and better chemical stability than the commercial Nafion membrane.

An High-Performance Carbon-Nano Onion Electrode for Vanadium Redox Flow Battery Simone Fiorini Granieri[1,2], Gerardo M. Pagano[1,2], Fabio Di Fonzo[1] and Matteo Zago[2]; [1]Istituto Italiano Di Tecnologia, Italy; [2]Politecnico di Milano, Italy

In order to get rid of fossil fuel energy, continuous production of energy through renewable sources is not sufficient, in fact, a direct connection of renewable energies to the electrical grid would unsure the grid stability. This incompatibility is due to renewable energies intermittency, which requires therefore a coupling with an energy storage system (EES). Among the different EES technologies, the Redox Flow Battey (RFB) is the most promising for the so-called “mid-term storage” (storage up to 12 hours), and in particular the all-vanadium RFB seems to be the most used. Even though RFB has some advantages with respect lithium ions battery, it still has to overcome some problems, such as the low power density. Power density is determined primarily by the electrodes, these are typically porous carbon media responsible for the production of the electron by a redox reaction with electrolyte. Focusing on electrodes, there are two possible solutions to increase the power density: (i) increasing surface area and (ii) increasing reaction kinetic. Many authors improved the nowadays commercial electrode carbon felt increasing the surface area, e.g. by thermal treatment, or the reaction kinetic, e.g. by bismuth electrodeposition [Zhao, T.S. et al. Energy Storage Material, 2020]. Carbon felt due to its millimeter range thickness suffers from a high overall ohmic resistance, and this feature cannot be neglected when operating the device at high current density. In our work, we propose to increase the surface area of a carbon paper, a 300 um porous carbon electrode with lower ohmic resistance, by covering the fibers with a turbostratic hierarchical assembly carbon nanostructure, composed of carbon nano onions (CNO). For the deposition of the carbon nano particles, a prototypal deposition method has been adopted, called plasma enhanced, nanoparticle jet deposition, NanoJeD. This deposition method offers a green, high throughput and dry process with potential for easy scale-up. A detailed description of the working principle is shown at the following article [Nava et al., Nanotechnolgy 29, 2018]. By mean of this deposition technique and a vacuum annealing process, is possible to maximize the surface area, electrical conductivity and catalytic activity made by the hierarchical assembly of turbostratic CNO. The CNO kinetic properties has been tested by cyclic voltammetry in a three-electrode setup and with electrochemical impedance spectroscopy. From the cyclic voltammetry performed at different scan rate, a net increasing catalytic activity has been observed in both the chemical reaction. At the negative site, which is known to be the limiting one, a separation peak of 80mV at 10mV/sec has been reported, giving a clear indication of quasi-reversibility reaction mechanism. By EIS analysis following the procedure explained in [U. Stimming, ChemPhysChem, 2019] it is possible to extract the kinetic reaction constant, at the negative site a clear increase in kinetic reaction constant with the annealing temperature has been reported, while at the positive site no effect on kinetic reaction constant from the annealing temperature have been observed. The deposited electrode on carbon paper, has been tested with different deposition thicknesses and annealing temperatures in a symmetric cell to evaluate systematically the overpotentials of each configuration towards the V2+/V3+ and VO(2+)/VO2(+) reactions. A current density sixfold higher with respect to the untreated carbon paper resulted from the test. Combining the high surface area with the high catalytic activity we are able to reach, in a full cell composed of two electrodes per side, a current density of 400 mA/cm2 and 600 mA/cm2 with an energy efficiency of 81% and 74%, together with an electrolyte utilization of 70% and 59% respectively. Moreover, the stability test showed a low degradation rate, valued in a 1000 cycles test.

Derivatization and Optimization of Iron Bipyridine Complexes for Non-Aqueous Flow Batteries Travis M. Anderson, Claudina X. Kolesnichenko and Cassandria E. Poirier; Sandia National Laboratories, United States

Non-aqueous flow batteries containing earth-abundant elements offer the possibility of higher voltage and a wider temperature range than many of their aqueous counterparts. Here we show the optimization of a symmetric flow battery with baseline $Fe(bpy)_3(BF_4)_2$ and derivatized $Fe(bpy\text{-}R)_3(BF_4)_2$ (R is electron donating or electron withdrawing groups) to lessen capacity fade and improve energy efficiency over 20 cycles. The cause of the capacity fade in these systems was determined to be ligand shedding in the negolyte upon reduction. Recognizing that the free ligands are often more stable and more tunable, we then evaluated pseudo-symmetric flow batteries containing a family of bipyridinium materials as negolytes with the corresponding iron coordination complex as the posolyte. Methylation of the bipyridine nitrogen sites increased electrochemical stability but left the reduced molecule susceptible to radical-induced bond cleavage and caused poor capacity utilization. Additional functionalization of the bipyridine with carbomethoxy groups resulted in improved battery performance with high Coulombic and voltage efficiency, and improved cycling stability. Current work is underway to look at other iron-organic systems for improved performance.

Fullerene C76 as a Novel Electrocatalyst for VO^{2+}/VO_2^+ and Chlorine Evolution Inhibitor in All-Vanadium Redox Flow Batteries Nageh K. Allam; American University in Cairo, Egypt

The effect of thermal treatment of carbon cloth and the deposition of fullerene C_{76} on the performance of the VO^{2+}/VO_2^+ redox reaction was investigated in G1 (H_2SO_4) and G3 (H_2SO_4/HCl, mixed acid) VRFBs. Thermally treated carbon cloth was shown to improve the kinetics of the redox couple due to the increase in its hydrophilicity, graphitic nature, and defects such as oxygen functional groups, which would act as active sites. Incorporation of C_{76} on treated carbon cloth (TCC) and untreated carbon cloth (UCC) was shown to equally and significantly enhance the reversibility of the electrochemical reaction, as indicated by an average peak separation value of only 109 mV and a charge transfer resistance of 4 Ω, compared to 230 mV for TCC and 403 mV for UCC, in both electrolytes. This could be attributed to C_{76}'s great conductivity, presence of oxygen functional groups, and electron cloud around the nanoparticles, which would appreciably facilitate vanadium adsorption and electron transfer. This also reveals that there is no need to treat carbon cloth before depositing C_{76}; hence saving time and energy. In addition, C_{76} was demonstrated to hinder chlorine evolution in G3 VRFBs, compared to TCC and

TCC-C_{76}, while also maintaining its stability over a repetitive 100-cycle CV, suggesting its great resistance against corrosion. Overall, the extraordinary reduction in overpotential and facile diffusion of vanadium ions, combined with the hampering of chlorine evolution and its great stability render fullerene C_{76} as a suitable electrode material towards more efficient VRFBs.

EN01.04.02
Investigation of Iron and Organic-Based Bipolar Redox Molecules for Non-Aqueous Flow Batteries Cassandria E. Poirier, Chad L. Staiger and Travis M. Anderson; Sandia National Labs, United States

Non-aqueous redox flow batteries are being studied as a more attractive option than their aqueous counterparts due to their higher voltage window, less environmental impact, and lower cost of active species. One of the most promising non-aqueous redox chemistries are the ferrocene-phthalimide family of bipolar molecules where the ferrocene moiety is the posolyte and phthalimide is the negolyte. However, only static cell studies of these molecules have been published. We now report full flow cell studies and optimization of these molecules. We also investigate the effects of (1) membrane compatibility, (2) electrolyte volume, (3) functional group, and (4) solvent and supporting electrolyte on battery performance.
Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

EN01.04.03
Reversible Metal Ionic Catalysts for High-Voltage Aqueous Hybrid Zinc-Manganese Redox Flow Batteries Minsoo Kim, SooBeom Lee, Jinyeong Choi, Jihan Park and Minjoon Park; Pusan National University, Korea (the Republic of)

Redox flow batteries (RFB) have been considered as a promising candidate for large-scale electrochemical energy storage systems (EES) due to excellent scalability, high efficiency, and long lifetime. Among the various types of redox flow batteries, the aqueous zinc-manganese batteries have attracted tremendous attention due to its intrinsically abundant resources, low-cost and environmentally friendliness. The development of the rechargeable zinc-manganese batteries has focused on the reversible Zn ions insertion and extraction into MnO_2 structures. However, the aqueous zinc-based batteries have fundamental problems such as the dissolution of manganese ions, which usually causes the structure collapse of MnO_2, eventually resulting in a potential degradation with low electrochemical performances. Accordingly, the aqueous-based Mn^{2+}/MnO_2 redox couple has been studied to avoid the insertion and deintercalation of zinc ions into crystalline MnO_2, which could prevent the undesirable phase transformation of crystalline MnO_2 structures. Moreover, the acidic and alkaline electrolytes in the aqueous hybrid batteries have been reported to overcome the low operation voltage and effectively use the Mn^{2+}/MnO_2 redox couple with a high redox potential (E =1.228 V vs. standard hydrogen electrode (SHE)).
The critical issue for the aqueous-based Mn^{2+}/MnO_2 redox couple is low reversibility because of the incomplete dissolution of MnO_2 with the exfoliated dead MnO_2 species. The dead MnO_2 species eventually block the ion transport channel of the membrane and are considered an irreversible species with the main reason for the decreased active areas. Herein, we report the aqueous hybrid zinc manganese redox flow battery (ZMFB) with double-membrane-based three-electrolytes, using an alkaline zinc redox couple ($Zn/[Zn(OH)_4]^{2-}$) and an acidic manganese redox couple ($Mn^{2+}/MnO_2(s)$), showing a high operating voltage of 2.75 V at the state of charge 100%. To improve the manganese redox couple kinetics, we utilized the bismuth nanoparticle embedded carbon felt (BCF) electrode and metal ionic catalysts (MIC) consisting of nickel and magnesium ions. This unique strategy demonstrated the outstanding performance in the aqueous hybrid ZMFB for 150 cycles corresponding to 35 hours at 20 mA cm^{-2}. It also demonstrated an energy density of 25.2 Wh L^{-1} with respect to catholyte volume at a concentration of 1 M manganese. Notably, the hybrid ZMFB with BCF-MIC electrode shows an energy efficiency of 89.8% at 15 mA cm^{-2}. The BCF improved the electrodeposition of MnO_2 by creating atomically reconstructed Bi nanocrystals from dissolved Bi^{3+} ions. Simultaneously, the use of Ni^{2+} ionic catalysts in catholyte help to maintain the high oxidation state of manganese, resulting in high energy efficiency and long cycle performances with the reversible reaction of metal ionic catalysts. We believe that our approach for the high-voltage aqueous hybrid ZMFB is advantageous for the development of stable and large-scale energy storage systems.

EN01.04.04
Anion Exchange Membrane for Sustainable Vanadium-Manganese Redox Flow Batteries with Reduced Overpotential via Ni-Bi Alloy Oxide Derived Etched Carbon Felt Anode Jihan Park, Minsoo Kim, SooBeom Lee, Jinyeong Choi and Minjoon Park; Pusan National University, Korea (the Republic of)

Recently, intensive studies have been conducted on vanadium/manganese redox flow batteries (V/Mn RFBs) with advantages of abundant element reserves and higher energy density (35 Wh L^{-1}) than VRFBs (20 Wh L^{-1}). Especially, the cell voltage of V/Mn RFBs is 0.5 V higher than VRFB because of the high standard redox potential of the MnO_2/Mn^{2+} couple (1.224 V vs. SHE). Despite these merits, the cycling performance was deteriorated due to disproportionation reaction of the Mn^{3+}/Mn^{2+} couple which decay the capacity and power of the V/Mn RFBs. Therefore, previous studies have been focused on improving the reversibility of MnO_2 particles to extend the lifetime of V/Mn RFBs. However, we focused on the loss of cations between anolyte and catholyte through membrane and low redox activity of V^{2+}/V^{3+} couple as the main cause of performance degradation.
In this study, two strategies were applied to realize sustainable V/Mn RFBs. First, the cation exchange membrane (CEM) was replaced with an anion exchange membrane (AEM) to prevent the loss of redox–active species and allowed the passage of charge balancing species only. In the V/Mn RFB systems using CEM, the loss of redox–active species was attributed to the attractive force between cations (V^{2+}, V^{3+}, Mn^{2+}, and Mn^{3+}) and SO_3^- in the cluster network of Nafion 117. On the other hand, the repulsive force between cations and NR_3^+ in selemion DSV effectively inhibited the net cation transfer through membrane, which was confirmed using ICP–OES and electrochemical performances. Second, the Ni–Bi alloy oxide derived etched carbon felt (NB–ECF) was used as a negative electrode to increase the low redox activity of V^{2+}/V^{3+} couple. In particular, the NB–ECF anode significantly improved the reduction activity of V^{3+} ion compared to commercial CF and reduced the overpotential of 191 mV for the V/Mn stack. Additionally, BET, XRD, XPS, and electrochemical analysis demonstrated that NB–ECF provides a large specific surface area, the oxygen functional groups on the carbon surface, and the embedded bi–metal alloy oxide. V/Mn flow battery to which both strategies were applied achieves excellent cycle performance over 70 cycles at 20 mA cm^{-2}, maintained voltage efficiency above 90%. These novel strategies can be applied to other systems that use cations as redox couple in both tanks and expected to broaden the range of advanced flow batteries through etching of other alloys.

EN01.04.05
Aqueous High-Voltage Zinc-Vanadium Redox Flow Battery with the High-Index Facets Polyhedron $Ce_{2/3}TiO_3$ Electrocatalyst Jinyeong Choi, Jihan Park, SooBeom Lee, Minsoo Kim and Minjoon Park; Pusan National University, Korea (the Republic of)

Aqueous redox flow batteries (RFBs) have been considered as the most promising energy storage systems which have several advantages of using inexpensive and nonflammable electrolytes, long lifetime. Most importantly, the independent and tunable power and capacity make it suitable technology for large energy storage systems. Although the reliable cycling performance and stability have been demonstrated, traditional aqueous RFBs still suffer from the limited voltage range and low energy density because of the limited operating voltage by the water splitting voltage of 1.23 V to avoid the hydrogen and oxygen evolutions. In addition, carbon-based electrode materials for RFBs such as carbon paper, graphite felt, and carbon felt were suffered from low electrolyte access to the electrode surface due to the hydrophobic nature which was ascribed to the high graphitization temperature.
To overcome the narrow voltage of aqueous RFBs, we demonstrated the hybrid zinc-vanadium RFB with high operating voltage of 2.3 V, which was composed of two-membranes and three-electrolyte reservoirs. According to the Pourbaix diagram, the redox potential of the active materials was mainly affected by pH value. Therefore, we dissolved the zinc redox couple in alkaline solution ($Zn/ [Zn(OH)_4]^{2-}$, −1.26 V vs standard hydrogen electrode, SHE) to exhibit a higher operating voltage than the zinc redox couple in neutral solution ((Zn/Zn^{2+}, −0.76 V vs SHE), allowing the different types of electrolyte combinations. Furthermore, to fully utilize the high voltage of the hybrid zinc-vanadium RFB, we fabricated binary cerium titanium oxide ($Ce_{2/3}TiO_3$, hereafter referred to as CTO) with abundant defects and prepared the CTO catalyst ink with mixing Ketjen black (KB) as conductive agent and binder solution, then coated onto the carbon felt electrode for VO^{2+}/VO_2^+ redox couple. We firstly found that the CTO-KB electrocatalysts could improve the VO^{2+}/VO_2^+ redox reaction, which could be attributed to synergistic effect of conductive KB. Specifically, the CTO-KB composite electrocatalysts showed a significantly improved peak separation potential (ΔE) of 227 mV, which was 140 mV less than that of the pristine carbon felt electrode. In addition, the reference carbon felt electrode had only 140.95 and 131.08 mA cm^{-2}, whereas CTO-KB represented high oxidation and reduction peak current densities of 167.4 and 159.11 mA cm^{-2}, respectively, and the CTO-KB showed superior performance than other composite electrocatalysts due to the synergistic effect of KB nanoparticles. The abundant defects with edge dislocation, planar defects, and oxygen vacancies were observed in the microstructure of the CTO, which also gave rise to the high catalytic activity. The hybrid zinc-vanadium RFB showed excellent cell efficiency at a current density of 40 mA cm^{-2} and recovered to initial state at the decreased current density. the composite electrocatalysts exhibited higher capacity characteristics than the cell to which pristine CF was applied even after 50 cycles due to low overpotential. As a result, we presented the possibility of driving next-generation energy storage devices with higher efficiencies and showed the possibility of using a high voltage energy storage device using a low potential zinc anode active material.

EN01.04.06
A High-Voltage Aqueous Zinc-Vanadium Redox Flow Battery with Bi-Modal Tin and Copper Clusters by a Continuous-Flow Electrometallic Synthesis SooBeom Lee, Minsoo Kim, Jihan Park, Jinyeong Choi and Minjoon Park; Pusan National University, Korea (the Republic of)

Aqueous zinc-based redox flow batteries are promising large-scale energy storage applications due to its low cost, high safety, environmental friendliness and low redox potential of the zincate couple of $Zn/[Zn(OH)4]^{2-}$ in the alkaline media. However, there have still tremendous obstacles towards practical use, such as zinc dendritic growth during the charging process, resulting in internal short circuit. These can create the dead zinc metal, which accumulate on the porous electrode or membrane and increase the cell resistance. In addition, the formation of the zincates has a problem of a low reversibility in the strong alkaline electrolytes, which can degrade the cycle efficiency and performance. Currently, several methods have been proposed to reduce the zinc dendritic growth in the zinc-based redox flow batteries, such as the surface modification of the carbon felt electrode and membrane developments. However, there were still limitations in terms of the complicated modification process. Also, the water splitting limits the voltage enhancement of the aqueous RFBs, allowing the narrow potential window under 1.23 V. Therefore, it is necessary to develop a low-cost and high energy density aqueous RFB system with the high voltage.
In this work, we report a bi-modal sized tin and copper (Sn, Cu) incorporated carbon felt (SCCF) via a novel multi-step, continuous-flow electrometallic synthesis method to solve the zinc dendrite issue in the zinc-based redox flow batteries. The SCCF electrode lowers the zinc nucleation overvoltage in the zinc symmetric flow battery and zinc-based hybrid redox flow battery, inducing the homogenous zinc plating and suppressing the zinc dendritic growth. A combined electrochemical and computational investigation reveals that the bi-modal tin and copper particles could suppress unwanted alloy formation, such as Cu-Zn alloy, strongly adsorbing zinc without the dendrite formation. The SCCF electrode exhibits 75% improved cycling stability than the pristine carbon felt electrode in the zinc symmetric flow battery. The pH differential hybrid Zn-V redox flow battery with the double membrane, pairing the VO^{2+}/VO_2^+ catholyte with the $Zn/[Zn(OH)_4]^{2-}$ anolyte, affords a high average cell voltage over 2.31 V at 40 mA cm^{-2}. The SCCF electrode in the hybrid Zn-V redox flow battery led to high coulombic efficiency (>99.9%), average energy and voltage efficiency 92.6% and 92.3% over 100 cycles, respectively. We anticipate that this facile preparation method assisted by the continuous-flow electrometallic synthesis and high voltage hybrid Zn-V redox flow battery can pave the way to be large-scale applied in ZFBs, and even expanded into a wide range of energy storage system.

EN01.04.07
Strategies to Mitigate Solvent Degradation to Obtain Deep Reduction Potential Anolytes for Non-Aqueous Redox Flow Batteries Nicolas Daub, Dimitar Georgiev and René Janssen; Technische Universiteit Eindhoven, Netherlands

Redox flow batteries (RFBs) are very promising storage systems in the transition towards renewable energy sources. They can be broadly classified in aqueous and non-aqueous systems. Last-named operate with organic solvents, which allow for a much broader potential window (up to three times higher) compared to water. Combination of organic solvents with organic redox active materials could pave the way for all carbon-based RFBs with superior energy densities compared to aqueous systems.
In this contribution, a new class of organic anolytes will be presented, focusing on their performance as RFB materials in acetonitrile with quaternary ammonium electrolyte salts. To push the limits of energy density, we investigated multi-electron reduction reactions on a single molecule.
Current state-of-the-art anolytes for non-aqueous redox flow battery (NARFB) having a deep reduction potential, all contain carbonyl groups.[1-5] As already proposed by Wei et al.,[1] these anions could possibly attack acetonitrile. Yet, no clear evidence for that was shown. We investigated alkyl terephthalates

which exhibit two consecutive, deep reduction events at about -2.1 and -2.5 V vs Fc/Fc+. Upon accessing the second reduction couple, evidence was seen for a deprotonation of acetonitrile. Besides the analysis of the degradation, we suggest a design strategy to mitigate this reaction which results in a suitable anolyte for a NARFB with a deep reduction potential.

Membrane-Free Redox Flow Batteries Jianbing J. Jiang; University of Cincinnati, United States

While membrane-free batteries have been successfully demonstrated in static batteries, membrane-free batteries in authentic flow modes with high energy capacity and high cyclability are rarely reported. Here, we present a biphasic flow battery with high capacity employing organic compound in organic phase and zinc in aqueous phase. Under ambient flow testing conditions, a capacity retention of 94.5% is obtained over 190 charging/discharging cycles with a Coulombic efficiency of > 99% at a current density of 8.54 mA cm^{-2}. Self-discharge at full state-of-charge of the membrane-free RFB is negligible (potential drop = 0.78 mV h^{-1}). DFT calculation and *operando* UV-visible and FT-IR spectroscopies are performed to probe minor side reactions during cycling and monitor the water content in the organic electrolyte in real time. The successful demonstration of the prototypical membrane-free battery under flow conditions, together with the developed *operando* spectroscopic techniques, will open a new avenue towards detailed mechanistic studies and practical applications of redox flow batteries for cost-effective energy storage.

Efficient Harvesting and Storage of Solar Energy of an All-Vanadium Solar Redox Flow Battery with a MoS2@TiO2 Photoelectrode Gengyu Tian; Queen Mary University of London, United Kingdom

Solar redox flow batteries constitute an emerging technology that provides an intelligent alternative for the capture and storage of discontinuous solar energy through the photo-generation of the discharged redox species employed in traditional redox flow batteries. Here, we show that a MoS_2-decorated TiO_2 (MoS_2@TiO_2) photoelectrode can successfully harvest light stored in a solar redox flow battery using vanadium ions redox-active species in both catholyte and anolyte, and without the use of any bias. MoS_2@TiO_2 photoelectrode achieved an average photocurrent density of ~0.4 mA cm^{-2} versus 0.08 mA cm^{-2} for bare TiO_2 when tested for the oxidation of V^{4+} to V^{5+}, attributed to a more efficient light harvesting and charge separation for the MoS_2@TiO_2 relative to TiO_2. The designed solar redox flow cell exhibited an optimal overall solar-to-chemical output energy conversion efficiency (SOEE) of ~4.78%, which outperforms previously reported solar redox flow batteries. This work demonstrates the potential of MoS_2@TiO_2 photoelectrode to efficiently convert solar energy into chemical energy in a solar redox flow battery, and it also validates the great potential of this technology to increase reliability in renewable energies.

10:00 AM *EN01.05.05
Investigating Indirect Redox-Targeting Reactions for High Energy Density Redox Flow Batteries Sundar R. Aravamuthan[1], Shyam K. Pahari[2], Shabdiki Chaurasia[1], Jennifer Bolibok[2], Benjoe Rey B. Visayas[2], Maricris L. Mayes[2], Patrick J. Cappillino[2] and Ertan Agar[1]; [1]University of Massachusetts Lowell, United States; [2]University of Massachusetts Dartmouth, United States

Redox flow batteries (RFBs) are considered to be one of the key technologies for addressing the intermittency problem in renewable energy sources, due to their unique architecture that allows for unprecedented scalability and flexibility, and cost-effectiveness in long-duration storage [1]. Despite their promise, typical RFBs suffer from low energy density because of the limit imposed by the solubility of the redox active species in the electrolyte [2]. One promising approach to address this limitation is the utilization of solid charge storage materials in the tanks to reversibly reduce or oxidize dissolved species in the electrolyte via indirect redox-targeting reactions without being connected to an external circuit [3-4]. In this way, the capacity is no longer dependent on the concentration of soluble species but rather the quantity of solids in the tanks. This concept [5] demonstrates the promise for exploiting the unique benefits of solid- and liquid-phase redox chemistry, combining the high-energy-density of Li-ion batteries, and the scalability and safety of RFBs.

In this presentation, we demonstrate a high energy density redox-targeting flow battery (RTFB) using a highly stable bio-inspired active material (vanadium(IV/V)bis-hydroxyiminodiacetate (VBH)) and a suitable solid storage material [5]. VBH [2,5] provides an ideal scaffold to investigate the complex electrochemical processes that occur during RTFB operation, which remain virtually unexplored [6]. For the solid storage material, a Prussian Blue Analogue (PBA) is synthesized and coupled with VBH mediators. Our recent efforts on understanding the interplay between two kinetic processes: electrochemical reaction in the flow cell and an indirect redox-targeting reaction in the tank are discussed. Cycling experiments are performed with and without the solid energy booster material to provide evidence that the addition of a compatible solid material greatly improves the energy density. Optimization of the critical parameters such as the amount of solid storage material, the operating current density, and the electrolyte flow rate is presented. Furthermore, an empirical approach to matching RTFB mediators with solid charge storage materials is introduced.

Higher Energy Density Mediated Lithium-Sulfur Flow Batteries Melissa Meyerson, Adam Maraschky and Leo J. Small; Sandia National Laboratories, United States

There is a need for safe, reliable, high-capacity storage for long duration energy storage. The low cost and high capacity of sulfur make Li-S batteries ideal for this purpose. However, sulfur has poor electrical conductivity and Li-S batteries are prone to polysulfide shuttling that decreases the battery life. Additionally, lithium metal cannot be cycled at high rates or dendritic growth is produced. We have previously addressed the issues with the S by combining aspects of a static Li-S battery with aspects of a redox targeting system and flow battery. With this system we demonstrated that fundamental Li-S chemistry and novel SEI engineering strategies can be adapted to the hybrid redox flow battery architecture, obviating the need for ion-selective membranes or flowing carbon additives, and offering a potential pathway for inexpensive, scalable, safe MWh scale Li-S energy storage. However, these tests were done at lab scale with low S loadings and limited charge rates, limiting both the energy and power density of the proof-of-concept system. In this study we present recent progress scaling up the system from 2.5 mg_S cm^{-2} to over 50 mg_S cm^{-2} and increasing the current density from 0.5 mA cm^{-2} to 10 mA cm^{-2} to decrease the charge/discharge time. The increase in S loading results in an increase in energy density and the increase in applied current increases the power density of the system.
To scale up the flow cell we address limitations of the small-scale architecture including examining the flow field used with the catholyte and the structure of the Li metal anode. We first tested high surface area scaffolds in Swagelok cells to examine the effect of the increased effective surface area and lithiophilic seed materials like ZnO on Li metal deposition independent of the flow cell or S chemistry. Using a high effective surface area anode support enables us to increase the applied current density from 0.5 mA cm^{-2} to 10 mA cm^{-2} greatly increasing the charge/discharge speed. Furthermore, the addition of a lithiophilic seed layer decreases the nucleation overpotential and encourages uniform Li electrodeposition. A tailored flow field also improves the uniformity of Li deposition on the anode by improving the uniformity of the catholyte flow velocity. These improvements are first evaluated separately and then combined in a mediated Li-S flow battery where cycling rate and capacity retention are compared against a traditional planar Li anode and open flow field.
Sandia National Laboratories is a multi-mission laboratory managed and operated by National Technology and Engineering Solutions of Sandia, LLC., a wholly owned subsidiary of Honeywell International, Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

A High-Voltage Aqueous Zinc-Based Redox Flow Batteries with Reversible Metal Ionic Catalysts and Bi-Modal Tin and Copper Clusters Minjoon Park, Minsoo Kim, Jinyeong Choi, SooBeom Lee and Jihan Park; Pusan National Univeristy, Korea (the Republic of)

With the increasing interest of renewable energy sources, the electrical energy storage (EES) system has received great attention to solve uncertainty of power input and output. Among many EES systems, a redox flow battery is the most promising candidate due to design flexibility for large scale. Recently, low cost and earth abundant transition metal based redox couples have attracted significant attention to replace the expensive vanadium redox couples. Conventional Mn-based aqueous zinc-ion battery is highly safe energy storage system, but low operating voltage (<1.5V) and low energy density limits its broad application in large-scale energy storage system. Recently, a novel aqueous zinc-manganese dioxide redox flow battery is reported. This battery is composed of Mn^{2+} based acidic catholyte and Zn^{2+} based alkaline anolyte, respectively, exhibiting an open circuit voltage of 2.66 V. Also, a neutral electrolyte was located between two different membranes to prevent the cross contamination of acidic and alkaline electrolytes, maintaining the charge balance. However, Mn^{3+} ions suffer from the disproportionation side reaction, lowering battery performance. Thus, the low reversibility of Mn/MnO_2 redox couple should be improved for broad application of Zn-Mn redox flow batteries. In addition, the formation of zinc dendrite should be suppressed when the zinc-based anolyte was used, which could deteriorate the cell performance.
In this work, we report a high voltage aqueous Zn−Mn hybrid redox flow battery with a high operating voltage of 2.75 V at the 100% state of charge. This work is a significant step forward by exploring the pH differential hybrid flow cell with the double-membrane, three-electrolyte configuration. The manganese cathode was deposited on carbon felt electrode with bismuth using carbothermal reduction process. Moreover, metal ionic catalysts are added as solution catalysts. We found that the reversibility of Mn ions was improved, and side reactions were suppressed by adding the metal ionic catalysts, maintaining a higher oxidation state of Mn ions. As a result, our works suggest that the zinc-manganese dioxide redox flow battery can be operated at high voltage with the excellent reversibility. Considering zinc dendrite issues, we introduced the bi-modal sized tin and copper (Sn, Cu) incorporated carbon felt in the negative electrode. The zinc nucleation overpotential was lowered by surface modified carbon felt electrode, also minimizing hydrogen evolution.

Research Directions in Perovskite Solar Cell Toward Theoretical Efficiency Nam-Gyu Park[1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]SKKU Institute of Energy Science and Technology (SIEST), Korea (the Republic of)

Since the ground-breaking report of the 9.7% efficient and 500 h-stable solid-state perovskite solar cell (PSC) in 2012 based on methylammonium lead iodide, perovskite photovoltaics have been surged swiftly due to high power conversion efficiency (PCE) obtainable via facile fabrication procedure. As a result, a PCE of 25.7% was recorded in 2022. According to Web of Science, number of publications on PSCs increases exponentially since 2012, leading to the accumulated publications of more than 28,000 as of June, 2022. PSC is regarded as a game changer in photovoltaics because of low-cost and high efficiency surpassing the conventional high efficiency thin film technologies. High photovoltaic performance was realized by compositional engineering, device architecture and fabrication methodologies for the past 10 years. Toward theoretical efficiency over 30% along with long-term stability, exquisite control of light absorptivity and photo-excited charges is highly required, along with thermodynamic phase stability. In this talk, light-morphology relation is discussed, where a specific crystal facet is found to have strong interaction with photon, leading to high photocurrent. Compressive strain via wrinkling process is found to control the top surface tensile strain of perovskite film, which is beneficial to charge carrier transport and lifetime. As a result, we could achieve a QSS-measured PCE approaching 25% under one sun illumination.

11:00 AM EN02.01.02
Indoor and Outdoor Performance Tracking of Perovskite Photovoltaic Modules Nutifafa Y. Doumon[1], Michael Owen-Bellini[1], Jack Schall[1], Dana B. Sulas-Kerna[1], Paul Ndione[1], Kent Terwilliger[1], Timothy J. Heben[4], Yanfa Yan[4], Devin J. MacKenzie[5], Reinhold Dauskardt[6], Angelique M. Montgomery[7], Bruce King[7], Joshua S. Stein[7], Joseph J. Berry[1] and Laura T. Schelhas[1]; [1]National Renewable Energy Laboratory, United States; [2]CFV Laboratories, United States; [3]University of North Carolina at Chapel Hill, United States; [4]The University of Toledo, United States; [5]University of Washington, United States; [6]Stanford University, United States; [7]Sandia National Laboratories, United States

A little over a decade of intensive research into the enormous potential of metal-halide perovskite (MHP) materials for photovoltaic (PV) applications led to record efficiencies of 25.7% for a single junction cell with 29.8% for tandem/multijunction cells [1]. MHP PV module technology with efficiency around 17.9% [2] is believed to be on the verge of commercialization. However, one of the major bottlenecks of the technology is in its reliability and long-term durability. To date the reported studies of devices in outdoor conditions is small relative to the large volume of work on these materials for photovoltaic applications. Understanding their degradation and failure modes in various environments is critical for advancing the MHP technology even further. And developing accelerated stress tests (AST) underscoring MHP PV failures modes unique to these types of devices sets the ground for qualification testing for perovskite PV modules. In this talk, we highlight the development of accelerated stress test protocols for perovskite PV module reliability testing. We then use a combination of characterization tools for destructive post-mortem analysis. Here we aim to understand the indoor and outdoor performance of modules via in-depth characterization of the MHP films, individual cells, and modules. Modules from different manufacturers, are run through the ongoing prototype indoor AST protocols and are then investigated and compared to those in outdoor field testing to grasp differences if any in their degradation pathways and/or failures modes. We believe these indoor-outdoor cross-examined tests would serve as the foundation for establishing standardized test protocols for MHP modules qualification testing, which are crucial for the technology to break through the PV market.

Engineering Ligand Reactivity Enables High-Temperature-Operating-Stable Perovskite Solar Cells So Min Park[1], Mingyang Wei[2], Jian Xu[1], Kenneth R. Graham[3], Michael Graetzel[2] and Edward H. Sargent[1]; [1]University of Toronto, Canada; [2]École Polytechnique Fédérale de Lausanne, Switzerland; [3]University of Kentucky, United States

Stability remains an area needing improvement on the path to the adoption of perovskite photovoltaics. Perovskite solar cells (PSCs) consisting of interfacial 2D/3D heterostructures via ammonium ligand intercalation have shown promise in the union of performance and stability; however, ligand penetration may contribute to performance degradation in 2D/3D PSCs at elevated temperatures. To date, the 2D/3D approach has not yet produced PSCs that are operating-stable at 85°C – and yet this is a prerequisite for impact on the photovoltaic sector. Here we explore the use of ammonium ligands that are instead non-reactive with the bulk of perovskites, investigating libraries through which we vary ligand molecular structure systematically. Aided by angle-resolved X-ray photoelectron spectroscopy, we find that anilinium exhibits the lowest tendency to penetrate the perovskite film, despite being the

simplest aromatic ammonium ligand – a quality achieved via the introduction of steric hindrance near the ammonium group. We leverage this to synthesize new ammonium ligands, such as fluorinated anilinium, that offer interfacial passivation and simultaneously minimize ligand reactivity. We find experimentally that this reactivity engineering is crucial to overcoming the stability and non-radiative recombination limitations: the new ammonium ligands enable perovskite material stacks that are thermally stable at 85°C, and that simultaneously improve PLQY by a factor of three compared to relevant controls. Using this approach, we report 23.3% certified quasi-steady-state PCE for inverted-structure PSCs; and we document 800-hour T80 (time to 80% of initial PCE) for encapsulated device operated at 85°C and 50% relative humidity, which represents a fourfold enhancement over the operating lifetime of optimized 2D/3D PSC controls. Our strategy of interface engineering provides a facile route to efficient and stable perovskite solar cells.

Addressing the Operational Instability Challenges of Perovskite Solar Cells Yang Yang, Shaun Tan, Yepin Zhao and Qiyu Xing; University of California, Los Angeles, United States

Perovskite solar cells (PSCs) have reached 25.7% power conversion efficiency, but their long-term stability under operational conditions is far behind the standards required for technology commercialization. In this presentation, we summarize our recent progress at UCLA to address the stability of PSCs from the perspective of understanding how the surface/interface energetics, lattice strain, defects, and charge transport affect the degradation of PSCs. Particularly attention are on (1) surface passivation and the formation of ideal interface for the NIP structure; and (2) management of ion-migration.

SESSION EN02.02: Characterization and Stabilization of Metastable Phases

Stabilization and Crystallization Control of α-$FAPbI_3$—Towards Efficient and Stable Perovskite Solar Cells Sooeun Shin, Pronoy Nandi, Hyoungmin Park and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

Formamidinium lead triiodide ($FAPbI_3$) is gaining interest with an optimal band gap of ~ 1.5 eV. Although α-$FAPbI_3$ is the most thermodynamically stable photoactive phase, it can kinetically stabilize δ-$FAPbI_3$ in ambient. Many attempts were studied to stabilize the black α-phase, for example, pseudo-halide anion engineering, ionic liquid engineering, and incorporation of additives. Incorporating with methylammonium chloride (MACl) as an additive not only induces the stabilized α-$FAPbI_3$, but also affects the crystallization kinetics of α-$FAPbI_3$. Along with the role of methylammonium chloride (MACl) as a 'stabilizer' in the formation of α$FAPbI_3$, we pointed out the additional role as a 'controller' in the crystallization kinetics. Herein, we examined the crystallization process of MACl, as higher concentration of MACl induces slower crystallization kinetics. Which results in larger grain size and [100] preferred orientation in a-$FAPbI_3$ films as the MACl concentration increased from 10 to 20, 30, and 40%. Microscopic observations, such as electron back-scattered diffraction (EBSD), confocal photoluminescence (PL), time-resolved photoluminescence (TRPL) mapping, and conductive atomic force microscopy (C-AFM), were conducted to examine the optoelectronic properties of [100] preferentially oriented grains. Reduction in the non-radiative recombination, a longer lifetime of charge carriers and less photocurrent deviation between each grain induce higher short-circuit current density (J_{sc}) and fill factor (FF) in a-$FAPbI_3$ based perovskite solar cells (PSCs) with MACl40%. Resulting the PSCs with MACl40% to attain the highest power conversion efficiency (PCE) of 23.5%. Furthermore, we confirmed these observations by enhancing the grain size and [100] preferred orientation of the MACl10% sample through a two-step heat treatment. As the lower heat treatment induced suppression of nucleation and enhancement of the crystal growth in a-$FAPbI_3$ films with MACl10%. The two-step processing resulted in an improvement in the PCE from 18.4% to 21.8%. It indicates the impact of adding MACl to control the crystallization kinetics resulting in a preferred orientation and a large grain size.
It highlights the importance of crystallization kinetics resulting in desirable microstructures for device engineering.

2:00 PM EN02.02.02
Quantitative Multiscale Diffusion Framework for Halide Perovskites Establishes Stability-Hysteresis-Diffusion Relationship Masoud Ghasemi[1,1], Boyu Guo[1,1], Chiung-Wei Huang[2], Garrett Baucom[1,1], Kasra Darabi[1,1], Laine Taussig[1,1], Tonghui Wang[1,1], Taesoo Kim[1,1], Joanna Atkin[2] and Aram Amassian[1,1]; [1]North Carolina State University, United States; [2]University of North Carolina at Chapel Hill, United States

Anomalous properties such as operational instability and photocurrent hysteresis in metal halide perovskite (MHP)-based devices present a major obstacle to their future commercialization. Halide ion/defect migration has been widely accepted as one of the main mechanisms behind these limiting properties, but a definitive explanation of this relationship has remained elusive. Here, we present a quantitative multi-scale diffusion framework that fully describes halide diffusion in polycrystalline MHPs. By using time-of-flight secondary ion mass spectroscopy (ToF-SIMS) technique we could simultaneously monitor both the fast grain boundary (GB) diffusivity and three to four orders of magnitude slower volume/bulk diffusivity. Our framework reveals an inverse relationship between the diffusion coefficients of GBs (D_{GB}) and volume (D_V) diffusions, such that MHPs (such as $MAPbI_3$) with a larger D_V also possess a smaller D_{GB}. Importantly, this relationship explains some of the most conflicting observations in the literature, namely that MHPs with improved stability (linked to D_V) typically exhibit reduced hysteresis. This nontrivial relation between volume and GB halide diffusivities is observed across a wide range of MHP systems, including MA- and FA-based iodide and bromide perovskites and is valid when GB passivation approaches are used. The quantitative elucidation of multiscale halide diffusion in polycrystalline MHPs provides an important path toward addressing outstanding issues of stability and hysteresis in MHP device technologies, as will be discussed in this presentation.

2:15 PM EN02.02.03
Addressing Chemical and Thermomechanical Instabilities in Metal Halide Perovskites Across Length Scales Yanan Li, Patrick Lohr, Anton Samoylov, Matthew Dailey and Adam Printz; University of Arizona, United States

The chemical and thermomechanical instabilities of metal halide perovskites represent barriers to long operational lifetimes of perovskite-based devices. There is no single magic bullet to address these instabilities, and so multiple complementary strategies must be undertaken. I will discuss the work by our research group to address these instabilities at multiple length scales, including the effects of the molecular structure and functionality of additives on their interactions with perovskite surfaces, the enhancement of mechanical toughness of perovskite layers by compositing with polymeric nanofibers, and the use of confined volume printing to rapidly produce perovskite films with large grains and reduced surface area of grain boundaries detrimental to stability. Together, these approaches provide one possibly pathway toward significantly increasing the operational lifetimes of perovskite-based devices.

2:30 PM *EN02.02.04
Halide Ion Migration-Induced Instability in Metal Halide Perovskites Preethi S. Mathew, Jeffrey DuBose and Prashant Kamat; University of Notre Dame, United States

Generation of holes through above-bandgap excitation or through electrochemical injection increases ion migration and leads to phase segregation in metal halide perovskites (MHP). The thermodynamic and redox properties of halide perovskites provide a strong driving force for hole trapping and oxidation of iodide species in MHPs. However, mobile halide species within the perovskite lattice take time to migrate and generate halide-rich domains. When in contact with a non-polar solvent, the migration of iodine species is further extended to expulsion of iodine from the perovskite film. Thus, the mobility of halides and their susceptibility to hole-induced oxidation play a crucial role in determining the long-term stability of metal halide perovskites. Strategies to gain kinetic control over ion migration to slow phase segregation are needed to overcome these hurdles and achieve stable mixed halide perovskites. Modification of the perovskite composition through introduction of different cations, halide ions, or introduction of low-dimensional perovskite phases may suppress phase segregation will be discussed. Thus, in achieving stability and improving efficiency of perovskite solar cells and light emitting devices with minimal impacts, suppression of segregation remains the key factor.

3:00 PM BREAK

3:30 PM EN02.02.05
Substrate Functionalization to Improve the Stability of α-$FAPbI_3$ Andres Felipe Castro Mendez and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

One of the major limitations of the commercialization of perovskite solar is the scalability of the different fabrication processes. In this context, thermal evaporation offers several advantages compared to solution processes, such as higher uniformity, better control of the thickness, deposition of non-soluble materials, and avoiding the removal of solvent orthogonality. Co-evaporation of $FAPbI_3$ is a promising choice for the fabrication of highly efficient and scalable perovskite solar cells. However, the presence of the non-perovskite hexagonal phase, which is the most stable phase at room temperature, is detrimental to the device's performance. Here, grazing incident wide-angle X-ray scattering (GIWAXS), X-ray diffraction (XRD), and X-ray fluorescence (XRF) techniques are used to understand the role that intermolecular forces (i.e. hydrogen bonds, dipole-dipole, van der Waals) between the perovskite and the substrate plays in determining the crystalline structure and crystallographic orientation of $FAPbI_3$ deposited by thermal evaporation

3:45 PM EN02.02.06
Water and Oxygen Synergy Induce Undesired Phase Transitions in Formamidinium Lead Iodide Perovskites—Strategies to Stabilize the Perovskite Metastable Phase Juanita Hidalgo[1], Yu An[2,1] and Juan Pablo Correa Baena[1]; [1]Georgia Institute of Technology, United States; [2]Tianjin University, China

Formamidinium (FA) lead halide perovskites have shown to be promising materials for solar cells, having achieved a maximum power conversion efficiency greater than 25%. FA-rich compositions have an ideal bandgap close to 1.5 eV and show enhanced thermal stability [1]. However, the FA-rich perovskite structure is metastable at room temperature and can easily degrade into non-perovskite hexagonal polytypes. The addition of Cs to the FA-based perovskite has led to a more stable perovskite structure [2], but not when exposed to humidity. The instability upon humidity exposure is a challenge limiting the efficacy of encapsulating technologies acting as humidity barriers. Beyond the development of encapsulating technologies, it is important to understand the degradation mechanism of FA-rich perovskites when exposed to humidity to design a highly efficient and stable material. The humidity degradation mechanism leading to crystallographic phase transitions in FA-rich perovskites is still poorly understood. Therefore, it is essential to unravel the structural degradation pathways of these materials caused by humidity exposure.

Herein, we studied the phase transformations and degradation kinetics of an FA-rich perovskite, $Cs_{0.17}FA_{0.83}PbI_3$, upon exposure to humidity, through *in-situ* grazing incidence wide-angle X-ray scattering (GIWAXS). We investigated the effect of the humidity carrier gas (i.e., nitrogen, air) in the degradation pathway of $Cs_{0.17}FA_{0.83}PbI_3$. Degradation kinetics were investigated and quantified, suggesting that water and oxygen synergy accelerates the non-perovskite $FAPbI_3$ hexagonal 2H phase formation. Through X-ray photoelectron spectroscopy, we observed that water degradation begins at the surface, where oxygen is present. To study the effect of humidity on the bulk of the film, we observed that iodine content decreases after humidity exposure by X-ray fluorescence maps. For a comprehensive bulk understanding, we synthesized $Cs_{0.17}FA_{0.83}PbI_3$ powders and studied the structure and vibrational modes before and after humidity degradation. We found that the origins of the phase transitions of the FA-rich perovskite go beyond humidity: oxygen plays an important role in determining the degradation pathway, which starts at the surface of the films. By studying the humidity degradation pathway, we understand how surface passivation, a strategy to enhance charge carrier extraction, can act as a barrier to oxygen and water, preventing the degradation of FA into hexagonal polytypes.

4:00 PM *EN02.02.07
Defects Activity in Wide and Narrow Bandgap Metal Halide Perovskite Semiconductors Annamaria Petrozza; Istituto Italiano di Tecnologia, Italy

Metal halide perovskites (MHPs) have demonstrated huge potential to build a rich library of materials for a new disruptive optoelectronic technology. The main strength comes from the possibility of easily tune the semiconductor bandgap in order to integrate it in devices with different functionalities – in principle. In reality, this cannot be achieved yet. In fact, while defect tolerance is claimed for MHPs with a bandgap of about 1.6 eV, the model system object of intense investigations, MHPs with lower and higher bandgaps are far from this claim. They show various forms of instabilities which are mainly driven by a strong defect activity.

Here I will discuss our studies on the nature of defects and their photo-chemistry as a function of the semiconductor bandgap and chemical composition in order to identify their role in defining the semiconductor electronic properties and stability.

4:30 PM EN02.02.08
$FAPbI_3$ Perovskite Solar Cells—Thermal Evaporation vs Solution Processing Terry Chien-Jen Yang[1,1], Satyawan D. Nagane[1,1], Yu-Hsien Chiang[1,1], Affan Iqbal[1,1], Tiarnan A. Doherty[1,1], Dengyang Guo[1,1], Jordi Ferrer Orri[1,1], Kyle Frohna[1,1], Juliane Borchert[1,2], Bart Roose[1,1], Miguel Anaya[1,1] and Samuel

D. Stranks[1,1]; [1]University of Cambridge, United Kingdom; [2]Center for Nanophotonics, AMOLF, Netherlands

Thermal evaporation is an upscalable vacuum deposition technique for fabricating perovskite solar cells (PSCs). The advantages of thermal evaporation include better control of film thickness and reproducibility as well as conformal coating over large substrate areas which could be better suited for multi-junction solar cell fabrication. Furthermore, various thermal sources from inorganic to organic, for example PbI_2, $PbBr_2$, SnI_2, CsBr, FAI (formamidinium iodide), and MAI (methylammonium iodide) can be used allowing maximum compositional control and flexibility during the solvent-less deposition. To date, evaporation has been far less explored versus more conventional solution processing techniques[1].

The $FAPbI_3$ perovskite composition has attracted much attention given its optimal bandgap for single-junction PSCs. In this study, we compare the properties of thermally co-evaporated $FAPbI_3$ (PbI_2 and FAI sources) versus solution processed spin-coated $FAPbI_3$, by characterizing both pristine $FAPbI_3$ films and solar cells. We examine chemical properties such as PbI_2 to FAI ratio, structural properties such as the perovskite crystallization conditions, and device architectures comprising different electron/hole transport layers and contacts. In literature, cation (Cs^+ and MA^+) or other additives are typically used to improve the properties of the $FAPbI_3$ perovskite allowing higher efficiency devices and long-term stability as a result of octahedral tilting in their crystal structure[2].

Interestingly, scanning electron diffraction (SED) results show that thermally co-evaporated $FAPbI_3$ films exhibit some inherent octahedral tilt in their crystal structure, which results in the slower conversion to the non-perovskite yellow hexagonal δ-phase in air over time. This intrinsic thermodynamic conversion occurs faster in our solution processed pristine $FAPbI_3$ films as shown through various characterization techniques, which could be due to the different crystallization process or effects of residual solvents. This unwanted conversion of $FAPbI_3$ is exacerbated in the presence of moisture, heat, and light as shown widely in literature[3].

Currently, solution processed $FAPbI_3$ solar cells have achieved much higher efficiency (record 25.7%[4]) compared to thermally evaporated $FAPbI_3$ devices (<21%[5,6]). This is largely due to the fact that vastly more time and effort has been invested in optimizing solution processed PSCs, compared to thermal evaporation. Our work suggests that thermal evaporation could have a marked advantage over solution processing of $FAPbI_3$ based PSCs and will attract other researchers to further optimize thermally evaporated PSCs. If performance similar to solution processed methods can be achieved, the better scalability will make thermal evaporation a promising route to commercializing PSCs.

Effect of Residual Chloride in $FAPbI_3$ Film on Phase Stability and Photovoltaic Performance of Perovskite Solar Cell Dong-Ho Kang and Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

The chloride ion in additive is found to have beneficial effect on enhancing photovoltaic performance due to the grain growth of $FAPbI_3$ perovskite. However, we found that the residual Cl incorporated in crystal lattice can aggravate the crystal phase and device stability. Thus, it is necessary to find an effective way to remove chloride ion from the perovskite film without sacrificing the photovoltaic performance. Here, we report a methodology to improve the stability of perovskite solar cell via elimination of the residual chloride ion. The extended X-ray absorption microstructure (EXAFS) combined with X-ray diffraction (XRD) reveal that the lattice distortion of PbI_6 octahedra is reduced due to the increased (Pb-I) bond distance after removal of chloride ion. The absence of chloride ion, confirmed by X-ray photoelectron spectroscopy (XPS), improves charge carrier lifetime, leading to higher power conversion efficiency (PCE) from 21.57 % for the perovskite film with residual chloride ion to 22.76%, mainly due to the enhancement of open-circuit voltage from 1.129 V to 1.168 V. Long-term stability test for over 1000 h under relative humidity of about 45% shows clearly that the device employing the chloride-removed perovskite film is much less degraded than the control one with perovskite film having residual chloride.

Rational Design of Photoelectrochemical Perovskite-$BiVO_4$ Tandem Devices for Scalable Solar Fuel Production Virgil Andrei[1,1], Judith L. MacManus-Driscoll[1], Robert Hoye[2], Richard H. Friend[1] and Erwin Reisner[1]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Metal halide perovskites have emerged as promising alternatives to commonly employed light absorbers for solar fuel synthesis, enabling unassisted photoelectrochemical (PEC) water splitting[1,3] and CO_2 reduction to syngas.[2,4] While the bare perovskite light absorber is rapidly degraded by moisture, recent developments in the device structure have led to substantial advances in the device stability. Here, we give an overview of the latest progress in perovskite PEC devices, introducing design principles to improve their performance and reliability. For this purpose, we will discuss the role of charge selective layers in increasing the device photocurrent and photovoltage, by fine-tuning the band alignment and enabling efficient charge separation. A further beneficial effect of hydrophobicity is revealed by comparing devices with different hole transport layers (HTLs).[1,3] On the manufacturing side, we will provide new insights into how appropriate encapsulation techniques can extend the device lifetime to a few days under operation in aqueous media.[1,2]

To this end, we replace low melting alloys with graphite epoxy paste as a conductive, hydrophobic and low-cost encapsulant.[3,5] The combined advantages of these approaches are demonstrated in a perovskite-$BiVO_4$ tandem device archiving selective unassisted CO_2 reduction to syngas.[4] These design principles are successfully applied to an underexplored BiOI light absorber, increasing the photocathode stability towards hydrogen evolution from minutes to months.[6] Finally, we take a glance at the next steps required for scalable solar fuels production, showcasing our latest progress in terms of device manufacturing. A suitable choice of materials can decrease the device cost tenfold and expand the device functionality.[7] Such materials are compatible with large-scale, automated fabrication processes, which present the most potential towards future real-world applications.[8]

EN02.03.02

Mechanochemistry-Driven Engineering of $Cs_4PbX_6/CsPbX_3$ (X=Cl, Br, I) Heterostructure for Designing Highly Luminescent Perovskites Kyeong-Yoon Baek[1], Woocheol Lee[1], Hyungbin Lim[1], Jae Il Kim[1], Richard H. Friend[2], Tae-Woo Lee[1], Jeongjae Lee[1], Keehoon Kang[1] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]University of Cambridge, United Kingdom

Embedding metal–halide perovskite emitting particles within an insulating host matrix has proven to be an effective strategy for enhancing and stabilizing the outstanding luminescence properties of perovskites as an emerging class of light emitters [1,2]. Particularly, unexpected bright green emission observed in a nominally pure zero-dimensional cesium–lead–bromide perovskite (Cs_4PbBr_6) has triggered intensive research in better understanding the serendipitous incorporation of emissive guest species $CsPbBr_3$ within the insulating Cs_4PbBr_6 host [3]. However, a limited controllability over such heterostructural configurations in conventional solution-based synthesis methods has limited the degree of freedom in designing synthesis routes for accessing different structural and compositional configurations of these host–guest species. In this study, we provide means of enhancing the luminescence properties in the nominal Cs_4PbX_6 (X=Cl, Br, I) powder through a guided heterostructural configuration engineering enabled by solid-state mechanochemical synthesis. First, we investigate the reaction kinetics underlying the formation process of Cs_4PbBr_6 [4]. Realized by an in-depth study on time-dependent evaluation of optical and structural properties during the synthesis of Cs_4PbBr_6, we target-design highly luminescent Cs–Pb–Br composite perovskite through promoting the endotaxial formation of $Cs_4PbBr_6/CsPbBr_3$ heterostructure. Next, we tune the emission wavelength of 520 nm which corresponds to the green emissive Cs–Pb–Br perovskite to the entire visible spectrum range of 410–690 nm. This is achieved through employing the substitution of monovalent halide with other halide components and controlling their stoichiometric ratio in the heterostructural samples ($Cs_4PbCl_mBr_{6-m}$ and $Cs_4PbBr_{6-m}I_m$) [5]. Our study provides key insights for understanding and designing kinetics-guided synthesis of highly luminescent perovskite emitters and introduces the entire family of 0D/3D heterostructural perovskites for light-emitting applications.

Entirely Roll to Roll Coated Perovskite Photovoltaics Enabled by Carbon Ink Formulation David Beynon, Ershad Parvazian, James McGettrick, Rahul Patidar, Rodrigo Garcia Rodriguez, Tom Dunlop and Trystan Watson; Swansea University, United Kingdom

Perovskite photovoltaics have been the subject of intense scientific interest due to their suitability for solution processing, simple device structure and meteoric rise in efficiency. The world record certified efficiency of 25.2% for single junction perovskite solar cells and much of the development leading to this point has been achieved using lab-scale spin-coating methods in controlled environments. This has demonstrated the potential of perovskite solar cells as a competitor of conventional silicon solar cells, however to realise that potential requires an alternative fabrication approach that is capable of high volume manufacture. Spin-coating is an ideal deposition method for the laboratory setting as it allows controlled layer thickness, dynamic drying and rapid solvent evaporation with the potential incorporation of an anti-solvent in a reproducible setup but it suffers high material wastage and scaling challenges that mean it is critical to evolve this process.

Scaling of PSC layers has been achieved in recent studies through roll-to-roll coating techniques with the slot die coating method showing the greatest promise. Slot-die coating is a cost effective coating method that allows significant control in coating and can deposit layers with little material wastage, high control on film thickness and flexibility to coat layers with several stripes. In addition slot-die coating via the roll-to-roll method allows material to be deposited indefinitely (with continuous ink supply) at high line speeds.

Perovskite solar cells are yet to fully transition to roll-to-roll fabrication despite the major impact that this would achieve. The method has been demonstrated on a number of occasions for all-layers (including at this institution) except for the back electrode which has always been deposited via an evaporated metal contact in an off-line process. This means that true fully roll-to-roll perovskites has yet to be achieved.

Printed carbon inks have the potential to provide the solution; however solvent incompatibility, interface incompatibility and incorrect rheology profile mean that simple deposition of a standard carbon ink to finalise the device is not the solution and leads to detrimental printing performance and poor or negligible device performance. Despite recent effort in this field, none of the alternative carbon inks have so far been suitable for application as a R2R top-contact, as they mostly focused on overcoming one of the challenges discussed earlier instead of considering them as one major related issue.
Here, we formulate a new carbon ink that has solvent compatible with the perovskite stack and that, crucially, has suitable boiling point for low temperature, high speed processing coupled with very low toxicity (no work place exposure limit). The solid loading of the ink has been optimised for a rheological profile suitable for slot die and we demonstrate the roll to roll slot die coating of the electrode sequentially following the roll to roll coating of the NIP device stack incorporating a low temperature processed PEDOT:PSS p type interlayer. Our work introduces the very first entirely roll to roll devices achieving over 10% efficiency matching equivalent evaporated gold electrodes. This first fully roll-to-roll coated perovskite prototype represents a

game changer in unlocking the potential of industrial scale, high volume, continuous manufacture of perovskite solar cells.

EN02.03.04
Morphology-Controlled Lead-Free Halide Double Perovskite Nanocrystals by Chemical Vapor Deposition Anupam Biswas, Pushpender Yadav, Kyeongdeuk Moon and Seokhyoung Kim; Michigan State University, United States

Materials are vital for the advancement of science and technology in the modern world. Over the last few decade materials like silicon (Si) has dominated the industry owing to their superior stability and reliability. Compared to traditional Si-based technology, lead halide perovskite (LHP) has demonstrated considerable promise for efficient solar energy conversion and light generation. However, the toxicity of lead (Pb) in LHPs is a major barrier that inhibits practical applications. By employing lead-free halide double perovskites, both energy and environmental concerns can be directly addressed. Although lead-free double perovskites have been investigated extensively in the bulk form, their structural behavior and optoelectronic properties have yet to be fully explored in the nanoscale. Here, we present a vapor-phase synthetic control over the size and shape of lead-free double $Cs_2AgBiBr_6$ perovskite nanocrystals using a chemical vapor deposition (CVD) system. The synthetic parameters used for the growth control include temperature, deposition position, gas flow rate, and growth time. At optimal conditions, we could obtain a uniform, submicron-sized single-crystals of $Cs_2AgBiBr_6$. The structural and compositional properties were characterized by X-ray diffraction (XRD), scanning electron microscopy (SEM), and energy-dispersive X-ray spectroscopy (EDS), which showed good agreement with the known values from the literature. The elemental composition of the CVD-grown $Cs_2AgBiBr_6$ was further confirmed along with their corresponding oxidation state by X-ray photoelectron spectroscopy (XPS). We observed an experimentally measured bandgap of 2.1eV and band-edge photoluminescence at 627 nm with a full-width-half-maximum (FWHM) bandwidth of 150 nm and they are in close agreement with reported values in the literature. We believe our research finding on controlling the morphology and growth of $Cs_2AgBiBr_6$ nanocrystals by CVD has the potential to extend to other lead-free halide perovskites and will open a new getaway for the development of future photovoltaics, photodetectors, and related applications.

EN02.03.05
3D Printing of Ruddlesden-Popper Perovskites with High Color Purity and Stability Sixi Cao and Ji Tae Kim; The University of Hong Kong, Hong Kong

Ruddlesden–Popper (RP) lead halide perovskites have emerged as a new class of tunable two-dimensional semiconductors that demonstrate high performance in optoelectronics due to their enhanced stability and structural tunability[1,2]. The nanostructured RP perovskites with forms of films or wires are the basic building blocks for manufacturing high-density integration of optoelectronic circuitries and devices[3,4]. However, their nanostructures are limited due to the complex organic−inorganic layered crystalline features[5]. Some clever methods based on template growth[6], lithography[7], inkjet printing[8] and chemical vapor deposition[9] have been devised to produce RP perovskite nanostructures but new methods are still in great demand for high-resolution, three-dimensional integration. Furthermore, the engineering challenges associated with how to engineer the perovskite phase in the nanostructure still remains unresolved[10]. Here, we report a nanoscale 3D printing method for RP perovskites with programmed shape and crystallinity. The method exploits a femtoliter precursor meniscus formed on a nanopipette to guide RP perovskite crystallization at will under strong evaporation of solvent. Guiding the meniscus in three-dimension leads to the formation of a freeform, freestanding RP perovskite nanowire exhibiting a polycrystalline nature. It is observed that the crystalline feature is successfully controlled in in-situ by adjusting temperature and humidity during the 3D printing process. In this talk, I will present my research progress on the development of 3D printing for RP perovskites and discuss prospects of our work for potential applications in electronics and optoelectronics.

EN02.03.07
Perovskite and Organic Photoanodes with Low-Temperature Printed Carbon Layer for Solar Water Splitting Matyas Daboczi, Junyi Cui and Salvador Eslava; Imperial College London, United Kingdom

Photoelectrochemical water splitting is a promising way of solar hydrogen generation, however in order to achieve both high efficiency and stability photoelectrodes significant further improvements are needed. Perovskite and organic photoactive materials have attracted great scientific interest by reaching record high single-junction solar cell efficiencies. In this presentation, we will show a cost-effective way of protecting organic (non-fullerene acceptor and polymer donor) as well as all-inorganic perovskite photoactive layers by a printed carbon layer and a functionalised graphite sheet in order to reach both stable (more than 60 hours) and high photocurrents (> 9 mA cm^{-2} and > 15 mA cm^{-2}, respectively). We have developed perovskite photoelectrodes using a low annealing temperature carbon paste with tuned energy level $CsPbBr_3$ photoactive layer. The effect of 2-dimensional ($CsPb_2Br_5$) and 0-dimensional (Cs_4PbBr_6) perovskite phases on efficiency and stability will be discussed including ways to control their formation. Photoanodes with stable photocurrents applying the currently best performing organic bulk-heterojunction non-fullerene acceptor photoactive layers will also be presented with particular focus on the role of NiFeOOH co-catalyst. We will share our most recent results towards reaching – instead of the often-reported hours-long – several days long stability at high photocurrent densities close to and above the current state-of-the art levels.

EN02.03.09
Co-Evaporation and Characterization of Tin Based Perovskite Films For Solar Cell Applications Joana A. Ferreira Machado, Jeremy G. Hieulle, Muhammad U. Farooq, Ajay Singh and Alex Redinger; University of Luxembourg, Luxembourg

Organic-inorganic halide perovskite solar cells have shown a promising increase in power conversion efficiency over the past decade, reaching over 25.5% [1]. Given their low-cost synthesis, perovskites are ideal candidates for the next generation thin film photovoltaics [2]. Nevertheless, the commercialization of this solar cell technology is hindered by the presence of lead in the most efficient halide perovskites, which raises health and environmental concerns [3]. Tin based perovskites are very promising alternatives to the mainstream Pb containing perovskites since they exhibit a lower bandgap, which is closer to the ideal value for single junction devices and they can be used as bottom cells in all perovskite tandem devices [4]. However, they are at present not as efficient and suffer from fast degradation.
In order to make Sn based perovskites a real alternative to the Pb based ones, a thorough understanding of the growth process is indispensable. Here, in order to prevent oxidation, we grow methylammonium tin tri-iodide ($CH_3NH_3SnI_3$) by co-evaporating tin iodide (SnI_2) and methylammonium iodide (CH_3NH_3I). We discuss in detail how the growth parameters affect the crystalline structure and the optoelectronic properties of $CH_3NH_3SnI_3$. We show that the SnI_2/CH_3NH_3I ratio during growth enables to manipulate the texture of the films. Photoluminescence measurements link the changes in crystal structure to the optoelectronic properties of the films.
In addition, we show via X-ray photoelectron spectroscopy (XPS) that the co-evaporated films are free of tin in the +4-oxidation state (Sn4+), contrarily to other methods reported in literature [5-6]. The presence of Sn4+ is often linked to the decrease in power conversion efficiency of the tin perovskites due to self-doping [7]. Thus, by avoiding this secondary phase completely, the stability is improved [8]. We show that the absence of oxygen during the whole process is absolutely crucial since films with small amounts of oxygen detected in the XPS spectra, also showed a Sn4+ secondary phase. This result provides evidence that the presence of Sn4+ in the perovskite films is directly linked to the presence of oxygen.
We use Kelvin Probe Force Microscopy in ultra-high vacuum to assess the local variations in work function. Both the topography and the workfunction maps are smooth and we do not find a prominent grain boundary contrast. A comparison of the workfunction inhomogeneities to other perovskites allows us to conclude that the Sn based perovskites are very homogeneous, which is important for the development of high-performance extraction layers.

Hierarchically Ordered Perovskites with High Photo-Electronic and Environmental Stability via Nanoimprinting Guided Block Copolymer Self-Assembly Hyowon Han, Hyeokjung Lee, Jin Woo Oh, Jihye Jang and Cheolmin Park; Yonsei University, Korea (the Republic of)

The development of a sub-50 nm nanopattern of a thin perovskite film is of significant interest with its excellent photo-electronic properties and environmental stability. By employing nanoimprinting of a moldable perovskite precursor self-assembled with a block copolymer, a thin perovskite nanopattern with excellent photo-electronic stability is developed over a large area. Approximately 40 nm nanodomains consisting of perovskite crystals 10 nm in diameter are templated in the block copolymer, and the registry of the perovskite nanodomains is further guided by the topological pattern with a periodicity of a few hundred nanometers. This method can produce hierarchically controlled nanostructures of the perovskites from molecular crystals to self-assembled domains with tens of nanometer scale and patterned structures of a few hundred nanometers. With an ultrathin top skin layer on a patterned perovskite/block copolymer film developed during the nanoimprinting, the hierarchically ordered perovskite is environmentally stable in ambient conditions over 100 days with its photoluminescence quantum yield of approximately 28 %. Furthermore, the enhanced photoconduction of the perovskite nanocrystals hierarchically structured in the nanopatterns allows for developing the arrays of photodetectors with long-term environmental stability over 90 days.

EN02.03.11
Air and Oxygen Stable Core/Shell Perovskite Nanocrystals for Deep-Blue LED Application Yongju Hong and Kwangyeol Lee; Korea University, Korea (the Republic of)

The visualization of accurate color information using metal halide perovskites has been explored recently with great fervor, because of their superior optical properties such as high photoluminescence quantum yield (PLQY), and excellent color purity, and facile bandgap tunability. The achievement of white light and accurate color renderings in real-world applications requires the development of efficient and stable perovskite light-emitting diodes to overcome their inherent instability. The cesium lead mixed-halide perovskite nanocrystal system in the form of a well-tailored core/shell structure with a semiconductor shell offers a pathway toward highly stable perovskite-based displays. However, it remains challenging to access the epitaxially well-tailored core/shell architecture because of the limited methodology. Here, we present a systematic strategy for preparing a uniform perovskite core with an epitaxially grown semiconductor shell. We found that post-synthetic treatment is effectively passivating surfaces by defect elimination in the crystalline structure, thereby facilitating the epitaxial growing of the shell and significantly improving the intrinsic stability with high luminescence efficiency. We constructed the perovskite-based light-emitting diodes (LEDs) that exhibit superior external quantum efficiency (EQE) and luminance, representing a performance superior to that of state-of-the-art deep-blue perovskite-LEDs. We anticipate that our core/shell perovskite deep-blue light-emitting devices can greatly facilitate the development of electroluminescent full-color displays using perovskites.

EN02.03.12
Lighting Beyond Blue—Violet Metal Halide Perovskite Light-Emitting Diodes Manchen Hu and Daniel Congreve; Stanford University, United States

Ultraviolet and violet wavelengths of light are widely used in sterilization (e.g. food, medical equipment), sensing (e.g. gases, fluorescent labels), manufacturing (e.g. 3D printing, lithography), and other applications. However, the commercial violet and ultraviolet light-emitting diodes (LEDs) are based on InGaN/GaN/AlGaN materials grown via metal-organic chemical vapor deposition (MOCVD). This complex fabrication process uses toxic and explosive precursor gases (e.g., $Al(CH_3)_3$, $Ga(CH_3)_3$) while also requiring high temperatures and high vacuum. In order to increase the viability of UV and violet light-based technologies, it is crucial to explore cheaper and simpler alternatives to this current state-of-the-art. Metal halide perovskite LEDs (PeLEDs) have emerged as promising candidates for next-generation lighting technology, distinguished by high external quantum efficiency (EQE), high emission color purity and tunability, cheap facile solution processability. By rational engineering the perovskite crystallization during spin coating deposition, we have considerably improved the uniformity of 2D perovskite thin films, which leads to a fivefold increment of EQE over the control LED devices. Our PeLEDs emit violet light with a peak at 408 nm and exhibit a champion EQE of 0.41%. We believe this work reveals the strong potential of PeLEDs for violet emission, while simultaneously suggesting a new and simpler pathway towards realizing cost-effective UV LEDs based on metal halide perovskites.

EN02.03.13
On-Demand, 3D Printed Perovskite Nanolasers Shiqi Hu and Ji Tae Kim; The University of Hong Kong, Hong Kong

Inorganic metal halide perovskites are emerging as promising optoelectronic materials due to their strong, tunable, and high-color-purity photo- and electroluminescence, and solution processability[1–3]. Recently, extensive research has been made to utilize perovskite nanowires as lasers due to their structural benefits such as ultra-compact sizes, highly localized coherent output, and efficient waveguiding[4,5]. The current fabrication of perovskite nanowires relies on electron beam lithography, photolithography, chemical vapor deposition, solution-phase synthesis, and nanoimprinting. That is to say, these processes are energy- and labor-intensive, which is in stark contrast with the industrial low-cost requirements. Furthermore, technological challenges associated with individual tailoring of nanowire dimensions remain unresolved, making it difficult to manipulate stimulated emission characteristics at the single nanowire level. A new method that can fabricate perovskite nanowires with programmed shape, dimension, and placement is in great demand for addressing the abovementioned issue.
Here, we demonstrate an electrohydrodynamic (EHD) 3D printing of perovskite nanowires for high-performance bespoke lasers. The printed perovskite nanowire presents a two-photon pumped Fabry–Pérot (FP) mode lasing. By adjusting the height of a freestanding nanowire at will, we are able to select the lasing mode and also control the lasing threshold and mode spacing (△λ). On this basis, we successfully demonstrated the 3D printed nanowires arrays for multi-level anti-counterfeiting security labels by storing information in the cavity-height-dependent features such as the lasing threshold and mode spacing (△λ), which are unclonable. It is also worth mentioning that the advanced features of our technique such as maskless operation and low-cost production with high stability make it an effective platform to bring the proof-of-concept demonstration into practical commercial application. Likewise, these outcomes not only give us inspiration for the function-oriented design of the nanolaser-based devices but also facilitate the development of high-performance perovskite-based photonic anti-counterfeiting applications. Last but not least, our method could provide an excellent platform to construct scalable, on-demand laser-based photonic devices.

EN02.03.14
Dry, Fast and Low-Cost Synthesis Method for Polymer Encapsulated Halide Perovskite Color Converters Bas A. Huisman and Henk J. Bolink; University of Valencia, Spain

Halide perovskites are an interesting candidate for high-end color converters due to their outstanding optical properties[1–3]. One of the reasons these perovskite color converters are not yet commercialized is due to a lack of fabrication processes which meet the industry standards such as scalability, low cost synthesis and high performance end product. In this talk an easy method to fabricate high luminescent (PLQY>50%) color pure (FWHM~20nm range) halide perovskite color converters is presented. Additionally, the color converters show air stability and temperature stability at 85°C in inert atmosphere for at least a month. The outstanding stability is due to the encapsulation of the perovskite particles with a desired polymer. The fact that the whole process is a dry synthesis technique, there are no difficulties in using additives, different polymers or perovskites. To show the possibilities of this method, MAPbBr3 with an additive of amantadine hydrochloride is synthesized by dry mechanochemical synthesis together with a desired polymer (here, PMMA, PS and PEO are researched)[4]. The powder is then heated to the glass temperature of the polymer and pressed into a color converter within a couple of seconds. This dry process makes it possible to accurately adjust and change compositions. As a proof of concept a multiple compound color converter, by introducing an extra light emitting polymer (RedF) into the powder, reveals that it is possible to produce a single layer color converter which convert blue light to red and green. The possibility to use one layer to convert both colors, instead of the normally used double layer, reduces the fabrication costs even more and reveals the flexibility of the process. Due to the conditions of this process method and the properties of the color converters, this work shows an interesting route towards synthesis process of polymer embedded halide perovskite color converters for industrialization.

Vapor Transport Co-Deposition of Perovskite Photovoltaics Tamar Kadosh, Ella Wassweiler, Harry Tuller and Vladimir Bulovic; Massachusetts Institute of Technology, United States

Halide perovskites have demonstrated remarkably high solar to electrical energy conversion efficiencies and are therefore of great interest for rapid commercialization. Popular solution-based fabrication routes do not lend themselves to rapid scale, up as required. Vapor Transport Deposition (VTD) is beginning to be considered a readily scalable, low-cost technique alternative method for perovskites production. Vapor-based processes promise to overcome many challenges imposed by solution-based techniques. Being solvent-free, they bypass solvent-related challenges, namely uniform coverage of large areas, chemical compatibility, and toxicity. As a low-cost alternative to thermal evaporation, VTD has the potential to deposit organic and inorganic perovskite precursor materials either sequentially or via co-deposition. Furthermore, VTD potentially offers higher tunability of deposition parameters, to enable film growth with improved composition and microstructure control.
We are currently working with a custom-made VTD system, focused on optimization of co-deposition of lead iodide and methylammonium iodide with the aid of carrier gases. We report our progress in investigating the influence of substrate and sublimation temperatures, chamber pressure, and flow rate ratios on the morphology and stoichiometry of the forming perovskite film, and in turn, its photo-active and electronic properties.

EN02.03.16
***In Situ* Core/Shell Perovskites for Ultra-Bright, Efficient and Stable Light-Emitting Diodes** Joo Sung Kim[1], Jung-Min Heo[1], Gyeong-Su Park[1],

Seung-Je Woo[1], Changsoon Cho[2], Hyung Joong Yun[3], Dong-Hyeok Kim[1], Jinwoo Park[1], Seung-Chul Lee[1], Sang-Hwan Park[1], Eojin Yoon[1], Neil Greenham[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]University of Cambridge, United Kingdom; [3]Korea Basic Science Institute, Korea (the Republic of)

Metal halide perovskites are attracting great attention as next-generation light-emitting materials due to their excellent emission properties with narrowband emission. However, perovskite light-emitting diodes (PeLEDs) irrespective of their material types (polycrystalline film or nanocrystals) have not realized high luminance, high efficiency, and long lifetime simultaneously, as they are influenced by the intrinsic limitations related to the trade-off properties between charge transport and confinement in each type of perovskite materials. Here, we report bright, efficient, and stable PeLEDs made of core/shell perovskite nanocrystals obtained using a simple *in-situ* reaction. The ligand passivates the surface defect states, and thereby greatly reduces trap density in films while maintaining good charge-transport properties. Our work sheds great light on the possibility that PeLEDs can be commercialized in the future display industry.

EN02.03.17
All-in-One Process for Film-State Color Patterning of Perovskite Quantum Dot Light Emitting Diodes Junho Kim and Jung-Yong Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Perovskite quantum dots (PeQDs) are promising material for next-generation display owing to their superior optoelectronic properties. However, the multi-color patterning of PeQDs remains fundamental challenging because the PeQDs are very vulnerable for conventional patterning process containing direct exposure of ultra-violet (UV) ray, electron-beam (E-beam), or polar solvents used as developer. Furthermore, the shorter ligand exchange and halide anion exchange are required to use the PeQDs as active materials and express various emitting-light colors easily in PeQD LED devices.
In this study, we propose a novel all-in-one process simultaneously exchanging ligands and halide anions in film-state for enhancing the LED performance, converting emitting-light color, and patterning of cesium lead halide PeQD LEDs for full-color display.[1] The proposed all-in-one process significantly enhanced the performances of PeQD LEDs by passivating the PeQDs with shorter ligands. The dense passivation with shorter ligands also enhanced the chemical stability of PeQDs. In addition, we fabricated red (R), green (G), and blue (B) LEDs with extremely narrow emission spectra using cesium lead bromide PeQDs and appropriate butylammonium halide solution. Furthermore, the proposed all-in-one process in film-state facilitated rapid color change in localized areas, thereby aiding in realizing fine patterns of narrow widths (300 μm) using simple contact masks. Consequently, the all-in-one process made it possible to from the multi-color patterning without direct exposure of UV ray, E-beam, and developer to PeQD films. Finally, we can fabricate various R/G/B multi-color patterning electroluminescence (EL) LED devices such as R/G/B pixels in a substrate, one pixel containing R/G/B colors between a pair of electrodes, and word-patterned ("KAIST") LEDs, using the all-in-one process.

EN02.03.18
A Novel Strategy for Preparing Chiral Perovskite Nanocrystals with High Chiroptical Activity and Stability Based on Self-Assembly of Achiral Block Copolymer Minju Kim[1], Jiweon Kim[1], Jieun Bang[1], Yu Jin Jang[2], JaeHong Park[1] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Research Center for Energy and Environmental Sciences, Sungkyunkwan University, Korea (the Republic of)

Chiral hybrid halide perovskites have emerged as promising candidates in next-generation optoelectronic and spintronic applications due to their remarkable chiroptical and electrical properties. However, designing chiral perovskite nanocrystals (NCs) that exhibit high stability as well as outstanding chiroptical performance under ambient condition remains a challenge. In this study, we present a novel and facile strategy to fabricate chiral perovskite NCs based on block copolymer inverse micelles with supramolecular chirality obtained by self-assembly of optically-inactive building blocks, polystyrene-*block*-poly(2-vinyl pyridine) (PS-*b*-P2VP) and DL-alanine (DL-ala). The selective incorporation of perovskite precursors within the confined chiral micellar cores enables effective chirality transfer to the electronic states of perovskite NCs, leading to high chiroptical response at the bandgap with an anisotropy factor of -2.0 x 10^{-4}, similar to that of chiral octylamine-capped perovskite NCs. In addition, the robust surface passivation of perovskite NCs by PS-*b*-P2VP/DL-ala inverse micelles protects NCs from moisture, heat, and air more efficiently than neat PS-*b*-P2VP inverse micelles, manifesting long-term stability in harsh conditions and long fluorescence lifetime. This approach can not only realize large-scale and low-cost fabrication of chiral perovskite nanostructures but can also be extended to the advanced engineering of chiral perovskite nanostructures by judiciously adjusting block copolymer self-assembly.

EN02.03.19
Low-Dimensional Bismuth and Copper Halide Perovskites for Multilevel Resistive Switching Memory So-Yeon Kim and Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Here, we report low-dimensional halide perovskite having bismuth or copper metal ion for multilevel resistive switching memory. Layered double perovskite with chemical formula of $BA_2CsAgBiBr_7$ was synthesized by phase conversion of 3D $Cs_2AgBiBr_6$, which showed endurance of 1,000 cycles and retention time over 2×10^4 s at operational voltage as low as 0.5 V, along with ON/OFF ratio as high as ~10^7. The ON/OFF ratio of 2D Ag-Bi system was five orders of magnitude larger than those of 3D counterparts. Modification of Schottky conduction at high resistance state (HRS) is found to be responsible for high ON/OFF ratio in 2D structure. 2D $(BzA)_2CuBr_4$ (BzA = benzylammonium) perovskite was synthesized on Pt substrate, which delivered higher ON/OFF ratio over 10^8 even at lower operational voltage around +0.2 - -0.3 V. Longer endurance of 2,000 cycles was observed with similar Schottky conduction at HRS. A thin film less than 1 micrometer was applied to the low-dimensional $Cs_3Bi_2Br_9$, where synthetic $Cs_3Bi_2Br_9$ powder precursor enabled uniform thin film formation. A bipolar resistive switching behavior was observed. Thin film exhibited reliable cell-to-cell and device-to-device resistive switching behavior. The studied low-dimensional bismuth and copper based halide perovskites showed much better stability under high humidity and at elevated temperature than the 3D and/or lead-based counterparts, which is beneficial for practical applications.

EN02.03.20
Achieving 9.16% Applied Bias Photon-to-Current Efficiency with Monolithic Lead Halide Perovskite Photoelectrochemical Cell Tae Gyun Kim and Jong Hyeok Park; Yonsei University, Korea (the Republic of)

Solar-to-hydrogen conversion from water splitting is of great interest and photoelectrochemical (PEC) cell water splitting is one of the notable technologies for H_2 production. To commercialize PEC water splitting, highly efficient photoanode materials are the governing key factor. Recently, organic-inorganic lead halide perovskite (LHP) materials have emerged as a promising alternative that can overcome the drawbacks of metal-oxide-based photoelectrodes because of their excellent optoelectronic properties such as broad photoresponse range in the solar spectrum, bandgap tunability, and low exciton binding energy. Although LHP-based solar cells can be externally applied to water electrolysis for solar-to-hydrogen conversion, an LHP device with a monolithic configuration for PEC cells is more economically ideal for viable hydrogen production.
Herein, we report monolithic PEC cells with a double-cation perovskite solar cell (PSC) connected to a robust 3D oxygen evolution reaction (OER)

catalyst using conductive carbon powders (CCP). CCP has superior conductivity for efficient charge transfer from LHP-based solar cells to OER catalysts. Surprisingly, LHP devices physically interconnected with the OER catalyst by CCP show almost zero current and voltage loss.
To achieve an efficient and stable performance in the LHP photoanode, the individual efficiencies and stabilities of the two parts (PSC part and OER catalyst part) should be guaranteed. First, efficiency and stability of the PSC part can be improved by modifying LHP layer. We introduced a smaller cation (methylammonium, MA) to the $FAPbI_3$ (formamidinium, FA) lattice to stabilize the a-phase by enhancing hydrogen bonding between FA and the PbI_6 octahedron. It was confirmed by UV-vis absorption spectra, X-ray diffraction (XRD), and X-ray photoelectron spectroscopy (XPS). At OER catalyst part, we applied 3D-structured NiFe to an Ni foil substrate to increase the catalytic activity and stability. The 3D porous architecture improves the catalytic activity and stability by facilitating holes supplied from the PSC and increasing the electrochemically active surface area. Finally, integrating optimized PSC part and OER catalyst part, the LHP photoanode exhibits 0.56 V onset potential and a maximum photocurrent density of 24.26 mA/cm^2 at 1.23 V_{RHE} (reversible hydrogen electrode (RHE)), with a 9.16% applied bias photon-to-current efficiency. We further achieve an enhanced stability of 48 h in pH 14 aqueous solution under simulated solar light (1 sun).
In summary, we fabricated an LHP-based photoanode using inexpensive CCP as an electrical connector between PSCs and OER catalyst. CCP not only has great conductivity for efficient charge transfer but also is economical for wide deployment. Additionally, we stabilized PSC by using souble-cation LHP and optimized the OER catalyst by forming a 3D structure NiFe on the Ni foil. Our LHP photoanode exhibited remarkable performance and durability under continuous illumination in an aqueous electrolyte. We believe that these findings demonstrate the potential of LHP photoanodes with CCP for the future development of low-cost, high-performance, and stable monolithic devices.

EN02.03.21
Scalable Fabrication of High-Performance Perovskite Solar Modules and Their Application to High Power Output Solar Charging Batteries
Young Yun Kim, Se-Hee Kim, Nam Joong Jeon and Jungdon Suk; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Rapid climate change and increasing global power demands require active implementation of transition of traditional power sources to renewable energy sources. Perovskite solar cells (PSCs) have been of great interest due to the inherent superior optoelectronic properties of organometallic halide perovskite itself, such as high absorption coefficient, long carrier diffusion length, ambipolar charge transport and solution-processability. Over 25 % of power conversion efficiency (PCE) has been achieved recently for PSCs via composition engineering, optimization of interlayer, and defect management. Aside from the high PCE, the fabrication of PSCs by scalable process in large-area is prerequisite for the PSCs to fully utilize the aforementioned advantages, so to be applied to self-powered personal mobility and electronics, smart textiles, custom-shaped building-integrated photovoltaics, and so on.

Several successful demonstrations of scalable production of PSCs have been reported. However, successful demonstration of fully scalable production of large-area perovskite solar modules (PSMs) is still lacking. The major hurdles to be jumped are uniform wet-film formation via scalable process in large-area, and complete phase conversion of perovskite precursor to photoactive phase. Therefore, reliable scalable production methods should be established including wet-film formation and phase conversion steps.

In addition, the direct integration of energy generation and storage devices have attracted a lot of interest recently in order to correspond to the fluctuation of power input from the Sun and increasing demand for self-powered electronics. However, inherent mismatch of voltage and current range for charging and discharge from PSCs to Li-based batteries is a major obstacle to realize the direct integration between them. Additionally, power output from PSCs under continuous light illumination, and storage capacity from charging-discharging cycles from Li-ion batteries should be retained.

In this work, we successfully demonstrate high-performance PSMs and solar charging batteries by integrating PSMs and Li-ion batteries in a single substrate. All the layers constituting PSMs can be fabricated via solution shearing coating, with optimized rheological and interfacial properties, at a low temperature (<160°C). An electron transporting layer (ETL) is designed to be uniform and compact in large-area, by systematically investigating the effect of leaving group in sol-gel precursor and applying an optimal tin precursor with organic crosslinkers. As a result, high-efficiency over 23% can be achieved, retaining over 80% relative efficiency compared to initial one after over 1000 h. Complete conversion of perovskite precursor to photoactive phase in a large area can be achieved via careful selection of proper antisolvent and bathing in it. PSMs are carefully designed to have a proper area and structure to exactly match the charging voltage-current range of high-capacity Li-ion batteries. Consequently, over 20% efficiency of PSMs and over 14% of overall charging to storage efficiency can be achieved. The photo-charging can be repeatedly conducted over 30 cycles because of stable power output and storage of integrated PSMs and Li-ion batteries.

EN02.03.22
Green Non-Toxic Cs_3MnBr_5 Phosphor Using Silicon Nitride Nanofilters Using Nanoimprinting Minji Ko, Hyeng Jin Kim, SeungJe Lee, Eunha Hong, Keyong Nam Lee and Young Rag Do; Kookmin University, Korea (the Republic of)

In this study, we tried to reduce impure phases in nonstoichiometric compositions of non-toxic green Cs_3MnBr_5 by using various filtration processes to remove nano and microscale impurities (> 200nm) dissolved in reaction solutions and to induce precipitation of impure phase after crystallization. Green Cs_3MnBr_5 phosphors were synthesized using purified reactant solutions, which filtered with silicon nitride nanofilters through water-based evaporative crystallization. To improve photoluminescence quantum yield (PLQY) of green Cs_3MnBr_5 phosphors, it is necessary to reduce reactant solution impurities such as manganese oxide and undissolved precursors. Therefore, reactant solutions were filtered through silicon nitride nanofilters that included nanopore pattern silicon nitride nanofilters succesfully-realized by nanoimprint lithography and etching process on 6 inch Si wafer. The reactant solutions of green Cs_3MnBr_5 phosphors were filtrated using fluid devices with built-in silicon nitride nanofilters with nanopore size adjusted from 50 nm to 200 nm via deposition of Al_2O_3 to increase PLQY. Finally, PLQY of green Cs_3MnBr_5 phosphors synthesized using 50 nm nanopore size silicon nitride nanofilters is 2.3 times higher than that of non-filtrated green Cs_3MnBr_5 phosphors. Therefore, synthesized grren Cs_3MnBr_5 phosphors have potential for applcation to lighting devices and photovoltaic, and other fileds. Also, SiN_x nanofilters using nanoimprint lithography have potential for application to chemical purification, biological purification, and other fields.

EN02.03.23
High Luminescence and Efficiency in Perovskite Quantum-Dots -Embedded Thin Film or Fiber Membranes for Light-Emitting Diodes Chi-Ching Kuo, Wei-Cheng Chen and Dai-Hua Jiang; Institute of Organic and Polymeric Materials Department of Molecular Science & Engineering, National Taipei University of Technology, Taiwan

Perovskite quantum dots (PeQDs) have been under commercial and functional development in recent years since they offer outstanding optoelectronic properties and solution processability. However, both insulating ligands around PeQDs and instability impair the performance of photoelectronic devices. Therefore, we introduce multi-step ligands exchange by silver (Ag)- trioctylphosphine (TOP) as short alkyl ligands to reinforce the optical properties and stability for PeQDs and successfully elevated light-emitting diodes characters. The PeQDs with Ag-TOP ligands (Ag@QD) perform higher

photoluminescence quantum yield (PLQY, ~93%), higher exciton binding energy (57.6 meV) with better solvent, temperature, and ambient stability over 1 month presenting better performances on comparison with conventional di-dodecyl dimethyl ammonium bromide (DDAB) or TOP ligands. Nuclear magnetic resonance (NMR), X-ray photoelectron spectroscopy (XPS), and time-resolved photoluminescence (TR-PL) measurement provides clear insight on bilateral affinity in Ag@QD illustrating excellent defect passivation and appropriate steric hindrance. Furthermore, we demonstrate Ag@QD with lower turn-on voltage (~2.8 V), high electroluminescence (~3820 cd/cm−2), and high efficiency (EQE ~9.43%). Furthermore, PeQDs with excellent intrinsic properties have been employed universally in optoelectronic applications but undergo hydrolysis even when exposed to atmospheric moisture. In the present study, composite CsPbX3 (X = Cl, Br, and I) PeQDs were encapsulated with stretchable [poly(styrene-butadiene-styrene); SBS] fibers by electrospinning to prepare water-resistant hybrid membranes as multicolor optical active layers. Brightly luminescent and color-tunable hydrophobic fiber membranes (FMs) with PeQDs were maintained for longer than 1 h in water. A unique remote FMs packaging approach was used in high-brightness perovskite light-emitting diodes.

EN02.03.24
Enhancing Charge Diffusion Length by Pyrene Incorporation in Multi-Cation Halide Perovskites Yu Jin Lee, Taehee Kim, Jung Hwan Lee, Jong Hyeok Park and Dongho Kim; Yonsei University, Korea (the Republic of)

Multi-cation halide perovskites are gathering attention with remarkable optoelectronic properties as materials for light-harvesting and light-emitting applicants. This study suggests strategies to achieve device stability and long carrier diffusion length, which are essential properties in optimizing perovskite device performances. Pyrenes are planar conjugated systems and strong electron donors at the same time, thus can effectively passivate defects at grain boundaries. Due to the large size difference with cations, pyrenes are selectively located in grain boundaries and employed as pi-conjugated bridges to interconnect the adjacent grains. We incorporated pyrene in the precursor with anticipating the effects of suppressing ion migration within the perovskite film and assisting charge carrier transport. Aided by confocal fluorescence lifetime imaging microscopy (FLIM), distribution of photoluminescence (PL) lifetime and charge carrier diffusion dynamics were directly visualized in space and time in pyrene incorporated multi-cation halide perovskites. We suggest that the addition of pyrene precursors reduces spatial energetic disorder at the perovskite surface.

Pyrene is found to enhance emission and increase the PL lifetime at the grain boundaries. A smaller deviation in grain-to-grain emissivity and a more uniform spatial distribution of PL lifetime at the perovskite surface are observed, suggesting reduced grain boundary defects. We also spatiotemporally analyzed the exciton population evolution to study the improvement in diffusion dynamics with pyrene incorporation. Using the trap-state limited diffusion model equation, we tracked the turnover from the normal diffusion and trap-state limited transport regime. Trap depth can be estimated using the Boltzmann relation and can be correlated with diffusion properties. The reduction of trap density by pyrene precursor addition expedites the charge carrier transport and allows longer diffusion length. Pyrene incorporation especially boosted free exciton diffusivity. Thus, diffusivity and charge diffusion length of optically excited states are greatly enhanced to over 1 μm.

EN02.03.26
Lead-Free Double Perovskites—$Cs_2Na_{1-x}Ag_xIn_{1-y}Bi_yCl_6$ as a Warm White Light Emitter with Unit Efficiency Daniela Marongiu[1], Fang Liu[1], Angelica Simbula[1], Stefano Lai[1], Luyan Wu[1], Qingqian Wang[2], Riccardo Pau[1,3], Selene Matta[1], Federico Pitzalis[1], Alessio Filippetti[1], Francesco Quochi[1], Michele Saba[1], Andrea Mura[1] and Giovanni Bongiovanni[1]; [1]Universita di Cagliari, Italy; [2]Southern University of Science and Technology, China; [3]Univesrity of Groningen, Netherlands

Double perovskites have been developed to alternatively replace the divalent cations Pb^{2+} in single perovskite with a combination of a monovalent and trivalent cation, forming structure as $A_2BB'X_6$. Among them, the compounds $Cs_2Na_{1-x}Ag_xIn_{1-y}Bi_yCl_6$ can emit warm white light with almost unity quantum efficiency and are thus among the most promising materials for solid-state lighting (1). The emission spectrum is attributed to self-trapped excitons (STEs), the emission efficiency is, however, sensitive to the material composition since it is strictly related to the simultaneous presence of a small percentage of Ag and Bi.
Whether Bi atoms cure extrinsic defects or provide natural recombination centers is still a wide-open question while the addition of Ag has been linked to parity breaking in valence band orbitals, increasing the oscillator strength of the interband optical transitions (2,3).
A comprehensive understanding of the microscopic mechanisms producing the rules for efficient emission is fulfilled by a systematic study of the structural and optical properties as a function of the composition to understand the role of Ag and Bi in the high efficiency emission. Photoluminescence quantum yield (PLQY) measurements are complemented with photoluminescence excitation (PLE) and ultrafast spectroscopy in the form of differential transmission (DT/T) and time-resolved photoluminescence (TRPL). The dynamic of optical excitation is studied to investigate the formation of STEs and their decay times.
Ag atoms are found to promote the formation of STEs that then produce efficient emission. The radiative recombination of STEs is instead favored by the presence of at least 0.1% Bi inhibiting trapping of optical excitations in long-lived, dark STEs thus achieving emission efficiency near unity with a warm white light spectrum in a wide variety of compositions.
Double perovskites realize therefore an almost ideal platform for solid state lighting and these results provide guidance for rational optimization of such compounds in view of the use as phosphors and active materials for LEDs and displays.

Ion-Migration-Induced Degradation of Flexible Perovskite Module Under Working Condition Jiyeon Nam, Wonkyu Lee, Hae-Seok Lee, Donghwan Kim and Yoonmook Kang; Korea University, Korea (the Republic of)

In this study, perovskite modules were fabricated on PET flexible substrates. Perovskite light-absorbing layers and ETL (electron transfer layer, SnO2) are coated using the blade-coating method. The HTL (hole transfer layer, spiro-OMeTAD) layer is spin-coated. The electrodes are deposited by the thermal evaporation method. All patterns are scribed by laser. Modules consist of 10 sub-cells and their area is 5*5cm2. Modules used in the experiment are distinguished from the perovskite solar cells fabricated on a rigid substrate like glass in which sub-cells are connected monolithically and patterned. Also, there exist lots of fractures on the modules due to the tensile stress originating from the flexible substrates. In P2, where the Au electrode and perovskite are directly contacted, the decomposition of perovskite and migration of ions occurs. Near the fractures, deep-level defects exist as they do at grain boundaries, where they act as ion transfer channels. Under working conditions with light and electric fields, degradation in the fractures and near the patterns are analyzed. This degradation causes the decomposition of perovskite and the movement of ions, and prevention strategies are needed for the commercialization of modules.
The initial efficiency of the module was 11.03% with 10.3V Voc, Jsc of 1.76mA/cm2. Maximum power point (MPP) is tracked in ambient air. The temperature was kept around 33 C and the humidity was maintained below 40%. The modules encapsulated with diffusion barriers were placed under 1 sun illumination. After 25 hours of MPPT, the efficiency decreased to about 50% of the initial efficiency.
We acquired Electro-luminescence (EL) images before and after MPPT and intensities of EL decreased around fractures and P2 patterns. Non-radiative recombination sites can be distinguished from EL images where ion migration occurs followed by the decomposition of perovskite layers.
The series resistance has increased significantly, due to the increase in non-conductive materials such as PbI2, the byproduct of perovskite layer decomposition. In addition, the shunt resistance decreased slightly, which shows a similar tendency to lock-in thermography (LIT) results. A thermal imaging camera attached to the LIT system senses the Joule heat from the shunt. The number of heating points and their temperature increased.
Finally, the element distribution of the module along the depth direction was measured through SIMS analysis. The measurements were performed on the fresh and 25hr-worked modules. Depth profiles are acquired from the neat site, near pattern, and at fractures.
Near the pattern, the intensity of Au was higher than that of the neat area. This shows that Au has diffused from P2 and the top electrode. In the case of fracture, Au was already diffused along with the depth before MPPT, and it spread more after MPPT. Also, the I-2 peak has broadened, which is the result of the decomposition of perovskite.
By comparing the cells with and without applied voltage under light, it is found that the driving force of ion migration is the electric field across the module. In this way, perovskite decomposition and ion diffusion around the pattern and fracture cause changes in Voc and Jsc as well as Rsh and Rs, and affect module stability. In future work, to suppress the ion migration, deposition of the diffusion barrier layer and reforming of HTL and perovskite will be conducted.

EN02.03.28
Defect Passivated All-Inorganic Perovskite Film by Metal-Organic Framework-Assisted Metal-Ion Doping Process for Dual-Mode Image Sensing Display Jin Woo Oh, Hyowon Han, Hyeokjung Lee, Jihye Jang and Cheolmin Park; Yonsei University, Korea (the Republic of)

Crystal engineering based on defect passivation with metal ions doped into halide perovskites is of considerable interest for tailoring the photoelectric properties of perovskites. Herein, a simple and robust approach for doping metal ions into a thin all-inorganic $CsPbBr_3$ perovskite film by employing metal-organic framework nanoparticles is presented. Zeolitic imidazolate framework-8 nanoparticles, which can adsorb water, are dispersed and embedded in a thin perovskite film. The particles self-decompose at a certain humidity, releasing Zn^{2+} ions into nearby perovskite crystals. The Zn^{2+} ions efficiently passivate the undercoordinated defect sites of the defective perovskite crystals, resulting in environmentally stable, and enhanced photoluminescence of the perovskite with the quantum yield of approximately 14 % more than 24 times greater than that without nanoparticles. Further, a thin Zn-doped $CsPbBr_3$ film is employed to fabricate arrays of ultraviolet photodetectors, and approximately 90 % of the initial photocurrent is maintained over 15 days in RH 60 %, facilitating the development of a dual-mode image sensor using which programmed images are visualized based on both photocurrent and photoluminescence.

EN02.03.29
Three-Color White Electroluminescence Emission of Perovskite Quantum Dots Mixed with Organic Emitters Hyukmin Kwon, Hayoon Lee, Seokwoo Kang, Sunwoo Park, Seong Jun Kang and Jongwook Park; Kyung Hee University, Korea (the Republic of)

To realize a full-color display in the research field of perovskites or perovskite-structured quantum dots (PeQDs), the development of white-light-emitting devices that operate by emitting light of three primary colors (red, green, and blue) has emerged as an active research topic. In the present study, we report for the first time three color white-light emission with high brightness from white-emitting PeQD organic light-emitting diodes (WPeQD-OLEDs) fabricated using a PeQD material and organic emitters. A WPeQD-OLED bilayer was prepared by depositing a blue-emitting organic layer on top of a $CsPb(Br/I)_3$ QD layer mixed with N^9 ,N^{10}-Bis(4-(tert-butyl) phenyl)-N^9 ,N^{10}-Di-*o*-Tolylanthracene-9,10-Diamine (*p*-Tb-*o*-Me-TAD), which were spin-coated as red and green emitters, respectively. The WPeQD-OLED device was stable during operation and demonstrated emission of three primary colors. In the WPeQD-OLED device, charge carriers were distributed by an 9-(naphthalen-1-yl)-10- (naphthalen-2-yl)anthracene (α,β-ADN) blue-emitting host material with a deep highest occupied molecular orbital level. The electroluminescence (EL) spectra of the WPeQD-OLEDs showed EL maximum peaks at 460, 527, and 640 nm; the CIE color coordinates of the emitted light were (0.33, 0.40). The EL results confirmed that the maximum luminance was 49,000 cd/m^{-2} and the maximum luminance efficiency and power efficiency were 4.48 cd/A^{-1} and 2.16 lm/W^{-1}, respectively.

EN02.03.30
Atmospheric Humidity Underlies Irreproducibility of Formamidinium Lead Iodide Perovskites Keonwoo Park[1], Maged Abdelsamie[2], Ji-Sang Park[3], Carolin M. Sutter-Fella[2] and Jin-Wook Lee[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Lawrence Berkeley National Laboratory, United States; [3]Kyungpook National University, Korea (the Republic of)

Atmospheric humidity has been considered as a critical factor worsening irreproducibility of the perovskite solar cells (PSCs). The institutional research laboratories, startups, and large enterprises often experience poor reproducibility of the PSC performance, resulting in stagnated development and waste of resources. From a commercial standpoint, such irreproducibility can critically impede quality control and reduce yield and profit margin of the photovoltaic modules. In this study, we reveal critical roles of atmospheric humidity in regulating the formation and crystallization of widely used formamidinium lead triiodide ($FAPbI_3$) perovskite by in-situ investigations under controlled atmospheric environments. We show that the humidity content during film fabrication underlies significant changes in perovskite stoichiometry, thermodynamic stability, and optoelectronic quality. Thus, well controlled humidity during fabrication of formamidinium perovskite is perhaps indispensable to reproduce phase stable and efficient $FAPbI_3$-based PSCs.

EN02.03.32
Advance in the Scalable Fabrication of Perovskite Solar Cells Anush Ranka, Inseok Yang, Zhenghong Dai and Nitin P. Padture; Brown University, United States

High performance lab-scale perovskite solar cells (PSCs) with power conversion efficiency (PCE) over 25% have been reported recently. However, most of the reported high-PCE devices have an active area of <0.15 cm^2, and spin-coating is used to fabricate the perovskite thin films and the electron- and

hole-selective transport layers. While future commercialization of PSCs requires us to move to scalable fabrication methods, an increase in sheet/series resistance, inhomogeneity of the film over large areas, loss in active area due to carrier collectors, *etc*. are inevitable in large scale PSCs. This, along with the technological barriers to entry, makes it difficult to obtain high PCE in PSCs fabricated using scalable processes. To obtain a deeper understanding of the factors that govern these shortcomings, we have investigated the effects of different parameters that need to be controlled to achieve high-quality, large-scale PSCs. We use processes such as chemical bath deposition, and nitrogen 'knife' assisted blade-coating and slot-die coating, and discuss the pros and cons of each process. We begin with controlling factors such as solution composition, nitrogen-knife pressure/speed, *etc*., that have the biggest effects on the film quality, and then move on to other factors such as molarity, humidity, and substrate roughness, which are more relevant to the device performance. This research aspires to make scalable processes more controllable, reliable, and accessible to the PSCs community.

EN02.03.33
Low-Vacuum Conversion for Sequential Processing of Perovskite Solar Cells Nathan Rodkey, Cristina Roldan-Carmona and Henk J. Bolink; Universitat de València, Spain

Vacuum-based technologies have proven to be a promising route for industrial scale production of perovskite photovoltaics, but performance is still lagging behind its solution-based counterparts. Currently, vapor-based methods such as co-evaporation struggle to grow complex perovskites (6 or more elements), being limited by the number of sources available and the ability to control them. This further limits the ability of many vacuum-based processes to introduce passivating or stabilizing agents. In particular, these are needed for the synthesis of high-efficiency low-bandgap materials (e.g. Sn/Pb) needed for perovskite-perovskite tandems or silicon-perovskite tandems. In this work, we present a conformal, low-vacuum process (1- 100 mbar) for the sequential conversion of evaporated PbI_2 thin-films or co-evaporated PbI_2/SnI_2 and PbI_2/CsI thin-films. The technique relies on the control of 3 crucial parameters: temperature of the source material, temperature of the substrate, and the working pressure. Using this method, we show fully converted films >1 um thick, with um-sized grains for a variety of perovskite compounds: $MAPbI_3$, $FAPbI_3$, $Fa_yCs_{1-y}PbI_3$, $MAPb_ySn_{1-y}I_3$, and $FAPb_ySn_{1-y}I_3$. To our knowledge, converting thick films (>1 um) in a 2-step process in this way is previously unreported. Counter-intuitively we find that films with small grains (<100 nm) and PbI_2 or amorphous phases show higher photoluminescence than their large-grained counterparts (>1 um). To circumnavigate this and grow large grains with increased photoluminescence we introduce reactive gasses and/or passivating agents during the conversion process, that appear to quench defects. This method is fully compatible with conformal growth, making it a good candidate for silicon-perovskite tandems. Lastly, these layers are reported in fully vacuum-processed devices, taking advantage of a low-vacuum (1-100 mbar), sequential process with high industrial potential.

EN02.03.34
Stable Near-to-Ideal Performance of a Solution-Grown Single-Crystal Perovskite X-Ray Detector Kostiantyn Sakhatskyi[1,2], Bekir Turedi[3], Gebhard Matt[1,2], Muhammad N. Lintangpradipto[3], Rounak Naphade[3], Omar Mohammed[3], Sergii Yakunin[1,2], Osman M. Bakr[3] and Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]King Abdullah University of Science and Technology, Saudi Arabia

The ideal photodetector is the one able to detect every single incoming photon. In particular, in X-ray medical imaging, the radiation dose for patients can then approach its fundamentally lowest limit set by the Poisson photon statistics. Such near-to-ideal X-ray detection characteristics have been demonstrated with only a few semiconductor materials such as Si and CdTe; however, their industrial deployment in medical diagnostics is still impeded by elaborate and costly fabrication processes. Hybrid metal halide perovskites – newcomer semiconductors – make for a viable alternative owing to their scalable, inexpensive, robust, and versatile solution growth and recent demonstrations of single gamma-photon counting under high applied bias voltages The major hurdle with perovskites as mixed electronic-ionic conductors, however, arises from the rapid material's degradation under high electric field, thus far used in perovskite X-ray detectors. Here we show that both near-to-ideal and long-term stable performance of perovskite X-ray detectors can be attained in the photovoltaic mode of operation at zero-voltage bias, employing thick and uniform methylammonium lead iodide ($MAPbI_3$) single crystal (SC) films (up to 300 μm), solution-grown directly on hole-transporting electrodes. The operational device stability is equivalent to the intrinsic chemical shelf lifetime of $MAPbI_3$, being at least one year in the studied case. Detection efficiency of 88% and noise equivalent dose of 90 pGy_{air} (lower than the dose of a single incident photon) are obtained with 18 keV X-rays, allowing for single-photon counting, as well as low-dose and energy-resolved X-ray imaging. These findings benchmark hybrid perovskites as practically suited materials for developing low-cost commercial detector arrays for X-ray imaging technologies.

EN02.03.35
Designing Perovskite Solar Cells for High-Efficiency Wireless Power Transfer Francesco Guarnieri, Julia Huddy and William J. Scheideler; Dartmouth College, United States

Metal halide perovskites are a promising material system for wireless energy harvesting due to their amenability to flexible form factors offering high power per weight as well as their potential for low cost via high-speed manufacturing. We present an investigation of the performance of high-efficiency planar double cation perovskite solar cells in harvesting monochromatic illumination via Sentaurus TCAD simulations and experimental validation. We provide an examination of metal halide perovskites under a wide range LED illumination profiles in the μW - mW / cm^2 range, experimentally demonstrating a power conversion efficiency (PCE) above 37 %. Our TCAD simulations provide design rules for engineering wide bandgap perovskite cells to maximize wireless power transmission (WPT) for a given monochromatic source. These results also reveal the device physics limiting efficiency for low-intensity constant illumination and very high intensity pulsed illumination profiles. Based on these results, we model perovskite solar cells' potential for high-efficiency medium to long range power transfer at 10 m – 500 m for power levels of 1 mW to 1 W, directly comparing the efficiency against alternative inductive WPT. These results suggest the promising role of perovskite solar cells in powering a more sustainable, battery-free future of the Internet of Things (IoT).

EN02.03.36
Proposal for Novel Direction of Front Transparent Electrodes Towards the Breakthrough of High-Efficiency and Stability Perovskite Solar Cells Hae-Jun Seok, Su-Yeong Choe and Han-Ki Kim; Sungkyunkwan University, Korea (the Republic of)

To attain the Shockely-Queisser limit, unceasing researches have been focused on improving efficiency and stability of perovskite solar cells. However, an aspect overlooked in these studies is the crucial role of transparent conductive electrodes on solar cell performance. So far, despite attempts to develop various front transparent electrodes, research on PSC-only front transparent electrode that surpasses the existing performance is still inadequate. Here we reveal the optimal Sn dopant concentration in In_2O_3 using a co-sputtering process, and develop an advanced perovskite-Sn doped In_2O_3 front electrode that can outperformance the commercial front transparent electrodes. As a results, the optimal perovskite-Sn doped In_2O_3 electrode shows ultra-low resistivity, high optical transmittance, smooth surface morphology and markedly enhanced thermal stability. Through these improvements for high-performance perovskite solar cells, we achieve a maximum efficiency of 23.35%. Moreover, the device retained 97.6% initial efficiency after 1000 h maximum power point tracking under continuous 1 sun illumination.

EN02.03.37

Methacrylate-Functionalized Perovskite Nanocrystals Encapsulated by Siloxane Hybrid for Highly Stable Color-Converting Layer in Display

Yongmin Shin[1], Hyungwoo Suh[2], Junho Jang[1], Byoung-Hwa Kwon[2] and Byeong-Soo Bae[1]; [1]Korea Advanced Institution of Science and Technology, Korea (the Republic of); [2]Electronics and Telecommunications Research Institute, Korea (the Republic of)

Organic-inorganic hybrid perovskite nanocrystals (PNCs) with ABX_3 crystal structure (A: organic cation, B: metal cation, X: halide anion) have been promised as color-converting material in display, because of their various advantages of low fabrication cost, facile bandgap tunability, very narrow emission bandwidth and high photoluminescence quantum yield, which lead to wide color gamut. However, when they are exposed to heat and light, aggregation or ion migration in PNCs can be generated, causing huge degradation of their optical properties. To overcome these instability issues, various strategies have been suggested such as fabrication of inorganic shell structure and dispersion into polymeric matrix to prevent permeation of oxygen and moisture to surface of PNCs. However, these methods entail complex processes and encounter limited stability due to physical blocking water to PNCs. In addition, to guarantee stability in high temperature with high humidity, the passivation of PNCs by surface ligands with robustness and functionality is also necessary. Therefore, stable PNCs with robust ligand that chemically interacts with the polymer matrix should be developed.

Herein, we report highly stable photoluminescent perovskite nanocrystals (PNCs) to achieve long-term stability in various environments by employing two types of siloxane-based materials (surface ligand and encapsulating matrix). Our approaches are followed: (i) synthesis of PNC passivated by robust methacrylate-functionalized siloxane-based ligand (M-PNC), and (ii) chemical encapsulation of PNCs by siloxane hybrid matrix (M-PNC/siloxane film). Passivation of PNCs by robust ligand induces improved compatibility and rigid chemical cross-linking of between M-PNC and siloxane hybrid matrix, resulting M-PNC/siloxane film maintains PLQY (> 70%) over 100 days in air, water, acid or base solutions, and various polar solvents, 85 C /85% relative humidity (RH), and continuous blue light irradiation. Fabricated M-PNC/siloxane film presents the homogeneous distribution of M-PNC in siloxane hybrid matrix. To confirm feasibility of our stability enhancement method, we demonstrate M-PNC-based white color-converted organic light-emitting diodes by integrating Cd-based QD as red components, which shows wide color gamut and excellent reliability.

EN02.03.38

Stoichiometry Control of Vapor-Deposited Multication Hybrid Halide Perovskites—From a Single-Source to Solar Cells Tatiana Soto Montero, Suzana Kralj, Wiria Soltanpoor, Junia Shelomi Solomon Sathiaraj, Chris Baeumer and Monica Morales-Masis; University of Twente, Netherlands

Vapor-deposited halide perovskites are highly attractive for the fabrication of monolithic perovskite-silicon tandem solar cells using readily available textured Si bottom cells. However, vapor-deposited halide perovskites have been less explored as top cells as compared to solution-processed or two-step deposited perovskites. Moreover, stoichiometry control remains a challenge for vapor-deposited halide perovskites. Here we explore Pulsed Laser Deposition (PLD) as a single-source room temperature vapor deposition technique of multication halide perovskites. Specifically, we demonstrate that it is possible to fabricate mixed-cation MA^+:FA^+ thin films from a single solid target containing tunable MAI: FAI: PbI_2 amounts to achieve the desired film stoichiometry with the photoactive cubic α-phase.

During PLD, a mechanochemically synthesized target containing the desired MA^+: FA^+ ratio is ablated pulse by pulse, creating a confined plasma plume that transfers the ablated species towards the substrate. Due to the different atomic masses of the target constituents (H, C, N, Pb, I), excess of MAI/FAI compared to PbI_2 is incorporated to compensate for the losses of volatile compounds upon the laser ablation. Thus, the solid target composition and the MA^+: FA^+ cation ratio are critical to growing films with the desired stoichiometry. Using X-ray Photoelectron Spectroscopy (XPS), solid-state Nuclear Magnetic Resonance (NMR), and X-Ray diffraction (XRD), we confirmed the successful transfer of species from target to film with PLD, including the integrity of the molecules and the desired MA^+:FA^+ ratio. PLD-deposited films containing 25% to 60% of FA^+ ($MA_{1-x}FA_xPbI_3$, x= 0.25-0.60) showed the stabilization of the cubic α-phase. Optical bandgap tuning from 1.61 to 1.55 eV is demonstrated with tuning stoichiometry of the film, as confirmed by photoluminescence, XPS and NMR. MAFA-based compositions are attractive for single junctions applications; however other compositions containing FA-Cs are also promising in terms of wide bandgap for perovskite/silicon tandem solar cells and to improve the stability of MA^+-free hybrid halide perovskite. Following a similar approach as with the MAFA-based perovskites, the replacement of MA with Cs was furthermore tested, representing a step closer to the desired stoichiometry for wide-bandgap top cells. At the device level, the critical role of the film composition and device contact layers in NIP and PIN configurations will be discussed. Mainly, we found a strong link between PLD parameters to achieve columnar grain growth and tunable composition with the final solar cell performance.

Overall, we demonstrate the potential of PLD as a solvent-free single-source vapor-deposition technique to grow mixed-cation and multi-compound perovskites conformally on several substrates, opening the path for future developments of wide-bandgap perovskite thin-films for monolithic tandem devices with the desired stoichiometry control from a single source.

EN02.03.40

Combinatorial Vacuum-Deposition of Wide Bandgap Perovskites Films and Solar Cells Isidora Susic[1], Lidón Gil-Escrig[1], Adi Kama[2], Chris Dreessen[1], Francisco Palazon[3], Michele Sessolo[1], David Cahen[2] and Henk J. Bolink[1]; [1]Universidad de Valencia, Spain; [2]Bar-Ilan University, Israel; [3]Universidad Politécnica de Cartagena, Spain

The development of vacuum deposited perovskite materials and devices is partially slowed down by the minor research effort in this direction (at least when compared with the field of solution-processed perovskites), but also from one of its intrinsic characteristics: long timeframe for the optimization of even a single perovskite composition since in one deposition run only a single set of parameters can be used (i.e. set of deposition rates for a certain set of precursors). Combinatorial materials science (CMS) is a method that can be used to accelerate the study of compositionally varying perovskites. When CMS is applied to thin-films, a compositional gradient is deposited on purpose on a single large area substrate, referred to as a library, forming many different compounds or materials in a single deposition run. Here we report the combinatorial vacuum-deposition of wide bandgap perovskites of the type $FA_{1-n}Cs_nPb(I_{1-x}Br_x)_3$, by using 4 sources and a non-rotating sample holder. From initial deposition rates calculated based on stoichiometry and properties for each precursor, we run a combinatorial deposition and high throughput characterization. By using small pixel substrates, we are able to produce >100 solar cells with different perovskite absorbers in a single deposition run. The materials are thoroughly characterized by spatially resolved and/or high throughput techniques, including optical, morphological and structural techniques. By subsequent fine tuning of the deposition rates, we can alter the gradient and reproduce the best performing formulations in standard depositions with rotation. We extended the method for optimizing wide bandgap CsMAFA triple-cation perovskite solar cells, which are found to be efficient but not thermally stable. With the aim of stabilizing the perovskite phase, we add guanidinium (GA^+) to the material formulation, and obtained CsMAFAGA quadruple-cation perovskite films with improved thermal stability, as observed by X-ray diffraction and rationalized by microstructural analysis. The corresponding solar cells showed similar performance with a remarkable thermal stability, when compared to the triple-cation perovskite devices.[1] We believe this approach can encourage the discovery of materials, and serve as a basis to prototype other compositions (low bandgap, lead- free) overcoming the current limitations of vacuum deposition as a research tool for perovskite films.

EN02.03.41

Cold Sintering and Cold Flow of $MAPbBr_3$ for Large-Area Radiation Detectors Maxwell Tolchin, Sarah Lowum, Ibrahim Dursun, N. C. Giebink and Jon-Paul Maria; The Pennsylvania State University, United States

Methylammonium lead bromide ($MAPbBr_3$) is classified as a metal hybrid perovskite (MHP), a subset of hybrid organic-inorganic semiconductors with compelling photovoltaic and optoelectronic properties, as well as facile synthesis. Thus, emerging as a candidate to improve current commercial products. While single crystal $MAPbBr_3$ embodiments have indicated best-known optoelectronic behavior, their integration into commercial utility remains unfeasible due to slow growth kinetics and intensive post-processing procedures. These limitations encourage researchers to investigate new synthetic approaches to shorten production timelines and achieve high-throughput assemblies while maintaining appreciable electronic application viability. One opportunity to reach these industrial advances is through bulk ceramic processing, particularly cold flow (CF) and the cold sintering process (CSP). Keys to these techniques, mild temperatures (< 200 °C) and pressures (< 1 GPa), are favorable industrial fabrication methods. Additionally, CF and CSP provide opportunity for managing microstructure, density, and composition, when adapting single crystal fabrication to size-configurable bulk monolith geometries. Because the coordination of the organic and halogenic components to lead, seen in $MAPbBr_3$, offers plastic and solubilizing properties amenable to low-temperature CF and CSP.

Herein, $MAPbBr_3$ crystals prepared via inverse temperature crystallization (ITC) can be densified using CF and CSP into ceramic monoliths with densities near the 100% theoretical limit. The process is scalable from millimeters to several centimeters, drawing interest for bulk polycrystalline radiation detectors which require thick slabs of material. Densification and key morphological responses are shown by altering pressure and temperature, as well as varied liquid and crystalline transport phases in CSP. To connect microstructure to electrical performance, radiation test results show photoelectric response upon hard x-ray exposure and time-of-flight (ToF) *i-v* analysis upon super bandgap laser excitation for carrier mobility. These microstructure-property trends will build our investigation into densification modes that can produce bulk $MAPbBr_3$ ceramics that are viable, large-area radiation detectors.

EN02.03.42
High Photoluminescence Quantum Yield Near-Infrared Emission from a Lead-Free Ytterbium-Doped Double Perovskite Minh N. Tran, Iver J. Cleveland and Eray S. Aydil; New York University, United States

Redshifting the solar spectrum entering a solar cell by creating near-infrared (NIR) photons from ultraviolet (UV) and blue photons via luminescence down conversion can increase the solar cell's efficiency. Shifting the UV and blue spectrum to NIR reduces thermal losses and the recombination of electron-hole pairs generated from shallow light absorption near interfaces. Ytterbium (Yb) is a well-known luminophore for solar spectral shifting because the Yb^{3+} emission via $^2F_{5/2} \rightarrow {}^2F_{7/2}$ electronic transition at 1.24 eV is close to the bandgap of silicon (~ 1.1 eV). Typically, Yb is doped into a host, which absorbs in the UV and visible regions of the electromagnetic spectrum and transfers energy to the Yb^{3+}, exciting it from the $^2F_{7/2}$ ground state to the $^2F_{5/2}$ state. The excited Yb^{3+} emits NIR photons at ~1.24 eV upon relaxation. Thus, depositing a layer of a Yb-doped film with high photoluminescence quantum yield (PLQY) on top of a silicon solar cell can improve its solar cell efficiency by modifying the incident solar spectrum. Ideally, all blue (UV) photons are converted to NIR photons, and the maximum possible photoluminescence quantum yield (PLQY) is 100%. However, there is another possibility. If the host bandgap is greater than twice the Yb^{3+} $^2F_{5/2} \rightarrow {}^2F_{7/2}$ electronic transition (> 2.5 eV), the energy transfer from the host to Yb^{3+} can be via quantum cutting, a process wherein one UV-blue photon is converted to two NIR photons. PLQY can be >100% in this case with a maximum of 200%. Indeed, Yb-doped $CsPbX_3$ (X=Cl, Br) have been shown to exhibit quantum cutting with PLQY as high as 190%.[1] However, lead is toxic, and NIR PLQY from $CsPbX_3$ decreases at high photon fluence.[1] In the search for non-toxic alternatives to $CsPbX_3$, double and bismuth-based perovskites are emerging as promising hosts because they have high absorption coefficients and tunable bandgaps in the visible range. Specifically, Yb doping of $Cs_3Bi_2Br_9$, $Cs_2AgInCl_6$, and $Cs_2AgBiBr_6$ has been reported.[2-4] Unfortunately, 28%, the highest PLQY from Yb-doped $Cs_2AgBiBr_6$ thin film, is still much lower than the minimum PLQY estimated to increase solar cell efficiencies (69% for typical Si solar cells).

Herein, we employ physical vapor deposition to synthesize Yb-doped $Cs_2AgBiBr_6$ films with high PLQY. $Cs_2AgBiBr_6$ has a stable cubic structure at room temperature and an indirect bandgap of ~2.2 eV. Yb^{3+} ions are hypothesized to replace Bi^{3+} and Ag^+ ions in the 3D network of corner-sharing $[AgBr_6]^{5-}$ and $[BiBr_6]^{3-}$ octahedra. Since the perovskite host sensitizes Yb^{3+}, its emission depends strongly on the Yb^{3+} concentration and location in the crystal structure, which are determined by the synthesis conditions. We show that near-infrared PLQY depends strongly on the precursors' evaporation rates and the substrate temperature during the deposition. Ramping the substrate temperature during the deposition promotes the reaction forming $Cs_2AgBiBr_6$ and helps Yb^{3+} substitute Bi^{3+} and Ag^+ ions in the crystal structure. Excess $BiBr_3$ is needed to compensate for the $BiBr_3$ loss at high substrate temperature and reduce Bi-deficient phase formation. Robust, reproducible, and stable PLQYs as high as 95% are achieved with 8% Yb-doped $Cs_2AgBiBr_6$ films deposited with excess $BiBr_3$ and ramping temperature. PLQYs are consistently in the 75-95% range for the excitation energy above the host bandgap (>2.2 eV) and retain 91% of the initial values after two months in the ambient conditions.

Synthesis of Violet-Emitting Ruddlesden-Popper Microcrystals of Monolayered Lead Halide Perovskite by Chemical Vapor Deposition Pushpender Yadav, Kyeongdeuk Moon and Seokhyoung Kim; Michigan State University, United States

Organic-inorganic hybrid perovskite (OIHP) has drawn considerable attention owing to the unprecedented rapid advancement of optoelectronic performance both in the bulk and nanoscale. Typically, OIHPs bear an inherent poor stability in ambient conditions, which was resolved by reducing the dimensionality of the materials by incorporating dielectric organic spacer cations. These dimension-reduced Ruddlesden-Popper (RP) layered perovskite shows a range of unique properties including thickness-dependent quantum confinement effects and high luminescent yields. Early research efforts have been primarily devoted towards solution-based methods, to which chemical vapor deposition (CVD) adds a vapor-phase route that is more suited for creating epitaxy and heterointerfaces needed for the fabrication of microelectronics devices. Major challenges such as a high imbalance in vapor pressures of the organic and inorganic precursors need to be addressed to achieve stable growth of single-crystalline nano/microstructures of layered OIHPs. Here, we present a controlled synthesis of RP-phase microcrystals of monolayered OIHP, $(C_4H_9NH_3)PbBr_4$, using CVD. We have systematically investigated the growth parameters that include temperature, pressure, and gas flow rates to grow morphology-controlled microcrystals, which we summarize in a growth phase diagram. Morphological, structural, and crystallographic properties of our crystals grown at different conditions are characterized by optical microscopy, scanning, and transmission electron microscopy (SEM and TEM), and X-ray diffraction (XRD). The elemental compositions are confirmed by energy-dispersive X-ray spectroscopy (EDS) and X-ray photoelectron spectroscopy (XPS). We observed a sharp excitonic absorption around 400 nm and strong photoluminescence at ~406 nm. The violet emission from the microcrystals indicates the potential to be utilized as a lasing material and for advance

optoelectronic applications. We believe that the fine control of crystallinity, purity, and morphology of $(C_4H_9NH_3)PbBr_4$ microcrystals by CVD opens a new pathway and invigorate more research effort towards the investigation of layered OIHPs for a wide range of optoelectronic applications.

EN02.03.45
Growth of $CsPbBr_3$ Nanocrystals in a PTFE-Based Microfluidic System Fuqian Yang; University of Kentucky, United States

Understanding the growth of semiconductor nanocrystals in a microfluidic system is of practical importance for continuous fabrication of semiconductor nanocrystals of high quality. We demonstrate the feasibility to synthesize $CsPbBr_3$ nanocrystals in a PTFE-based microfluidic system via antisolvent method for the synthesis temperature ranging from 303 K to 363 K and study the effects of flow rate and PTFE capillary length on the size of the synthesized $CsPbBr_3$ nanocrystals. Increasing the flow rate and/or decreasing the PTFE capillary length produce $CsPbBr_3$ nanocrystals of small sizes. A simple relation is developed between the photoluminescence peak wavelength of the synthesized $CsPbBr_3$ nanocrystals and the flow rate and supported by the experimental results. The activation energy for the growth of the $CsPbBr_3$ nanocrystals in the PTFE-based microfluidic system is 2.05 kJ/mol.

This work is supported by the NSF through the grant CMMI-1854554 and CBET- 2018411.

EN02.03.46
High Performance Tin Perovskite Photodetectors Fabricated via Hot Casting Method in Air Kwang Ro Yun, Tae-Ju Lee and Tae-Yeon Seong; Korea University, Korea (the Republic of)

Lead-free tin halide perovskite materials (THP) have emerged as promising candidates for photodetection applications owing to their outstanding optoelectronic properties such as high carrier mobilities ($\approx 10^2$-10^3 $cm^2V^{-1}s^{-1}$), narrow bandgaps (1.2-1.4 eV), and low exciton binding energies (≈18 meV). However, THP suffers from poor stability in air because Sn^{2+} is easily oxidized to Sn^{4+}. This "self-doping" effect causes rapid degradation in the performance and reproducibility of THP-based devices. Furthermore, the high-defect density associated with Sn vacancies in the crystal structure creates high mobile holes, resulting in large dark currents and relatively low specific detectivity of THP photodetectors (PDs). Thus, it is essential to be able to adjust "self-doping" effect of THP for the improvement of the performance of THP PDs.
In this study, we prepared lead-free 2D Ruddlesden-Popper perovskite PEA_2SnI_4 films using the nitrogen quenching hot casting (NQHC) method in air. To the best of our knowledge, the formation of THP PDs in air has not been reported because of its vulnerability to oxygen and moisture. By employing dimethyl sulfoxide solvent and SnF_2 additive, air-processed PEA_2SnI_4 films were successfully prepared for PDs. Then, the effects of SnF_2 additive on the optoelectronic properties of the THP films and PDs were investigated. XRD patterns of the PEA_2SnI_4 films show typical diffraction peaks of (00l), indicating a layered structure in which an organic spacer is sandwiched between two inorganic sheets. The crystallinity of the films was not affected by the SnF_2 doping concentration. To examine the surface morphology and surface composition of the PEA_2SnI_4, SEM and XPS examinations were conducted. All samples were shown to have a uniform and pin-hole free smooth morphology with large domain sizes. With increasing SnF_2 doping concentration, the peak intensity of Sn^{4+} decreased, whereas that of Sn^{2+} increased. This implies that the SnF_2 additive can effectively suppress the formation of Sn vacancies. To investigate the effect of the SnF_2 doping concentration on photodetector performance, PEA_2SnI_4-based photodetectors with different SnF_2 doping concentrations were fabricated. It was shown that the dark current and responsivity of PDs decreased with increasing SnF_2 doping concentration. The addition of SnF_2 was found to be effective in reducing Sn vacancies, background hole concentration and dark current of PDs. However, an excessive SnF_2 concentration (e.g., 30%) did not affect the passivation of Sn vacancies; The optimal doping concentration was observed to be 20%. Consequently, PDs with 20% SnF_2 exhibited a high responsivity of 509 A W^{-1}, excellent specific detectivity of 6.32×10^{13} Jones and fast response time of 0.56 ms. These results show that use of lead-free 2D PEA_2SnI_4 with SnF_2 additives can be an important material system for the fabrication of high-performance optoelectronic devices such as photodetectors and image sensors.

EN02.03.47
Ultra-Fast and On-Demand Fabrication of Multicolor Light-Emitting Diodes and Photodetectors with Perovskite/Polymer Composite Photoactive Layers on Paper and Textile Substrates Junyi Zhao[1], Li-Wei Lo[1], Zhibin Yu[2] and Chuan Wang[1]; [1]Washington University in St. Louis, United States; [2]Florida State University, United States

Owing to the unique properties such as tunable bandgap and strong optical absorption, perovskite holds great potential for applications in optoelectronic devices. In this work, we report all-solution-processed perovskite light-emitting diodes (LEDs) and photodetectors (PDs) that are fabricated on a variety of unconventional substrates including paper, textile, plastic film, rubber, metal, and even three-dimensional surfaces using a versatile and low-cost direct handwriting approach. Compared with conventional spin-coating and vacuum-evaporation processes, the handwriting approach enables mask-free patterning and allows even untrained individuals to "draw" a batch of high-performance LEDs/PDs within minutes in a time-efficient and energy-saving manner. One of the greatest challenges associated with implementing optoelectronic devices on paper and textile is the rough surface morphology of the yarn and fiber networks, which could result in nonuniform printed film thickness and leakage current. To address this issue, we have shown that poly(ethylene oxide) (PEO) blended into poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) could not only helps improve the conductivity and stretchability of conducting polymer electrodes, but also help planarize the substrate. For the emissive layer, by substituting the halide elements in the perovskite material ($MAPbX_3$) and formulating inks with different compositions of two halide elements, we have achieved multicolor LEDs covering the entire visible spectrum on paper substrates. Meanwhile, the brightness and efficiency of LEDs could be further boosted by introducing the butylammonium (BA) group to reduce the perovskite structure dimensionality to form 2D Ruddlesden−Popper perovskite (RPP) structures. Moreover, we have also systematically investigated the perovskite-polymer composite and have shown that the morphology and optoelectronic properties of the perovskite photoactive layer can be tuned by introducing different polymer additives. More specifically, PEO could tune the ink rheology and viscosity to realize more precise and smoother perovskite film deposition; polystyrene (PS) could increase the density and uniformity of crystal arrangement to boost the brightness of LEDs and lower the current leakage; poly(methyl methacrylate) (PMMA) could reduce grain defects and boundaries to benefit the diffusion of carriers for photodetectors. Our hand-drawn LEDs on paper substrates exhibited a brightness as high as 15,225 cd m^{-2}, a current efficiency of 6.65 cd/A, and a turn-on voltage of 2.4 V; the PDs exhibited an on-off ratio over 10^4, a responsivity up to 132 mA/W, and a response time of less than 15 ms. Owing to the extraordinary flexibility of each functional layer, the handwritten LEDs on the paper substrate could be bent to a 1 mm extreme curvature radius for over 5000 cycles without decay in performance. In summary, our handwritten perovskite optoelectronic devices are ideally suited for low-cost and large-area application scenarios such as E-Textiles, E-Packaging, and E-Papers with less stringent requirements on resolution.

EN02.03.50
Effects of Residual Intermediate Phase Buried in $MAPbI_3$ Films on Photocurrent Generation Weijie Xu, Anusha Srivastava, Bishal Bhandari and Julia W. Hsu; The University of Texas at Dallas, United States

Defects and impurities in halide perovskite can have negative effect on device performance and long-term stability. Here, we report an overlooked impurity in $MAPbI_3$, $MA_2Pb_3I_8(DMSO)_2$, which reduces photocurrent generation in perovskite solar cells (PSCs). We observe a substantial loss of the external quantum efficiency (EQE) spectrum at 400 nm in PSCs made by photonic curing despite good device performance. This EQE reduction feature has also

been reported in the literature. We then find that these samples contain $MA_2Pb_3I_8(DMSO)_2$ phase, which is a commonly reported intermediate phase after the addition of DMSO in $MAPbI_3$ precursors. Previously, $MA_2Pb_3I_8(DMSO)_2$ phase is known to be beneficial by retarding the perovskite growth rate to get high-quality perovskite films. By varying incidence angle in the X-ray diffraction, we show that $MA_2Pb_3I_8(DMSO)_2$ is buried in the substrate/$MAPbI_3$ interface. Because the high boiling temperature of DMSO, the result could be explained by the solvent DMSO is hard to escape the precursor films. We further study how $MA_2Pb_3I_8(DMSO)_2$ affects the long-term stability of PSCs. Additionally, the resulting parasitic absorption reduces the photogeneration in the short wavelength region. This is an obstacle while applying PSC as indoor photovoltaics because indoor light-emitting diode spectra are narrower compared to the AM 1.5G. This work is a reminder to the field to rethink the role of $MA_2Pb_3I_8(DMSO)_2$ in $MAPbI_3$ films and to investigate a mitigation strategy.

EN02.03.52
Performance Improvement and Stabilization of Wide-Bandgap Perovskite Solar Cells by Adding Bication Thiocyanate Salt Mi-Seon Bae[1] and Tae-Youl Yang[1,2]; [1]Chungnam National University, Korea (the Republic of); [2]Korea Research Institute of Chemical Technology, Korea (the Republic of)

In general, Br-rich wide-bandgap perovskite solar cells (PSCs) have higher defect density and deeper trap states than narrow perovskite solar cells. In addition, the halide separation is caused by light and heat, which has been raised as a problem that limits the performance of PSCs. Surface treatment with additional coating with organohalide has been known to be effective to passivate surface defects, however, that requires an additional process with precise thickness control. The addition of ionic liquid additives to the perovskite precursor solution is a simple method and is effective for passivating grain boundaries and surface defects.
In this study, 1-butyl-3-methylimidazolium thiocyanate (BMIM-SCN), a thiocyanate (SCN)-based ionic liquid, is added into a wide-bandgap perovskite material. The ionic liquid passivates uncoordinated lead sites on the grain boundary and the surface of the perovskite material, which ensure the improved quality and long-term stability of PSCs. The secondary additive, $Pb(SCN)_2$, is additionally included in the perovskite to neutralize the excess charge of $BMIM^+$ ions and passivates uncoordinated halide defect, thereby improving the performance of the PSCs: High open-circuit voltage (V_{OC}), decreased hysteresis. In addition, enhanced stability to high temperature and light illumination was also observed. The PSCs showed long-term stability of more than 500 hours under AM1.5G-1SUN illumination in ambient air without encapsulation.

EN02.03.53
Inserting Potassium Chloride for Interlayer between Sputtered-SnO_2 and Perovskite to Eliminate the Hysteresis and Enhance the Efficiency of Perovskite Solar Cells Seok-Hyun Jeong, Ji-Seong Hwang, Wonkyu Lee, Sang-Won Lee, Jae-Keun Hwang, Solhee Lee, Hae-Seok Lee, Donghwan Kim and Yoonmook Kang; Korea University, Korea (the Republic of)

In perovskite solar cells (PSCs), Tin Oxide (SnO_2) has been widely used as the electron transport layer (ETL) due to its higher bandgap and higher electron mobility compared to the other metal oxide materials. Generally, SnO_2 is fabricated by a solution-based process (e.g. spin coating, chemical bath deposition) for high-efficiency PSCs. Meanwhile, it has an advantage in commercialization when ETL is deposited using the vacuum deposition method with RF sputtering. However, few studies have been reported on manufacturing PSCs using sputtered-SnO2 because conventional PSCs with sputtered SnO_2 is subjected to severe hysteresis. It is known that the hysteresis is caused by the defect site that exists at the interface between ETL and perovskite. Additionally, these defect sites induce non-radiative carrier recombination, causing a decrease in open-circuit voltage (Voc) and fill factor (FF) of the device. To solve this problem, a number of studies reported that an increase in Voc and elimination of hysteresis can be achieved by passivating the surface of SnO_2 with various chloride. In this paper, SnO_2 was deposited by RF-sputtering as ETL, and then the surface of as-prepared SnO_2 is passivated with Potassium Chloride (KCl) aqueous solution. Through this surface passivation, it was possible to passivate a defect site that forms traps at the interface with perovskite and change the band alignment for effective electron transport. As a result, the trap density of perovskite is reduced and the efficiency of PSCs is achieved by 21.7% (V_{oc} of 1.11V, FF of 78.2%, and hysteresis index of 2%). This study shows that vacuum-deposited SnO_2 can be adopted by hysteresis-free and high-efficiency PSCs as ETL by inserting KCl between SnO_2 and perovskite.

EN02.03.55
The Influence of Halides on the Interactions of Ammonium Acids with Metal Halide Perovskites Yanan Li[1], Patrick Lohr[1], Allison Segapeli[2], Dorian Werner[1], Juliana Baltram[1] and Adam Printz[1]; [1]The University of Arizona, United States; [2]The University of Texas, United States

Constructing mixed-dimensional 2D/3D metal halide perovskite *via* organic additives incorporation has been demonstrated as a promising approach to simultaneous improve power conversion efficiency (PCE) and stability of perovskite solar cells (PSCs). Amino/Ammonium acids such as 5-aminovaleric acid (5-AVA) or its ammonium/halide salt (5-AVAX) are the most commonly reported additives to prepare 2D/3D perovskites, however, the role of 5-AVA/5-AVAX and how they interact with perovskite are still not fully understood. Here, we systematically investigated the halide effect on the interactions of ammonium acids and perovskite by incorporating pristine 5-AVA and two of its halide salts 5-AVAI and 5-AVACl into $MAPbI_3$ perovskite and found they showed very different behaviors in directing 2D perovskite formation. Because of the high electronegativity, the Cl in 5-AVACl was strongly bonding with one of the H atoms in the ammonium group then volatilized as HCl, leaving an identical structure to that of 5-AVA. X-ray diffraction (XRD) results showed 5-AVA and 5-AVACl led to a similar Ruddlesden-Popper (RP)-2D structure formation, with a bilayer of $5\text{-}AVA^+$ between adjacent perovskite sheets. In contrast, 5-AVAI mainly interacted with 3D perovskite surface *via* coordinating interaction of carboxyl group and Pb and did not form 2D perovskite. In addition to structure characterizations, morphology and optical properties of the perovskite films and photovoltaic devices performance were also studied in this work. We hope this work will provide further insight into the role of halides in additives and their effect on molecular interactions in perovskite precursors.

EN02.03.56
A Computational Study of Ammonium Acid Interactions with Metal Halide Perovskites Patrick Lohr, Yanan Li, Krishna Muralidharan and Adam Printz; The University of Arizona, United States

Metal halide perovskite semiconductors exhibit exceptional optoelectronic properties, including high carrier lifetime, high carrier mobility, and extraordinary power conversion efficiencies (PCE) in photovoltaic devices. Despite these favorable characteristics, the thermomechanical and chemical stability of these devices is insufficient to provide robust performance in most real-world scenarios, a significant roadblock to technological relevancy. A key driver of these instabilities are defects that form on the surface of grains during crystallization in polycrystalline perovskite films.

Additive engineering – the addition of organic molecules during perovskite manufacturing – has been demonstrated to inhibit the formation of defect sites in perovskite films and reduce ion migration, enhancing PCE retention. However, the properties that determine an organic additive's ability to passivate defects and coordinate precursor ions during crystallization in perovskite materials are not well-understood on the atomic scale. By using an *ab-initio* modeling approach, we have systematically studied the interactions between the class of multifunctional additives known as 5-aminovaleric acid (5-AVA)

halide derivatives and methylammonium lead iodide perovskite, revealing key molecular insights into the coordination of grain boundaries and the formation of quasi-2D perovskite heterostructures through self-interactions. Combined with experimental evidence, we believe that our results clarify the role of halides and explain the discrepancy of ammonium-chloride salts.

EN02.03.57
Improving the Thermomechanical Stability of High Efficiency Perovskite Solar Cells via Polymeric Nanofiber Reinforcement Anton Samoylov, Nick Swenson, Chi V. Nguyen, Antonio Murrieta, Juliana Baltram, Matthew Dailey and Adam Printz; University of Arizona, United States

Perovskite solar cells (PSC) currently rival traditional silicon and other third-generation solar cells, becoming increasingly investigated for commercial applications due to their compatibility with scalable processing techniques.[1] However, the poor stability of the perovskite photoabsorbing layer—both chemical and thermomechanical—has thus far inhibited the commercial viability of perovskite-based photovoltaics.

We show that the mechanical stability of perovskite thin films can be increased by an order of magnitude by nanocompositing with polymeric nanofibers using a scalable method. We discuss the increase in fracture resistance energy, G_c, in the nanocomposite samples with respect to nanofiber orientation. We demonstrate this platform with commodity polymeric nanofibers including nylon-6,6 and polyvinyl alcohol. The fiber network reduces the mechanical fragility of the PSCs by increasing their fracture energy several-fold, while maintaining comparable morphology, chemical composition, and device efficiencies to pristine perovskite. Improved power conversion efficiency stability of the nanocomposites under accelerated aging conditions is demonstrated. This platform is a promising advance toward the commercial viability of PSCs.

Optimization of Vapor Flow Geometry for Highly Uniform Deposition of Perovskite Thin Films Chaeeun Yu, Dela Quarme Gbadago, Sungwon Hwang and Naechul Shin; Inha University, Korea (the Republic of)

Organic-Inorganic Hybrid Perovskites (OIHPs) have great potential in photovoltaics (PVs), photodetectors, and light emitting diodes (LEDs) owing to their excellent optoelectronic properties. Currently, a majority of studies on perovskite thin-film fabrication are employing solution-based approaches (*i.e.*, spin-coating), which have limitations in scalable production and suffer from reproducibility. While the vapor deposition method is promising to this end, regulating the as-grown film thickness and roughness over the whole substrate, a prerequisite for highly uniform optoelectronic performance, remains challenging.
In this study, we report the optimization of the flow geometry of vapor precursors to grow high-quality OIHP thin films with uniform thickness over the substrate. By varying the substrate position (e.g., horizontal vs. vertical) relative to the flow direction of vapor precursors in the CVD tube system, we confirmed that the vertical substrate position yielded a more uniform and smooth deposition of the [0001]-oriented lead iodide (PbI_2) primary layers than the horizontal position. Furthermore, the precursor flow simulation based on the computational fluid dynamics (CFD) calculation predicted that the distribution of substrate temperature and molecular transport within the flow boundary layer is more regulated for the vertical position. Interestingly, horizontal flow exhibited a higher degree of uniformity in converting the pre-grown PbI_2 layer into the $CH_3NH_3PbI_3$ perovskite thin film *via* the vapor transport of methylammonium iodide (CH_3NH_3I), suggesting that the solid diffusion following intercalation of CH_3NH_3I to PbI_2 layers dominates the conversion process. Our results present a systematic approach to optimizing the vapor-based fabrication of OIHP thin films for uniform optoelectronic properties and scalable production with high reproducibility.

EN02.03.59
Optimization of tin fluoride concentration for enhanced stability in narrow band gap perovskite solar cells Lana M. Kessels, René Janssen and Martijn Wienk; University of Technology Eindhoven, Netherlands

Incorporating tin into mixed-halide lead perovskites has gained considerable attention as it allows for a narrower bandgap (between 1.2 and 1.5 eV), making it suitable for all-perovskite-based tandem solar cells. However, with the incorporation of tin comes the challenge of higher oxidation levels and different crystallization rates. To evade such problems, the processing method is often altered or various additives are added to the precursor solution or applied as a passivation layer. One of the main additives used for tin-containing perovskites is tin fluoride. It has been shown that a certain percentage (ranging between 5 and 10 mol% of the SnI_2 concentration) enhances the performance significantly.[1,2] Tin fluoride has shown to enhance the number of nucleation sites[1,3], allow halide exchange to obtain SnF_4 and SnI_2[4], and reduce defects[5]. While most studies focus on enhancing the performance of the device, stability measurements of the device over time are often neglected. In this study, a range of tin fluoride concentrations was tested and analyzed using current tracking at the maximum power point voltage and open-circuit voltage tracking to investigate the stability of the photovoltaic parameters under working conditions. Results show that devices with higher SnF_2 concentrations suffer drastic current density losses when exposed to V_{MPP} or V_{OC}. Instead, a concentration of 4-5 mol% gives a steady current density under these conditions and also yields the overall highest performance. In order to investigate the origin of the discrepancy in stability various methods such as quasi-Fermi level splitting and ultra-sensitive sub-bandgap photocurrent spectroscopy were performed.

EN02.03.61
Formamidine Acetate Assisted Antisolvent Free Crystallization of Wide Band-Gap Hybrid Perovskites for Slot-Die Coating Nischal Khakurel[1], Drew Amyx[1], Chandan Q. Howlader[1], Greg Gibson[2], Yoichi Miyahara[1] and Wilhelmus Geerts[1]; [1]Texas State University, United States; [2]FAS Holding Group, United States

Mixed halide Hybrid perovskites (HP) poor thermal stability remains a fundamental barrier that can limit their use to a low temperature range. Although formamidinium (FA) based HP are known to be more stable than their Methylammonium (MA) counterparts, they are metastable and transform to the non-photoactive δ-phase over time. The black photoactive α-phase can be stabilized by replacing some of the FA in the lattice with Cesium. Most HP are

deposited using an anti-solvent quenching process - adding an extra layer of complexity to the production process. In this work, we utilize FA based ionic liquid FA Acetate (FAAc) in wide band-gap perovskite $FA_{0.78}Cs_{0.22}Pb(I_{0.85}Br_{0.15})_3$ (Cs22Br15) that assists in nucleation and grain growth of a continuous pinhole free layer without the use of anti-solvent or quenching. We also use the same composition to slot-die coat using nitrogen gas assisted quenching on glass/ITO substrates in ambient conditions.
Inks with various concentrations of FAAc were made by adding 20, 40, 60, 80, or 100 mg FAAc/ml in a 1M Cs22Br15/ N, N- Dimethylformamide solution. θ-2Θ XRD scan were measured prior and after annealing. The pre-anneal XRD scans show intermediate peaks in-between 5 and 10 degrees which do not show up in films spun from ink without FAAc additive. The post-anneal XRD scans shows peaks of the cubic α-phases. The Scanning electron microscopy images show continuous pin-hole free films for samples spun from inks containing 40 mg/ml or more of FAAc. It was noticed that the crystallization of HP takes place only after the concentration of FAAc is equal to or above 40mg/ml. Moreover, the roughness of the films measured with an Atomic Force Microscope decreases from 11 to 8.33nm when the FAAc concentration is increased from 0 to 40 mg/ml.
The band-gap of these films were determined from UV-Vis spectroscopy and was not affected by the addition of FAAc to the ink (1.63 eV). The inks were spin-casted into perovskite films to make solar cells (6.25mm^2) having the structure: glass/ITO/PTAA/Cs22Br15.FAAc/C60/BCP/Al. The champion devices for 40mg/ml, 60mg/ml and 100mg/ml show a power conversion efficiency of 13.63%, 14.82% and 15.12% respectively. Additionally, preliminary slot-die coating experiments in ambient conditions have shown that this ink has a wider printing processing window as it can be coated and results in pin-hole free thin films at chuck temperatures from 30ºC-70ºC unlike ink without FAAc additives.
This work was in part funded by NSF through STTR Phase II grant 1927020 and in part by the U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy (EERE) under the Solar Energy Technologies Office Award Number DE-EE0009526. A Systematic Vapor-Phase Treatment Process for Efficient Perovskite Solar Cells and Solar Modules Soyeon Park and Kai Zhu; National Renewable Energy Laboratory, United States

In recent years, the surface passivation using the bulky organic cations in hybrid organic-inorganic perovskite solar cells (HPSCs) have been introduced to boost device efficiency and stability. The precise selection and use of bulky organic cations for surface passivation on 3D perovskite film have enabled fine-tuning of the dimensionality of perovskite and/or suppression of inherently formed defects, leading to enhaced optoelectronic properties and device stability. However, conventional solution process of passivation method using bulky organic cations could face difficulties in controlling and predicting the dimensionality of the resulting capping layer and avoiding the negative affects of the solvent and uneven reaction during the solution process.
In this study, we developed a systematic butylamine-based vapor-phase treatment processing method adapted from an atomic layer deposition (ALD) equipment to perform uniform and reproducible treatment on 3D perovskite films. This new approach has enabled us to fabricate the state-of-art HPSC configuration, with enhanced perovskite optoelectronic properties (charge carrier lifetime and mobility) and much-enhanced device stability. When using this vapor-phase treatment, a power conversion efficiency (PCE) was enhanced for both lab-scale devices and mini-modules with excellent long-term operational stability and environmental stability. Remarkably, the vapor-treated devices exhibited enhanced device stability and efficiency than the solution-treated devices with better reproducibility. We believe that this systematic vapor-phase treatment processing method adapted from an ALD system can provide a general processing strategy of interfacial engineering for future commercial-scale HPSCs development.

EN02.03.63
Novel Method of Recycling Lead Perovskite Solar Cells Using Iodide Solutions Tanner Y. O'Hara; South Dakota School of Mines and Technology, United States

The implementation of green energy solutions has become increasingly common as the global demand for electricity rises along with concerns regarding environmental release. Interest in solar energy has led to the advancement of thin film solar cells, especially lead perovskites as they offer a cheap and simple alternative to existing technologies. Lead perovskite solar cells (PSCs) utilize the compound $CH_3NH_3PbI_3$ as a light harvesting material and have shown promising advancements in power conversion efficiency (PCE) comparable to current products. One hindrance to the large-scale application of PSCs is the use of lead compounds which are highly toxic to humans and the environment. Attempts to replace the lead compounds with those of similar metals such as Sn, Sb, and Bi have resulted in considerably lower PCEs. For this reason lead based perovskites have maintained prominence, and various methods to recycle the panels have been investigated. Unfortunately many of these recycling processes utilize harmful solvents such as DMF, DMSO, and chlorobenzene. The glass backing is often crushed and reduced into scrap, making them unusable for remanufacture.

A novel recycling method utilizing aqueous iodide solutions has proven effective at recovering the lead and preserving the glass substrate for direct remanufacture of new cells. Above a specific concentration of iodide in solution, the solubility of lead begins to increase as several complex ions are formed. Iodide solutions selectively interact with the perovskite photovoltaic (PV) layer and dissolve it from the edge in, allowing for the exfoliation of back contact materials. The back contact material can be physically separated and dissolved lead can be recovered from solution. The glass substrate represents a large portion of the panels material cost, by reusing them for remanufacture the price per panel decreases and minimizes the environmental footprint.

EN02.03.64
Carbazole Based Self Assembly Monolayer as HTL for Highly Efficient Methyllamonium Free Mixed Sn/Pb- Based Perovskite Solar Cells Matteo Pitaro[1], Javier Sebastian Alonso[1], Lorenzo Di Mario[1], Malin B. Johansson[2], Erik Johansson[2], Gerrit Boschloo[2] and Maria Antonietta Loi[1]; [1]University of Groningen, Netherlands; [2]Uppsala universitet, Sweden

Highly performing mixed tin-lead perovskite materials are among the most promising options as an alternative active layer in perovskite solar cells to reduce Pb content. Moreover, these compounds open the possibility of fabricating full perovskite tandem solar cells, owing to their reduced band gap. The most efficient single junction mixed Sn/Pb perovskite solar cells have been fabricated using methyl ammonium cations (MA^+), and a p-i-n structure where poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT: PSS) is implemented as hole transport layer (HTL).[1] However, these record devices show limited stability. Specifically, MA^+ cations easily desorb at high temperature (85 C°) from the perovskite surface, introducing trap states. PEDOT: PSS, due to its hygroscopic and acid nature, reacts with the perovskite active layer, affecting the long term stability.
In this work to improve the thermal stability of these devices, cesium cations (Cs^+) are partially or entirely substituted to MA^+. The incorporation of Cs^+ cations leads to the contraction of the perovskite crystals, enhancing the organic cations-halides interactions and finally limiting the organic cations

desorption.[2] To solve the HTL issue, in this work we employ 2-(9H-carbazol-9-yl)ethyl)phosphonic acid (2-PACz), and [2-(3,6-dibromo-9H-carbazol-9-yl)ethyl]phosphonic acid (Br-2PACz). We fabricate devices in a p-i-n structure, where the intrinsic layer is formed by a $Cs_{0.25}FA_{0.75}Sn_{0.5}Pb_{0.5}I_3$ perovskite layer. The perovskite layer deposited on PEDOT: PSS exhibited poor quality and a large number of pin-holes with the champion device efficiency of 16.33%. On the contrary, devices fabricated on 2PACz and Br-2PACz show an enhanced quality of the active layer, leading to an improved efficiency of 18.44% and 19.57% with 2PACz and Br-2PACz, respectively. 19.57% efficiency is a record efficiency for the aforementioned perovskite composition.

Lead-Free $FASnBr_3$/PDMS-Based Flexible Piezoelectric Nanogenerator for Self-Powered Wireless Electronics Md. Masud Rana[1], Asif Abdullah Khan[1], Weiguang Zhu[1], Md Fahim Al Fattah[1], Sathursan Kokilathasan[1], Shazzad Rassel[1], Shuhong Xu[2], Chunlei Wang[2] and Dayan Ban[1]; [1]University of Waterloo, Canada; [2]Southeast University, China

In the modern era of thriving inventions, energy sources play a vital role. Conventional fossil fuel-based energy sources are gradually being replaced by unconventional ones to address imminent challenges, such as inadequacy of resources, environmental pollution, and global warming. Alongside large-scale conventional energy harnessing sources, many unconventional systems including solar, thermoelectric, electrostatic, piezoelectric, and electromagnetic were developed to convert the energy available in the ambient environment into usable electrical energy for self-powered electronic applications. Following the first reported development of PENGs based on zinc-oxide nanowires in 2006, numerous piezoelectric nanostructures were utilized to construct nanogenerators, such as gallium-nitride nanorods, lead zirconate-lead titanate (PZT) nanofibers, and polyvinylidene fluoride polymer (PVDF)nanofibers. Owing to their high d_{33} value, inorganic perovskite piezoelectric crystals, such as $Pb(Zr,Ti)O_3$ (PZT), $BaTiO_3$ (BTO), and $PbTiO_3$ (PT), were extensively investigated and explored for their energy-harvesting applications. However, the inherently brittle and rigid nature and requisite high-temperature synthesis of these ceramic materials often limit their applications. Moreover, a major concern and obstacle to commercialization related to traditional lead-based perovskite materials is the environmental toxicity of these materials. After exposure to water, the lead-based materials can easily form a solution containing the life-threatening lead, which may be released to the environment where it can accumulate in the food chain and impose deleterious impacts on ecosystems and human health.
Recently, lead-free flexible piezoelectric nanogenerators (PENGs) have drawn much attention because of the threat posed by lead (Pb)-based piezoelectric materials to the environment. Here, we reported an organic-inorganic hybrid perovskites (OIHP) PENG, which is a combination of lead-free formamidinium tin (Sn) halide perovskite ($CH(NH_2)_2SnBr_3$ ($FASnBr_3$)) nanoparticles (NPs) and polydimethylsiloxane (PDMS) polymer matrix. The OIHPs combine the advantages from both the organic molecular part and inorganic octahedron of the perovskite structure at a microscopic level, have been the focus of research for quite some time as a potential alternative to ceramics. Besides their distinct optoelectronic properties, OIHPs exhibit great advantages in terms of their compositional variability, structural flexibility, and room-temperature and solvent-based synthesis process.
The fabricated PENGs produced open circuit voltage (V_{oc}) of 94.5V, short-circuit current (I_{sc}) of 19.1 μA, and power density of 18.95 $\mu W/cm^2$. The fabricated $FASnBr_3$@PDMS PENGs was encapsulated between a Cu and PET/ITO electrode. We noticed a 180° change in the phase-hysteresis loop at the time of V-PFM measurements, and also observed a characteristics butterfly feature in the amplitude. Finally, to demonstrate the wireless communication capability an energy-efficient charging circuit was developed which functions in two different steps. In this process, the rectified electrical output from the PENG was stored to a smaller capacitor (1 μF) (step-1 charging). A commercial LTC-3588-1 unit was used to regulate the maximum charging level of this capacitor to 5 V. As soon as the output voltage of this capacitor reaches 5 V, the step-2 charging cycle begins and it transfers a portion of the stored electrical energy to a larger capacitor of 220 μF. In this periodic manner, electronic or wireless circuits can be repeatedly powered up using stored energy from the PENG, thus yielding potential to realize self-powered wireless sensing, structural health monitoring, self-powered implantable biomedical devices, and other critical sensor technologies. This study demonstrates the great potential of lead-free OIHPs materials in next-generation high-performance PENG applications.

Toward Commercialization of Perovskite Solar Cells Through Advances in Materials and Process Hyun Suk Jung; Sungkyunkwan University, Korea (the Republic of)

All solid-state solar cells based on organometal trihalide perovskite absorbers have already achieved distinguished power conversion efficiency (PCE) to over 25% and further improvements are expected up to 27%. Now, the research on perovskite solar cells (PSCs) has been moving toward commercialization. To facilitate commercialization of these great solar cells, some technical issues such as long-term stability, large scale fabrication process, and Pb-related hazardous materials need to be solved. Also, flexible perovskite solar cell using plastic substrate can be used in niche applications such as portable electrical chargers, electronic textiles, and large-scale industrial roofing.
This talk is dealing with our recent efforts to facilitate commercialization of perovskite solar cells. For examples, we introduce a recycling technology of perovskite solar cells, which covers the regeneration process of Pb contained perovskite layer as well as recycling process of Au electrodes and transparent conducting oxide glass. Also, simple fabrication technologies for realizing large scale perovskite module are introduced and recent effort for achieving high efficiency module is going to be presented. Precursor technology is of great importance for yielding high efficiency and reproducibility of PSC, which is one of topics in this talk. Finally, recent interesting results regarding ultra flexible perovskite cells will be discussed.

2:00 PM EN02.05.02
Continuous Perovskite Solar Module Manufacturing—Scale-up Challenges and Solutions Rebecca Bolton, Sarah-Jane Potts, Carys Worsley and Trystan Watson; Swansea University, United Kingdom

Transitioning from research to industrial scale manufacture is a challenging task; renewable technology in particular must ensure that the pursuit of highly efficient and highly stable laboratory devices does not impose the requirement for expensive fabrication processes, scarce resources and inadmissible greenhouse gas emissions. Single junction metal halide perovskite cells (PSC), representing the next generation of solar energy harvesting, have recently achieved 25.7% certified efficiency on a lab scale: doubling in less than ten years. Screen-printed triple mesoscopic carbon electrode modules (mCPSC) are

one of the leading perovskite solar cell technologies earmarked for scale-up and commercialisation as a consequence of the inherent lower manufacturing cost and exceptional stability. The reality of scaling from “lab to fab” requires three key stages to be addressed and overcome:

What is the optimum laboratory scale design that can be successfully up-scaled?
What industrial scale optimisation is needed to best replicate the laboratory scale?
How can industrial scale devices be measured and validly compared back to laboratory scale?

This work highlights the difference between a good laboratory cell a good scalable cell and how the end goal of scale-up has directed recent research into laboratory architecture. This includes incidental improvements to full scale modules made from separate studies, such as green perovskite technology research leading to an unexpected improvement in the infiltration process. Industrial scale optimisation to accommodate the batch fabrication of mCPSC modules is also detailed with consideration for further development to continuous production. Notably, the curing and subsequent cooling of triple stack devices constructed on glass substrate is identified as a significant bottleneck for a continuous production line and requires precise optimisation for large area modules. Similarly, the infiltration process is specifically adapted to account for a greater surface tension effect of the perovskite precursor. Finally, recent improvements in technological capability have granted the ability for 520 cm^2 modules to be measured and accurately correlated to their laboratory scale counter parts; underlining the successful scale-up efforts made in the last year. The culmination of systematically addressing the three key challenges is marked by the construction of a large outdoor array of modules at the Solar Heat Energy Demonstrator (SHED) in Port Talbot, UK. The external data collected from these modules over the last 10 months will be discussed and the route to full scale manufacture presented.

2:15 PM EN02.05.03
Amorphization of Crystalline PbI_2 Stabilizes High Efficiency Perovskite Solar Cells Shaun Tan, Tianyi Huang, Qiyu Xing and Yang Yang; University of California, Los Angeles, United States

Residual PbI_2 in the halide perovskite thin film is known to beneficially increase the performance of perovskite solar cells (PSCs). The residual PbI_2 exists in its crystalline hexagonal phase, distributed along the perovskite grain boundaries. However, it is also known that the presence of this crystalline PbI_2 is a double-edged sword, and sacrifices the long-term operational stability of PSCs. Under illumination, PbI_2 can undergo photolysis to decompose into metallic Pb and I_2 gas – the former constitutes a deep-level trap state, while the latter aggravates the perovskite phase degradation.

In this work, we demonstrate a strategy to suppress the crystallization of residual PbI_2. Synchrotron-based in-situ wide-angle X-ray scattering (in-situ WAXS) measurements were used to monitor the perovskite formation from solution and during thermal annealing, confirming the amorphization of PbI_2 into a secondary, non-crystalline phase. We observed that this amorphization of PbI_2 significantly improved the ambient, humidity, and photo stability of the perovskite thin films. Control experiments on perovskites with residual crystalline PbI_2 showed reduced or comparable stability under the same testing conditions. We verified the universality of our results on a variety of different perovskite compositions. Lastly, our champion devices also reached power conversion efficiencies approaching 25%, with an open-circuit voltage (V_{OC}) loss as low as 0.33 V.

2:30 PM EN02.05.04
Stable Ruddlesden-Popper Phase Inorganic-Cation Pseudohalide 2D $Cs_2Pb(SCN)_2Br_2$ Perovskite Single Crystal for Photodetector Chwenhaw Liao[1,2], Chu-Chen Chueh[2] and Anita W. Ho-Baillie[1]; [1]The University of Sydney, Australia; [2]National Taiwan University, Taiwan

3D metal halide perovskites (ABX_3 where $A = Cs^+$, CH_3NH^{3+}, $CH(NH_2)^{2+}$; $B = Sn^{2+}$, Pb^{2+}; $X = Cl^-$, Br^-, I^-) have outstanding optoelectronic properties but suffer from poor long term stability or durability. 2D or quasi-2D layered perovskites may be part of the solution by introducing a separation between $[PbX_6]$ octahedron inorganic layers using long carbon chain spacers in the A-site or the X-site. As organic spacers are insulating, appropriate selection is important to ensure the resulting perovskites retain small enough exciton binding energy and sufficient conductivity at least in a vertical direction through each inorganic slab. Here we demonstrate the advantage of X-site substitution over A-site substitution for layered perovskite resulting in much smaller separation between the constituent perovskite layers and hence optoelectronic properties.
This report is the 3rd one on X-site-substituted Ruddlesden-Popper (RP) phase perovskite single crystals since 2015 [1-3] and the first report on inorganic-cation pseudohalide 2D phase perovskite single crystal, $Cs_2Pb(SCN)_2Br_2$. We have been able to synthesize the crystal at room temperature (lower than those reported previously [1-2]) using the antisolvent vapor-assisted crystallization (AVC) method. Interestingly, the 2D single crystal undergoes first-order phase transformation to 3D cubic $CsPbBr_3$ above 450K but the transformation is reversible. Mechanisms of reversible transformations will be presented in the conference. A significant advantage of this $Cs_2Pb(SCN)_2Br_2$ single crystal is its small exciton binding energy of 160 meV, which is one of the lowest values reported for 2D perovskites (n = 1) and is comparable to the quasi-2D A-site substituted RP phase perovskite values. Finally, a $Cs_2Pb(SCN)_2Br_2$ single crystal photodetector is demonstrated with a respectable responsivity of 8.46 mA W^{-1} and a detectivity of $\approx 1.2 \times 10^{10}$ Jones at a low bias voltage of 0.5 V.

2:45 PM EN02.05.05
Utilizing Automated Gas Quenching for Improved Reproducibility in Perovskite Solar Cells Samantha Kaczaral[1], Samuel Schreiber[2], Daniel Morales Jr[2], Keith White[2], Michael F. Toney[1,2], David Moore[3] and Michael McGehee[1,2,3]; [1]University of Colorado, Boulder, United States; [2]University of Colorado Boulder, United States; [3]National Renewable Energy Laboratory, United States

An automated gas quenching process improves the reproducibility of perovskite solar cells by eliminating processing variables that change over time or from facility to facility. Broad human error can be eliminated by automating the process. Gas quenching, in comparison to antisolvent quenching, prevents the buildup of solvents in the spinning atmosphere. However, a further understanding of how gas quenching parameters can affect perovskite film formation is necessary to develop a robust methodology to create high performing devices. The developed methodology minimizes performance differences between batches of devices and allows for systematic film formation studies.

Gas quenching film formation has previously been studied with respect to the complexing solvent, NMP compared to DMSO. However, our experiments show that film formation changes based on the nitrogen quenching pressure/flowrate. The experiments were done on a 1.73 eV bandgap perovskite with a composition of $DMA_{0.1}Cs_{0.3}FA_{0.6}Pb(I_{0.8}Br_{0.2})_3$. As the nitrogen quench pressure increases, the homogeneity of the film improves based on XRD analysis.

As the gas quench pressure increases from 30 psi to 80 psi, the ratio of peak area for PVK(100):PbI_2(100) increases from 0.77 to 5.54 respectively. Based on in-situ photoluminescence spectra, PL transients also change as a function of gas quench pressure during the fabrication process. At pressures less than 50 psi, a dual peak is observed in the first 10 seconds of the quench which then homogenizes into a single peak. However, at pressures over 50 psi, only a single peak is observed during the entire duration of film formation.

One explanation of increasing heterogeneity at lower pressures is that certain salts (e.g. $PbBr_2$, CsI) nucleate first during the spin process when they cannot complex strongly with DMF/NMP. Excess PbI_2 that remains complexed with NMP increases the final film heterogeneity. As pressure increases, the solvents are removed at a faster rate which decreases the PbI_2 remaining in the solvate phase. In-situ GIWAXS data will be shown to describe the structural evolution of the film as a function of quenching pressure.

Film formation using the gas quenching method is less sensitive to the processing environment, compared to the antisolvent method. Gas quenched films show almost identical PL transients during film formation in a solvent free environment and a DMF saturated environment. Dual PL peaks were present at the same location and duration for both environments and the films ended at the same bandgap post quench. For the antisolvent method in a solvent free environment, dual PL peaks were present throughout the entire duration of the spin. However, in a DMF saturated environment, only a single PL peak was present for the duration of fabrication and the post-spin coat bandgap did not match that of the clean environment. Resiliency against solvent buildup during fabrication further improves the reproducibility of our automated gas quench system.

Upon setting up an automated gas quench system at both CU Boulder and NREL, our first observation is that pressure at the nitrogen source outlet is not a sufficient metric for describing our fabrication parameters. The optimum pressure for gas quenching at NREL is 100 psi; however, that caused the perovskite solution to be blasted off the substrate at CU. Based on this observation, it is necessary to report the flowrate of the nitrogen quench instead of the pressure, since tube diameter, curvature, and length can all result in different flowrates for a given input pressure. Using a systematic procedure, multiple researchers at NREL can obtain over 18% devices across multiple batches. The developed methodology can be applied to other facilities to achieve over 18% efficiency across multiple batches. The automated gas quenching process reproducibly resulted in high performing devices and allowed for systematic film formation studies.

Taming Defects in Halide Perovskites—Insights from Atomistic and Molecular Simulations Shuxia Tao; Eindhoven University of Technology, Netherlands

Like any other semiconductors, the defects in halide perovskites determine the performance and long-term stability of the resulting optoelectronic devices. Understanding the electronic properties and chemical stability and their interplay are paramount. In this talk, I will present our recent findings on these aspects using atomistic simulations from Density Functional Theory and reactive Molecular Dynamics. By determining the electronic and dynamical properties of several defects, we identify the harmful ones which lead to either recombination losses or chemical degradations. I will also show several strategies to mitigate and passivate these defects. These include engineering compositions of perovskite absorbers/emitters and interfaces in the devices, applying additives and optimizing growth conditions, etc.. The atomistic insights provide a basis for further improving the performance and stability of perovskite devices by optimizing the interplay of these factors.

4:00 PM EN02.05.07
Halide-Dependent Formation Dynamics of 2D Ruddlesden-Popper Phases on 3D Perovskites Tim Kodalle[1], Carlo Andrea Riccardo Perini[2], Mriganka Singh[1], Juan Pablo Correa Baena[2] and Carolin M. Sutter-Fella[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Georgia Institute of Technology, United States

While organic-inorganic perovskites achieved competitive power conversion efficiency within a short time[1], they still suffer from insufficient stability[2]. A promising approach to improve their long-term stability is the incorporation of bulky, hydrophobic molecules into the perovskite layer[3]. The addition of these species onto the 3D perovskite induces the formation of 2D Ruddlesden-Popper (RP) phases, and their formation dynamics along with the effects of these 2D layers on the material's optical/electrical response in solar cells are under intense debate. Recently, we showed that the formation dynamics of these RP phases strongly depend on the choice of the bulky molecules.[4]
In this study, we investigate the role of the halide (Iodine, Bromine, and Chlorine) in Phenethylammonium halides (PEAX) on the formation dynamics of RP phases on triple cation, mixed halide perovskite thin films. Using a multimodal approach combining *in situ* photoluminescence (PL), and *in situ* grazing incidence wide-angle X-ray scattering (GIWAXS) measurements during spin-coating and annealing, we monitor the deposition of the PEAX molecules and investigate the formation mechanics of the subsequently forming RP-phases. We find that the formation dynamics strongly depend on the halide used for the RP phase: In the case of Iodine, we see clear evidence for a slow conversion from the PEAI salt to pure 2D (n = 1 in $A'_2A_{n-1}B_nX_{3n+1}$, where A' is PEA, A is Cs,MA,FA, B is Pb, and X is the halide) and quasi-2D (n > 1) phases. In the case of PEABr and PEACl, however, we observe a rather fast formation of solely n = 1 RP-phases indicating different reaction dynamics and phase stability depending on the halide used. Furthermore, we observe an intermixing of Br and I when PEAI or PEABr is deposited on the I- and Br-containing 3D perovskite but no significant intermixing in the case of the PEACl. The latter might suggest a further increase of the chemical stability of the 2D RP phase with decreasing size of the used halide.
Our results illustrate how multimodal *in situ* characterization can provide mechanistic insights into the 2D layer formation and its interaction with the 3D perovskite. Therefore, it can be utilized to deliberately optimize the annealing sequence targeting an ideal 2D/3D interface satisfying enhanced charge transport and stability. We will further correlate these mechanistic insights with device performance and stability.

Does the Solvent Matter?—Influence of the Solvent in Hybrid Halide Perovskites Precursor Solution Ana Palacios Saura[1], Joachim Breternitz[1], Armin Hoell[1] and Susan Schorr[1,2]; [1]Helmholtz-Zentrum Berlin für Materialen und Energie, Germany; [2]Freie Universität Berlin, Germany

Hybrid halide perovskites (HHPs) are highly promising photovoltaic absorbers not only for using low-cost solution-based processing methods but also for the outstanding increase in power conversion efficiency of solar cells up to 25.5% in 2021[1].

Despite HHPs popularity, the growth mechanism of HHP crystals in solution is still unknown. With this study, we aim to bring more clarity about the precursor arrangement in solution prior to crystallization and how the solvent affects the atomic arrangement in this early state. For this purpose, we applied small angle synchrotron X-ray scattering (SAXS) to investigate precursor solutions of different HHPs ($MAPbI_3$, $MAPbBr_3$, $MaPbCl_3$, $MAPb(I,Br)_3$ and $FAPbI_3$) in different common solvents used to synthesize HHPs layers, such as γ-butyrolactone (GBL), dimethylformamide (DMF), dimethyl sulfoxide (DMSO) and mixtures thereof.
SAXS is a non-destructive characterization technique based on the difference between elastic scattering objects in a solution. With SAXS, it is possible to investigate the size and shape of scattering objects ranging between 1 – 100 nm, determining also the distance between adjacent scattering objects and their interaction with each other[2,3]. We performed SAXS experiments at the HZB synchrotron radiation source BESSYII, at the four-crystal monochromator beamline of the Physikalisch-Technische Bundesanstalt[4] using the ASAXS endstation[5]. Samples have been prepared by dissolving binary precursors (e. g. MAI and PbI_2 to synthesize $MAPbI_3$) in a solvent. The solutions with a concentration of 0.8 M were measured by SAXS 60 minutes after their preparation.
Our measurements show a clear maximum in the scattered intensity at q-values of ~3 nm^{-1}, which holds two essential pieces of information: it demonstrates the agglomeration of scattering objects and the peak position corresponds to the most abundant distance of scattering objects in a range of 2-3 nm. While all solutions show agglomerations, we were able to demonstrate that the size of those agglomerates changes with the composition of HHP precursors, but also with the solvent. Based on this information, we have developed a core-shell model with [PbX_6] octahedra (X = Cl, Br, I) in the core surrounded by solvent molecules to describe the scattering objects. The size of the solvent molecules as well as the radii of Pb and halides forming [PbX_6] octahedra were derived from a combination of experimental values from diffraction and computationally obtained electron density distributions. We can explain the solvent dependent variation of the experimentally determined distance between the scattering objects by a core size variation realized by a combination of isolated octahedra or corner-sharing octahedra as core, respectively. Since the solvent molecules can be described as an ellipsoid, their orientation must be taken into account. We can explain the variations of the minimal possible distance between the scattering objects (R_{HS}), evaluated from the structure factor determined by analyzing the SAXS data (using SASfit) by a preferred orientation of the solvent molecules in the solvent shell of the scattering objects. Therefore, the choice of the solvent may not only depend on the precursor solubility but also on their chemical and physical behavior. We will discuss the influences of precursor composition and solvent on the core as well as the solvent shell of the scattering objects, since they have the potential to influence the crystallization process of the HHP and therefore the performance of a device produced from solution processing.

Formation, Stability and Crystallization in Two-Dimensional Perovskites—From Nanoplates to 2D/3D Interfaces Analyzed by *In Situ* Experiments Ana F. Nogueira; University of Campinas, Brazil

Metal halide perovskite solar cells have reached the recent efficiency breakthrough of 25.6%, higher than silicon polycrystalline photovoltaics. Such fantastic result was only possible due to a precise control and engineering of the morphology, interfaces, defects, and the use of multiple cations in perovskite A-site, as Rb, Cs, MA (methylamonnium), FA (formamidinium) and long alkyl cations as phenylethylammonium (PEA). Dimensionality of perovskite materials can be easily controlled by the choice of the cation in the A site, providing structures from zero (OD), one (1D), two (2D) and three-dimensions (3D), amplifying the use of these materials in lighting, lasers and sensors. For tandem perovskite solar cells, a mixture of different anions, as Br and I is also desired to adjust the band gap. Such cocktail of different cations and anions influences not only the structure and dimensionality, but the formation of undesirable phases, halide segregation, defects, etc. They have also a huge impact on device's efficiency and stability.
In this presentation, we will summarize important results using *in situ* experiments to probe the formation of 2D perovskite materials, from nanoplates to micro-sized structures as well 2D/3D interfaces. Dynamics of the formation of these structures and interfaces in solution or solid state, their stability under thermal stress and aggregation, were studied by *in situ* experiments probing the samples with both X-rays and/or visible radiation. For that, we employed time-resolved grazing incidence wide angle X-ray scattering (GIWAXS), small angle X-Ray scattering (SAXS), high-resolution XRD and PL spectroscopy taken at the Brazilian Synchrotron National Laboratory and Lawrence Berkeley National Laboratory.

Interlayer Engineering in Halide Perovskite Solar Cells Jun Hong Noh; Korea University, Korea (the Republic of)

Halide perovskite solar cells (PSCs) have a typical device structure of polycrystalline thin-film solar cells such as CdTe and CIGS solar cells. PSCs have

surpassed the conventional polycrystalline thin-film solar cells, and now it has become an important issue whether low-temperature solution-processed polycrystalline PSCs can reach the radiative limit like epitaxial GaAs thin-film solar cells. In this talk, our recent approaches to improving the photovoltaic performance of PSCs in terms of the electrical and optical design of PSCs will be discussed. The local electric field design within the perovskite layer between charge transport layers (CTLs) by introducing a wide-bandgap halide layer enabled improved power conversion efficiency. In addition, the boosting radiation of the stacked perovskite layer between CTLs in the complete device by efficient reduction of interfacial non-radiative recombination could also bring performance gain by photon recycling and scattering. The electrical field and optical radiation design by interlayer engineering could be one of the strategies to reach the radiative efficiency limit. Our recent results of oxide CTLs will be discussed to improve the processability and long-term stability of PSCs.

2:00 PM EN02.07.02
Interfacial Toughening in Perovskite Solar Cells Zhenghong Dai and Nitin P. Padture; Brown University, United States

Metal halide perovskites (MHPs) have emerged as the most promising light-absorber materials in the photovoltaic community due to their near-ideal bandgaps and extraordinary optoelectronic properties. However, MHPs are inherently compliant, soft, and brittle. While significant progress has been made in improving the stability of MHPs, perovskite solar cells (PSCs) will also need to be mechanically reliable if they are to operate efficiently for decades. In this context, we study the fracture behavior of PSCs by measuring their cohesion energies (Gc) using double cantilever beam method. By revealing the fractured pathway, we conclude several factors determining the Gc of PSCs including grain size, crystallinity, and interfacial toughness. Also, we report a dual interface reinforcement approach to strategically enhance the interfacial adhesions of two important interfaces in PSCs (electron transporting layer/MHP, and MHP/hole transporting layer), the resulting PSCs demonstrate unprecedented performance, stability, and reliability. This work points to a new route for designing mechanically robust PSCs with long-term durability.

2:15 PM EN02.07.03
Targeted Crystallization of 3D/Polytype Phase Heterostructures in High-Bromide Content Perovskites Joel Smith[1], Margherita Teddei[2], Pietro Caprioglio[1], Benjamin Gallant[1], Saqlain Chaudhary[1], David Ginger[2] and Henry Snaith[1]; [1]University of Oxford, United Kingdom; [2]University of Washington, United States

Mixed-dimensionality metal-halide perovskite films comprising heterostructured interfaces, grain boundaries or surfaces primarily using '2D' phases enable control over optoelectronic properties, interfaces and stability in functional devices. Less explored are low-dimensional polytype phases maintaining ABX_3 stoichiometry, but with mixtures of face- and corner-sharing octahedral arrangements. Here we present our latest data exploring deliberate introduction of targeted polytype phases via both surface treatment and bulk solution additive approaches applied primarily to high-bromide content methylammonium-free perovskite compositions with 1.7 eV and 1.8 eV band gaps. By blade-coating solutions and monitoring using synchrotron-based *in situ* grazing-incidence wide-angle X-ray scattering (GIWAXS) we look at the impact on the crystallization process of different additives. Drawing on the chemical structure and stability of formamidinium, these include ethylenediamine, imidazolium and guanidinium derivatives. From this we find significant differences in the heterogeneity of the perovskite phase and demonstrate enhancements in the ambient stability of these materials. Combining solution characterisation methods including nuclear magnetic resonance (NMR) spectroscopy, we establish a clear understanding of the bridge between solution chemistry, precursor phase formation and resulting material properties across a range of perovskite compositions. Our work provides important insight into the controlled growth of stable perovskite materials by engineering the composition of benign secondary phases.

Surface Passivation Strategies for Stable Tin Halide Perovskite Solar Cells Studied by Hard X-Ray Photoelectron Spectroscopy Roberto Félix[1], Jorge Pascual[1], Meng Li[1], Mahmoud Hussein[1], Lucas Bodenstein-Dresler[1], Elif Hüsam[1], Claudia Hartmann[1], Regan G. Wilks[1,1], Antonio Abate[1,2] and Marcus Baer[1,1,3]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; [2]University of Naples Federico II, Italy; [3]Helmholtz-Zentrum Berlin für Materialien und Energie (GmbH), Germany

Halide perovskite (HaP) solar cells – particularly those using $APbX_3$ [A = $CH_3NH_3^+$ (MA^+), $HC(NH_2)_2^+$ (FA^+), Cs^+ and X = I^-, Cl^-, Br^-] as the absorber layer – have recently achieved power conversion efficiencies (η) over 25%, surpassing the record η of well-established photovoltaic technologies based on multicrystalline silicon-wafers or chalcopyrite and cadmium telluride thin-film solar cell absorbers [1]. A major concern related to HaP absorbers is, however, the toxicity of Pb. Ongoing efforts to replace Pb by Sn have so far yielded relatively low-performing solar cells (with record η below 15 % [2]), likely limited by defect formation in the absorber material due to the tendency of Sn to oxidize from Sn^{2+} to Sn^{4+} [3]. To overcome this obstacle, preparation recipes of Sn-based perovskite absorbers routinely include the use of SnX_2 additives (SnF_2 being the mostly widely used) to produce a Sn-rich precursor environment; this is reported to lead to better-quality films, in terms of morphology, decreased presence of secondary phases and Sn^{4+} content [4]. Moreover, it has been demonstrated that the halide anion (e.g., F^-) can influence positively the perovskite crystallization process, in addition to complexing with Sn^{4+} and preventing it from being introduced into the absorber films [5]. Recently, another approach to improving the stability of Sn perovskites has entailed the use of two-dimensional (2D) Ruddlesden-Popper phase-layered perovskites [6,7], where long and/or bulky chain organic cations [e.g., alkylammonium cations, phenyl ethyl ammonium (PEA), etc.] with more hydrophobic properties than A^+ cations (commonly found in HaPs) form a hydrophobic surface (i.e., spacer) expected to prevent oxidizing agents from reaching the absorber. Although the implementation of these strategies is becoming more widespread in Sn-based HaP devices, the underlying passivation/antioxidation mechanisms, as well as the effect of the treatments on the chemical and electronic properties of resulting absorbers, are not fully understood.

Because these strategies focus on the surface nature of the films, characterizations of treated samples by (near) surface sensitive techniques are uniquely suited to provide valuable insight to fill this knowledge gap. For this purpose, we have employed hard X-ray photoelectron spectroscopy (HAXPES) to study the chemical and electronic structure of $FASnI_3$ thin-film sample series treated (i) by using different tin halide additives (i.e., SnI_2, SnI_4, $SnBr_2$, SnF_2 and SnF_4) during preparation and (ii) with a combination of bulky and long organic surfactants (i.e., PEACl and perfluorinated carbon chain molecules with varying concentrations) during and after preparation. Employing different excitation energies allows the probing depths of HAXPES measurements to be varied, facilitating a depth-dependent assessment of the effect of the treatments. Evidence of highly heterogenous Sn and I chemical environments is found for untreated $FASnI_3$ samples (being more pronounced at the surface than towards the bulk of the sample), turning more homogeneous (e.g., exhibiting enhanced Sn^{2+}-character) in samples submitted to performance-enhancing additive treatments. The relation between the HAXPES-determined $[Sn^{2+}]/([Sn^{2+}]+[Sn^{4+}])$ values of the investigated samples and their electronic structure is discussed in this contribution, as well as a comparison of the chemical and electronic properties with the device performance (improvements) of the corresponding solar cells.

Homogeneously Miscible Fullerene Inducing Vertical Gradient in Perovskite Thin-Film Towards Highly Efficient Solar Cells Il Jeon[1,2], Han Y. Woo[3], Kyusun Kim[1], Ziang Wu[3] and Jiye Han[1,2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of); [3]KU-KIST, Korea (the Republic of)

One of the strategies for obtaining high PCE in PSCs is to use additives for perovskite films. Small amounts of added materials in the perovskite precursor function as a crystal growth template and a crystal growth retarder, which increase the perovskite crystal size and subsequently reduce the interfacial area of grain boundaries. This, in effect, decreases the charge traps that exist at the grain interfaces. Moreover, some additives remain in the perovskite films even after the fabrication, passivating the perovskite defect sites via the Lewis acid-base coordination and sometimes function as charge bridges or charge extractors. A variety of materials have been reported to function as additives and passivation layers, which range from polymers to nanocarbons, such as fullerene derivatives. Among the fullerene derivatives, phenyl-C_{61}-butyric acid methyl ester ($PC_{61}BM$) has shown promising prospects owing to its high electron affinity and appropriate bandgap. Accordingly, various fullerene derivatives synthesized by modifying $PC_{61}BM$ have been reported. However, there is a significant challenge in using those fullerene derivatives; they are immiscible with polar solvents while most perovskite precursors are dissolved in polar solvents. Conventionally, fullerene additives are either introduced during the antisolvent stage using chlorobenzene (CB) or dispersed directly in the perovskite precursor solution. This restricts the amount of the additives that can be added, and the device architecture to the inverted-type which gives a lower PCE than the normal-type counterparts.
In this work, we attached, triethylene glycol monomethyl ether (TEG) chains to $PC_{61}BM$ to greatly enhance its miscibility with the perovskite precursor. The synthesized TEG-attached $PC_{61}BM$, [6,6]-phenyl-C_{61}-butyric acid 2-[2-(2-methoxyethoxy)ethoxy]ethyl ester ($PC_{61}B$-TEG), and a branched substituent with two TEGs-attached $PC_{61}BM$, [6,6]-phenyl-C_{61}-butyric acid 1-methyl 3-[2-(2,5,8,11-tetraoxadodec-1-yl)-4,7,10,13-tetraoxatetradec-1-yl] ester ($PC_{61}B$-BiTEG) were highly polar and miscible with the perovskite precursor. Here, we explored three ways to introduce novel fullerene derivatives into PSCs: direct mixing with the precursor prior to film fabrication, overcoating the electron-transporting layer, and overcoating + waiting between drop-casting and spin-coating of the perovskite precursor solution on the overcoated layer of $PC_{61}B$-TEG to induce gradient dispersion into the perovskite precursor. The initial optimization and tests were conducted using $MAPbI_3$ ($CH_3NH_3PbI_3$)-based PSCs. The results showed that the devices in which $PC_{61}B$-TEG was directly added to the perovskite precursor gave a high open-circuit voltage (V_{OC}), while the overcoating and waiting approaches yielded a high fill factor (FF). We postulate that such a tradeoff arises from the balance between the perovskite grain defect passivation and the electron-transporting (hole-blocking) effect. In either case, an average PCE of ~19.6% was obtained, which is much higher than ~17% of the reference devices without $PC_{61}B$-TEG. Contrary to our expectation, the newly synthesized $PC_{61}B$-BiTEG was not as effective as $PC_{61}B$-TEG, because of its high-lying highest occupied molecular orbital (HOMO) level, which induced charge recombination. Applying the fullerene additive to a more advanced formamidinium/methylammonium mixed cation lead halide ($FA_{0.65}MA_{0.35}PbI_{3-}$$Cl$$) system using a combined approach of direct mixing with the precursor and overcoating + waiting techniques manifested even greater effectiveness. A PCE of 23.34% was exhibited when $PC_{61}B$-TEG was used in $FA_{0.65}MA_{0.35}PbI_{3-}$$Cl$$-based PSCs. The same device was taken to a national laboratory for verification and a forward and reverse bias-combined efficiency of 21.24% was officially certified. This, to the best of our knowledge, is one of the highest efficiencies reported among the fullerene additive-used PSCs reported thus far.

Reactive Interfaces—How Metal Oxides Interact with Halide Perovskites and Their Precursors Selina Olthof; University of Cologne, Germany

In optoelectronic devices, the function and performance depends crucially on the proper choice of charge transport layers. In perovskites it turned out that interfaces towards these layers can be rather complex. On the one hand, interface dipoles and band bending occur. But more importantly, the perovskite composition and formation can be significantly influenced by chemical reactions taking place, in particular next to metal oxides.
In this talk, I will summarize our work on a variety of metal oxides such as SnO_x, NiO_x, MoO_3, ZnO, TiO_2 etc. in which we use photoelectron spectroscopy to analyze which components are responsible for the strong interface chemistry. For this, we investigated a variety of different perovskites (i.e. organic vs. inorganic ones, I vs. Br, etc.) as well as the individual perovskite precursors. We find that the reactivity strongly depends on the individual material combination and that different metal oxides show fundamentally different reaction/degradation pathways. Intriguingly, we find that by changing the metal oxide post-treatment we alter the surface defect density and thereby affect the degree of thin film degradation significantly.
Overall, I will show how photoelectron spectroscopy measurements can help to probe and understand the processes going on at these various bottom contact materials which should ultimately help to improve the stability of perovskite related devices.

Reconfiguring Perovskite Surface States to Maximise Perovskite Solar Cells Sam Teale, Hao Chen, Bin Chen and Edward H. Sargent; University of Toronto, Canada

Non-radiative recombination rates are orders of magnitude higher at the interfaces of perovskite solar cells (PSCs). Here we illustrate that the cause of interfacial recombination is dependant on both contact type (n-type or p-type) and perovskite composition, each of which must be considered in all-perovskite tandem cells. For example, at p-type contacts, quantum confined (2D) perovskite interfaces have produced single junction cells with > 25% certified power conversion efficiency (PCE), whereas 2D layers hinder charge transport at the n-type contact. Considering composition, we find that the surfaces of wide bandgap (≥40% Br) perovskite films crystallize into PbI_2 and Br-rich perovskite regions which induce recombination. Using surface sensitive spectroscopy, we address the specific problem at each interface of a monolithic all-perovskite tandem: first we tune confinement in 2D layers to improve transport at the n-type contacts, and then remove surface inhomogeneity using diammonium salts in wide bandgap layer. This enables record efficient monolithic perovskite tandems with 2.19 V V_{OC} (89% of the theoretical voltage limit) and > 27% PCE.

Understanding Light Induced Dynamic Ion Motion in Metal Halide Perovskite Bilayers Through Surface Photovoltage Tomi Baikie[1], Philip Calado[2], Krzysztof Galkowski[1], Zahra Andaji-Garmaroudi[1], Akshay Rao[1], Samuel D. Stranks[1] and Piers Barnes[2]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Surface photovoltage measurements (SPV) on highly doped semiconductors, such as those used in commercially available photovoltaics and LEDs, can reveal rich information on photoinduced charge dynamics. However, SPV measurements on mixed ionic-electron conductors, such as perovskites, have been poorly understood. We outline a new understanding of SPV measurements, supported by experimental evidence on perovskite bilayers. Our model, which includes mobile ionic carriers, accurately reproduces these complex SPV measurements, even upon the application of different surface treatments and backing contacts. Importantly, we conclude that the SPV in the perovskite bilayer context is a measurement of the change in potential associated solely

with changes in the net electronic charge within the system. Our understanding of the SPV measurement naturally leads to avenues for the selective control of ion migration in perovskite bilayers, demonstrated here by altering the surface passivation treatment. This opens new avenues for the rational design of strategies to improve the photovoltaic properties of perovskite solar cells and LEDs.

***In Situ* Buried Interface Passivation for Efficient and Stable Perovskite Solar Modules** Mingyang Wei[1], Lin Li[2,1], Xiong Li[2] and Michael Graetzel[1]; [1]Swiss Federal Institute of Technology Lausanne (EPFL), Switzerland; [2]Huazhong University of Science and Technology, China

Scaling-up perovskite solar cells (PSCs) is a prerequisite to the adoption of perovskite photovoltaics. High-performance perovskite solar modules (PSMs) require the passivation of device interfaces; however, this is challenging for the buried interface, i.e., the interface between the bottom charge transport layer (CTL) and perovskites, because the passivating agents on the substrate surface may be redissolved during the perovskite deposition. Here, we report that this limitation can be overcome with in-situ buried interface passivation using nickel oxide (NiO_x) as the bottom CTL – a quality established via directly adding traces of molecular additives into the perovskite precursor solution. Molecular dynamics (MD) simulations indicate that a cyanoacrylic acid-based organic dye, namely BT-T, can achieve monolayer passivation with planar configurations at the perovskite/NiO_x interface. Density functional theory (DFT) calculations reveal that BT-T exhibits a stronger interaction with NiO_x than perovskites. As a result, we find a preference for BT-T molecules to passivate the buried interface during perovskite film formation. The BT-T passivation facilitates interfacial hole transfer and improves the quasi-Fermi level splitting (QFLS) of the perovskite/NiO_x bilayer by ca. 40 meV. Using this strategy, we demonstrate a power-conversion efficiency (PCE) of 22.1% for 1-cm^2-sized PSCs and a record-setting PCE of 20.3% (certified stabilized PCE: 18.94%) for NiO_x-based PSMs with an active area of 17.11 cm^2. The encapsulated PSM retained 90% of its initial PCE (20.1%) following 1000-h maximum power point (MPP) tracking under 1-sun-equivalent light illumination at 50 °C. This work demonstrates the potential of organic dye molecules as scalable and efficient buried interface modifiers for PSMs.

Utilisation of PEDOT as a Hole Selective Layer for Reproducible Efficient Tin-Based Perovskite Solar Cells with the DMSO-Free Solvent System Ece Aktas[1], Diego Di Girolamo[1], Corinna Ponti[1] and Antonio Abate[1,2]; [1]University of Federico II, Italy; [2]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany

Hybrid metal-organic lead-based perovskite solar cells (PSCs) have shown great performance as a photovoltaic energy source, having comparable high efficiency to commercialised silicon solar cells.[1] Moreover, they are prone to be deposited on variable substrates using cost-effective techniques likewise roll-to-roll processing.[2] At this point, considering the toxicity of the lead counterparts used will be a critical step in overcoming the commercialization challenge, especially for market niches such as wearable photovoltaics. Tin-based perovskites have gained considerable attention owing to having similar optoelectronic properties to lead-based counterparts such as high charge carrier mobility, small exciton binding energy, and a bandgap close to the ideal value which guarantees a PCE approaching 15%.[3,4] However, Sn^{2+} quickly oxidizes to Sn^{4+} in the presence of oxygen or even with a mildly oxidative solvent system,[5] limiting their performance in PSCs. Here, we discuss the advantages of adopting water-free poly(3,4-ethylenedioxythiophene (PEDOT) formulation in hybrid metal-organic tin-based PSCs. We effectively alternated the surface energy of the water-free PEDOT to form a high-quality perovskite film over macroscopic areas. Moreover, we performed a careful perovskite optimization to achieve a power conversion efficiency above 7% for tin-based perovskite solar cells with a DMSO-free solvent system and good operational stability.

EN02.08.02
Tuning the Surface Potential of Hybrid Perovskite Active Layers Through Interfacial Engineering Using Fluorinated Compounds Riva Alkarsifi[1,2], Thierry Buffeteau[1], Lionel Hirsch[2], Thierry Toupance[1] and Dario M. Bassani[1]; [1]University Bordeaux, ISM, CNRS UMR5255, F-33405 Talence, France., France; [2]University Bordeaux, IMS, CNRS, UMR 5218, Bordeaux INP, ENSCBP, F-33405 Talence, France, France

Despite the tremendous increase in their overall power conversion efficiency over the past decade, organic-inorganic hybrid perovskite solar cells are still plagued by issues related to their long-term device stability.[1] In particular, the hydrophilicity of the hybrid organic-inorganic perovskite surface due to the ionic nature of the perovskite crystal plays a key role in determining device stability.[2] In order to improve device stability and performance, the localization of a thin interfacial monolayer can be used to reduce the wettability of the perovskite and also to modify the surface potential of the active perovskite layer.[1,3] For instance, fluorocarbons possess strong hydrophobicity and exhibit specific binding interactions with the perovskite surface.[2] Because of this, they may be good candidates for passivating the surface while also optimizing its surface potential.[2] We investigate self-assembled monolayers on top of the $CH_3NH_3PbI_3$ surface using various fluorinated molecules with different heteroatoms including tin, phosphorous, and boron. The chemical nature of the fluorinated monolayers, their interaction, orientation, and thickness were investigated by contact angle measurement, X-ray diffraction, X-ray photoelectron spectroscopy, and polarization-modulation infrared reflection absorption spectroscopy. The formation of stable monolayers with specific orientation on top of the perovskite surface was achieved without altering the bulk crystallinity of the active layer as evidenced by XPS. In addition to the increased hydrophobicity of the $CH_3NH_3PbI_3$ surface, the surface potential of $CH_3NH_3PbI_3$ was easily tuned over a 160 mV range upon SAMs deposition. This work clearly shows that chemically engineering the composition of the monolayer allows for modifying the perovskite work function, and hence the electrical behavior of the active layer.

EN02.08.03
Hole-Transporting Self-Assembled Monolayer Enables 23.1%-Efficient Single-Crystal Perovskite Solar Cells with Enhanced Stability Khulud M. Almasabi; KAUST, Saudi Arabia

The challenge of growing perovskite single crystals in suitable configurations for efficient photovoltaic devices has severely hindered their exploration as solar cell materials, in spite of their potential to advance perovskite solar cell technology owing to their excellent optoelectronic properties and lower defect densities. While polycrystalline films can be deposited on myriad substrates, perovskite single crystals suitable for high-efficiency devices have only been illustrated on hydrophobic hole transport layers (HTLs, e.g., poly(triaryl amine) (PTAA)), which has restricted the development in both device efficiency and stability. In this work, we report the growth of mixed-cations $FA_{0.6}MA_{0.4}PbI_3$ perovskite single crystals on a hydrophilic self-assembled monolayer (SAM, [2-(3,6-dimethoxy-9H-carbazol-9-yl) ethyl]phosphonic acid), (MeO-2PACz)) HTL surface. Solar cells constructed with SAM MeO-2PACz exhibit improved mechanical adhesion, operational stability, and a record efficiency of 23.1% for single-crystal perovskite solar cells.

EN02.08.04
Solvent Engineering of NiO_x Solutions for Rapid Depositions as Hole Transporting Layers for Flexible Perovskite Solar Cells Peter Armstrong, Sashil Chapagain, Siva Chandra Sekhar Pakanati, Thad L Druffel and Craig Grapperhaus; University of Louisville, United States

State of the art perovskite solar cells (PSCs) have reached record efficiencies on laboratory scale systems. However, transitioning to large scale fabrication of PSCs is still a work in progress. A part of the next steps necessary for upscaling the fabrication of PSCs is the demonstration of uniform charge transport layers, such as metal oxides, at scale. NiOx is a popular inorganic hole transport material for upscaling as it is easy to produce at scale, is environmentally stable and has been highly successful in small scale systems. Large area deposition of NiOx nanoparticles has been demonstrated at slow speeds of 5 mm/s by blade coating from aqueous solutions. Increasing deposition speeds to 10 mm/s or 30 mm/s requires the addition of a surfactant to improve surface wetting and film uniformity. The addition of traditional surfactants such as cetrimonium bromide or triton X-100 has been observed to obstruct charge extraction when low temperature annealing is used. Herein, we demonstrate that the addition of short chain alcohols such as isopropanol and tert-butanol effectively improve surface wetting while not interfering with charge extraction when followed by low temperature annealing. Additionally, uniform films were able to be deposited at 2 m/min by blade coating and roll-to-roll slot die coating on ITO coated PET substrates. Changes in zeta potential, surface tension, film uniformity, and power conversion efficiency were quantified as a function of alcohol concentration to identify key traits necessary for high quality film deposition. Films deposited using the optimized solution composition showed improved fill factor, open circuit potential, power conversion efficiency compared to solutions without the alcohols present.

EN02.08.05
Potentiometry of Operating Perovskite-Based Devices with Kelvin Probe Force Microscopy Konstantinos Bidinakis, Shuanglong Wang, Paul Blom, Wojciech Pisula, Tomasz Marszalek and Stefan A. Weber; Max Planck Institute for Polymer Research, Germany

During the past decade, hybrid perovskite materials have attracted considerable attention for application in electronic devices due to the favorable properties their organic and inorganic structural elements grant them. Such devices include solar cells and field-effect transistors (FETs), which exhibit respectable performances with very low production costs. By employing Kelvin probe force microscopy (KPFM), we can scan a probe along the perovskite active area of such devices and quantitatively determine the evolution of potential across them, from one electrode to the other, in order to gain information about their charge transport and charge extraction characteristics. At the same time, we can subject our samples to conditions simulating real-life operation, i.e. application of a gate and source-drain voltage for FETs, or illumination and bias voltages in solar cells.

In this poster, we explain how in-situ nanoscale potentiometry in active devices can help understand the underlying working principles and performance bottlenecks. For example, mapping the potential distribution across the gate channel of FETs revealed that devices with better crystallinity exhibit fewer energetic barriers and a more uniform electric field. These results provide a microscopic explanation for their better performance, as estimated by current-voltage measurements of their transfer characteristics. For solar cells, the perovskite absorbing layer is covered by the layers deposited on top of it and is therefore not readily accessible for a scanning probe measurement. Therefore, a few extra steps are required in order to conduct the experiment: the device is initially cleaved in the direction perpendicular to its constituent layers and subsequently, the exposed cross-section is polished in order to eliminate cross-talk from a rough topography. Here, the potential profiles reveal the charge separating junctions on both sides of the perovskite absorbing layer, as well as the relative barriers for charge extraction at the interfaces with the electron and hole transport layers, which depend on the choice of these materials.

EN02.08.06
Low Temperature Synthesized Y:SnO_2 as an Effective Electron Transport Layer for Inverted Perovskite Solar Cells on Flexible ITO-PET Substrate Sashil Chapagain, Peter Armstrong, Thad L Druffel and Craig Grapperhaus; University of Louisville, United States

Flexible perovskite solar cells (f-PSCs) on plastic substrate have drawn appreciable attention as they have high power-per-weight and potentially wide applications in portable and wearable electronics, aviation, integration in vehicles and buildings, and aerospace. However, the power conversion efficiencies of these f-PSCs are still far below conventional perovskite solar cells on glass substrate. In this study, we investigated the direct deposition of a metal oxide electron transport layer on the top of perovskite for the high-performance f-PSCs. Metal oxide electron transport materials are inexpensive and scalable as compared to their organic counterparts. However, deposition of fully solution-processed metal oxide on perovskite to fabricate f-PSCs is limited by solvent incompatibility of typical metal oxide dispersion media with the underlying perovskite layer and the high processing temperature of metal oxides nanoparticles. Here, we synthesized SnO_2 nanoparticles using the sol-gel method and functionalized them with acetate through ligand exchange allowing their dispersion in anhydrous ethanol. Additionally, we investigated *in situ* yttrium doping of SnO_2 during synthesis. Nonaqueous dispersions of pristine and yttrium doped SnO_2 were directly deposited on the perovskite by blade coating followed by air knife treatment. There was no detectable damage to the underlying perovskite layer as evidenced by x-ray diffraction and scanning electron microscopy. Photoluminescence spectroscopy and device performance statistics confirm superior electron extraction by yttrium doped SnO_2 as compared to pristine one. After yttrium doping, the champion power conversion efficiency was increased above 18% from 15%, which is unprecedented for an inverted device in flexible ITO-PET substrate employing SnO_2 as an ETL. This work highlights the possibilities of the scalable deposition of fully solution-processed metal oxide charge transfer layers directly on the perovskite to achieve highly efficient large-area flexible perovskite solar cells

EN02.08.08
Enabling Perovskite/Perovskite/Silicon Triple Tandem Based on Transparent Conductive Adhesive Lamination Process In Choi, Bonkee Koo and Min Jae Ko; Hanyang University, Korea (the Republic of)

Organic-inorganic hybrid perovskite solar cells (PSCs) are expected to become future renewable energy sources among the emerging photovoltaics.

Perovskite materials are very promising for the tandem solar cells due to the largely tunable band gap energy (E_g). Recently, PSCs based multijunction solar cells are intensively and extensively investigated to achieve higher performance over silicon solar cells. For the fabrication of tandem, conventional vacuum deposition methods have been widely used even though the high-cost and their applications to fabricate multijunction solar cells. However, to realize the simple process to reduce total fabrication cost, simple fabrication process is highly required. Here, we developed a transparent conductive adhesive (TCA) based lamination method for the fabrication of the multijunction solar cell, which is comfortable and cost-effective method. Based on low-temperature and low-pressure lamination conditions, we achieved over 2.2 V open-circuit voltage and 11.16 % power conversion efficiency in perovskite/perovskite/silicon triple-junction solar cells. The TCA lamination method developed through this study is expected to present a new horizon in future research and industrialization of multijunction solar cells.

EN02.08.09
Defect-Stabilized Tin-Based Perovskite Solar Cells Enabled by Multi-Functional Molecular Additives Jinhyeok Choi, Seok Joo Yang and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Lead-based perovskite solar cells (Pb-PSCs) with efficiency over 25% and high stability have been reported, however, the toxicity of Pb turns into main hurdle for commercialization of PSCs due to the environmental hazards. Tin-based perovskite solar cells (Sn-PSCs) are most viable candidates for replacing the Pb owing to the high carrier mobility, small exciton binding energy, and narrow optical bandgap. However, facile oxidation of Sn^{2+} and high defect density on surfaces and grain boundaries in Sn-PSCs complicate the task of obtaining highly stable Sn-PSCs. Here, for the first time, a fulleropyrrolidine with a triethylene glycol monoethyl ether side chain (PTEG-1) is introduced as a multi-functional molecular additive to passivate both surfaces and grain boundaries of formamidnium (FA)-based tin triiodide ($FASnI_3$) perovskites. The ether group and fullerene group in PTEG-1 interact with Sn^{2+} and I^-, respectively, and thereby inhibit formation of Sn^{4+} and I_3^-, which is detrimental to the stability of Sn-PSCs. We observed that this multi-functional molecular additive suppresses non-radiative recombination and increases both power conversion efficiencies (PCEs) and the stability of Sn-PSCs. As a result, Sn-PSCs with PTEG-1 additives exhibited PCEs of 7.40 %, which is accompanied by retaining 65 % of its initial PCE of encapsulated PSCs after 1000 h of exposure to ambient air with light illumination. Our results would provide a guideline for future design of multi-functional molecules with suitable functional groups to fabricate highly stable Sn-PSCs.

EN02.08.10
Perovskite-Based Multijunction Solar Cells for Efficient Continuous Solar-Assisted Water Splitting Kunal Datta[1], Yifeng Zhao[2], Bruno Branco[1], Junke Wang[1], Valerio Zardetto[3], Nga Phung[1], Dong Zhang[3,1], Andrea Bracesco[1], Willemijn Remmerswaal[1], Luana Mazzarella[2], Martijn Wienk[1], Mariadriana Creatore[1], Olindo Isabella[2] and René Janssen[1]; [1]Technische Universiteit Eindhoven, Netherlands; [2]Delft University of Technology, Netherlands; [3]TNO-Solliance, Netherlands

The intermittency of solar radiation is a key characteristic that impedes the widespread use of photovoltaic systems. As a result, a critical component of any decarbonized energy economy is solar electricity storage for release on demand.[1] Hydrogen (H_2) evolution through electrochemical (EC) water splitting is an effective method for energy storage due to the high energy density of H_2 fuel. However, present-day H_2 generation relies on byproducts of fossil fuel extraction leading to a high indirect carbon cost.[2] Photovoltaic (PV)-assisted EC water splitting methods that employ concentrated photovoltaics, on the other hand, use inorganic multijunction devices whose high manufacturing costs can undermine future commercial competitiveness. As a result, a cost-effective PV device delivering high current without light concentration, coupled to a flow EC system, can potentially provide an efficient method for H_2 generation.[3]

Metal halide perovskite semiconductors have been used to develop high-performance photovoltaic devices. Their tunable optical bandgap, high defect tolerance, and easy processing, are assets that allow their use in efficient multijunction devices.[4] As a result, high open-circuit voltages can be achieved which results in a high current at the operating potential for water splitting (> 1.23 V). This work describes the development of 1 cm^2 active area all-perovskite and perovskite-silicon tandem solar cells by combining wide-bandgap perovskites with lead-tin based narrow-bandgap perovskite and silicon heterojunction bottom-cells respectively. Upon integrating with continuous flow EC cells, high solar-to-hydrogen (STH) conversion efficiencies can be achieved without using light-concentration techniques.

Mixed-halide wide-bandgap perovskite compositions are developed for each multijunction structure and the defect-rich interface between the perovskite and the electron transport layer is passivated in order to increase radiative yield. Recombination layers in the multijunctions, based on thin atomic layer deposited (ALD) NiO_x (perovskite-silicon) and SnO_x (all-perovskite) layers, are used to maintain charge neutrality while ensuring low interfacial losses. The ALD NiO_x interfacial layer increases surface hydroxyl content, thereby improving the binding of self-assembled hole-transporting monolayer (2PACz) in the top-cell in the perovskite-silicon tandem device.[5] In the all-perovskite tandem solar cell, the SnO_x layer also acts as a solvent barrier to protect underlying layers from damage from subsequent solution processing steps.[6] Lastly, advanced optical simulations are used to identify key regions of parasitic absorption and reflection losses, which are mitigated by light-management strategies to yield current-matched tandem devices with a power conversion efficiency of > 23% (all-perovskite) and > 25% (perovskite-silicon) in 1 cm^2 active area solar cells. By integrating the device with a flow electrochemical cell using RuO_2 and Pt catalysts for H_2 and O_2 evolution respectively, a continuous water splitting system with a high STH conversion efficiency of > 18% (with all-perovskite) and > 21% (with perovskite-silicon) is achieved.

***In Situ* Metrology of Hybrid Halide Perovskite Single Crystals—Investigating Growth Dynamics of Inverse Temperature Crystallisation** Alice Dearle, George Lewis, Edward Saunders, Ye Fan, Lucas Mogg, Samuel D. Stranks and Stephan Hofmann; University of Cambridge, United Kingdom

Following the discovery of inverse temperature crystallisation phenomena of single crystal hybrid halide perovskites in specific solvent pairings,[1,2] the rapid growth of high quality single crystal perovskites by this technique has been widely adopted. This has proven immensely useful in differentiating fundamental material properties from those derived from the granular structure of thin-film counterparts.[3] As methods to structurally characterise halide perovskite systems become increasingly intensive, it remains imperative to provide due care to simultaneously advancing our understanding of materials synthesis.
Here, we present an *in-situ* study and analysis of methylammonium lead bromide ($MAPbBr_3$) single crystal growth. The space-confined inverse

temperature growth of $MAPbBr_3$ crystals is monitored in real-time using optical microscopy methods examining many relevant experimental conditions including temperature and solute concentration. $MAPbBr_3$ is selected as an ideal model system, with stable cubic phase within the relevant temperature window of growth and convenient solubility profile. Individual surface facets are monitored and growth rates extracted. We understand this to be the first time that the tracking of individual hybrid perovskite crystal facets has been demonstrated using advanced image analysis techniques.
Our method reveals inhomogeneity in the growth rates of crystallographically identical facets and the importance of mass transfer and concentration gradients. Regions of accelerated growth rate lead to excess defect incorporation and diminished crystalline quality within one "single crystal". We identify the often overlooked complexities of relevant thermodynamic and kinetic crystal growth within the phenomena of inverse temperature crystallisation, the fundamental understanding of which has remained limited since first reported in 2015.

High-Efficiency Perovskite Light-Emitting Diodes Enabled by a Combination of Molecular Additives and Self-Assembled Hole Injecting Interlayers Despoina Gkeka, Murali Gedda, Mohamad I. Nugraha, Jafar Khan, Emre Yengel, Iain Hamilton, Frederic Laquai, Donal Bradley and Thomas D. Anthopoulos; KAUST, Saudi Arabia

Low-dimensional hybrid perovskites have recently emerged as promising candidates for light-emitting diode (LED) applications due to their outstanding physical characteristics that include high photoluminescence quantum yield (PLQY), color purity, operating stability and processing versatility. Unfortunately, controlling the microstructure of the solid layers during solution deposition remains very challenging. Introducing molecular additives into the perovskite layer during processing has recently emerged as an effective strategy towards improving both the quality of the formed perovskite layer and the overall performance of the ensuing perovskite LEDs (PeLEDs).
Here we report on the development of highly efficient green PeLEDs based on blends of the quasi-two (q2D) dimensional perovskite $PEA_2Cs_4Pb_5Br_{16}$ and a known small molecule (SM) organic semiconductor. The presence of the SM enables the formation of single-crystal-like q2D perovskite domains that are uniform, large in size and highly luminescent. We show that combining the q2D-Perovskite:SM blends with self-assembled monolayers (SAMs) as the hole-injecting layers (HILs), results in green emitting PeLEDs that exhibit greatly enhanced performance over pristine perovskite LEDs including, maximum external quantum efficiency (EQE) of 18.6 %, current efficiency of 46.31 cd/A, maximum brightness of ≈ 45,000 cd m^{-2}, and a longer operational lifetime. Using a complementary suite of characterization techniques, we show that the improved performance of the blend PeLEDs to originate from multiple synergistic effects including, the enhanced hole-injection due to SAM HILs and the single crystal-like quality of the perovskite phase. Our work highlights perovskite:organic semiconductor blends as promising strategy towards high performance PeLEDs, while the use of SAM HILs creates new opportunities for simpler and more reliable materials for application in next generation light-emitting diodes.

Improved Charge Balance in Green Perovskite Light-Emitting Diodes with Atomic-Layer-Deposited Al_2O_3 William B. Gunnarsson, Zhaojian Xu, Nakita K. Noel and Barry P. Rand; Princeton University, United States

Perovskite light-emitting diodes (LEDs) have experienced a rapid increase in efficiency over the last several years and are now regarded as promising low-cost devices for displays and communication systems. However, it is often challenging to employ ZnO, a well-studied electron transport material, in perovskite LEDs due to chemical instability at the ZnO/perovskite interface and charge injection imbalance caused by the relatively high conductivity of ZnO. In this work, we address these problems by depositing an ultrathin Al_2O_3 interlayer at the ZnO/perovskite interface, allowing the fabrication of green-emitting perovskite LEDs with a maximum luminance of 21,815 cd/m^2. Using atomic layer deposition, we can precisely control the Al_2O_3 thickness and thus fine-tune the electron injection from ZnO, allowing us to enhance the efficiency and operational stability of our LEDs.

EN02.08.16
Large-Area Perovskite Modules with 'Sol-Gel' Processed Metal Oxide Charge Transport Layer Soonil Hong[1], Eun Young Park[1], Sooncheol Kwon[2] and Nam Joong Jeon[1]; [1]Korea Research Institute of Chemical Technology, Korea (the Republic of); [2]Dongguk University, Korea (the Republic of)

The formation of well-connected metal-oxygen gel networks in 'sol-gel' processed transition metal oxide (TMO) interlayer on top of the entire photoactive layer has long been a research goal to ensure large-area PSC modules with high performance and long-term stability; however, it has not yet been achieved because very little is known about the actual nanomorphology from atomic-scale reactions of TMO precursors and its impact on device characteristics. Here, we report for the first time a direct observation of continuous metal-oxygen network in 'sol-gel' processed metal oxide film on top of favorable photoactive layer, which can be used as an ideal inner encapsulation layer for achieving large-area organic and perovskite modules with long-term stability. By employing a high-resolution Auger electron spectroscopy, which provide an advantage of short data acquisition times and thus an improved surface sensitivity and accuracy, we successfully obtain the lateral and vertical distribution of chemical components throughout the entire metal oxide thin film surface, indicating that a low surface energy difference at the organic/metal oxide interface allows long-range diffusion of metal ion precursors to promote continuous chemical synthesis associated with oxo-bridge formation. The features of resultant continuous metal-oxygen network can prevent the permeation of surrounding moisture and oxygen into the photoactive layer, resulting in PSC modules with long-term stability, approaching an efficiency of 14.5% and maintaining over 80% of their initial efficiency until 2000 hours with an area of 9.06 cm2, respectively.

EN02.08.17
The Role of SnO_2 Processing on Ionic Migration in Multi-Halide Perovskites Holland Hysmith[1], Soyeon Park[2], Anton V. Ievlev[3], Yongtao Liu[3], Kai Zhu[2], Mahshid Ahmadi[1], Joseph J. Berry[2] and Olga Ovchinnikova[3]; [1]University of Tennessee Knoxville, United States; [2]National Renewable Energy Laboratory, United States; [3]Oak Ridge National Laboratory, United States

Moving towards a future of efficient, accessible, and less carbon reliant energy devices has been at the forefront of energy research innovations for the past 30 years. Multi-halide perovskite (MHP) thin films have gained significant attention due to their flexibility of device applications and tunable capabilities for improving power conversion efficiency. Many behavioral aspects to MHP's are thoroughly investigated: functionality of grain boundaries, recombination effects, ionic migration patterns, and hysteresis. Each avenue serving as gateway to optimize device performance, consideration must be given to chemical synthesis processing techniques.

Chemical Vapor Deposition (CVD) is a widely used technique for thin film coatings due to its ability for producing high volume batches of MHP's with

larger grain sizes, fewer defects, and fewer grain boundary formations. Additionally, nanoparticle processing has been applied to induce enlargement of grain boundaries, showcasing larger current signals than its MHP counterparts. Therefore, how does common substrate processing techniques (i.e. CVD, nanoparticles, hybrid) influence the behavior of MHP phenomenon such as ion migration and grain boundary formation? Speculated as inducing ionic recombination and driving I-V hysteresis in MHP's, understanding how chemistry can be tuned to reduce such effects would be optimal.

We demonstrate how a hybrid approach of CVD and nanoparticle SnO_2 substrate processing significantly improves the performance of $(FAPbI_3)_{0.97}(MAPbBr_3)_{0.03}$ perovskites in comparison to each technique utilized on its own. Higher performing hybrid devices exhibit fused grain boundary formations, not seen in exclusive CVD or nanoparticle devices. Conductive Atomic Force Microscopy (c-AFM) was used to track fused boundary locations and differentiate them from topographic features. Such fusing behavior has been previously observed to showcase higher counts of current and reduce defects such has halide vacancies.

In summary, to understand the chemistry behavior with respect to each device interface, Time of Flight Secondary Ionization Mass Spectrometry (ToF-SIMS) depth profiling was applied. Migration of K^+, Na^+, Ca^+, FA^+, MA^+ was found in hybrid devices, in addition to Ca^+ and Na^+ clustering on the perovskite/air layer. Salt clustering could be correlated to the fusing effect demonstrated in the surface morphology imaged in c-AFM. Presence of K^+ has shown to reduce defects driven by alkali iodides like NaI^- and Ca^+ can help with enlarging the bandgap layer in studies where Ca+ was used to replace Pb^+. Furthermore, reduced separation between positive ion such as MA^+ and FA^+ from negative ions can decrease the potential responsible for I-V hysteresis.

EN02.08.19
Oxide/Halide/Oxide Architecture for High Performance Semi-Transparent Perovskite Solar Cells Min Ju Jeong and Jun Hong Noh; Koera university, Korea (the Republic of)

We report a device architecture with n-type oxide/perovskite halide/p-type oxide for the sputtering damage-free semi-transparent perovskite solar cells (PSCs). A p-type nickel oxide (NiO_x) nanoparticle overlayer on a perovskite layer is introduced to act as both a hole transporting layer and buffer layer to avoid sputtering damage during deposition of transparent conducting oxide. The NiO_x based semi-transparent PSCs exhibited superior durability under harsh sputtering conditions such as high temperature and sputtering power, enabling the high quality of transparent electrodes. With optimal sputtering condition for tin-doped indium oxide (ITO) as a top transparent electrode, the semi-transparent device showed an enhanced power conversion efficiency (PCE) of 19.5% (20.5% with a back reflector), which is higher than that of opaque device (19.2%). The semi-transparent devices also showed superior storage stability without encapsulation under 10% relative humidity, retaining over 90% of initial PCE for 1000 hours. By controlling the molar concentration of perovskite solution, we fabricated semi-transparent PSC with a PCE of 12.8%, showing a high average visible transmittance (AVT) of 30.3%. We believe that this architecture with n-type oxide/perovskite halide/p-type oxide presents a cornerstone for the high performance and commercialization of semi-transparent PSCs.

EN02.08.20
High-Performance Semi-Transparent Perovskite Solar Cells Based on 3D-Structured FTO Sucheol Ju, Dongwoo Chae, Soomin Son, Hangyu Lim, Jisung Ha and Heon Lee; Korea University, Korea (the Republic of)

In semi-transparent perovskite solar cells (PSCs), the short-circuit current density (J_{SC}) greatly decreases with an increase in transmittance, and this results in a significant decrease in PCE. Our semi-transparent PSCs were fabricated by controlling the absorption layer thickness and aperture ratio using a 3D-structured FTO manufactured via direct printing and mist-CVD. This strategy has an advantage in that the aperture ratio (transmission/entire area) can be controlled easily by adjusting pattern specification. Also, the 3D-structured FTO enhanced the diffuse transmittance and shortened the carrier travel distance; further, it minimized the decrease in PCE because of an increase in transmittance. Our fully semi-transparent PSCs (F-PSCs) achieved a PCE of 12.0% to 14.6%, and an average visible transmittance (AVT) of 13.4% to 17.0%. These results demonstrate that the parameter of semi-transparent PSCs (transmittance and PCE) can be easily tailored to the application by controlling the specification of the pattern.

EN02.08.22
Cathode Interlayer Engineering with Vacuum Thermal Evaporated N-type Rylene Diimide Derivatives in Highly Efficient Inverted Perovskite Solar Cells Hye Seung Kim and Myoung Hoon Song; Ulsan National Institute of Science and Technology, Korea (the Republic of)

In inverted perovskite solar cells (PeSCs), choosing cathode interlayer plays key role in determining performance of solar cell. Among various processing methods, vacuum thermal evaporation (VTE) is already adopted in electron transporting layer (ETL) such as C_{60} and cathode interlayer such as bathocuproine (BCP), LiF and Ca in inverted PeSCs. Especially, cathode interlayer have been already utilized to suppress the interfacial resistance and lower the energy barrier between ETL and cathode. N-type rylene diimide derivatives such as perylene diimide (PDI) and naphtahlene diimide (NDI) have attracted great attention due to their advantages of easy molecular modification, high electron mobility and good thermal and chemical stability so that have been applied to cathode interlayer by solution processing such as spin-coating method.
In this study, we demonstrate for the first time rylene diimide derivatives such as PDI and NDI family organic small molecules as cathode interlayer candidates using VTE method. Rylene diimide derivatives films show thin thickness about ~5 nm. In comparison with widely used BCP, underlying rylene diimide materials exhibit different silver cathode growth phenomenon. In addition, we compare the effect as a cathode interlayer by considering the energy levels and metal cathode growth phenomenon by the number of amine-functionalized groups of each material.
Consequently, the PeSC with N,N'-Bis[3-(dimethylamino)propyl]perylene-3,4,9,10-tetracarboxylic diimide (PDIN) shows a enhanced power conversion efficiency (PCE) of 21.60%, which is higher than that of the PeSC without cathode interlayer and with BCP or NDI-based interlayer. Excluding the solvent consideration in solution processing, PDI-based materials that are easily vacuum thermal evaporated are expected to be in the spotlight in inverted PeSCs for cathode interlayer.

EN02.08.23
Facile Interface Modification via Self-Assembled Monolayer for P-Type Metal Oxide for Efficient and Stable Perovskite Solar Cells Kyeongsu Kim, Jae Woong Jung and Jung Jae Do; Kyung Hee University, Korea (the Republic of)

Recently, organic-inorganic hybrid perovskite solar cells (PSCs) received significant attention due to its remarkable progress on record-breaking efficiency of perovskite photovoltaics. P-type metal oxides are an interesting class for robust HTLs of high performance PSCs with high durability, however poor surface morphology and low conductivity are unsatisfactory to achieve ideal optoelectronic properties as HTLs. To overcome these issues, we suggest straightforward strategy of interface modification of metal oxide surface using self-assembled molecule (SAMs) The anchoring the phosphonic acid moiety of SAM form ideal linkage to the metal oxide surface, realizing optimal hole transport pathway at the interface of perovskite absorber and metal oxide HTLs. Moreover, the defect sites at the interface of perovskite/metal oxides successfully passivated by SAMs, providing reduced defect-assisted charge-carrier recombination. As a result, the SAM-passivated NiO_x achieves $FA_{0.85}Cs_{0.15}PbI_3$-based PSCs up to >20% efficiency. There is significant improvement on photovoltaic performances under dim indoor light-emitting diode (LED) conditions (6500 K 1000 lux), 27.19%, 24.84% and 16.05%,

NiO_x/MeO-2PACz, NiO_x and MeO-2PACz each. Details of device and film analyses will be discussed in the presentation.

EN02.08.24
Systematic Design of Conjugated Polymers to Achieve High Efficiency and Thermally Stable Perovskite Solar Cells Sanggyun Kim, Sina Sabury, Austin Jones, John Reynolds and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Despite significant progress in organic-inorganic hybrid perovskite solar cells (PSCs) with a certified power conversion efficiency of 25.2%, long-term stability remains to be one of the critical challenges for PSC commercialization. While hole transport layers (HTL) play a crucial role in device performance of PSCs, they are shown to be a limiting factor toward achieving long-term stability in devices, stemming from interfacial degradation between perovskites and HTLs, thermal/moisture induced degradation, and ionic migration. Here, we explore new dopant-free conjugated polymer-based HTLs that are resistant to high temperatures. The new conjugated polymers are designed accordingly with various side chains, functional groups, and/or degree of polymerizations to obtain good film-forming properties, high hole mobility, high glass transition temperature (T_g), and suitable HOMO-LUMO energy levels. These new polymers are further incorporated into devices to analyze their effect on perovskite solar cell efficiency and stability at elevated temperature and under illumination over 500 hours.

EN02.08.25
Enhanced Stability of Perovskite Solar Cells with Stoichiometrically Controlled Cobalt Sulfide Functional Nanocrystal Based Hole Transport Layer Wooyeon Kim and Min Jae Ko; Hanyang University, Korea (the Republic of)

Perovskite solar cells (PSCs) have emerged as promising next-generation photovoltaic devices because of their superior optical and electronic properties. In recent years, organic hole transporting material (HTM) based PSCs have been reported with remarkable increase in the photovoltaic performance. As power conversion efficiency (PCE) of PSCs employing organic HTM has dramatically increased, expectations toward commercialization of PSCs are increasing. However, traditional organic HTMs have a couple of issues such as cost and stability. In the view of this limitation, we have developed the new p-type inorganic HTM. Cobalt sulfide compounds are one of the promising materials to replace conventional organic HTMs, which are less expensive and earth-abundant. Nevertheless, synthesis of cobalt sulfide is tricky to control the stoichiometric ratio. Here, we synthesized novel inorganic HTMs as a stoichiometrically adjusted p-type cobalt sulfide nanocrystals (Co_xS_y NCs). Cobalt sulfide nanocrystals synthesized in this study display the excellent hole transport ability owing to its high conductivity and suitable energy levels for hole extraction for PSCs. Co_xS_y NCs HTLs-based PSCs exhibited power conversion efficiency (PCE) nearly comparable to dopants-free spiro-OMeTAD HTM-based PSCs. Especially, the PSCs with mixed Co_xS_y NCs (with undoped Spiro-OMeTAD) HTLs exhibited PCE of 20.48 % which belongs to the high-performance, considering ionic additive-free HTMs. Furthermore, the PCSs employing cobalt sulfide showed an initial efficiency of 92 % even after exposure to 70 % relative humidity for 1000 hours. These new p-type Co_xS_y NCs would support environmentally and economically sustainable development of PSC and diverse optoelectronic area.

EN02.08.26
Effect of Adding Bromine and Changing Temperature on Crystallinity, Phase Segregation and Stability of Methylammonium–Free Lead Halide Perovskites Diana K. LaFollette, Juanita Hidalgo, Carlo Andrea Riccardo Perini and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

One of the ever-present issues with perovskite solar cells (PSCs) is the lack of long-term stability, particularly because popular material methylammonium (MA) lead iodide undergoes a phase transition at 57C and decomposes into PbI_2 even in an inert environment. Past work exploring the formamidinium (FA) and cesium (Cs) compositional space demonstrated that these compositions have increased thermal stability while approaching the impressive efficiency of MA-based PSCs. However, it has still proven to be extremely difficult to stabilize the photoactive phases of these mixed-cation mixed-halide perovskites, due to the favorability of the photoinactive phases at room temperature.
A thorough investigation of 14 compositions with varying Cs-FA and I-Br ratios was carried out using in-situ XRD and in-situ GIWAXS in combination with X-ray fluorescence and X-ray beam induced current. This established that rather than directly matching phase transitions of pure compositions, chemical changes such as varying Cs-FA and I-Br ratios change the relationship between temperature, crystallinity, and phase purity of these mixed-halide compositions. These studies illuminate how and when crystalline phase formation, segregation, and degradation occur. This in turn allows for increased understanding of stability of these compounds from a molecular standpoint, particularly in previously established high performing compounds like $Cs_{17\%}FA_{83\%}PbI_3$ and $Cs_{17\%}FA_{83\%}PbI_{83\%}Br_{17\%}$.

EN02.08.27
A Doping Strategy and Mechanism of Magnetron Sputtered Tin Oxide Serving as Electron Transport Layer for Perovskite Solar Cells Shuai Lan, Wenting Zheng and Han-Ki Kim; Sungkyunkwan University, Korea (the Republic of)

Perovskite solar cells (PSCs) using SnO_2 electron transport layers (ETLs), especially the magnetron sputtered SnO_2 ETLs, are faced with the problem of intrinsic point defects. The presence of intrinsic point defects located at the interface between SnO_2 and perovskite results in serious charge recombination, limiting the open-circuit voltage (V_{OC}) and fill factor (FF). In this work, we attempted to passivate the intrinsic point defects in magnetron sputtered SnO_2 via Mg doping so as to minimize the non-radiative charge recombination pathways in the bulk and at the interfaces and boost the device performance of PSCs. Mg is chosen as the dopant for the following two reasons: a) Mg^{2+} ions have a similar ionic radius (71 pm) to that of Sn^{4+} ions (69 pm); the introduction of Mg^{2+} into SnO_2 may not lead to a large distortion of lattice constant, which benefits the high carrier mobility. b) The lower valence of divalent Mg dopants than the quadrivalent host Sn atoms will consume the donors and thereby passivate the defects in SnO_2. Taking advantage of Mg doping, the V_{OC} and FF of PSCs were significantly improved, resulting in a champion PCE of 19.55%. This study not only demonstrated a facile method to passivate the defects in low-temperature magnetron sputtered SnO_2 ETL but also reveals the factors influencing the performance of PSCs from the perspective of carrier behaviors in the ETL.

EN02.08.28
Lamination Bonding at Perovskite-Perovskite and Perovskite-Transport Layer Interfaces to Inform Single Junction and Tandem Perovskite Solar Cell Design Clare L. Lanaghan[1], Srinivas K. Yadavalli[1], Jack Palmer[2], Mengyao Zhang[1], Moses Kodur[2], Orlando Trejo[1], Sean P. Dunfield[2], David P. Fenning[2] and Neil P. Dasgupta[1,1]; [1]University of Michigan–Ann Arbor, United States; [2]University of California San Diego, United States

Perovskite solar cells (PSCs) have achieved similar power conversion efficiency to commercially available options, but still lack operational stability due to unstable interfaces with transport layers and atmospheric induced degradation. Laminated PSCs (L-PSCs) using two half-cell stacks to complete a full device, offer a processing route to relax restrictions on transport layer selection and improve device stability through self-encapsulation. While functional L-PSCs have been previously demonstrated, there is a lack in understanding of how temperature, pressure, time, cell architecture, and lamination interface affect bonding, which will be critical to enable optimization of L-PSCs.
In this study, we explore the optimal bonding of L-PSCs at various interfaces using a range of conditions. Bond quality is quantified by measuring the

interfacial toughness of the system using a double cantilever beam method, as well as calculating the area bonded over the substrate area, and comparing successful bonding conditions with device performance. Design of experiments and predictive statistical analysis are used to identify promising bonding conditions from survey datasets varying the lamination temperature, pressure, and time. A key finding is that the cell architecture has a significant effect on bond quality. Understanding the interplay between lamination conditions and interfacial toughness, area bonded, and device performance is necessary to find regions of optimal bonding. Moreover, deconvolution of how lamination parameters impact mechanical bonding will inform optimization of L-PSCs, strategic development of tandem L-PSCs, and allow design of optimal bonding within the processing constraints of scalable manufacturing.

EN02.08.29
Suppression of Defect Concentrated Planes, Ruddlesden-Popper Faults, via Post Halide Treatment for Blue Perovskite Light Emitting Diodes Ah-young Lee and Myoung Hoon Song; Ulsan National Institute of Science and Technology, Korea (the Republic of)

The one of the critical issues in PeLEDs is low efficiency of blue LEDs. Even though the recent studies have been fabricated the highly efficient red and green perovskite LEDs above 20%, the blue perovskite LEDs still have low efficiency with ~5%. The major factors reducing the efficiency of blue LEDs are non-radiative defects in blue perovskite nanocrystals. Even if the colloidal PNC solutions are well known as the defect tolerant, the PNCs films are no more tolerant to the surface defects. Moreover, the chloride vacancies in mixed halide perovskite induce the deep trap states in PNCs band structure. These non-radiative defect states in blue PNCs films hinder the effective radiative recombination of blue PNCs LEDs during operation. The recent advances show the near unity photoluminescence quantum yield (PLQY) of as-synthesized Cl-based PNCs. Especially, $CsPbCl_3$ PNCs, expected to large number of deep trap states, also shows near unity PLQY, arranging short-order distance with adding nickel precursors during synthesis. However, efficiency of blue LEDs is still insufficient to follow up the green and red counterparts.
In this study, I hypothesized that the mixed halide synthetic procedures induce several problems inside PNCs. To understand the atomic arrangement of mixed halide blue PNCs, I measured the high-resolution TEM images. In mixed-halide synthetic procedures, stacking faults, called Ruddlesden-Popper faults (RPFs), are introduced inside the PNCs. In contrast, mono-halide PNCs, $CsPbBr_3$, did not introduce the internal defects. To further deliberate analysis of RPFs, halide intensity mapping near RPFs was conducted with annular dark field images of TEM. The intensity mapping of halide positions revealed the severe intensity drops near RPF. In specific, the halide intensity was dropped in 1st equatorial sites (EQS) and 2nd EQS. The intensity drops can be interpreted as two ways: chloride localization and halide vacancies. To understand the origin of intensity drops, formation energy of chloride substitutions and halide vacancies were calculated. In here, low energy of halide vacancies in 1st and 2nd EQS near RPF were calculated, suggesting the severe defect concentration near RPF. Further, band structures of chloride localization and halide vacancies near RPF were calculated. While chloride localization did not introduce in-gap defect states, halide vacancies introduced the severe in-gap defect states. In summary, unwanted RPF structures were generated during mixed halide blue PNCs synthesis, deteriorating the optical properties of blue PNCs.
Therefore, suppression of blue PNCs was further conducted to obtain highly efficient blue PNCs LEDs. At first, I tried to relieve the internal defects of mixed-halide PNCs (MH-PNCs) with post synthetic dual halide and ligand exchange. In here, MH-PNCs are defined as the blue mixed-halide PNCs synthesized with mixed halide precursors in hot injection and didodecyldimethylammonium chloride (DDAC) was applied to the MH-PNCs for halide and ligand sources, called MHS-PNCs. However, the internal defects were remained even after treating DDAC. That is, the post-synthetic procedures cannot recover the internal defects. I supposed that these kinds of internal defects might degrade the performance of blue MH-PNCs. Therefore, another blue synthetic procedure with post synthetic DDAC treatment toward mono-halide $CsPbBr_3$ PNCs (CPB-PNCs) was conducted, called post-halide exchange PNCs (PHE-PNCs). In the system, the chloride in DDAC acted as anion exchange precursors, making pure blue PNCs. As expected, PHE-PNCs did not introduce any internal defects. I further compared optical properties of PHE-PNCs with MHS-PNCs in PLQY, showing average 60% of PLQY in PHE-PNCs and average 22% of PLQY in MHS-PNCs. Finally, the device fabrication of MHS-PNCs and PHE-PNCs were conducted, achieving highly efficient blue PNCs LEDs in PHE-PNCs with 2.12% of EQE.

EN02.08.30
Van der Waals Metal Contacts for Estimating Defect Density in Metal Halide Perovskite Thin Films via Space–Charge–Limited Current Measurements Joo-Hong Lee and Jin-Wook Lee; Sungkyunkwan University, Korea (the Republic of)

Reducing a crystal defect density is one of the critical issues for achieving high–performance perovskite optoelectronic devices. For devising effective mitigation strategies, it is imperative to accurately measure the defect density of perovskite thin films. Space–charge–limited current (SCLC) measurement has been commonly used to investigate the defect density of the perovskite thin films. In this study, we show that the physical vapor deposition process of the top metal contact generates unintended defects in underlying metal halide perovskite films to overestimate defect density by more than twofold during conventional SCLC measurement. We suggest an alternative metal contact approach to address this issue using van der Waals metal contact (vdWC) formed by transferring the physically laminated pre–deposited metal onto the perovskite layer. The vdWC approach enables formation of a defect–free metal/perovskite junction for accurate measurement of the defect density. The vdWC can also be a useful platform technology for development of high-performance and reliable electronic devices based on the perovskite thin films.

EN02.08.33
Intact 2D/3D Halide Junction Perovskite Solar Cells via Solid-Phase In-Plane Growth Seungmin Lee[1], Yeoun-Woo Jang[2,2], Kyung Mun Yeom[1], Kiwan Jeong[2], Kwang Choi[1], Mansoo Choi[2,2] and Jun Hong Noh[1,1]; [1]Korea University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Ruddlesden-Popper two-dimensional (2D) perovskite in the junction between the three-dimensional (3D) perovskite and hole transporting layer of a device provided not only the effective improvement for performance through the defect passivation on the top of the surface, but also endowed the stability for the device. However, a solution process, general approaches forming 2D $(C_4H_9NH_3)_2PbI_4$ perovskite on the surface, must accompany a quasi-2D perovskite because it was based on the surface reaction. The intact 2D/3D perovskite bilayer architecture, formed by the “Solid-state Inplane-Growth (SIG)” method, can permit enhancement of performance and stability through the growth of a stable and highly crystalline 2D perovskite on the 3D surface. Also, it was observed that the thickness of intact 2D perovskite depended on an open-circuit voltage and that the built-in potential was formed at the 2D layer in the 2D/3D junction. Thereby, the 2D/3D p-p isotype heterojunction with the thicker 2D layer maximizing the potential furnished the device with a certified 24.35% of quasi-steady-state efficiency with 1.185 V of the open-circuit voltage in 1.55 eV bandgap. The device with intact 2D/3D showed stabilities of 94% of initial efficiency for a damp heat test (85°C/85% relative humidity) after 1,056 h, as well as 98% after 1,620 h under 1-sun illumination.

EN02.08.34
Unveiling the Relationship of the Iodoplumbate Species in the Perovskite Precursor and the Resulting Film SunJe Lee and Jong Hyeok Park; Yonsei University, Korea (the Republic of)

The power conversion efficiency (PCE) of solution-processed (e.g., spin coating, blade coating, and spray coating) organic–inorganic halide perovskite (OIHP) solar cells has been drastically improved. Representatively, since the emergence of OIHP photovoltaics in 2012, the PCE of the photovoltaics exceeds 25% nowadays. Despite this considerable progress, systematic research on precursor solution chemistry and its effects on the film morphology and

photovoltaic parameters has been limited thus far.
In typical halide perovskite precursor solutions, Group 14 transition metal ions (mainly Pb^{2+} and Sn^{2+}) form bonds with other ions or solvent because the d orbitals and s orbitals of transition metals are filled with electrons. Therefore, depending on the position of an anion or a solvent near the empty bond of metal ions, various complexes can be formed in a solution. When lead iodide (PbI_2) is dissolved in the solution, iodide ions (I^-) and solvent (S) coordinate around the lead (Pb^{2+}) center, forming iodoplumbate complexes, i.e., $PbIS_5^+$, PbI_2S_4, $PbI_3S_3^-$, $PbI_4S_2^{2-}$, PbI_5S^{3-}, and PbI_6^{4-}.
Herein, we report on the tracking of changes in chemical species in a $MAPbI_3$ precursor solution under solar illumination as an imposed energy and investigate the correlation between the iodoplumbate species development in the solution and the corresponding perovskite film formation. According to the solution Raman spectroscopy and UV-vis spectroscopy, the illuminated OIHP precursors display a higher density of high-valent iodoplumbate along with the detachment of dimethylformamide (DMF) from Pb. As DMF contributes to uncontrolled crystal growth and that higher iodoplumbate species result in crystalline perovskite with fewer defects, we analyzed trap density and electrical properties with conductive AFM (c-AFM). We revealed that trap density of illuminated groups was reduced, and electrical conductivity was significantly enhanced.
Subsequently, we compared the photovoltaic parameters of the control and illuminated groups. The reproducibility significantly increased in the illuminated groups with highly concentrated fill factor and increased short circuit voltage (J_{SC}). Increased photocurrent can also be observed in mixed cation OIHP solar cells, which indicates that analysis of the perovskite precursor chemistry can also contribute to the fabrication of high-quality perovskite thin films in the mixed perovskite system. This discovery shows robust control of perovskite precursor solutions from a simple treatment and suggests that the resulting uniform film may be applicable to various halide perovskite-based devices.

EN02.08.35
Inorganic-Cation Pseudohalide 2D $Cs_2Pb(SCN)_2Br_2$ Perovskite Single Crystal Chwenhaw Liao[1,2], Chu-Chen Chueh[2] and Anita W. Ho-Baillie[1]; [1]The University of Sydney Nano Institute, Australia; [2]National Taiwan University, Taiwan

While solar cells, light-emitting diodes, photodetectors, and field-effect transistors based on 3D metal halide perovskite with the molecular formula of ABX_3 (A = Cs^+, $CH3NH^{3+}$, $CH(NH2)^{2+}$; B = Sn^{2+}, Pb^{2+}; X = Cl^-, Br^-, I^-) have demonstrated outstanding performance in recent years, 2D or quasi-2D perovskites achieved by space insertions have attracted intensive research effort. This is because of the added stability that accompanies these materials while still inheriting the advantages of 3D counterparts The versatility of engineer A-site cations or X-site anions in the spacers to achieve lower dimensionality also expands perovskite material choices.
Most of the reported 2D Ruddlesden–Popper (RP) phase lead halide perovskites with the general formula of $A_{n+1}B_nX_{3n+1}$ (n = 1, 2, …) comprise of layered perovskites separated by A-site-substituted organic spacers. This layered structure is constructed with long carbon chain spacers introducing a large separation between BX_6 octahedron inorganic layers. The organic spacers work as an insulating layer that provides large exciton binding energy and reduces the conductivity in a vertical direction through each inorganic layer. Therefore, the X-site substituted layered perovskite presents a much smaller separation between the constituent perovskite layers than the A-site substituted layered perovskite, moderating the exciton binding energy.
To-date, only three X-site-substituted RP phase perovskites have been reported [1-3]. Herein, we reported the first inorganic-cation pseudohalide 2D phase perovskite single crystal, $Cs_2Pb(SCN)_2Br_2$. It is synthesized by the antisolvent vapor-assisted crystallization (AVC) method at room temperature. The crystal exhibits a standard single-layer (n = 1) RP phase structure described in the space group of *Pmmn* (#59) with a slight separation (d = 1.69 Å) between the perovskite sheets. Interestingly, the SCN^- anions are found to bend the 2D $Pb(SCN)_2Br_2$ framework slightly into a kite-shaped octahedron, limiting the formation of a quasi-2D perovskite structure (n > 1). Above 450K, the 2D single crystal undergoes an unusual but reversible first-order phase transformation to 3D $CsPbBr_3$ (*Pm3m* #221). According to the small separation between perovskite sheets, Pb-Br-Pb coordination can be formed to drive the SCN^- anion away and transform into a more stable 3D $CsPbBr_3$ structure at high temperatures. Once the temperature cools down to 250K, the existed SCN^- free anions within the grains break the weak Pb-Br-Pb coordination to reconstruct the $Pb(SCN)_2Br_2$ octahedral due to the preferable Gibbs energy. Again, due to the small interlayer separation, $Cs_2Pb(SCN)_2Br_2$ exhibits a minuscule exciton binding energy of 160 meV measured by temperature-dependent PL. It is one of the lowest values reported for 2D perovskites (n = 1) and comparable to the quasi-2D A-site substituted RP phase perovskite values. Finally, a $Cs_2Pb(SCN)_2Br_2$ single crystal photodetector is demonstrated with a respectable responsivity of 8.46 mA W^{-1} and a detectivity of ≈1.2×10^{10} Jones at a low bias voltage of 0.5 V.

Application of Black Phosphorus for Interfacial Engineering in Perovskite Solar Cells Damir Aidarkhanov, Zhuldyz Yelzhanova, Gaukhar. Nigmetova, Mannix Balanay and Annie Ng; Nazarbayev University, Kazakhstan

Nowadays, the hybrid organic-inorganic perovskite solar cells (PSCs) are considered as the most promising third generation photovoltaic (PV) technology with the highest increasing rate of power conversion efficiency (PCE) among other types of emerging PVs. To date, the PCE values are comparable to the most of the established photovoltaic technologies. Intensive research activities on perovskite materials and their devices have been being performed since last decade, aiming to further boost the device performance including efficiency and stability as well as to accelerate the commercialization progress of the developed technologies via different strategies. The emerging 2D black phosphorus (BP) is a novel class of semiconducting material owing to its unique characteristics, allowing them to become attractive materials for applications in a variety of optoelectronic devices. In this work, the optimized BP materials are incorporated with PSCs at the interface between the electron transport layer and perovskite absorber. Systematic characterizations have been performed on the materials and devices. The obtained results indicate that the incorporation of BP facilitates the crystallization of the perovskite and promotes the carrier transports in PSCs. The device stability with incorporation of BP is also found to be improved significantly.

EN02.08.41
High-Heat and Photo-Stable Perovskite Solar Cells Through Ion Capture Layer Young Wook Noh, Han-Hee Cho and Myoung Hoon Song; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Organic-inorganic hybrid perovskite solar cells (PSCs) have seen a steep rise in power conversion efficiency (PCE) in recent decades and commercialization is just around the corner. Nowadays, they have achieved over 25.5% of PCEs with their excellent properties, such as long diffusion length, high absorption coefficient, and balanced ambipolar carrier transports. In order to commercialize photovoltaic (PV), a product lifetime of at least 20 years is essential, as a conventional crystalline silicon PV module. However, perovskite suffers from low thermal stability and light stability. In this study, we dramatically increased the thermal and light stability of PSCs by introducing a layer capable of inhibiting migration of ions called ion capture layer. Unlike the former materials that block ion migration, a material with tetramethylammonium (TMA^+) and SO_3^-, which are ion groups that could be directly

bonded to iodide and silver ions, was used as the ion capture layer. As a result, PSCs achieved a PCE of 23.3% and maintained >95% of their initial value after >1560 hours at 85 ºC heat and retained >80% of their initial PCEs after 700 hours at 1 sun condition.

EN02.08.42
Transparent Electrodes with Enhanced Infrared Transmittance for Semitransparent Perovskite Solar Cells and Four-Terminal Tandem Applications Hyunmin Jung[1], Geunjin Kim[1], Gyeong Sun Jang[1], Jihoo Lim[2], Moonyong Kim[2], Chan Su Moon[1], Xiaojing Hao[2], Nam Joong Jeon[1], Jae Sung Yun[2], Helen H. Park[1] and Jangwon Seo[1]; [1]Korea Research Institute of Chemical Technology (KRICT), Korea (the Republic of); [2]University of New South Wales (UNSW), Australia

Indium oxide doped with titanium and tantulum with high near-infrared transparency is applied to potentially replace the conventional indium-tin-oxide transparent electrode used in semitransparent perovskite devices and top cells of tandem devices. The high near-infrared transmittance of this electrode is possibly explained by the lower carrier concentration suggesting less defect sites that may sacrifice its optical transparency. Incorporating this electrode to semitransparent perovskite solar cells for both the top and bottom electrodes improved the device performance through possible reduction of interfacial defect sites and modification in energy alignment. Furthermore, applying this multi-doped indium oxide to the semitransparent perovskite top cell in four-terminal perovskite-silicon tandem configurations improved the photocurrent response in the bottom silicon cell by more than 7% and 15% without and with an anti-reflection layer, respectively. Finally, effects on the optical and electrical properties and performance of working devices will be addressed, and the mechanisms involved in the enhanced performance will also be discussed.

EN02.08.45
Chloride-Based Additive Engineering for Efficient and Stable Wide-Bandgap Perovskite Solar Cells Xinyi Shen[1], Benjamin Gallant[1], Philippe Holzhey[1], Joel Smith[1], Melissa McCarthy[1], Karim Elmestekawy[1], Yen-Hung Lin[1], Zhongcheng Yuan[1], Akash Dasgupta[1], Laura Herz[1,2] and Henry Snaith[1]; [1]University of Oxford, United Kingdom; [2]TU Munich, Germany

Metal halide perovskite-based tandem solar cells combining absorbers of different bandgaps are promising to achieve light-to-electricity power conversion efficiencies (PCE) beyond the theoretical limits for their single-junction counterparts. However, significant open-circuit voltage deficits present in wide-bandgap perovskite solar cells remain major hurdles for realising efficient and stable perovskite tandem cells. The underlying mechanisms widely believed to be responsible for mediocre wide-bandgap perovskite solar cells include non-radiative interfacial losses,[1–3] halide segregation,[4] as well as heterogeneous crystallisation,[5] resulting in low open-circuit voltage (V_{OC}). Moreover, compared to narrow-bandgap perovskite solar cells (i.e., 1.6 eV and below), wide-bandgap perovskite solar cells exhibit more rapid perovskite degradation under accelerated ageing conditions (e.g., light, moisture, heat and oxygen),[17] mainly due to the complex composition and processing requirements of this class of perovskite, which can be a great concern for perovskite solar cells stability. Hence, effective strategies to form low-loss and stable wide-bandgap perovskites will be the key to helping the commercial deployment of perovskite tandem solar cells in the near future.

In this study, we report a holistic approach to overcoming challenges in 1.8-eV perovskites by examining a series of chloride additives to engineer intermediate phases during the crystallisation process. Utilizing a carbazole-based self-assembled monolayer as the hole transport layer, synergistic improvement of the perovskite materials, and its interface with the hole transport layer allows us to achieve a maximum power point-tracked PCE (η_{mpp}) of 17% and a steady-state V_{OC} of 1.25 V. In addition, the chloride-modified perovskite material demonstrates improved ambient stability (25 °C, relative humidity = 40% in the air in dark) and suppressed halide segregation compared to no-chloride reference perovskites. In the meantime, we elucidated the role of chloride additives in controlling the intermediate phase formation and detailed subsequent materials properties of chloride-engineered wide-bandgap perovskites. Understanding such underlying mechanisms will help address one of the most challenging aspects in the commercial deployment of perovskite tandem technologies.

EN02.08.46
Photo-Crosslinkable Naphthalene Diimide (NDI) Polymer as Electron Transport Layer for Solution-Processed n-i-p Perovskite Solar Cells Yangwei Shi[1,1], Declan McCarthy[2], Kevin Ho[1], Fangyuan Jiang[1], Stephen Barlow[2], Seth R. Marder[2] and David S. Ginger[1]; [1]University of Washington, United States; [2]Georgia Institute of Technology, United States

Organic-inorganic halide perovskite has demonstrated great potential in application of photovoltaics with power conversion efficiency (PCE) surging from 3.8% to current record efficiency of 25.7% for a single junction perovskite solar cell. The start-of-art perovskite solar cell usually adopts inorganic metal oxide such as TiO_2, SnO_2 as electron transport layers (ETLs). However, these ETLs generally require high annealing temperature and can cause instability issues due to their photocatalytic nature. Here we report a photo-crosslinkable naphthalene diimide (NDI) polymer with a cinnamate side chain as ETL for solution processed n-i-p perovskite solar cells. Our solar cell device results show that crosslinked NDI polymer exhibit better VOC, FF, PCE, and less hysteresis than its non-crosslinked counterpart. We ascribe this PCE increase to improved perovskite crystallinity and energy level alignment, reduced nonradiative recombination and series resistance of the crosslinked NDI polymer-based perovskite solar cells.

EN02.08.47
Glass-Crystal Transformation Kinetics in a Hybrid Metal Halide Perovskite Akash Singh and David B. Mitzi; Duke University, United States

Metal halide perovskites (MHPs) are the widely celebrated family of crystalline semiconductors that has led to significant advancement in the fields of photovoltaics, emitters, and sensors. Though most of the research is condensed towards studying the crystalline MHPs, the study of MHPs that can access a glassy/amorphous state could help broaden the fundamental understanding of the structure-property relationship as well as their application space.

Our recent discovery of glass formation and reversible crystal-glass switching in an exemplary 2D lead bromide perovskite [1], with distinct optoelectronic properties in either state, has spurred interest into their potential applicability in areas where phase change characteristics could be exploited. To recognize the suitability of glass forming MHPs into such application space, it is imperative to study the kinetics of glass crystallization. Such a study would offer the

potential to understand the underlying nucleation and crystal growth mechanisms, as well as the activation energy requirement to drive such a change, providing important information for prospective phase-change applications.

In this work, we demonstrate the underlying kinetic effects of glass crystallization in a representative MHP family member, [S-(−)- 1-(1-naphthyl)ethylammonium]$_2$PbBr$_4$. By making use of iterative calorimetry and numerical modelling techniques, such as the Ligero [2] and Kissinger [3] kinetic models, we extract the activation energy of glass crystallization in the studied MHP. The activation energy (~350 kJ/mol) is found to be higher than those determined for most fast-crystallizing chalcogenides but smaller than for most of the stable oxide glasses. Furthermore, the extracted Avrami parameter of ~2 suggests a heterogeneous surface-mediated nucleation mechanism with two-dimensional crystal growth, as also corroborated by in-situ and ex-situ microscopy. Our present work serves as the first study to model the glass crystallization kinetics of MHPs and thus, with the advent of more glass forming MHPs, these results are expected to serve as a starting point for comparing crystallization kinetics parameters as a function of MHP composition and organic cation choice. The results should therefore also help in establishing a framework for selecting suitable candidates for use in new prospective applications for MHPs, such as memory, computing, phase change energy storage, glass-composites, metamaterials, and reconfigurable photonic devices.

EN02.08.48
Phase Co-Existence During Hybrid Halide Perovskite Crystallization Mriganka Singh, Maged Abdelsamie, Tim Kodalle and Carolin M. Sutter-Fella; Lawrence Berkeley National Laboratory, United States

Halide perovskites with mixed A- and X-site cations and anions, respectively, are important to overcome challenges such as thermal and structural instability, and moisture sensitivity in single cation MA/FA/CsPbX$_3$. Triple cation, mixed halide perovskite compositions have been reported to be more thermally stable, exhibit fewer phase impurities, and are less affected by the processing conditions than single cation perovskites. In this work, we present a multimodal in situ study on the formation of $Cs_{0.05}FA_{0.81}MA_{0.14}Pb(I_{0.85}Br_{0.15})_3$ by combining structural information from grazing-incidence wide-angle synchrotron X-ray scattering (GIWAXS) and optical properties from photoluminescence (PL) spectroscopy. This study covers the predominantly used solvents and solvent systems DMF, DMSO, and mixtures thereof. We are looking at the effect of the solvent used and the application of antisolvent dropping. We find that the non-perovskite delta-FAPbI$_3$ appears in all crystallization pathways. It is strongly correlated with the antisolvent dripping and temporally close to the perovskite phase formation. It was also found that the delta phase is more stable in DMF than in DMSO systems. These findings provide novel insights into perovskite phase evolution and its correlation with the solvent and antisolvent to allow for better synthetic control.

EN02.08.49
Advanced Characterization of Three-Terminal Perovskite/Silicon Tandem Solar Cells Philipp Tockhorn[1], Philipp Wagner[1], Sebastian Hall[1], Steve Albrecht[1,2] and Lars Korte[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Technische Universität Berlin, Germany

Perovskite solar cells have been shown to be ideal partners to silicon (Si) in tandem devices due to their flexibility in band-gap engineering by means of compositional variation, and potentially cost-effective fabrication [1,2]. Combining a perovskite top with a silicon heterojunction (SHJ) bottom cell has recently led to a new record power conversion efficiency (PCE) of close to 30% for perovskite/silicon (Si) tandem devices [3]. Most commonly, either a two- (2T) or four-terminal (4T) arrangement of the subcells are studied [1]. In a two-terminal (2T) arrangement, both sub-cells are connected in series in a monolithic device, sharing a common electron and hole contact. In this relatively straightforward device architecture, both sub-cells must, however, provide the same current for optimal operation. Opposed to that, four-terminal (4T) tandems feature electrically decoupled sub-cells with relaxed requirements regarding their respective electrical performance. On the downside, more complex subcell interconnection and potentially intricate module integration are major drawbacks of this concept. As an alternative, here we focus on a third approach that has gained attention only recently for perovskite/Si tandems, namely three-terminal (3T) tandems [4]. In 3T tandems, which are usually realized by using a bottom cell with interdigitated back-contacts (IBC), both subcells feature their own electron contact while sharing a common hole contact (or vice versa) [5]. This arrangement leads to a monolithic architecture that does not require current-matched sub-cells, and therefore combines the main advantages of the more commonly used 2T and 4T tandems. It has been shown that different sub-cell configurations, and especially the type of interconnection scheme, can lead to different electrical behaviors, even if the same materials are used in each case [6,7].
In this contribution, we will report on our recent progress in 3T perovskite/IBC SHJ tandem solar cells with a PCE > 25%. We will focus on different aspects regarding the measurement setup for such devices, the characterization of perovskite and silicon subcells and the visualization of advantages over 2T tandems through measurements and simulations. We will report on the design of a dedicated measurement setup featuring a dual-source source measure unit to accurately characterize the optoelectronic performance of 3T tandems. This is required since the solar cell characteristics of a 3T device cannot be retrieved from a single j-V scan but require simultaneous scanning of two voltages. This measurement setup and a tunable LED-based solar simulator are then used to study the response of 2T and 3T tandems to different illumination conditions. Further, we demonstrate how the individual measurement of the perovskite and Si subcell can be used to understand the behavior of not only 3T but also 2T. In addition to the experimental characterization of 3T, we use energy yield calculations to study the advantageous properties of 3T over 2T tandems. Lastly, we will point out pathways to achieving 3T PCEs in the range of state-of-the-art 2T and 4T tandems.

Revealing the Role of Graphite and Carbon Black in Carbon Electrodes of Carbon-Based Perovskite Solar Cells Ryuki Tsuji, Kenichirou Tanaka, Kouta Oishi, Takaya Shioki and Seigo Ito; University of Hyogo, Japan

Perovskite solar cells (PSCs) have a photoelectric conversion efficiency of over 20 % and they can be fabricated only by printing and coating processes, so it is expected as next-generation solar cells. However, the back-contact electrode (*e.g.* Au, Ag) and hole transport materials (*e.g.* Spiro-OMeTAD) used for PSCs are unstable against water and oxygen, and there is a problem with long-term stability. Therefore, we focused on fully printable carbon-based multi-

porous-layered-electrode PSCs (MPLE-PSCs) which have an electron transport layer (mesoporous TiO_2), an insulation layer (mesoporous ZrO_2), and hole transport/back contact electrode layer (carbon) [1-5]. MPLE-PSCs have long-term stability because the thick carbon layer (~15 μm) can be protected the light absorption layer from ambient water and oxygen. However, MPLE-PSCs have a low efficiency of less than ~18%, so it is necessary to aim for higher efficiency for commercialization. In this work, we focus on carbon electrodes, which have roles of hole transport and back contact. Typically, carbon electrodes are made from a mixture of large-sized graphite particles and nano-sized carbon black. However, the role of each material remains unclear. Therefore, carbon electrodes with different mixing ratios of graphite and carbon black are fabricated and compared. This fundamental comparison reveals the role of carbon materials used in MPLE-PSCs.

A TiO_2 compact layer was deposited by a spray pyrolysis method on patterned FTO glass. Then, porous TiO_2, ZrO_2, and carbon layers were deposited by a screen printing method, and each layer was sintered at 400 to 500 °C. Six mixing ratios of graphite and carbon black for carbon electrodes were prepared: 100-0, 80-20, 65-35, 50-50, 20-80, and 0-100. Finally, $(5\text{-AVA})_{0.05}(MA)_{0.95}PbI_3$ perovskite precursor solution was drop-casted and permeated through the carbon layer, and the MPLE-PSCs were completed by removing the solvent and crystallizing the perovskite material by heating and drying. Various measurements were performed on the obtained devices.

The results show that the mixing ratio of graphite to carbon black has a significant effect on the performance of MPLE-PSC devices. In the graphite-rich, the open-circuit voltage (V_{oc}) was higher. However, the short-circuit current density (J_{sc}) and fill factor (FF) were low. On the other hand, increasing the ratio of carbon black decreased V_{oc}, but improved J_{sc} and FF. To understand these changes, electrochemical impedance spectroscopy (EIS) and photoluminescence (PL) analysis were performed. The results show that carbon black has the effect of promoting hole extraction and graphite has the effect of efficiently transporting the generated charge. In summary, the MPLE-PSC device achieved maximum performance and a champion efficiency of 13% when graphite and carbon black were in a 50-50 or 20-80 ratio. This study is important for realizing inexpensive and sustainable carbon electrodes not only for PSCs but also for various electronic devices.

Formation of Superlattice in Organometal Halide Perovskite Solar Cells Satoshi Uchida and Hiroshi Segawa; The University of Tokyo, Japan

Recently, perovskite solar cells have become the latest research field among various new generation photovoltaic technologies due to their high performance and potentially low-cost production. The power conversion efficiency has already reached over 25% in 2020 much beyond another solar cells such as CIGS or amorphous Si. The further performance still looks promising toward the Shockley–Queisser limit at around 30%. For that purpose, physical chemistry understanding based on the crystallography must be essential to design the good light harvesting, good charge separation and good charge transfer.

Recently we reported the scientific revelation that the crystal phase of thin film $CH_3NH_3PbI_3$ consists of the mixture of tetragonal phase and cubic phase. Moreover, bold zebra pattern with d-spacing with 14.2Å (2θ=6.22° for CuKα by XRD) was clearly observed by high resolution TEM with FIB processing that consists with tetragonal and cubic phase superlattice. The typical high magnification In the TEM observation characteristic identity of perovskite can be seen as (1) Phase coexistence (2) Superlattice (3) Nano size domain (10~20nm).

To make more high performance as a solar cell, the crystal phase control with liquid nitrogen quenching just after the hot plate heating was newly examined. The resulting cell performance was impressive, about 2% more than that without Liq. N_2 treatment. Details on TEM observations are also provided for such procedures.

Additive Engineering for Enhancing Photovoltaic Performance and Stability of Sn-Pb Alloyed Perovskite Solar Cells Kyu-Woong Yeom and Nam-Gyu Park; Sungkyunkwan University, Korea (the Republic of)

Here, we report on additive engineering in Sn^{2+} and Pb^{2+} bearing precursor solution to improve photovoltaic performance and stability of Sn-Pb alloyed perovskite solar cells. Additives of urea as O-donor and thiourea as S-donor are compared, where oxygen is relatively hard base than sulfur. Photovoltaic performance is higher for the additives than for the control without additive, where thiourea is found to be more effective than urea in enlarging grain size and carrier lifetime. As a result, power conversion efficiency (PCE) of perovskite solar cell employing $FA_{0.5}MA_{0.5}Pb_{0.5}Sn_{0.5}I_3$ is improved from 14.58% for control (without additive) to 16.00 % for urea and to 18.59% for thiourea. FTIR study on SnI_2 (or PbI_2)-additive adduct shows that the C=S stretching frequency of thiourea is lowered from 729 cm^{-1} to 721 cm^{-1} and 708 cm^{-1} upon interaction with PbI_2 and SnI_2, respectively, which indicates that interaction of S with Sn^{2+} is stronger than that with Pb^{2+}. Shift to lower wavenumber is also observed for urea but the degree is marginal for both SnI_2 and PbI_2. Stronger interaction of thiourea with Sn^{2+} than Pb^{2+} is due to increased covalency by interaction of smaller Sn^{2+} ion with soft sulfur bearing thiourea. Thus, the significantly improved performance in the presence of thiourea is ascribed to underlying a kinetic control of crystal growth. X-ray photoelectron spectroscopic study reveals that oxidation of Sn^{2+} is effectively suppressed by thiourea, which is beneficial to not only photovoltaic performance but also phase stability.

EN02.08.54
Enhanced Electron Extraction by Tuning Space-Charge Layer of SnO_2 for Hybrid Perovskite Solar Cells Sarah S. Youn[1,2], Jihyun Kim[1], Junhong Na[3], William Jo[1] and Gee Yeong Kim[2]; [1]Ewha Womans University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Kyungnam University, Korea (the Republic of)

Perovskite solar cells (PSCs) have shown outstanding performance during the past decade. An important parameter that controls device performance is the charge transport properties at interfaces. Tin oxide (SnO_2) is a widely used electron transport layer (ETL) material in highly efficient perovskite solar cells owing to its superior electrical and optical properties. Therefore, understanding the interfacial effect of ITO/SnO_2 and its role in PSCs is crucial but it is not intensively studied. Here, we employ conductive atomic force microscopy and transfer length method as a function of SnO_2 thickness to identify space-charge effect at the interface. The results show that the critical kink point exists at about 10 nm of SnO_2 thickness, indicating electron depletion and expecting weak charge transfer behavior of the device. A thickness less than 20 nm was favorable for the best PSC performance because charge transport behaviors in the thin SnO_2 layer were modified by electron depletion. This study provides a strategy to tune the electron transport layer and boost the

charge transport behavior in PSCs, making important contributions to optimizing SnO_2-based PSCs.

EN02.08.55
Impact of Halide Composition in Copper Halide-Based Hole Transport Materials on Stability and Performance of Inverted Perovskite Solar Cells
Zhaojie Zhang, Hamza Javaid, Emily C. Smith and Dhandapani Venkataraman; University of Massachusetts, Amherst, United States

Copper halides are promising hole transport materials for inverted perovskite solar cells (PSCs) due to their advantages of low cost, tunable energy levels, good hole mobility, and excellent stability. However, the understanding of the role of mixed copper halides with fine-tuned energy levels and conducting properties in highly efficient inverted PSCs is still unclear. Here, we demonstrate that using CuI_xBr_{1-x} with an optimized Br/I ratio as HTL leads to a champion power conversion efficiency of 19.2% compared to PTAA (17.7%), CuI (16.6%), and CuBr (17.6%) based PSCs. We systematically investigate the influence of electronic properties of CuI_xBr_{1-x}, including hole mobility, hole density, energy level, and band gap on the performance (V_{oc}, J_{sc}, and FF) and stability of PSCs. We used hyperspectral photoluminescence imaging to quantify charge carrier transport dynamics and recombination loss. PSCs with fine-tuned CuI_xBr_{1-x} have a more homogeneous distribution of quasi-fermi level splitting and more efficient charge extraction, leading to improved fill factor. CuI_xBr_{1-x} also suppresses ion migration and phase segregation in mixed-halide perovskite films. This work provides design guidelines for improving the performance and stability of PSCs by tuning the electronic properties of hole transport layers.

EN02.08.56
Case Study—Applying Benzylamine as a Monoamine Additive Passivation in Wide-Bandgap Perovskites
Suer Zhou[1], Yangwei Shi[2], James Drysdale[1], Joel Smith[1], Margherita Teddei[2], Jian Wang[2], Akash Dasgupta[1], Ashley Marshall[1], David Ginger[2] and Henry Snaith[1]; [1]University of Oxford, United Kingdom; [2]University of Washington, United States

Silicon/perovskite tandem solar cells are a promising direction for increasing the power output of solar cells past the Shockley-Queisser limit for single junctions. The ideal bandgap of perovskite on top of silicon is around 1.68-1.70eV, which can be achieved by mixed cation, mixed halide perovskites, such as $FA_{0.75}Cs_{0.25}Pb(I_{0.8}Br_{0.2})_3$. However, there are still many challenges for wider bandgap compositions, such as ion migration and phase segregation effects. Under constant laser illumination, these compositions undergo light-induced halide segregation, which will impact the long-term stability during operation.

To stabilize wide-bandgap mixed halide perovskites, we employ benzylamine as a bulk additive. By optimizing the amount of additive in the film, we significantly improved the PLQY and charge carrier lifetime. Compared to applying benzylamine as a surface treatment[1,2], the bulk additive approach gave better reproducibility and higher overall device performance. Time-resolved PL and ToF-SIMS reveal that the benzylamine is mostly distributed near the top and bottom surfaces, forming lower dimensional phases. Benzylamine passivates both the grain boundary and surface defects while hindering ion migration. Furthermore, adding benzylamine does not introduce halides that could incorporate into the perovskite and change the bandgap, unlike the more common approach of adding ammonium halides. Perovskite thin films and devices with benzylamine have improved light and moisture stability, beneficial for perovskite/silicon tandem applications.

Creation of a Solution Processed Scalable Transparent Top Electrode for Application in Perovskite Solar Cells
Jack Horne, Trystan Watson, David Beynon and Chris Griffiths; Swansea University, United Kingdom

Perovskite solar cells frequently rely on a transparent substrate with a non-scalable thermally evaporated TCO for the transmission of photons to the active layers, however, when perovskites are used on an opaque substrate or for semi-transparent applications the top electrodes, which play a critical role in the performance of a solar cell, must instead be transparent to allow photons to reach the active layer, with semi-transparent solar cells too allowing photon to reach the active layers from both sides.
This work presents how single walled carbon nanotubes (SWCNTs) and silver nanowires (AgNWs) can be used in combination to create a low temperature solution processable transparent top electrode for use in opaque substrate-based and semi-transparent perovskite solar cells.
Using a hybrid electrode consisting of low-cost, commercially available inks to create a carbon nanotube in a silver nanowire matrix provides a scalable solution for creating an electrode compatible with roll-to-roll lines. This was achieved through experiments optimising the ratio between the CNT and AgNW solutions using UV-Vis-NIR to measure the transparency and 4-point probe to measure the sheet resistance and repeated over various thicknesses which was further investigated through AFM. The use of opaque substrates, like steel, and the application of a solar cell coated directly onto it provides an additional function outside of their structural uses, giving existing materials the ability to generate electricity utilizing their surface area for energy generation.
This solution processed electrode can be deposited through both spray and slot die coating techniques. The hybrid electrode layer provides improved adhesion over a film of AgNWs alone with the interaction between the CNTs and AgNWs creating a more stable layer reducing the movement of silver ions towards the perovskite. The network of intermeshed nanomaterials creates a high conductivity of charge with the spaces between them creating a small variance in the percentage transmission of wavelength across the visible spectrum.
Using this electrode, we were successfully able to create working perovskite solar cells using both sprayed and slot die deposition with devices performing the same when measure either through a transparent substrate, as in traditional devices, or through the top electrode.

EN02.08.58
Discovering Novel Halide Perovskites Using Multi-Fidelity Machine Learning
Panayotis T. Manganaris, Jiaqi Yang and Arun Kumar Mannodi Kanakkithodi; Purdue University, United States

We report a materials design pipeline for halide perovskites. The primary objective being to recommend perovskite alloy compositions corresponding to targeted properties. Here targets are chosen to yield stable compounds with high photovoltaic (PV) performance. Thus, we focus on models of the electronic band gap, decomposition energy (therefore, perovskite stability), and PV efficiency. We use Spectroscopic Limited Maximum Efficiency (SLME) for synthetic data and Power Conversion Efficiency (PCE) for physical data. We use nanoHUB, an NSF-funded, Purdue-based computational repository, to host reproducible notebooks documenting our model development workflow [1]. We also host an interoperable database and inverse design pipeline for public access. Thereby, we enable the scientific community to use and improve these tools. Thus perovskites with alternative optoelectronic properties, possibly targeting quantum computing or metrology, may be discovered. The design pipeline makes recommendations using continuous

surrogate models trained to connect a discretely sampled composition space to the targeted properties. A Genetic Algorithm (GA) selects optimal compositions where fitness involves minimizing euclidean distance between the predicted and targeted properties and by ensuring compositional feasibility.

Our GA optimizer prioritizes exploration so locally optimal candidates can be found without fixating on a small subset of fit regions. GA is also efficient in high dimensional space. In our past published work [2], the discrete alloy space based on a finite supercell experiences combinatorial scaling with supercell size. Going from discrete sampling to continuous surrogate models sees this scaling continue to infinite resolution. We provide machine learning (ML) models for the optimizer to work on: A rigorously optimized Random Forest Regressor (RFR), a Gaussian Process (GP) Regressor, and a Sure Independence Screening and Sparsifying Operator (SISSO) regressor. Naturally, the GA's solutions will only be as good as the ML accuracy.

We subdivide approximately 1000 physical and synthetic records into tables by record accuracy. The largest table of ~500 compounds contains optoelectronic properties simulated using density functional theory (DFT). Here, geometry optimization of pseudo-cubic ABX3 supercells with arbitrary mixing at each site is followed by static band structure and optical absorption calculations performed at the GGA-PBE level of theory. Also, ~300 compounds were subjected to more expensive hybrid HSE06 computations, both with and without spin-orbit coupling (SOC), for better electronic properties. Finally, ~100 of the same compositions also record experimental measurements for band gap and efficiency.

We combine tables using multi-fidelity modeling techniques so each of our architectures can make predictions with physical accuracy. Currently we use only composition information as descriptors. This simplifies featurization because a composition vector can be procedurally obtained for experimental and synthetic data alike simply by parsing a string encoding the ABX3 perovskite formula corresponding to each record with relative ease.

No more than this composition vector is needed to make a prediction. However, additional predictors derived from elemental properties easily obtained from the trusted Mendeleev databases are included in model design. Finally, we discuss using state of the art graph based surrogates to extend this optimization loop to none-cubic phases. The nanoHUB pipeline is constantly improving with fresh DFT data, ML models, and design tools.

Magnetism in 1D and 2D Hybrid Perovskite Induced Through Water-Assisted Self-Assembly Method Ariany Bonadio, Fernando Sabino, Aryane Tofanello, André L. de Freitas, Vinicius G. de Paula, Gustavo Dalpian and Jose A. Souza; Universidade Federal do ABC, Brazil

Methylammonium lead iodide ($MAPbI_3$) is an important light-harvesting semiconducting material with excellent optical and electronic properties for the use in optoelectronic devices, including photovoltaic and light-emitting devices. Doping of halide perovskites allows the manipulation of the magnetic, optic, and electronic properties. The successful insertion of magnetic dopants is important to the development of functional devices and is also able to open new potential applications such as in magnetic/semiconducting devices. Therefore, effective strategies to incorporate different ions into the structure have been very appealing. In this work, doped magnetic/semiconducting perovskite microwires have been successfully produced by using a novel strategy involving a self-assembly growth process of $[PbI_6]^{4-}$ octahedra chains in the presence of liquid water. In this process, a monohydrate compound with a monoclinic structure is formed. The 1D $[PbI_6]^{4-}$octahedra chains are stabilized by the presence of both water and MA^+, forming large channels between chains. This monohydrate compound can easily be reversed to $MAPbI_3$ through heat treatment or in an evacuated atmosphere eliminating the water present in the channels of the structure. Therefore, we were able to produce paramagnetic perovskite microwires by incorporating iron and manganese ions in the organic channels during the recrystallization process. Afterward, the crystal structure collapses into the 3D perovskite structure through thermal annealing, trapping the magnetic ions within the perovskite structure. Structural and morphological studies confirm that the magnetic ions were successfully introduced in the perovskite structure. From first principles calculations, we determined that the magnetic ions are localized in the interstitial sites. Electric transport characterizations were also carried out to study the influence of the two different magnetic ions on the crystal lattice and charge carrier dynamics. 2D ribbon-like magnetic perovskites were also produced by adding large organic molecules along with magnetic ions through this self-assembly growth process. The introduction of large ammonium cation as butylammonium leads to a 2D layered structure alternately stacked insulating organic spacer layer and inorganic BX_6 slabs. The general chemical formula is $(L)_2(A)_{n-1}B_nX_{3n+1}$, where L is the monovalent organic spacer, A is a monovalent cation, B is a divalent metal cation, X is a halide anion, and *n* represents the number of BX_6 layers. Structural analysis indicated that the 2D perovskite with a mix number of *n* is formed without traces of Fe or Mn binary impurity phases. The hydrophobic organic spacer layer provides a natural protective barrier for the penetration of ions and moisture offering long-term stability in the air atmosphere for the perovskites.

EN02.08.60
Physical Vapor Deposition of Yb-Doped Cesium Lead Halide Perovskites Iver J. Cleveland, Minh N. Tran and Eray S. Aydil; New York University, United States

Recently, ytterbium-doped $CsPb(Cl_{1-x}Br_x)_3$ ($x<0.35$) perovskite showed efficient quantum cutting, a process wherein photons absorbed at high energies (*e.g.*, > 2.5 eV) generate two photons with energies (~ 1.25 eV) close to the silicon bandgap energy (1.1 eV). The mechanism for this quantum cutting process is not well understood, but the leading theories suggest that Pb vacancy defects in the perovskite efficiently trap excitons and transfer energy to two nearby Yb^{3+} ions, which subsequently emit from the Yb^{3+} $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition.[1] A thin layer of this material on a silicon solar cell can convert blue photons to two near-infrared (NIR) photons, decreasing energy losses due to the relaxation of the high-energy charge carriers to the band edges. In this way, silicon solar cell efficiencies can surpass the Quessier limit. The majority of reports on ytterbium-doped perovskites rely on nanocrystal or solution-based synthesis to make the materials.[2,3]

We are exploring physical vapor deposition, a solvent-free technique, to synthesize halide-perovskite thin films. Specifically, we deposited $CsPb(Cl_{1-x}Br_x)_3$ and Yb-doped $CsPb(Cl_{1-x}Br_x)_3$ films by co-evaporating CsCl, $PbCl_2$, $PbBr_2$ and $YbCl_3$ and controlling the flux of each using quartz crystal microbalances. Films were characterized using x-ray diffraction, scanning electron microscopy, optical absorbance, x-ray photoelectron spectroscopy, photoluminescence, and photoluminescence quantum yield measurements. Specifically, we investigated the effects of deposition temperature, Yb-concentration, stoichiometry, post-deposition annealing, and annealing environment on the structure, morphology, and photoluminescence quantum yield of Yb-doped $CsPbCl_3$ films formed by PVD and using a combinatorial high throughput approach.

Yb-doped $CsPbCl_3$ films annealed at 350 ºC for 2 hours emitted NIR photoluminescence at ~990 nm (Yb^{3+} $^2F_{5/2} \rightarrow {}^2F_{7/2}$ transition, 1.25 eV) with quantum yields (PLQY) exceeding 70%, when excited with photons with energies above the $CsPbCl_3$ bandgap (*e.g.*, > 3.0 eV). PLQY was maximized at the lowest Yb concentrations and decreased as Yb concentration increased from 2% to 10%. This indicates that not all Yb are optically active. The PLQY is especially sensitive to the annealing environment. For some film compositions, identical films annealed in the air have higher PLQY than films annealed in an N_2-

filled glovebox, and films annealed in an N_2-filled glovebox followed by annealing in the air have even higher PLQY. We hypothesize that grain growth in the glove box followed by oxygen passivation of remaining defects in the air is responsible for the high PLQYs in these films. This PLQY trend with annealing environment, however, is sensitive to the Cs and Yb concentrations as well as the halide composition. For instance, Yb-doped orthorhombic $CsPb(Cl_{1-x}Br_x)_3$ films with $x \sim 0.35$ behave differently than Yb-doped cubic $CsPbCl_3$ films, with annealing in N_2-filled glovebox having the highest PLQY. SEM images show that annealing in air leads to smaller grains. Grain growth is also inhibited when as little as 2% Yb (relative to lead) is incorporated in the film. Surface analysis of Yb-doped $CsPbCl_3$ films with XPS shows that Yb is detected on the surface of films annealed in a glovebox but missing from the surface of films annealed only in the air.

EN02.08.61
Continuous $MASnI_3$ Perovskite Thin Films Deposited by Spin Coating without Antisolvent Treatment Chandan Q. Howlader[1], Nischal Khakurel[1], Wilhelmus Geerts[1], Greg Gibson[2] and Maggie Chen[1]; [1]Texas State University, United States; [2]nTact, United States

Organic-inorganic metal halide perovskite materials have emerging photovoltaic properties, thus high potential for applications in solar cells. Also, they are good competitors to the current market-dominant silicon solar cell as they are cheaper to manufacture. The most efficient perovskite solar cells show a power conversion efficiency of more than 24%. However, they contain lead (Pb), which is harmful to the human body as well as the environment. The most suitable substitute for the lead in the perovskite is tin (Sn) which is less toxic. However, most tin-based perovskite materials require an anti-solvent treatment to start the crystallization for getting a fully covered perovskite thin film. These anti-solvents steps add complexity to the deposition process and are anti-solvents are also often toxic. So, it is also necessary to eliminate the anti-solvent step from the solar cell fabrication process to make it more ecofriendly. In this work, we deposited the methylammonium tin iodide ($MASnI_3$) without any antisolvent and obtained fully covered perovskite thin films. The crystallization and coverage are highly dependent on the spin speed, spin time and concentration of the perovskite ink. The ink was prepared by dissolving 1 mole of methylammonium iodide (MAI), 1 mole of tin iodide (SnI_2), and 15 mol% of tin fluoride (SnF_2) into a mixed solvent. The mixed solvent contains N, N-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO) of a ratio of 4:1. The perovskite ink was spin-casted at 1000 rpm for 10 s and 6000 rpm for 110s on glass and glass/ITO substrates. The deposited films were cured at 70° C for 10 min on a hot plate inside the glovebox in a nitrogen (N_2) atmosphere. The optical properties of the thin films were determined from UV-Vis, Photoluminescence (PL), ellipsometry and the physical properties from scanning electron microscopy (SEM), atomic force microscope (AFM), and X-ray diffraction (XRD). XRD q-2q scans show that the deposited films have an a-phase $MASnI_3$ crystal structure with a predominant (001) texture. SEM images show continuous films with large crystallites up to 40 um. The bandgap determined from UV-Vis measurements is approximately 1.25 eV which matches up with the bandgap determined from the PL measurements (1.26 eV) and is similar to what others have found for $MASnI_3$. The effect of 0, 25 mol%, and 100 mol% MAAc additive in the ink on the properties of the spin cast films was investigated. The MAAc additive increased the PL signal but did not affect the film's morphology observed by SEM images.

This work was in part funded by the Department of Navy's HBCU/MI Program through ONR grant number N00014-19-1-2576 and in part by NSF through STTR Phase II grant 1927020. The authors would like to thank Dr. Holtz of Texas State for training access and help with the PL measurements.

EN02.08.62
High Gain, Stable Infrared Photodetectors Based on Electrospun Triple Cation Perovskite Nanofibers Min-Woo Kim and Stephanie Lee; New York University, United States

IR photodetectors fabricated using tri-cation (Cs/MA/FA) and dual-anion (Br/I) perovskite as light absorbers exhibit broad light absorption, large charge mobilities, and low-cost fabrication to realize inexpensive but efficient and stable photodetectors. A critical challenge facing their commercialization is their instability under prolonged IR exposure, which can cause parasitic chemical reactions between the perovskite and hole transfer materials (HTMs). Here, we demonstrate stable IR photodetectors based on electrospun tri-cation perovskite fibers infiltrated with hole-transporting π-conjugated small molecule 2,2′,7,7′-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9-spirobifluorene (Spiro-OMeTAD). These hybrid perovskite photodetectors show ultra-high gains as well as excellent environmental stability. Operating at a low voltage bias of 5 V, the photodetectors exhibit EQE values up to 3008.9 % under 808 nm irradiation, decreasing only to ~ 2769.8 % after 3 months of storage in air. These values are almost ten times higher than those measured for thin film/HTM photodetectors. Such large EQE values for fiber/HTM photodetectors are attributed to the presence of a high density of charge traps on electrospun fiber surfaces that gives rise to a photomultiplication effect in which photogenerated holes can travel through the active layer multiple times before recombining with trapped electrons. Time-resolved and steady-state photoluminescence measurements and conductive atomic force microscopy mapping revealed that charge transport dynamics are significantly improved in fiber/HTM layers compared to film/HTM layers due to large interfacial areas for exciton dissociation between the two phases in the former case. These results demonstrate the potential of electrospun perovskite hybrid layers to enable the inexpensive fabrication of high-performance IR photodetectors for applications ranging from information technology to imaging.

EN02.08.63
Halide Perovskite Nanocrystal-Enabled Stabilization of Transition Metal Dichalcogenide Nanosheets and Their Photodetective Applications Hyeokjung Lee, Jin Woo Oh, Jihye Jang, Hyowon Han and Cheolmin Park; Yonsei University, Korea (the Republic of)

Transition metal dichalcogenide (TMD) nanosheets exfoliated in the liquid phase are of significant interest owing to their potential for scalable and flexible photoelectronic applications. Although various dispersants such as surfactants, oligomers, and polymers are used to obtain highly exfoliated TMD nanosheets, most of them are electrically insulating and need to be removed; otherwise, the photoelectric properties of the TMD nanosheets degrade. Here, inorganic halide perovskite nanocrystals (NCs) of $CsPbX_3$ (X = Cl, Br, or I) are presented as non-destructive dispersants capable of dispersing TMD nanosheets in the liquid phase and enhancing the photodetection properties of the nanosheets, thus eliminating the need to remove the dispersant. $MoSe_2$ nanosheets dispersed in the liquid phase are adsorbed with $CsPbCl_3$ NCs. The $CsPbCl_3$ nanocrystals on $MoSe_2$ efficiently withdraw electrons from the nanosheets, and suppress the dark current of the $MoSe_2$ nanosheets, leading to flexible near-infrared $MoSe_2$ photodetectors with a high ON/OFF photocurrent ratio and detectivity. Moreover, lanthanide ion-doped $CsPbCl_3$ NCs enhance the ON/OFF current ratio to $>10^6$. Meanwhile, the dispersion stability of the $MoSe_2$ nanosheets exfoliated with the perovskite NCs is sufficiently high.

EN02.08.64
Modulation of Film Formation Kinetics to Achieve Perovskite Light-Emitting Diode Emitting Blue Electroluminescence Yoonseo Nah[1,2], Devan Solanki[1], Yitong Dong[3], Jason Rohr[4], Andre Taylor[4], Shu Hu[1], Edward H. Sargent[3] and Dong Ha Kim[2]; [1]Yale University, United States; [2]Ewha Womans University, Korea (the Republic of); [3]University of Toronto, Canada; [4]New York University, United States

Quasi-two-dimensional (Quasi-2D) metal halide perovskite consists of inorganic quantum wells sandwiched with organic spacers. It has attracted enormous interests due to its large exciton binding energy, tunable emission wavelength, and solution processability. In general, solution-processed quasi-2D perovskites contain multiple quantum slabs with a broad phase dispersity. Inhomogeneity induces charge funneling into the smallest bandgap components, which poses a challenge in achieving deep-blue electroluminescence. Here, we report a film modulation strategy that significantly narrows the quantum well distribution. We show that the phase dispersity in perovskite film is significantly narrowed with controlled, simultaneous evaporation of solvent and antisolvent. Our quasi-2D perovskite shows stable deep-blue electroluminescence with a peak emission wavelength of 466 nm and a narrow linewidth of 14 nm. Light emitting diodes records a maximum luminance of 280 cd m^{-2} at an external quantum efficiency of 0.1%. This synthetic approach will pave a way to produce new materials that widen the color gamut of next-generation displays.

EN02.08.66
Passivation and Defect Mapping in Lead Halide Perovskites Yenal Yalcinkaya, Pascal N. Rohrbeck and Stefan A. Weber; Max Planck Institute for Polymer Research, Germany

Defect tolerance behaviour of lead halide perovskites makes them significantly important for photovoltaic applications. However, defects at the interfaces such as grain or junction boundaries can result in deep trap states which lead to lower power conversion efficiencies. In this study, we studied effect of some passivation agents on methylammonium-free cesium formamidinium lead ioide (Cs-FAPI) which suffers from phase instability. To this end, we compared the phase stabilities, optical properties, and solar cell efficiencies of pristine and passivated Cs-FAPI films. Finally, we performed time-resolved Kelvin Probe Force Microscopy (tr-KPFM) measurements to map the defects and passivation effect by means of mapping the photovoltage behaviour. This study shows the improvements on Cs-FAPI films and devices by passivation agents on nanoscale.

EN02.08.68
Bulk and Micro-Photoluminescence Studies of Perovskites Stuart Thomson; Edinburgh Instruments Ltd., United Kingdom

Perovskite based solar cells are the subject of intense research interest due to the attractive properties of perovskite; high carrier mobilities, large absorption coefficients, tuneable bandgaps, and long carrier diffusion lengths. One of the challenges in any solar cell design is how to get the charge carriers efficiently out of the device. To aid charge extraction, electron and hole extraction layers are routinely incorporated into the device stack.

One promising material being investigated as a hole extraction layer are vertically aligned carbon nanotubes (VACNTs). The VACNTs can be grown in a grid pattern of ‘towers’ atop the ITO electrode in order to achieve improved charge extraction while maintaining high optical transmission through the ITO/VACNTs. Photoluminescence response from perovskite materials is proportional to the number of charge carriers in the layer and therefore sensitive to charge extraction into adjacent layers. This makes photoluminescence based techniques invaluable for investigating the performance of new extraction layers. In this work steady-state and time-resolved confocal photoluminescence microscopy and photoluminescence quantum yield studies were used to quantify hole transfer efficiency into the VACNT towers.

EN02.08.70
Lightweight, Floating Perovskite-$BiVO_4$ Tandem Devices for Scalable Artificial Photosynthesis Virgil Andrei[1,1], Geani M. Ucoski[1], Chanon Pornrungroj[1], Demetra S. Achilleos[1], Katarzyna Sokol[1], Judith L. MacManus-Driscoll[1], Robert Hoye[2], Richard H. Friend[1] and Erwin Reisner[1]; [1]University of Cambridge, United Kingdom; [2]Imperial College London, United Kingdom

Photoelectrochemical (PEC) artificial leaves hold the potential to lower the costs of sustainable solar fuel production by integrating light harvesting and catalysis within one compact device. However, current deposition techniques limit their scalability, while fragile and heavy bulk materials can affect their transport and deployment. Here, we demonstrate the fabrication of lightweight artificial leaves by employing thin, flexible substrates and carbonaceous protection layers.[1] Lead halide perovskite photocathodes deposited onto indium tin oxide coated polyethylene terephthalate achieve an activity of 4266 µmol H_2 g^{-1} h^{-1} using a platinum catalyst, whereas photocathodes with a molecular Co catalyst for CO_2 reduction attain a high CO:H_2 selectivity of 7.2 under a lower 0.1 sun irradiation. The corresponding lightweight perovskite-$BiVO_4$ PEC devices display unassisted solar-to-fuel efficiencies of 0.58% (H_2) and 0.053% (CO), respectively. Their potential for scalability is demonstrated by 100 cm^2 standalone artificial leaves, which sustain a comparable performance and stability of ≈24 h to their 1.7 cm^2 counterparts. Bubbles formed under operation further enable the 30-100 mg cm^{-2} devices to float, while lightweight reactors facilitate gas collection during outdoor testing on a river. The leaf-like PEC device bridges the gulf in weight between traditional solar fuel approaches, showcasing activities per gram comparable to photocatalytic suspensions and plant leaves.[1] The presented lightweight, floating systems are compatible with modern fabrication techniques,[2] and may enable open water applications, while avoiding competition with land use.

Hot-Spin Casting Synthesis of Freestanding $Cs_2AgBiBr_6$ Double Perovskite Facet-Oriented Microcrystals for Efficient Photodetectors Mozakkar Hossain, Md Sariful Sheikh and K. D. M. Rao; Indian Association for the Cultivation of Science, India

Facet-orientated double perovskite (DP) microcrystals (MCs) are of particular interest in optoelectronics due to the special symmetry and homogeneous interfaces, which extend the carrier lifetime and enhance the mobility to realize robust device performance. Here, a simple hot-spin casting method is developed to instantaneously synthesize the highly crystalline lead-free halide DP $Cs_2AgBiBr_6$ MCs with facet-orientation. The low temperature (130 °C) hot-spin casting synthesis of DP MCs instigates growth only along the highly packed (111) plane attributed to heterogeneous nucleation. The $Cs_2AgBiBr_6$ DP MCs demonstrate reduced lattice parameters with enhanced light absorbance resulting in decreased bandgap ($\Delta Eg \approx 0.23$ eV). The facet-oriented DP MCs exhibit the enhancement in photoluminescence and carrier lifetime compared to the nanocrystalline thin-film. Moreover, the DP MCs are successfully transferred on the desired substrate using micro-imprint lithography keeping its original orientation intact. The DP $Cs_2AgBiBr_6$ MCs-based photodetectors manifest broader spectral response, high detectivity (1.72×10^{11} Jones) and improved external quantum efficiency (EQE, 451%). The freestanding and facet orientated DP MCs synthesis is easily extendable to other types of halide perovskites and has the potential to fabricate high-performance optoelectronic devices.

Ultrahigh-Resolution Transfer Printing of Light-Emitting Nanocrystals for Next-Generation Advanced Displays Jiwoong Yang[1] and Moon Kee Choi[2]; [1]Daegu Gyeongbuk Institute of Science & Technology (DGIST), Korea (the Republic of); [2]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of)

High-resolution patterning techniques that can produce red/green/blue pixels are essential for next-generation advanced displays. Photolithography and inkjet printing have traditionally been applied to create patterns of light-emitting nanocrystals such as CdSe, InP, and perovskite based nanocrystals. However, these methods usually degrade the optical and electrical properties of those nanocrystals because of the severe processing conditions (associated to the use of various chemicals and ultraviolet radiation) and the presence of organic residues (photoresists and additives for photolithography and inkjet printing, respectively).
Here, we present the ultrahigh-resolution transfer printing techniques for next-generation advanced displays. This method does not use wet chemicals and does not remain organics in the created patterns, suggesting its potential to exploit unique properties of light-emitting nanocrystals. The method can produce ultrahigh-resolution colloidal quantum dot patterns.[1-5] Furthermore, the interfacial engineering between the stamps and nanocrystals broadens its applicability to a variety of materials, including perovskite nanocrystals.[6] We can successfully fabricate ultrahigh-resolution perovskite patterns, and the external quantum efficiencies of the printed perovskite light-emitting didoes are greater than those of previously reported printed perovskite light-emitting didoes. Our results highlight that the transfer printing is promising for ultrahigh-resolution display applications.

It's Not All About the Chemical Identity—Strong Impact of Substituent Position in PEAI Based Cations for Realizing Efficient and Stable 2D/3D Perovskite Solar Cells Gorkem Gunbas[1,2,2], Ummugulsum Gunes[1,2,3], Figen Varlioglu Yaylali[1,2], Zeynep Gozukara Karabag[1,2,3], Aliekber Karabag[1,2], Xiao-Xin Gao[3], Olga Syzgantseva[4], Bensu Cel Yildirim[1,2], Naoyuki Shibayama[5], Hiroyuki Kanda[3], Alwani Imanah Rafieh[3], Liping Zhong[3], Andreas Züttel[3], Joseph Paul Dyson[3], Selcuk Yerci[1,2,2] and Mohammad Khaja Nazeeruddin[3]; [1]ODTU-GUNAM, Turkey; [2]Middle East Technical University, Turkey; [3]École Polytechnique Fédérale de Lausanne, Switzerland; [4]Lomonosov Moscow State University, Russian Federation; [5]University of Hyogo, Japan

Perovskite solar cells (PSCs) became a household name in the solar energy community in less than a decade, and rightly so, by combining ease of fabrication and high efficiencies. However, the long-term stability and reproducibility are far from ideal for the commercial implementation of the technology. Stability of PSCs are dependent on several factors and encapsulation can only be a remedy, to a certain extent, for moisture and oxygen related degradations. Interfacial molecular dissociation and ion migration are main concerns for perovskites apart from environmental factors and several approaches have been pursued to address these issues. Surface passivation with 2D perovskites (2DPs) became an impactful strategy to achieve improved stability accompanied with enhanced performance. Phenylethyl ammonium iodide (PEAI) and its derivatives are the mostly commonly utilized cations for 2DPs, although various other cations have been implemented.
We envisioned that strongly electron releasing groups are the clear choice as substituents on PEAI, due to their potential to contribute hole extraction and favorable interaction with uncoordinated Pb^{2+} ions. We concentrated on the electron releasing methoxy (-OMe) group substituted at *-ortho*, *-meta*, and *-para* positions of the phenyl ring of PEAI to explore not only the effect of the chemical identity but also the effect of substituent position. We developed a three step, straightforward synthetic methodology, which gave us easy access to all target cations. XRD, GIWAXS and SEM analyses confirmed the formation of 2D films on 3D perovskites, independent of the substituent position. PL and TRPL studies revealed that for the *o*-OMe-PEAI treated surfaces, strong passivation, hence, lower defect densities were achieved, compared to reference along with *m*-OMe and *p*-OMe analogues. Device results showed that *o*-OMe-PEAI based cells outperformed the reference, *m*-OMe and *p*-OMe based ones, showing PCEs over 23.3% with excellent V_{oc}(1.2V) and FF(80%). Highest efficiencies for *m*-OMe-PEAI, *p*-OMe-PEAI, and reference cells were 22.2%, 22.6% and 21.4% respectively. Detailed DFT analyses attributed the outlier performance of *o*-OMe-PEAI incorporated cells to the favorable formation energy and desired vertical orientation along with optimal surface coating of the 2DP layer.
One major advantage of 2DP passivation is the increased hydrophobicity of the surface due presence of large organic cations, thus higher stability. Contact angle analyses showed that while all salts showed more hydrophobic character compared to reference, *o*-OMe-PEAI treated surfaces were far superior. Hence, unique orientation of the *o*-OMe-PEAI on 3D perovskite surface improves performance and provides best protection for the 3D perovskite layer against moisture, simultaneously. Long term stability studies are currently underway however, as of 300 hours, *o*-OMe-PEAI based devices preserve 95% of their initial efficiencies whereas reference cells only retain 60%.
Encouraged by these results, we pursued a larger set of cations to gain further insight to the effect of chemical identity and position of substituents on 2DP passivation and device performance. Here, we synthesized 9 salts, with fluorine, chlorine and bromine as the substituents at *-ortho*, *-meta*, and *-para* positions. Interestingly, independent of the halogen, salts substituted at *-meta* position outperformed their *-ortho* and *-para* counterparts (averages = *m*-XPEAI: 23.2%, *o*-XPEAI: 22.5%, *p*-XPEAI: 22.1, ref.: 20.8%). Among different halogens at *-meta* position, *m*-BrPEAI gave only slightly higher PCE. DFT analyses revealed that lower formation energies and higher interfacial dipoles achieved by *meta*-substituted derivatives was responsible for the enhanced performance.
We are currently creating a larger library of ammonium cations with electronically distinct substituents to device a general set of design principles that could hopefully lead to the optimal material for commercial 2D/3D PSCs.

EN02.08.74
Thiol-Functionalized MoS2 Induced High Quality α-phase FAPbI3 Crystal for Efficient Perovskite Solar Cells Yifan Yin[1], Yuchen Zhou[1], Miriam Rafailovich[1] and Chang-Yong Nam[2]; [1]Stonybrook University, United States; [2]Brookhaven National Laboratory, United States

Formamidinium lead iodide ($FAPbI_3$) has become one of the most promising materials for high performance perovskite solar cells (PSC) due to its ideal band gap and broad light absorption spectrum. However, the readily transformation from black α-phase $FAPbI_3$ to photoinactive yellow δ-phase makes it difficult to prepare a high-quality phase-pure $FAPbI_3$ active layer. Meanwhile, the in-plane tensile strain and out-of-plane compressive strain during conventional solution-based film processing technique will cause the lattice mismatches and composition distribution in the polycrystalline multigranular grains, which would further limit the lifetime of PSCs.

Here, we introduced the thiol (3-Mercaptopropionic acid, 3-MPA) functionalized molybdenum disulfide (MoS_2) nanoflakes (NFs) into the $FAPbI_3$ perovskite layer. The MPA-MoS_2 NFs are incorporated through mixing with $FAPbI_3$ precursors when preparing the ink. The NFs are believed to severe as the crystallization agent and passivates the defects in the as-prepared films. We tracked the crystallographic evolution during thermal annealing with synchrotron-based in situ grazing-incidence wide angle (GIWAXS). The result shows that the MPA-MoS_2 forms an intermediate structure with FAI at the initial stage then facilitate the orientated growth of $FAPbI_3$. Moreover, based on the depth-dependent GIWAXS, the $FAPbI_3$ films with MPA-MoS_2 shows a reduced compressive strain across the film thickness direction. The strong interaction between MPA-MoS2 and the uncoordinated Pb^{2+} makes the NFs

attached closely to the grain boundaries, which forms efficient heat spreading channels thus modifying the thermal gradient during film preparation. As observed in SEM and XRD, respectively, the MPA-MoS_2 incorporated $FAPbI_3$ shows increases in average grain size with a 3-fold enhancement in crystalline peak intensity, suggesting the promotion of the perovskite crystal quality after the incorporation of the NFs. In addition, as witnessed in photoluminescence (PL) and lifetime decay measurements, the FAPbI3 with MPA-MoS2 NFs functionalized by monolayer of the MPA thiols exhibits quenching in PL intensity and lifetime, indicating more efficient the charge transport likely occurs in the NFs incorporated FAPbI3. PSCs with MPA-MoS_2 with a champion PCE of 22.3% have been achieved successfully, and the corresponding unencapsulated devices retain over 90% of their initial efficiencies in the ambient environment after 1600 h.

EN02.08.75
***Don't Let 'A-Site' Out of Sight*—Decisive Role of A-Site Cations in Controlling Band Edge States, Optical Properties and Stability of 0D Hybrid Indium Chlorides** Anuraj S. Kshirsagar, Yashpal Singh, Udara Kuruppu, Bruno Donnadieu, Neeraj Rai and Mahesh Gangishetty; Mississippi State University, United States

Organic-inorganic hybrid metal halides have been drawing attention due to their exceptional optoelectronic properties. Like lead halide perovskites, the optoelectronic properties of hybrid metal halides are governed by B-site cations and X-site halides; the frontier orbitals are localized on B and X sites. However, the role of A-site cations remains restricted in governing optoelectronic properties as their electronic levels lie away from the frontier orbitals. Conventionally, A-site cations are only believed to be useful for the stabilization of crystal structure. Rational engineering of A-site cations can offer opportunities to tailor the role of A-site in governing optoelectronic properties beyond structural stabilization. In my presentation, I will discuss the role of three different anilinium-based A-site cations in Sb^{3+}-doped zero-dimensional indium chlorides to control optical properties through their contribution to the band edge states. Our experimental and theoretical results demonstrate that with the increase in methyl substitution at the *ortho* position, *p*-orbital contribution near the band edge states increases, leading to the delocalization of the frontier orbitals across organic and inorganic moieties. Sb^{3+}-doped 0D indium chlorides exhibit broadband emission with high PLQY (maximum 93%) and excellent stability in a range of polar and non-polar solvents for 21 days, including water.

EN02.08.76
Revealing a New Formamidinium-Based Lead Triiodide Perovskite Material Derived from Chemical Degradation of a Common Additive in High Efficiency Perovskite Solar Cells Benjamin Gallant[1], Elisabeth Duijnstee[1], Joel Smith[1], Dominik Kubicki[2], Harry Sansom[1], Silvia Collavini[3], Bernd Sturdza[1], Philippe Holzhey[1], Alexandra Ramadan[1], Adam D. Wright[1], Chelsea Xia[1], Murali Gedda[4], Santanu Saha[1], Marina Filip[1], Thomas D. Anthopoulos[4], Michael Johnston[1], Robin Nicholas[1] and Henry Snaith[1]; [1]University of Oxford, United Kingdom; [2]University of Warwick, United Kingdom; [3]POLYMAT: Molecular and Supramolecular Materials Laboratories, Spain; [4]King Abdullah University of Science and Technology, Saudi Arabia

Despite its attractive low band gap, a key challenge for formamidinium lead triiodide ($FAPbI_3$) is to overcome its inherent ambient phase instability. A range of chemical additives have been employed in $FAPbI_3$-based solar cells to produce record efficiencies and enhance the stability of the photoactive $FAPbI_3$ α-phase. Here we grow $FAPbI_3$ single crystals from a solution containing one such common additive ($FAPbI_3$-A), which has been widely employed in high-performance solution-processed perovskite solar cells. We demonstrate that $FAPbI_3$-A crystals are stable against transformation to the photoinactive δ-phase for more than one year under ambient conditions, while $FAPbI_3$ crystals grown from a neat solution degrade within days. Critically, we reveal via nuclear magnetic resonance (NMR) spectroscopy that this common additive is unstable in solution and does not play an active stabilising role itself, instead degrading fully within minutes to a range of stable products via a complex chemical pathway, which we present. We show that $FAPbI_3$ crystals grown from a solution containing a certain one of these degradation products ($FAPbI_3$-D) replicate the enhanced α-phase stability of $FAPbI_3$-A. By performing a combination of liquid- and solid-state NMR measurements, along with X-ray diffraction (XRD) techniques, we find that previously unreported organic species are present in the $FAPbI_3$-A and $FAPbI_3$-D crystals. Remarkably, however, these correspond to neither the common additive, any of its stable degradation products nor any of the intermediates in its degradation pathway. Instead we are able to show that interruption of the degradation pathway by reaction of these intermediates with excess FA^+ generates alternative organic species in-situ. It is these alternative products that are incorporated into the $FAPbI_3$ bulk material and lead to α-phase stabilisation. We anticipate that presentation of our new understanding of the complex solution chemistry associated with this common high-performance additive will provide crucial insight for other researchers, immediately enabling more effective and controllable use of it, and direct use of its degradation products, in the fabrication of highly phase-stable α-$FAPbI_3$ perovskite materials.

SESSION EN02.09: Multi-Junction Cells and Modules

Sn-Pb Perovskite Solar Cells and Modules with Enhanced Efficiency and Stability Jinsong Huang; University of North Carolina-Chapel Hill, United States

Tin-lead (Sn-Pb) narrow bandgap (NBG) perovskites show great potential in both single-junction and all-perovskite tandem solar cells. Sn-Pb perovskite solar cells (PSCs) are still limited by low charge collection efficiency and poor stability. Compared to Pb-perovskites, their degradation is much faster under operation test, despite that they were shown to pass thermal stability tests. Here I will start with our understanding of the issues that limit the light stability of Sn-Pb perovskites. Then I will present our strategies in enhancing the stability using perovskite material modifications and interfacial engineering. I will also present how to upscale the related tandem cells into minimodules with partial processes done in air.

9:00 AM EN02.09.02
Fully Textured Perovskite/Silicon Monolithic Tandems Certified at 29.23% Xin-Yu Chin[1], Deniz Turkay[2], Florent Sahli[1], Peter Fiala[2], Daniel Jacobs[2], Kerem Artuk[2], Quentin Guesnay[2], Christian Wolff[2], Quentin Jeangros[1] and Christophe Ballif[1,2]; [1]Centre Suisse d'Electronique et de Microtechnique, Switzerland; [2]Ecole Polytechnique Fédérale de Lausanne, Switzerland

Tandems solar cell technologies have the potential to continue the learning curve of photovoltaics beyond what is achievable with crystalline silicon (c-Si) solar cells as the latter are approaching their practical efficiency limit. Amongst the different options to produce a tandem, stacking a metal halide perovskite cell on a c-Si cell represents the most promising approach to overcome this efficiency limit without significantly increasing production costs. The deposition of a perovskite top cell on a c-Si solar cells however requires certain adaptations, e.g., either flattening or downsizing the front-side

pyramidal texture of the c-Si sub-cell. This texture promises higher photocurrents due to reduced reflection losses and increased trapping of infrared light. However, due to layer conformality/homogeneity challenges, the presence of this texture has also held back advances in performance due to a limited choice of materials and processes to passivate and contact the perovskite absorber.
In this contribution, we will discuss several advances to mitigate voltage and fill factor losses affecting textured tandems. Specifically, the perovskite absorber is deposited here using an "hybrid" evaporation/spin coating process for compatibility with micrometer-sized pyramids. We replace the spiro-derivative hole transport layer with another small-molecule organic compound (TaTM) or a self-assembled monolayer (Me-4PACz). Such HTLs improve open circuit voltage, consistent with the increase in quasi-fermi level splitting extracted via photoluminescence measurement. Moreover, we use a commercially available ligand as an additive in the perovskite synthesis. This additive segregates on the perovskite top surface to alleviate some of the recombination losses occurring at perovskite/C_{60} electron transport layer interface. The improved interfaces enable the production of single junction cells with a V_{oc} of 1.2 V (for a bandgap of ~1.68 eV) and tandem cell V_{oc}'s of >1.9 V. Combined with the high photocurrent provided by the textured c-Si wafer, these modifications lead to a certified efficiency of 29.23%, an important step towards >30%-efficient tandems featuring an industry-standard c-Si front side.

9:30 AM EN02.09.04
Nanostructures Enable Perovskite/Silicon Tandem Solar Cells with Certified Efficiency of 29.80% Philipp Tockhorn[1], Johannes Sutter[1], Alexandros Cruz Bournazou[1], Klaus Jäger[1], Felix Lang[2], Max Grischek[1], Philipp Wagner[1], Danbi Yoo[1], Martin Stolterfoht[2], Bernd Stannowski[1], Steve Albrecht[1] and Christiane Becker[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]University of Potsdam, Germany

Perovskite/silicon tandem solar cells (PSTSC) recently achieved power conversion efficiencies (PCE) exceeding 29% [1, 2]. So far, the highest efficiencies were obtained for tandem solar cells with fully planar wafer front sides and solution-processed perovskite layers. To further increase the performance of PSTSC, it is important to reduce optical losses by implementation of textures on the perovskite subcell and other advanced concepts [3]. In this work, we present PSTSC with tailor-made sinusoidal nanotextures at the perovskite/silicon interface with 750 nm period nm and 300 nm structure height.
The front side of a silicon wafer was nanotextured in a three-step process employing nanoimprint lithography, reactive ion and wet-chemical etching [4]. The back side of the silicon wafers carried random pyramidal textures. Perovskite layers, which are spin-coated on nanotextured silicon bottom cells feature a planar top surface and adapt perfectly to the sinusoidal texture of the wafer. Importantly, these films tend to form less macroscopic pinholes compared to perovskite layers on planar silicon bottom cells, thus increasing the production yield. The nanostructures reduce reflection losses and in turn lead to a small optical gain in the silicon bottom cell.
To further understand the optical effect of the nanotextured interfaces in PSTSC, optical simulations with the finite element solver JCMsuite were conducted. The optical performance was maximized with a global (Bayesian) optimization of several layer thicknesses. Interestingly, for the optimized parameter sets, the simulations find no clear improvement of the nanostructured in comparison to the planar PSTSCs. A detailed sensitivity analysis reveals that the major benefit of the nanostructures is a higher tolerance against variations in thickness of the hydrogenated nano-crystalline silicon oxide (nc-SiO_x:H) layer.
In addition to the optical improvement, we find that the average open-circuit voltage (V_{OC}) of nanotextured PSTSC increases by approximately 15 mV as also confirmed by photo- (PL) and electroluminescence (EL) measurements. These results indicate that —remarkably— the nanotextures improve not only the optical but also the electronic quality of PSTSC. To further improve light management at the rear side of the silicon bottom cell, we integrated a dielectric buffer layer in combination with screen-printed silver grid fingers into the PSTSC [5]. This back contact design allows to mitigate parasitic absorption losses by reducing the thickness of the transparent conductive oxide (TCO) layer and by diminishing plasmonic losses in the silver back contact. With the combination of both investigated light management measures, we achieved a certified PCE of 29.80% (world record, as of 16 June 2022). We are confident that further finetuning of our approach combining nanostructures and dielectric buffer layer will push the PCE of PSTSC well above 30% in the near future.

Carrier Control in Sn-Pb Narrow-Bandgap Perovskites via 2D Cation Engineering for Efficient and Stable All-Perovskite Tandem Solar Cells Qi Jiang, Jinhui Tong and Kai Zhu; National Renewable Energy Laboratory, United States

Perovskite solar cells (PSCs) represent a competitive photovoltaic (PV) technology with rapid progress of efficiencies reaching a certified 25.5% efficiency for single-junction devices. The bandgap tunability through perovskite composition engineering is attractive for developing ultrahigh-efficiency tandem solar cells, including perovskite/perovskite, perovskite/silicon, or perovskite/thin-film absorber (e.g., CIGS). All-perovskite tandem solar cells are particularly attractive for achieving photovoltaics with power conversion efficiencies above the detailed balance limit of single-junction cells, while retaining the low-cost, light weight and other advantages associated with metal halide perovskite photovoltaics. However, the efficiency and stability of all-perovskite tandem cells are limited by the Sn-Pb-based narrow-bandgap perovskite cells. In this presentation, I will discuss our recent progress on improving Sn-Pb based narrow-bandgap (1.2–1.3 eV) perovskite absorbers by a new 2D additive engineering approach. The structural and optoelectronic properties of the Sn-Pb based perovskite thin films can be significantly tailored by controlling the specific 2D additive composition and structure. Under certain processing conditions, the Sn-Pb perovskite thin films exhibit low dark carrier density, long carrier lifetime, and low surface recombination velocity. These improvements on structural and optoelectronic properties lead to much enhanced performance of Sn-Pb based narrow-bandgap PSCs. When coupling the narrow-bandgap perovskite subcell with a wide-bandgap (>1.7-eV) perovskite subcell, we obtained highly-efficient all-perovskite 2-terminal tandems with excellent long operational stability.

10:30 AM *EN02.09.06
Strategies for Preparing Highly Efficient and Stable Perovskite/Si Tandems with Efficiencies over 29% Jin Young Kim; Seoul National University, Korea (the Republic of)

The power conversion efficiency (PCE) of the perovskite solar cells has been improved to 25.7%, which is highest among that of all multi-crystalline solar cells and is gradually approaching to the Shockley-Queisser (SQ) limit. Therefore, perovskite-based tandem solar cells are currently attracting significant

interest as potential candidates for overcoming the SQ limit of single-junction.[1] Among various perovskite-based tandem cells, perovskite/Si tandems are the most attractive combination because their highest certified PCE (29.8%) already surpasses that of the best reported single-junction solar cell (GaAs, 29.1%)[1]. In this presentation, recent progresses in the perovskite-based tandem solar cells researches made in our laboratory will be introduced,[2,3] especially focusing on the key strategies (e.g., photon management and defect passivation) for achieving highly efficient and stable perovskite/Si tandems with efficiencies over 29%. More specifically, the optical/electrical properties of the ITO/C60 window and ITO recombination layers could be optimized with aid of the optical simulation and new 3-terminal characterization platform. The defects located either at the grain boundaries or on the top surface of the wide-bandgap perovskite top cells could be successfully passivated by various additives and their engineering. In addition, a rational strategy for preparing the pure-iodide-based wide-bandgap perovskite top cell that is fundamentally free from the halide segregation (i.e., photostability) issue, and thus, showing excellent stability will be introduced.

Universal Lossless Interconnect for Perovskite-Organic and All-Perovskite Tandem Solar Cells. Kai O. Brinkmann[1], Tim Becker[1], Florian Zimmermann[1], Jarla Thiesbrummel[2,3], Francisco Pena-Camargo[3], Cedric Kreusel[1], Manuel Theisen[1], Tobias Haeger[1], Selina Olthof[4], Christian Tückmantel[1], Manuel Günster[1], Timo Maschwitz[1], Christine Koch[4], Dirk Hertel[4], Pietro Caprioglio[2], Lorena Perdigón-Toro[3], Amran Al-Ashouri[5], Lena Merten[6], Alexander Hinderhofer[6], Leonie Gomell[7], Siyuan Zhang[7], Frank Schreiber[6], Steve Albrecht[5], Klaus Meerholz[4], Henry Snaith[2], Dieter Neher[3], Martin Stolterfoht[3] and Thomas Riedl[1]; [1]Bergische Universitat Wuppertal, Germany; [2]University of Oxford, United Kingdom; [3]University of Potsdam, Germany; [4]University of Cologne, Germany; [5]Helmholtz-Zentrum Berlin, Germany; [6]University of Tübingen, Germany; [7]Max Planck Institute for Iron Research, Germany

The concept of multi-junction solar cells is very promising for the future of the solar cell technology, because it provides the potential to overcome fundamental efficiency limits of single-junction devices. The facile bandgap tunability of metal-halide perovskite solar cells renders them particularly attractive for multi-junction architectures. Besides Pb/Sn based perovskite low band gap materials, organic solar cells are becoming increasingly interesting as tandem partner for a perovskite wide bandgap cell. Especially, since the introduction of non-fullerene acceptors has revived the field and enabled organic solar cells with >18% efficiencies and an absorption spectrum extending well into the infrared region.[1] On the other hand, low gap perovskite materials are almost exclusively based on Sn^{2+} containing structures, where fundamental stability issues are still a serious topic.[2] However, serious concerns currently exist about photo instability of most non-fullerene organic systems. Now, to alleviate these concerns, we evidenced an outstanding operational stability (~ 95% PCE remaining after > 5000 h continuous operation) of an organic single junction that is based on the PM6:Y6 active system, if excitons are exclusively generated on the acceptor material Y6 (which is the case in a tandem application).
Aside from the active materials (all-perovskite or perovskite-organic), two terminal tandem cells critically rely on an interconnect that facilitates the recombination of electrons (holes) from the bottom cell with the holes (electrons) from the top cell. In most cases a direct stacking of both cells without dedicated interconnect results in poorly performing devices with s-shaped J-V characteristics. Thus, thin layers (~ 1 nm) of a metal (Ag or Au) are frequently inserted between top- and bottom-cell.[3] However, even an Ag-layer as thin as 1 nm already introduces significant optical losses that lower the EQE of the back-cell and the overall J_{sc} of the tandem cell as we could show.
Therefore, we developed an ultra-thin, ALD grown, metal-like indium oxide interconnect. We leverage the unique property of ALD to provide utmost control of layer thickness even on the level of Angstroms, which is impossible with conventional deposition techniques. We show, that 32 ALD cycles are enough to achieve an amorphous and pinhole free indium oxide layer of only 1.5 nm thickness that provides a charge carrier density of 10^{20} cm^{-3}. By this it is able to render the interface between the sub cells ohmic. At the same time the AZO/SnO_x/InO_x layer stack on top of the bottom cell offers a strong protection against the detrimental impact of follow-up processing, which enables swift integration in both perovskite-perovskite and perovskite-organic tandem solar cells. Moreover, due to the very limited thickness, the indium oxide causes only negligible optical losses while simultaneously offering unprecedentedly high shunt resilience.
Finally, by combining the indium oxide interconnect with a multi facet optimization of the wide gap perovskite solar cell, we were able to present high efficiency perovskite-perovskite devices (> 23.5%)[4] and, even more, we were able to set a new world record for perovskite-organic tandem solar cells (PCE = 24 %).[5]
This result marks a huge step forward since tandem solar cells are a key topic in order to overcome fundamental efficiency limits of single junction perovskites (realistic PCE potential > 30 %). We could show that ALD grown indium oxide can be utilized for both: high efficiency, tin-perovskite containing all-perovskite as well as world record tin-perovskite free, perovskite-organic tandem solar cells.

Emerging Perovskites-Based Tandem Solar Cells—Towards Efficient, Stable and Commercially Viable Photovoltaics Yi Hou; National University of Singapore, Singapore

The development of perovskite-based tandem solar cells represents a promising strategy to enhance the performance of traditional photovoltaics beyond the single-junction Shockley-Queisser limit. This talk will deliver the rationale behind wide-bandgap perovskite design for the different tandems [1-2], explain how the thin-film-based tandem solar cells reached high efficiencies, and unveil the potential of this technology. The advances reported herein show that it is possible – and powerful – to marry the traditional PVs and perovskite technologies in tandems.

Stabilization of Photoactive Perovskite Phase for Photovoltaic and LED Applications Ivan Mora-Sero; Universitat Jaume I, Spain

Formamidinium lead iodide ($FAPbI_3$) is the 3D lead perovskite with the highest theoretical efficiency due to its narrower band gap in comparison with Cs or methylammonium perovskites. Unfortunately, the black phase allowing this narrow bandgap is not the most stable one at room temperature. Here, we shown as the fabrication conditions and the interaction with semiconductor quantum dots can boost significantly the stability of $FAPbI_3$. The interaction of halide perovskite and colloidal semiconductor nanostructures (quantum dots or nanoplatelets) can produce interesting synergistic interactions. We show that the interaction of PbS quantum dots and nanoplatelets can produce the stabilization of $FAPbI_3$and $FACsPbI_3$ perovskite black phase and also the increase of the efficiency, stability and reproducibility of the photovoltaic devices prepared with these halide perovskites. Incorporation of PbS QDs allows the dramatic decrease of the annealing temperature for the formation of black $FAPbI_3$ phase perovskite thin film, from the 170C required without QDs to 85C when QDs are present. In addition, stability of these systems including embedded nanostructures is extended not just for samples prepared in the glove box but fabricated in ambient conditions. These result points the interest of Perovskite-Quantum Dot Nanocomposites, for further development of advanced optoelectronic devices. Stabilization of tin based perovskite solar cells will be analyzed.
In addition, stabilization of halide perovskite nanoparticles is a necessary step for the development of high performance Halide Perovskite LEDs. Control of post synthetic washing processes allows the preparation of LEDs with enhanced performance and stability.

Strain Evolution in Hybrid Perovskite Thin Films Revealed by Simultaneous *In Situ* Multi-Modal Substrate Curvature, Spectroscopic and Structural Characterizations Boyu Guo[1,1], Mihirsinh Chauhan[1,1], Nathan Woodward[1,1], Gabriel McAndrews[2,3], Tonghui Wang[1,1], Kasra Darabi[1,1], Michael McGehee[2,2,3] and Aram Amassian[1,1]; [1]North Carolina State University, United States; [2]University of Colorado Boulder, United States; [3]National Renewable Energy Laboratory, United States

Hybrid metal halide perovskites are promising to displace other thin film photovoltaic technologies thanks to their high power conversion efficiency (PCE) up to 25.7%, low materials and fabrication costs, and overall ease of manufacturing. Hybrid perovskite thin films deposited on inorganic substrates are believed to exhibit a tensile strain due to mismatch of coefficient of thermal expansion (CTE), which is more than one order of magnitude larger for the hybrid perovskite than typical inorganic substrates like glass and silicon. For photovoltaic devices, the film strain is inevitably present, and several studies have linked device performance and stability to the presence of residual strain. Much effort has therefore been made to engineer the film strain, relying primarily on ex situ characterization methods. Therefore, significant questions remain about the origins of strain, its low magnitude in some instances, and its relationship to solution processing and halide diffusion in hybrid perovskites.

In this work we report, for the first time, integration of multi-beam optical sensor (MOS) experiments together with the entire solution processing and annealing workflows of metal halide perovskite thin films to measure in real time the changes in substrate curvature during solution processing and thin film formation. By combining *in situ* curvature measurements with *in situ* photoluminescence, absorbance, and GIWAXS measurements we reveal, for the first time how the anti-solvent drip triggers the phase transformation of hybrid perovskite near the surface of a supersaturated sol. Phase transformation leads to considerable volume reduction which is felt by the substrate within seconds. This insight reveals that even conversion of a small fraction of the sol into perovskite can cause strain evolution in the substrate, indicating substantial mechanical coupling to the substrate. We go on to demonstrate that thermal annealing causes compressive strain to form due to CTE mismatch, with tensile strain developing during subsequent cooling of the sample. The magnitude of the strain is considerably lower than predicted by the CTE mismatch and points to stress relaxation behavior at elevated temperature, which we will discuss briefly.

2:45 PM EN02.10.05
Role of Ion Migration and Reactivity with Contacts in Halide Perovskite Memristors Antonio Guerrero; Institute of Advanced Materials (INAM)), Spain

Halide perovskites are mixed electronic and ionic conductors that find applications in solar cells, light emitting diodes or memory storage devices.[1] The ionic conductivity is connected with the hysteresis observed in the electrical characterization of several electronic devices.[2] Ions can migrate and will interact with the external contacts *via* physical and chemical interactions leading in some cases to device degradation pathways.[3] Ion migration can be used to our advantage to promote formation of conductive and insulating states making them useful as resistive memories (memristors). Here we show that the working mechanism and performance of the memory devices can be tuned and improved by a careful selection of each structural layer. Several configurations are evaluated in which structural layers are modified systematically: the nature of the buffer layer,[4] nature of the metal contact[5] and formulation of the perovskite[6]. We show that the properties of the memory device may be modified upon desire from volatile to non-volatile memories. In addition, we also develop an electrical model to account for the observed j-V response.[7] Overall, we provide solid understanding on the operational mechanism of halide perovskite memristors that unveils the connection between electronic and ionic conduction.

Strategies to Tame Complexity and Variability in the Perovskite Composition-Process Space David P. Fenning, Deniz N. Cakan, Zhewen Deng, Connor Dolan, Sean P. Dunfield, Apoorva Gupta, Clark Han, Moses Kodur, Rishi E. Kumar, Eric Oberholtz and Jack Palmer; University of California, San Diego, United States

The compositional and process flexibility of perovskite halides is fundamentally attractive for discovering new materials and advancing figures of merit of existing perovskite technologies. However, the same flexibility also gives rise to challenges in reproducibility across research groups, across operators within single research groups, and across time, slowing cycles of learning. Furthermore, resultant microscopic heterogeneity has been linked to performance and durability losses. Here, steps to automate perovskite solution synthesis are discussed as a means to achieve precise reproduction of processing, allowing for the distinction between process-induced variability and the underlying materials chemistry. Alternative approaches to transport layer and perovskite processing that reduce the use of solvents, relax requirements for solvent compatibility, and show promise for narrow performance variation will also be discussed. Nanoprobe X-ray investigations of resulting perovskite films and devices for single-junction and tandem solar cell applications provide supporting evidence into process dependence on composition, strain and optoelectronic outcomes.

Elucidating the Mechanisms of Halide Perovskite Nanocrystal Syntheses Carola Lampe, Kilian Frank, Bert Nickel and Alexander S. Urban; LMU Munich, Germany

Halide perovskite nanoplatelets (NPLs) are a promising material for light-emitting applications, including LEDs and single-photon emitters. Two-dimensional $Cs_{n-1}Pb_nBr_{3n+1}$ NPLs with monolayer-precise control over their thickness can be obtained through a ligand-assisted synthesis. Through quantum confinement, they exhibit narrow and bright photoluminescence (PL) with an emission wavelength tunable between 435 and 515 nm. While the optoelectronic properties of perovskite NPLs are widely understood, little is known about how the synthesis of these promising emitters proceeds, impeding further improvement.

To this end, we developed an in-situ reactor cell to simultaneously acquire small-angle and total X-ray scattering (SAXS and TS) and PL emission at the DESY synchrotron during the synthesis of halide perovskite NPLs with a time-resolution of <50 ms. The NPL synthesis routine is based on combining a $PbBr_2$ ligand solution and Cs-oleate with a subsequent injection of the antisolvent acetone. The synthesis is carried out in a glass capillary within a copper block with stepper motor-controlled syringe pumps to inject precursor solutions.
An analysis of the SAXS data reveals that the NPLs begin to form immediately upon the combination of the two precursor solutions and not upon injection of the antisolvent. Accordingly, contrary to the common understanding, the $Cs_{n-1}Pb_nBr_{3n+1}$ NPL synthesis is not based on ligand-assisted reprecipitation but on well-defined precursor handling. However, the antisolvent still plays a crucial role, as it induces a superstructure assembly of the NPLs, leading to a greater monodispersity and enabling the sedimentation and purification of the NPLs. Furthermore, we investigated the structural and optical changes during the post-synthetic enhancement step and halide ion exchange within the same experimental setup. The presented combination of in-situ X-ray scattering and PL spectroscopy proves to be a powerful tool for understanding synthetic mechanisms.

4:15 PM EN02.10.08
Universal Mechanism of Luminescence Enhancement in Doped Metal-Halide Perovskite Nanocrystals from Symmetry Analysis Sascha Feldmann; Harvard University, United States

Metal-halide perovskite nanocrystals have demonstrated excellent optoelectronic properties for light-emitting applications. Isovalent doping with various metals (M^{2+}) can be used to tailor and enhance their light emission. Although crucial to maximize performance, an understanding of the universal working mechanism for such doping is still missing. Here, we directly compare the optical properties of nanocrystals containing the most commonly employed dopants, fabricated under identical synthesis conditions. We show for the first time unambiguously and supported by first principles calculations and molecular orbital theory that element-unspecific symmetry-breaking rather than element-specific electronic effects dominate these properties under device-relevant conditions. The impact of most dopants on the perovskite electronic structure is predominantly based on local lattice periodicity breaking and resulting charge carrier localization, leading to enhanced radiative recombination, while dopant-specific hybridization effects play a secondary role. Our results provide specific guidelines for selecting a dopant to maximize the performance of perovskite emitters in the desired optoelectronic devices.

How Can Synchrotron Measurements Support the Development of Perovskite Materials and Devices? Michael E. Stuckelberger; Deutsches Elektronen-Synchrotron DESY, Germany

Halide perovskites are arguably the most astonishing materials class of the last decade. The ensemble of uncommon and tunable properties predestines halide perovskites for their exploitation in devices for photovoltaic energy harvesting and sensing – at least theoretically. In practice, the tunability comes at the cost of lacking stability and uniformity, which hampers many large-scale applications.

While great efforts are made to experimentally address the stability and uniformity issues, the nanoscale understanding of halide perovskite materials challenge the characterization community at several levels: How to achieve at the same time nanoscale spatial resolution and large-scale statistics to support findings with evidence? How to disentangle measurement-induced artifacts from material and device properties? How to explore the perovskite chemistry in fully assembled devices in-situ and operando?

Synchrotrons offer X-ray sources with unprecedented intensity that can be exploited in multiple ways – each of them providing deep insight into specific aspects: Imaging in 2D and 3D shows details in buried layers with resolution beyond the diffraction limit of visible light, spectroscopy the nature of chemical bonds, diffraction crystallographic information from structure to lattice distortions.

The entire suite of X-ray modalities can be bundled into multi-modal scanning X-ray microscopy [1]. Advanced X-ray focusing schemes enable raster-scanning halide perovskite samples in multiple dimensions:
(i) X-ray fluorescence (XRF) unveils the distribution of elements [2]
(ii) Nano-diffraction (nano-XRD) unveils structural information at sub-grain level
(iii) X-ray beam induced current (XBIC) unveils the local charge-collection efficiency of devices [3]
(iv) X-ray excited optical luminescence (XEOL) in temporally- (TR-XEOL) or spectrally-resolved mode (SR-XEOL) unveil the local charge-carrier

lifetime and bandgap
(v) Ptychography unveils the electron density [4]

The simultaneous assessment enables point-by-point correlations [5], ultimately elucidating Materials Paradigm of halide perovskites by shining light on the synthesis-structure-property-performance relationship. Based on measurements at hard X-ray nano- and microprobe endstations at DESY, APS, ESRF, and NSLS II, we will introduce different scanning X-ray microscopy techniques [6] and showcase our latest measurements of halide perovskites.

Finally, we will give an outlook to current developments in the synchrotron world: in the coming years, the most brilliant diffraction-limited storage rings in the US (APS-U) and in Europe (PETRA IV) will bring scanning X-ray microscopy to an entirely new level. Discussing opportunities and challenges in X-ray based metrology, we seek to trigger a discussion about future needs for halide perovskite research and access to hard X-ray nanoprobes to enable efficient and timely use of synchrotron radiation for perovskite materials and devices.

2D or not 2D? What's Behind Interfacial Engineering in 2D/3D Perovskite Solar Cells Giulia Grancini and Matteo Degani; University of Pavia, Italy

Three-dimensional (3D)/low-dimensional (LD) perovskite solar cells (PSCs) offer an effective strategy to overcome the trade-off between perovskite solar cells device performance and stability. The most successful architecture consists of a bilayered structure where the LDP forms a thin capping layer on top of the 3D bulk, improving the device longevity, while concomitantly simultaneously enhancing increasing the solar cell open circuit voltage and fill factor of the solar cell. Despite being one of the most popular and effective way processing techniques, whether the presence of this surface LDP layer would be - or not-represents the winning crucial path for the future of this technology remains elusive. In particular, atomic layer combined surface and bulk passivation using surface modifiers such as organic dopants, casts the doubts on the effective need for of having an homogeneous LDP cover capping layer. In this talk I will compare recent results obtained in the 3D/LDP configuration with the surfacecation passivation strategy, which can still pushes produce the performances to values comparable to the LDP/3D bilayers. I will providing a comprehensive perspective on the benefits from of the two different strategies, but also presenting how LDP interfaces can play a role in alternative new configurations, such as tandem solar cells [1,2].

Acknowledgements I acknowledge the "HY-NANO" project that has received funding from the European Research Council (ERC) Starting Grant 2018 under the European Union's Horizon 2020 research and innovation programme (Grant agreement No. 802862).

Highly Performed Near Infra-Red Photodetector and Its Array Based on SnPb Based Perovskites Wallace C. Choy; University of Hong Kong, China

Sn-Pb perovskites have shown their potentials in wide-bandgap photovoltaics and near-infrared photodetection applications which could become alternatives to traditional silicon and inorganic devices. To achieve efficient devices, high-quality and thick Sn-Pb perovskite films featuring well-packed, smooth, pinhole/void-free are highly desirable. Besides, understanding the crystallization kinetics and tuning the crystallization are fundamentally important to reach the Sn-Pb perovskite films, and have been limitedly explored. Herein, we propose an approach of double-side crystallization tuning through low-temperature space-restricted annealing in MA-free Sn-Pb perovskite films. By simultaneously retarding the crystallization in the top of precursor films and promoting the crystal growth of the bottom of precursor films, we achieve high-quality and block-like 1 μm thick Sn-Pb perovskite films with improved crystallinity and reduced trap density [1]. The photovoltaic-mode Sn-Pb perovskite near infra-red photodetectors show a high and flat external quantum efficiency of ~80% at 760-900 nm, a recorded responsivity of 0.53 A/W, and a high specific detectivity of 6×10^{12} *Jones* at 940 nm. The high-quality Sn-Pb perovskite can also be fabricated on metal/ silicon substrates for promoting direct integration with CMOS electronics and realizing an efficient photodiode imaging array [2].
Meanwhile, with the incorporation of rubidium cation, we can achieve controllable crystallization for growing high-quality films with the improvements of increased crystallinity and strengthened preferred orientation. Our theoretical results show that rubidium incorporation causes lower surface energy of (110) plane, facilitating growth in the dominating plane and suppressing growth of other competing planes. Consequently, the Sn-Pb perovskite photodetectors simultaneously achieve larger photocurrent and lower noise current. Finally, highly efficient UV-VIS-NIR (300-1100 nm) photodetectors with record-high linear dynamic range of 110 dB and 3-dB cut-off frequency reaching 1 MHz are demonstrated. This work contributes to enriching the cation selection in Sn-Pb perovskite systems and offering a promising candidate for low-cost UV-VIS-NIR photodetection [3].

8:45 AM EN02.11.04
Sn-Based Perovskite Solar Cells with Inorganic Hole Transport Layer Liang Wang, Qing Shen and Shuzi Ishi-Hayase; The University of Electro-Communications, Japan

Sn-based perovskite solar cells (PSCs) shows the best power conversion efficiency among all Pb-free-based PSCs due to its ideal narrow bandgap (1.4eV), small exciton binding energy, high carrier mobility and environment friendly. It becomes a potential candidate to replace toxic Pb-based perovskite. Commonly, inverted device structure with PEDOT:PSS as hole transport layer (HTL) are broadly used in Sn-based PSCs. However, the sensitivity of humidity and acidity of PEDOT:PSS limits the improvement of Sn-based PSCs stability and performance because of its nature of Lewis acidity. Therefore, searching inorganic HTL materials is also an important part for industrial application due to their intrinsic stability and low cost. In this study, an inorganic HTL was in-situ prepared by simple method and applied for Sn-based PSCs directly. It shows rapid carrier transportation from perovskite to HTL than that of PEDOT:PSS based. Finally, a 11.97 % power conversion efficiency was obtained, which is comparable to PEDOT:PSS based device (11.68 %).

9:00 AM EN02.11.07
Monolithic All-Perovskite Triple-Junction Solar Cells with Suppressed Non-Radiative and Optical Losses Junke Wang, Lewei Zeng, Aidan Maxwell, Hao Chen and Edward H. Sargent; University of Toronto, Canada

Multijunction solar cells represent an effective approach to surpassing the ~33% power conversion efficiency limit of ideal single-junction devices by paring multiple absorber layers with cascaded bandgaps. Optical simulations suggest that monolithic all-perovskite triple-junction solar cell comprising 2.0 eV, 1.5 eV, and 1.2 eV perovskite absorbers has the potential to reach a high efficiency of 36.6%. Reducing V_{oc}-to-bandgap loss in the wide-bandgap sub-cell and enhancing optical response in the narrow-bandgap sub-cell are key to the performance of such devices.

In this contribution, we report effective strategies to manipulate defects at the buried and top interfaces of wide-bandgap perovskites. A dual surface treatment technique helps reduce the non-radiative recombination losses at the perovskite/charge transport layer heterojunctions, yielding a high open-circuit voltage of over 1.4 V and fill factor of 85% with a 1.98 eV perovskite absorber. Furthermore, an optically benign transparent electrode significantly improves near-infrared absorption in the 1.2 eV narrow-bandgap perovskite sub-cell, resulting in current-matched triple-junction solar cells with a short-circuit current density of over 10 mA cm^{-2}. After optimization, we demonstrate efficient all-perovskite triple-junction solar cells with power conversion efficiencies of over 26%.

9:15 AM EN02.11.06
Inkjet-printed lead-free red emitting LEDs based on 2D-perovskite PEA_2SnI_4 Giovanni Vescio[1], Jesús Sanchez-Diaz[2], Gayathri Mathiazhagan[1], Sergi Hernandez[1], Ivan Mora-Sero[2], Albert Cirera[1] and Blas Garrido[1]; [1]Universtat de Barcelona, Spain; [2]Universitat Jaume I, Spain

Lead Halide Perovskites (LHPs) have attracted attention over the last decades because of their excellent optoelectronic and semiconducting properties. However, Pb^{2+} presents a great inconvenience in the development procedure of these materials, as it is highly toxic and contaminant. The Sn^{2+} is the most obvious substitute for Pb because of the similar ionic radius and the similar electronic configuration to Pb^{2+}, which makes it possible to form a perovskite with a formula $ASnX_3$ like the lead-based counterparts.
In recent years, 2D halide perovskites have become a striking research spotlight. It is noteworthy that low-dimensional Sn^{2+}-based halide perovskites exhibit remarkably enhanced air stability in comparison with their 3D counterparts. Moreover, 2D perovskites presents large exciton binding energy and outstanding thermal stability.
In this work, the stability, because of the large organic cations, and emission properties of single-layer 2D tin perovskite nanoplates with chemical formula PEA_2SnI_4 (PEA= phenylethylammonium) and pure red emission are reported.
An ink solution of PEA_2SnI_4 based on molecular precursors dissolved on DMSO has been prepared for inkjet printing technology. The morphology of inkjet-printed films was characterized via SEM and optical microscopies to observe the uniformity of the films and obtaining the best conditions for producing pin-hole free layers. These results were combined with XPS measurements that allow characterizing the composition of the layers and XRD to determine crystalline structure and micro/nanocrystal size. Finally, optical analysis like absorbance and PL (photoluminescence) spectra allows measuring band gap and confirm that the layers are optically active with the expected narrow red emission at ~630 nm.
The inkjet-printed PEA_2SnI_4-based light-emitting diode (LED) exhibits a maximum external quantum efficiency (EQE) of 1% with an average of 0.7% and a brightness of 30 cd/m^2, which are comparable to that of the control devices obtained by spin coating. Moreover, lifetime test shows an operating half-life exceeding 3 hours at an initial brightness of 10 cd/m^2.
This work paves the way for inkjet-printed Cd- and Pb-free perovskite light-emitting devices for a wide variety of low-cost and customizable applications.

9:20 AM EN02.11.08
Efficient 2-Terminal All-Perovskite Tandem Solar Cells by Multisource Evaporation Yu-Hsien Chiang, Miguel Anaya, Kyle Frohna, Hayden Salway, Anna Abfalterer, Bart Roose and Samuel D. Stranks; University of Cambridge, United Kingdom

The rapid screen of perovskite solar cells optimization based on solution-processed methods have achieved historical successfully. The next stage of technology development is to transfer from the lab research to fab production lines. Therefore, another deposition route for scalability and modularity needs to be studied. Our work employs a novel dual-interface treatment to maximize the performance of evaporated perovskite devices, which show great promise when implemented into tandem architectures. We employ a 4-source vacuum deposition method to demonstrate perovskites of the tunable bandgap. Engineering the device architecture via the use of a MeO-2PACz layer as HTM demonstrates a 20.7% PCE in a 1.62 eV bandgap perovskite solar cell, which is among the highest performance in a multisource evaporated system. The use of several sources allows precise control over the halide content in the perovskite composition, which is crucial to enlarge its bandgap and make it relevant for widegap subcells for tandem architectures. Halide segregation is a key factor to consider when designing widegap perovskites and we find that a $FA_{0.7}Cs_{0.3}Pb(I_{0.66}Br_{0.34})_3$ film with a 1.77 eV shows great phase stability under light-soaking, though devices display suboptimal voltages. In order to minimize non-radiative losses, we introduce a surface treatment to passivate the evaporated perovskite that translates into 17.8 % PCE devices with a remarkable Voc of up to 1.26 V, which is among the best in evaporated perovskite solar cells. This method is versatile and reproducible, and we extend it to Pb/Sn-based narrow gap perovskite solar cells reaching a Voc of 0.86 V. Incorporating the narrowgap and widegap perovskite building blocks into a 2-terminal tandem solar cell, we obtain a PCE of 24.1% with a promising Voc of up to 2.06 V, which is unprecedented for a system where either of the subcells is deposited by dry methods. This result represents a major step forward in the realization of third-generation multijunction solar cells of superior performance. Our work opens a myriad of possibilities benefiting from the intrinsically scalable, conformal, and reproducible character of vacuum deposition methods, opening the path to the integration of advanced photonic strategies to push perovskite photovoltaics to their limits.

Controlling Spin-Orbit Interactions in Hybrid Metal-Halide Perovskites with Magnetic Doping and Chirality Felix Deschler; University of Heidelberg, Germany

Materials combining the optoelectronic functionalities of semiconductors with control of the spin degree of freedom are highly sought after for the advancement of quantum technology devices and provide exciting avenues for polarized light-emission.
In my talk, I will present our efforts on gaining control over spin dynamics and spin-orbit interactions through compositional and structural tuning in solution-processable hybrid perovskite semiconductors. In a first direction, we aim to exploit the exceptional optoelectronic properties of these hybrid perovskites, together with their tolerance in the electronic states to dopants and defects, to make advances towards high-performance dilute magnetic semiconductors. I will discuss how we can employ ultrafast optical spectroscopy for insights into exciton population dynamics and ultrafast optical control of spin dynamics in novel hybrid perovskite materials incorporating transition-metal dopants. In a second direction, we aim to design spin-orbit interactions by tailoring the chiral crystal symmetry of hybrid metal-halide perovskites. I will present our results on chiral lead-free low-dimensional bismuth-based materials, as well as recent advances in maximizing luminescence and polarization in lead-halide systems.

11:00 AM EN02.12.02
Structural and Electronic Characteristics of Double and Mixed Cs_2GeX_6 (X= Br, I, Cl) Perovskite from First Principles David Obada, Simeon Abolade, Syam Kumar and Akinlolu Akande; Atlantic Technological University, Ireland

Lead-free metal halide perovskites are increasingly receiving attention for the commercialization of optoelectronic devices. In this study, first principles simulation using density functional theory has been used to investigate the structural and electronic properties of non-toxic Cs_2GeX_6 (X= Br, I, Cl) with a mixed halide counterpart $Cs_2GeBr_xCl_{1-x}$ (x=0.25, 0.5) using the virtual crystal approximation (VCA). The trend in the gradients observed in the lattice constants of the perovskites followed the increase in ionic radius of the halides. The investigation of the electronic properties showed semiconducting properties for Cs_2GeCl_6 and Cs_2GeBr_6 perovskites, while semiconducting to metallic transitions were observed for the Cs_2GeI_6 and $Cs_2GeBr_xCl_{1-x}$ perovskites. The values obtained for the direct bandgaps of Cs_2GeCl_6 and Cs_2GeBr_6 were 2.28 eV, and 0.93 eV, respectively. The elastic constants calculations showed that the perovskite compounds were mechanically stable. The physics behind the semiconducting to metallic transitions for some of the perovskite compounds studied have been discussed. Our datasets provide useful information for fundamental research on Cs_2GeX_6 perovskites and its practical applications in emerging optoelectronics.

11:15 AM EN02.12.03
Regulating the Spatial Profile of Surface Potential Maximizes Open-Circuit Voltage in Wide-Bandgap Devices Hao Chen, Sam Teale, Bin Chen and Edward H. Sargent; University of Toronto, Canada

Wide-bandgap perovskites (>1.7 eV) are widely used in all-perovskite tandem solar cells, which have the potential to break the Shockley–Queisser limit. However, the open circuit voltage (V_{OC}) deficit in wide-bandgap perovskite solar cells (PSCs) is very large because of the inhomogeneous surface potential and poor energetic alignment between perovskite and ETL, which limits the V_{OC} below 1.3 V. Here, using quasi fermi level measurements, we reveal the key role of increased recombination when the perovskite is in contact with an electron transport layer (ETL). We find common monoammonium surface treatments fail to address this; whereas diammonium molecules modify the perovskite surface states and achieve a more favorable band alignment with a more uniform distribution of the surface potential in space. Processing the perovskite surface with diammonium salts increases the photoluminescence quantum yield of *pin*-stacks 40-fold, and increases the QFLS by 90 meV. Treated 1.78 eV PSCs achieve a certified 1.33 V V_{OC}, and > 19% power conversion efficiency (PCE).

11:30 AM EN02.12.04
A Simple Route to the Synthesis and Deposition of All Inorganic Perovskite $CsPbBr_3$ Films and Their Photocatalytic Properties Lorenzo Sirna[1,2], Anna L. Pellegrino[1,2], Francesca Lo Presti[1,2] and Graziella Malandrino[1,2]; [1]Università di Catania, Italy; [2]INSTM, Italy

The compounds belonging to the family of perovskites exhibit a wide range of mechanical, magnetic, and optical properties and for these reasons are currently key materials for many technologies, such as piezoelectrics, photocatalytic systems, and photovoltaic solar cells. Among perovskites, the all-inorganic halide perovskites (AIHPs) with the ABX_3 structure (with A = Cs, Rb; B = Pb, Sn and X = F, Br, I) represent an emerging class of materials that have drawn a growing interest due to the combination of the advantages of containing cheap and abundant elements with the excellent stability of these structures by excluding organic species sensitive to the external environment.

Particularly, our attention is devoted to $CsPbBr_3$ all-inorganic perovskites, which, among other effects, have emerged for photocatalytic degradation processes of different organic dye compounds. In fact, one of the most challenging applications of AIHP materials regards the wastewater purification process of textile effluents from industrial production. In this field, heterogeneous catalysis under light is widely accepted due to its high efficiency, yield of degradation, and cost effectiveness. For these reasons, $CsPbBr_3$ in the form of films, being immobilized and not used as a dispersed phase, has the advantage of a simple separation and recovery from the solution. Therefore, a smooth, continuous well-covering thin film on a regular substrate is preferred.

Herein, we report a novel method for the synthesis of $CsPbBr_3$ films on different substrates such as silicon, glass, quartz, and flexible substrates. The present synthetic strategy is a facile, one-step, and low-temperature approach to the synthesis of Cs-Pb halide perovskite and takes advantage of the Cs and Pb β-diketonate compounds as precursors, allowing, reproducibly and selectively, the synthesis of the $CsPbBr_3$ phase. The as obtained $CsPbBr_3$ suspension is deposited onto the substrates by spray deposition at room temperature and atmospheric pressure. This approach reveals to be very simple and extremely versatile and makes it possible to deposit the perovskite on a wide range of different kinds of materials.

Structural, morphological, and compositional analyses of the final products, carried out by X-ray diffraction (XRD), field-emission scanning electron

microscopy (FE-SEM), and Energy Dispersive X-ray analysis (EDX), show the formation of the pure $CsPbBr_3$ system. Uv-vis spectrophotometric analyses were performed in order to determine the bandgap energy (E_g) of the system. Preliminary results on photodegradation of an organic dye under both visible or UV light irradiation will be presented.

11:45 AM EN02.12.05
Anion Vacancy Defect Passivation of 2D-Layered Tin-based Perovskite Thin-Film Transistor Jaehyeok Cho and Myung-Gil Kim; Sungkyunkwan University, Korea (the Republic of)

Organic-inorganic hybrid perovskites have been intensively investigated for solar cells, optoelectronics and electronic applications with its high light absorption, defect tolerance, and high carrier mobility. Moreover, the hybrid perovskites offer the mechanical flexibility and solution processability. However, it is still challenging to achieve a reliable operation of electronic devices due to ion migration, which may lead to poor field-effect mobility with large current-voltage hysteresis. Such ion migration in perovskite films causes a screening of the applied electric field and thereby adversely impacts the device performance. In this research, we focused on using lead-free tin-based perovskites as the semiconductor in thin-film transistors (TFTs). we introduced anion vacancy suppressing additives in the perovskite precursor to passivate defects at the grain boundaries, thereby improving transistor characteristics. This work provides an effective way to achieve the high-performance in organic-inorganic hybrid perovskite TFT devices.

11:50 AM EN02.12.07
Photoluminescence Quenching Switching from Open- to Short-Circuit as a Figure of Merit for the Efficiency in Perovskite Solar Cells Valerio Campanari[1], Faustino Martelli[1], Antonio Agresti[2], Sara Pescetelli[2], Narges Yaghoobi Nia[2], Francesco Di Giacomo[2], Daniele Catone[1], Patrick O'Keeffe[1], Stefano Turchini[1], Bowen Yang[3], Jiajia Suo[3], Anders Hagfeldt[3] and Aldo Di Carlo[2,1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Roma Tor Vergata, Italy; [3]Uppsala University, Sweden

The photoluminescence (PL) intensity is often used as an indicator of the performance of perovskite solar cells (PSCs) and indeed steady-state PL is often used for the characterization of these devices and their constituent materials. However, some features of perovskite materials and devices, if not taken adequately into account, could lead to misleading results.[1] In this work we show that the value of the photoluminescence quenching occurring when the PSCs are switched from open- to short-circuit is an excellent figure of merit (FOM) for the evaluation of the PCS efficiency. Moreover, in order to take into account the large inhomogeneity of the performance in the PCS yield and their temporal instability, we have used a systematic approach to comparison the PCS conversion efficiency and their PL intensity using a large group of PSCs with efficiency varying from 5.63% to 21.5%.
The PSCs were fabricated using different materials both as regards the absorbing materials and the transport layers, different structures, and relatively different fabrication processes. We found that the use of the bare PL intensity in open-circuit (OC) is not a general and reliable indicator of the performances when a large heterogeneous ensemble of devices is used, Instead, considering the values of the PL intensity both at open OC and short circuit (SC)[2,3], it is possible to correlate the PL intensity to the device power conversion efficiency (PCE) through a FOM based on the quenching of the PL observed in SC conditions ($PLQ_{oc\text{-}sc}=(PL_{oc}-PL_{sc})/PL_{oc}$).[4] We explain the observed correlation between $PLQ_{oc\text{-}sc}$ and the PCE of the device by means of a simplified model based on the carrier density rate equation, in which the extraction time of the photoexcited carriers in the PSC is duly considered. We have also shown that the analysis of $PLQ_{oc\text{-}sc}$ using our model can provide a tool to estimate the carrier extraction time in PSCs through a simple cw-PL measurement, provided the carrier lifetime in OC conditions is known. Without suggesting that a PL measurement can substitute a *J-V* characterization, we point out that our study is an important contribution to the understanding the physical mechanisms underlying carrier recombination and extraction. Moreover, we have found a clear correlation between the increase over time of the PL intensity in SC conditions and the contemporary decrease of the short-circuit current, I_{sc}, a feature that can be easily understood within the framework of our model and FOM.

A Perspective on Sodium-Ion Batteries Marca M. Doeff, Wei Yin and Gozde Barim; Lawrence Berkeley National Laboratory, United States

Sodium-ion batteries (NIBs) have the potential for addressing cost and supply security concerns associated with energy storage for large-scale applications, such as grid storage and electric vehicles. Not only is sodium itself much cheaper and more abundant than lithium, but devices based on sodium also can avoid other strategic, scarce, or costly metals, including cobalt, nickel, and copper. The energy density of state-of-the-art sodium-ion batteries now meets or exceeds that of lithium-ion batteries with lithium iron phosphate cathodes. There are also some potential performance advantages over lithium-ion batteries such as higher power density, better low temperature performance and, possibly, better safety.
A disadvantage, however, is the limited choice of anode materials. Graphite does not intercalate sodium to a useful extent, so hard carbons are the most commonly used negative electrodes in NIBs. The very low potentials at which sodium intercalates into hard carbons means that there is a risk of sodium plating under certain use conditions. We have been investigating titanate anodes as a potential alternative to hard carbon anodes for NIBs. A number of stepped layered ternary or quaternary sodium titanates exist, which intercalate sodium reversibly at moderately low potentials (~0.3-0.6V vs. Na^+/Na). Some of these exhibit capacities in excess of 200 mAh/g, sometimes greater than that predicted solely by intercalation of sodium into available sites. A kinetic investigation of these interesting materials reveals hybrid redox mechanisms, in which both diffusional (intercalation) and surface (pseudo-capacitive) processes contribute to the electrochemistry. The relative contribution of these processes can be tuned by manipulating the structure; e.g. controlling surface defects, thermal treatments, or heterostructuring. The latter approach involves synthesis of titanate layers interleaved with carbon. This talk will cover these approaches and the electrochemistry of these titanates in detail.

11:00 AM EN03.01.02
A Study on Air Storage Characteristics of O3-type $Na[Ni_{1/2}Mn_{1/2}]_{1-x}Fe_xO_2$ Cathode Materials for Sodium-Ion Batteries Jehee Park[1,2], Jihyeon Gim[1], Seoung-bum son[1], Dewen Hou[3], Heonjae Jeong[1], Lei Cheng[1], Hui Xiong[3], Youngsik Kim[2], Christopher Johnson[1] and Eungje Lee[1]; [1]Argonne National Laboratory, United States; [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Boise State University, United States

Layered sodium transition metal oxides (Na_xMO_2) have been considered a promising cathode candidate for sodium-ion batteries due to their high theoretical capacity, low cost, easy synthesis, and scalable production ability. However, its poor air storage stability is one of the critical concerns that need to be addressed for practical application. The hygroscopic nature of the Na_xMO_2 cathodes makes them susceptible to hydration, Na extraction, and degradation on the air-exposed cathode surface, leading in turn to further process and performance issues such as gas evolution, slurry gelation, and electrolyte decomposition.[1] These incur extra costs in materials storage, transportation, and cell manufacturing. In this presentation, we will discuss the systematic investigation of the air-storage stability of $Na[Ni_{1/2}Mn_{1/2}]_{1-x}Fe_xO_2$ cathodes. Compared to Fe-free $Na[Ni,Mn]O_2$, which has severe moisture sensitivity and poor air-storage properties, the solid solution compounds of $Na[Ni,Mn,Fe]O_2$ showed significantly improved surface and bulk structural stability under ambient air. The role of Fe and detailed improving mechanism in the air-storage stability of $Na[Ni,Mn,Fe]O_2$ will be discussed. This presentation will provide useful insight into the cathode design and improvement strategies for practical-scale processing of layered cathode materials for sodium-ion batteries.

Reconfiguring Sodium Intercalation Process of TiS_2 Electrode for a Highly-Stable and Fast-Charging Sodium-Ion Battery by Solvent Co-Intercalation Jooha Park and Kisuk Kang; Seoul National University, Korea (the Republic of)

Titanium disulfide (TiS_2), which is a well-known first-generation cathode in lithium batteries, has also long attracted a broad interest as a potential electrode candidate for sodium-ion batteries (SIBs) due to favorable sodium intercalation kinetics and semi-metallic nature. However, the reversibility of sodium de/intercalation is far inferior to that of lithium, which has been often attributed to the unfavorable intermediate phase formation upon sodiation, leading to a poor electrochemical cycle life. Herein, we demonstrate that reconfiguring sodium intercalation process *via* partial solvent co-intercalation can induce a significant change in the phase-transition paths for the entire sodium intercalation reactions of Na_xTiS_2 ($0 < x < 1$), successfully detouring the formation of the unfavorable intermediates. And, it unexpectedly results in a remarkable enhancement of sodium intercalation reversibility, thereby boosting the cycle stability of sodium cell along with high power capability. Our comparative investigations reveal that the sodium intercalation in Diethylene glycol dimethyl ether (DEGDME)-based electrolyte involves a partial pre-intercalation of solvent molecules and subsequently undergoes distinct phase evolutions dissimilar to the bare sodium ion intercalation in conventional electrolytes. The new altered intercalation route allows the Na-TiS_2 cell to deliver a reversible capacity of 93 mAh g^{-1} over 1,000 cycles with 62 % of capacity retention at as high as 10 C rate. This re-discovery of intercalation behavior of TiS_2 offers a new insight in tailoring the reversibility and kinetics of intercalation process of commonly known electrodes for rechargeable batteries.

11:30 AM EN03.01.04

Impacts of Annealing Temperature on the Properties and Performance of $Na_2Fe_2F_7$ Cathode Rhiannon M. Kennard[1], Peter Gross[1], Yong-Seok Choi[2], Darren Ould[3], Enrique Sanchez-Perez[1], Christopher Thomas[1], Jethro Pryke[1], Dominic Wright[3], David O. Scanlon[2], Clare Grey[3], Serena Cussen[1] and Edmund J. Cussen[1]; [1]University of Sheffield, United Kingdom; [2]University College London, United Kingdom; [3]University of Cambridge, United Kingdom

The development of batteries free of Li, Co, and Ni is critical to meeting demands for grid-scale energy storage. Recent work has shown that weberite-type cathodes with structure Na_2MMF_7 (M = Fe, Ti, etc.) deliver competitive capacities with high energy density and cycling stability, with $Na_2Fe_2F_7$ performing particularly well. Weberites are also interesting for use as cathodes because their 3D open structure offers many pathways for Na diffusion, while simultaenosly avoiding the phase transitions that plague oxide cathodes. In addition, the electronegative F provides open-circuit voltages of > 3V. For fabrication of $Na_2Fe_2F_7$ to be truly sustainable, the processing temperature must be as low as possible. We therefore investigate how the fundamental properties of $Na_2Fe_2F_7$ are affected by annealing temperature. From structual analyses, we find that a vacancy-rich weberite is formed at lower temperatures, while a full $Na_2Fe_2F_7$ weberite forms at more elevated temperatures. Capacity and ion conduction are compared for both phases. We also clarify a debate regarding the polymorph of $Na_2Fe_2F_7$ via structural refinements and computational analyses. Primary particle size is modified from nanoscale to microscale by increasing the annealing temperature, and the consequences on capacity are explored. In addition, we find that mechanial milling post-synthesis is necessary to acheive good capacity, as large (>50 micron) secondary particles form during annnealing. Excessive mechanical milling post-synthesis creates an amorphous phase, which fortunately improves the capacity. This work combines experiment and computation to reveal the fundamental properties of $Na_2Fe_2F_7$, while simultaneously providing information necessary to the developemnt of this material.

Extending the Low-Temperature Operation of Sodium Metal Batteries Weiyang Li; Dartmouth College, United States

Nonaqueous sodium-based batteries are ideal candidates for the next generation of electrochemical energy storage devices. However, despite the promising performance at ambient temperature, their low-temperature (e.g., < 0°C) operation is detrimentally affected by the increase in the electrolyte resistance and solid electrolyte interphase (SEI) instability. Here, to circumvent these issues, we propose specific electrolyte formulations comprising linear and cyclic ether-based solvents and sodium trifluoromethanesulfonate salt that are thermally stable down to −150°C and enable the formation of a stable SEI at low temperatures. When tested in the Na||Na coin cell configuration, the low-temperature electrolytes enable long-term cycling down to −80°C. Via ex situ physicochemical (e.g., X-ray photoelectron spectroscopy, cryogenic transmission electron microscopy and atomic force microscopy) electrode measurements and density functional theory calculations, we investigate the mechanisms responsible for efficient low-temperature electrochemical performance. We also report the assembly and testing between −20°C and −60°C of full $Na||Na_3V_2(PO_4)_3$ coin cells.

2:00 PM EN03.02.02
Enabling Low-Cost Molten Sodium Batteries Through Engineered Catholyte-Separator Materials Chemistry Erik D. Spoerke, Adam Maraschky, Melissa Meyerson, Stephen Percival, Stephen Meserole, Lowry Daniel, Martha M. Gross and Leo J. Small; Sandia National Laboratories, United States

Cost-effective, safe, and reliable batteries are expected to be key components of the emerging electrical energy grid. We describe here a new class of low-temperature molten sodium-iodide batteries that employ a molten sodium anode, a solid-state NaSICON ceramic separator, and a low-cost molten salt catholyte. These unique batteries operate near 100°C, a dramatic reduction from the ~300°C operation of traditional molten sodium batteries, and they offer significantly higher voltages (>3.1V) than many other scalable battery chemistries. Enabling this low-temperature operation, however, requires significant understanding and control over materials chemistry and critical interfaces. Here, we will specifically discuss recent discoveries involving chemical interactions at the interface between the NaSICON ceramic and the molten sodium-iodide/aluminum chloride salt catholyte. We will discuss the unexpected dependence of battery cycling performance on molten salt composition and connect the battery performance to specific electrochemical and materials properties of the separator and the salt. In particular, we identify specific impact of catholyte Lewis acidity on key chemical interactions at this critical interface. Understanding these fundamental interactions provides key insights and guidance that are central to designing high performance molten sodium batteries that operate with low-cost catholyte salts.

2:30 PM DISCUSSION TIME

2:30 PM EN03.02.06
Operando Electrochemical Dilatometry (ECD)—Monitoring the Dynamic Behavior of Carbon Materials in Sodium-Ion Batteries During Cycling Ines Escher[1], Guillermo A. Ferrero[1], Mustafa Goktas[1], Yuliia Kravets[1] and Philipp Adelhelm[1,2]; [1]Humboldt Universität zu Berlin, Germany; [2]Helmholtz-Zentrum Berlin, Germany

Due to the continuously increasing demand for energy storage systems research on beyond-lithium technologies has gained much attention. In this field, sodium-ion batteries (SIBs) play an important role due to the greater availability of sodium compared to lithium, no need of critical cobalt as positive electrode material and the possible use of aluminum as current collector, which is cheaper and lighter compared to the commonly used copper.[1] Carbon electrodes have been effectively applied as negative electrode material in this case. The focus of this abstract is on the investigation of graphite and hard carbon as negative electrode material using operando electrochemical dilatometry (ECD). ECD is a technique that recently gained attention due to the improvement in measurement setups. In contrast to other analytical methods, like X-ray diffraction, that provide information on the structural changes of the active material, ECD gives information on the expansion of the complete electrode, also including inactive components and morphological characteristics. It has been recently used to investigate several electrode materials for sodium- and lithium-ion batteries (LIBs).[2]
Graphite, which is the standard material of choice in LIBs, can not be used with the same, carbonate-based electrolytes, in SIBs, as the formation of binary graphite intercalation compounds is thermodynamically not favorable.[3] To overcome this issue it was demonstrated that the use of ether-based electrolytes results in the formation of stable ternary graphite intercalation compounds, where the solvent molecules co-intercalate together with the sodium ions into the graphitic lattice.[4] This reaction results in a large electrode expansion which can be easily followed using ECD. Even though the reaction is highly

reversible a decrease of the electrode expansion is favorable, especially in full cell applications. Herein, the influence of different binder materials as well as the addition of a co-solvent on the electrode expansion has been investigated. The use of CMC (sodium salt of carboxy methylcellulose) as well as the addition of 10 vol% ethylenediamine has shown promising outcomes.[5]
Hard carbon is so far the standard material in commercial SIBs and benefits from its redox potential close to Na^+/Na, a storage capacity which is typically between 150-350 mAh g^{-1} and especially low cost.[6] Unlike graphite carbonate-based as well as ether-based electrolytes can be used in this case. However, a lot of research has been done to reveal the storage mechanism no clear answer has been found yet. ECD has been applied to get a further understanding of the storage mechanism in hard carbon electrodes. In this case ECD showed that the intercalation process of sodium ions can be divided in three steps, proposing an intercalation – pore filling – plating mechanism. In contrast, a two-step mechanism has been found in the case of lithium ions, assuming an intercalation – pore filling process.[7]
In conclusion, ECD was found to be a powerful operando tool to investigate the influence of different components (binder, co-solvent) on the co-intercalation of sodium ions in graphite as well as the charge storage mechanism in hard carbon electrodes.

2:45 PM BREAK

2:45 PM EN03.02.07
Influence of Cathode Processing on Cycle Life and Performance of Sodium-Zinc Chloride Batteries Louis Sieuw[1], Tu Lan[1], Enea Svaluto-Ferro[1], Wenjin Ding[2], Meike Heinz[1] and Corsin Battaglia[1]; [1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]DLR-Institute of Engineering Thermodynamics, German Aerospace Center, Germany

Current commercial sodium-nickel chloride (Na-$NiCl_2$) batteries possess long design and cycle lives of 20 years and >4500 cycles at 80% depth of discharge, respectively[1]. Combined with high cathode loadings and low energy-specific costs, this translates to competitive battery cycle costs of <0.1 $/kWh/cycle. While this high-temperature (~300 °C) battery technology displays a high potential for large-scale stationary energy storage, the cost of the cell components and their assembly still outranges that of state-of-the-art Li-ion batteries. The replacement of costly nickel, for which demand is increasing, with inexpensive zinc as cathode material, helps to cut down the cell production costs and could provide a sustainable solution for large-scale energy storage applications.

In this study, we assess the electrochemical processes involved in sodium-zinc chloride batteries (Na-$ZnCl_2$). In particular, we concentrate on understanding the relations between cathode composition, microstructure, capacity, rate limitations, and lifetime of Na-$ZnCl_2$ cells. Using pellets consisting of zinc powder mixed with rock salt, we investigate the influence of raw materials particle size and compaction pressure on the composite cathode density and electrical conductivity. We further compare the results with those obtained for filamentary nickel and rock salt mixtures to help understand the influence of metal powder morphology on the electronic and ionic conductivities. Moreover, we systematically assess through calculations the influence of secondary electrolyte volume, active metal content, and electrode filling level on cell capacity and pressure evolution at different SOC[2].

Using the prototype cell design formerly described by our group[3], we characterize the successive steps[4] of the chlorination and de-chlorination reaction of zinc by galvanostatic techniques and electrochemical impedance spectroscopy, as well as cyclic voltammetry. Based on these electrochemical data combined with structural post-mortem characterization, we attempt to resolve the electrochemical processes and degradation mechanisms governing both the efficiency and cycle life of the Na-$ZnCl_2$ system. By improving the structural understanding of the sodium-zinc chloride cells, we strive to optimize their cycle life, rate performance, and energy efficiency, with the aim of providing a new, cost-efficient generation of batteries for stationary energy storage applications[5].

Dextrin-DADMAC-MBAA Hydrogel for High Ionic Conductible Flexible Aqueous Sodium Ion Hybrid Battery Jung Woo Hong and HoSeok Park; Sungkyunkwan University, Korea (the Republic of)

For applications in energy storage devices, polymer electrolytes have attracted attention due to their favorable mechanical properties such as flexibility, strain stress, pressure and the ability to reduced reactivity with liquid electrolytes, suppression of dendrite growth. But the disadvantage that the ion conductivity is not as good as that of the liquid electrolyte is hindering the development of the polymer electrolytes. Here in, we demonstrate a high ion-conducting, flexible and double networked (DN) hydrogel films for Sodium Ion Hybrid Battery (SIHB). Hydrogel chain of DADAMC-Dextrin-MBAA is crosslinked by free-radical reaction of Dimethyldiallylammoniumchloride (DADMAC) and N, N′-methylene-bis-acrylamide (MBAA) and Dextrin chain.

In addition, DADMAC and $NaClO_4$ salt undergo ion exchange reaction that prevents excessive expansion of DADMAC structure (which occurs due to the hydrophilicity of the gel), and also has the advantage of increasing physical properties such as strain stress and pressure. The DDM hydrogel is found to have an ionic conductivity of 31.2 mS cm^{-1} at 25 °C, the tensile strength of 8000 KPa, electrochemically stable up to 2.5V.

EN03.03.02
Investigation of Thermodynamic and Structural Properties of Olivine Li- and $NaFePO_4$ Elizabeth Brown and Hillary Smith; Swarthmore College, United States

Olivine $NaFePO_4$ has the potential to be a high performing and cost-effective battery cathode material. However, key differences exist between the behavior of $NaFePO_4$ and isostructural $LiFePO_4$ that are not yet fully understood. In this work, the thermodynamic and structural properties of Na_xFePO_4 and Li_xFePO_4 ($0<x<1$) are investigated between 300 and 800K. We use neutron powder diffraction to examine the temperature dependent structural change of Na_xFePO_4 for x=0, x=2/3, and x=1 and Li_xFePO_4 for x=1 and x=2/3. Differential scanning calorimetry provides the isobaric specific heat as a function of temperature. The relationship of structure, specific heat, and entropy will be discussed in the context of improving our understanding of changes induced by ion intercalation and deintercalation.

EN03.03.04
Printed Zinc-Ion Batteries on Hydrogel Reinforced Cellulose Composite for Paper Electronics Peihua Yang[1], Jia Li[2], Seok Woo Lee[3] and Hong Jin Fan[4]; [1]The Institute of Technological Sciences, Wuhan University, China; [2]Rolls-Royce@NTU Corperate Lab, Nanyang Technological University, Singapore; [3]School of Electrical and Electronic Engineering, Nanyang Technological University, Singapore; [4]School of Physical and Mathematical Sciences, Nanyang Technological University, Singapore

Paper electronics provides a low-cost and sustainable option for the ever growing demand of Internet of Things (IoT) devices. Batteries are considered as the heart of those energy-consuming paper electronics.[1] Rapid development of flexible electronics not only poses severe challenges to traditional manufacturing methods, but also raises further concerns on their impact on environment. [2] Deriving from abundant biomass, cellulose paper presents an ideal building block for developing flexible and sustainable electronics.[3] Paper electronics could be the raising star of next-generation functional devices, especially in the field of paper-based flexible batteries, sensors, circuits, and diagnostic equipment.[4] Imagine if these devices can be integrated on a piece of paper, it will greatly facilitate the application scenarios and enhance the commercial values. Meanwhile, the compatibility of paper to printing techniques allows facile ink printing of a wide variety of functional materials. [5] Therefore, facile and scalable fabrication of paper-based batteries is crucial to build paper electronics systems.
In our study, we propose polyacrylamide hydrogel reinforced cellulose paper (HCP) for printable zinc batteries and paper electronics. By combining the characteristics of cellulose paper and hydrogel, the composite paper presents favourable mechanical and ioninc conductivity properties that are suitable to its function as the separator and electrolyte for zinc batteries.We have realized printing of quasi-solid, biodegradable aqueous Zn-Ni and Zn-Mn batteries and demonstrate its possibility of integrating with other paper electronics. In our strategy, HCP serves as the separator and electrolyte while maintaining its printability as a paper substrate, and electrodes are printed on both sides of the HCP to form flexible batteries. The hydrogel significantly improves the mechanical strength of the cellulose fibers and maintains the ion conductivity of the composite. As a result, the printed batteries are cuttable and flexible without the risk of short of contact failure.The printed zinc batteries deliver remarkable volumetric energy density of ~26 mWh cm^{-3} (based on total device volume), and feature of cuttability and compatibility with flexible circuits and devices.
Furthermore, The HCP holds great biodegradability as natural cellulose. Polyacrylamide and cellulose are decomposable in the presence of bacteria, fungi, and other microorganisms. When buried in natural soil (roof garden, NTU campus, Singapore), HCP became fractured after two weeks of burial. Hygroscopicity of hydrogel greatly facilitates the growth and reproduction of microorganism. HCP can be completely degraded within four weeks. In addition, the compatibility of the paper batteries with flexible circuits and devices allows the construction of a self-powered paper system that integrates printed battery with solar cells.
In conclusion, we demonstrate the possibility of printed paper batteries and integration with flexible electronics toward the new era of paper electronics.This paper batteries will be an important step to paper electronics when other electronic parts, such as solar cells, can be also printed on the same paper. With the facile synthesis and high performance, the HCP-based printed batteries hold great promise for next-generation sustainable paper electronics.

Methylthiourea as Electrolyte Additive Strategy for Zn-Metal Anode Stability and Reversibility of Zn-Ion Batteries Mahammad Rafi Shaik, Jihoon Kim and Sukeun Yoon; Kongju National University, Korea (the Republic of)

Zinc-ion batteries (ZIBs) are considered as a good choice in energy storage technologies due to their high safety and low environmental impact. However, various disadvantages related to Zn dendrite formation, hydrogen generation, and corrosion generated during the charge/discharge process greatly limit the commercialization of ZIBs. Among various electrode components, electrolytes are attracting attention from many researchers because they can solve problems occurring at the anode-cathode interface from a fundamental point of view. Here, we present the use of methylthiourea (MTU) as an electrolyte additive to inhibit the growth of zinc dendrites and obtain smooth Zn deposits. In the presence of MTU, Zn dendrite formation is successfully controlled, the electrochemical performance of the Zn|Zn symmetric cell is significantly improved over 1000 h at a current density of 1 mA cm^{-2}, and stripping of the deposited zinc is uniformly allowed. In addition, the Zn-ion full cell using the V_2O_5/C cathode exhibits consistent capacity retention up to 450 cycles. This study demonstrates that the use of methylthiourea as an electrolyte additive to enhance the electrochemical stability and reversibility of ZIBs can be cost-effective.

EN03.03.06
Fully 3D Printed Aqueous Zinc Ion Batteries for Wearable Electronic Devices Stefano Tagliaferri, Nagaraju Goli, Mauro Och, Maria S. Sokolikova and Cecilia Mattevi; Imperial College London, United Kingdom

Rechargeable Zinc Ion Batteries (ZIBs) based on aqueous electrolytes are among the most promising beyond-lithium energy storage systems, featuring large volumetric capacity, low cost and outstanding safety. The use of Earth-abundant, non-hazardous electrode materials and water-based electrolytes

makes ZIBs ideal power sources to meet the growing energy demand of wearable and portable electronics. Nonetheless, the large-scale commercialization of rechargeable zinc ion batteries is still hindered by significant technological challenges, primarily associated with the low electrochemical reversibility of such systems.

The structural re-design of the electrode architectures is an effective strategy to prolong the cycle life of ZIBs, reducing the local current density at the interface with the electrolyte and promoting a uniform and reversible zinc plating. 3D Printing is a sustainable manufacturing process that can be employed to fabricate electrodes with customized design, *via* the layer-by-layer deposition of suitable inks. The rationally-designed structure of 3D Printed electrodes provides enhanced electrochemical stability and superior specific capacity, simultaneously ensuring uninterrupted charge transport pathways and fast charge transfer inside the device.

Here, we present the fabrication of interdigitated Zinc Ion Batteries entirely *via* the 3D Printing of aqueous ink formulations, specifically tailored for the anode, cathode and gel electrolyte deposition. We electrochemically characterize the battery and we demonstrate it can power commercial wearable devices. We identify that the 3D architecture of the electrodes is crucial in increasing the reversibility of the printed battery, and investigate the degradation processes and electrochemical failure through *post-mortem* characterization.

EN03.03.07
Particle Size and Crystal Structure Engineering of λ-MnO_2 Particles as Cathodes for Zinc-Ion Batteries Zhichu Tang, Wenxiang Chen, Zhiheng Lyu, Oliver Lin, Kaijun Yin, Chen Zhang, Hong Yang, Jian-Min Zuo and Qian Chen; University of Illinois at Urbana-Champaign, United States

We use spinel λ-MnO_2 particles as a model system to study the effect of particle size and crystal structure engineering on Zn-ion diffusion and electrochemical performance in Zn-ion batteries. Through X-ray diffraction and energy-dispersive X-ray spectroscopy analysis, we demonstrate that Zn-ion insertion is enhanced in small nanoparticles (NPs) compared to large micron-sized particles due to larger surface area and solid-solution type phase transition pathway. Meanwhile, poor Zn-ion insertion/extraction reversibility leads to the poor cycling stability of NPs. To improve the cycling performance of λ-MnO_2 NPs, crystal structure engineering is employed to create defects in the spinel lattice. The crystal structure change of λ-MnO_2 is studied by a collocated four-dimensional scanning transmission electron microscopy. Results show that single-crystalline λ-MnO_2 will turn into more disordered polycrystals, which can enhance Zn-ion diffusivity. As a result, the cycling performance of λ-MnO_2 NPs is significantly improved, with a high capacity retention of over 94% after 100 cycles. Our work pinpoints the distinctive impacts of particle size and defects on the ion-diffusion process and cathode performance in Zn-ion batteries, providing guidance for the design of high-performance cathode materials for multi-valent ion batteries.

EN03.03.08
Investigation of the Electrochemistry and Functional Properties of Zn/ Manganese Oxide Rechargeable Aqueous Batteries Daren Wu[1], Lisa Housel[2], Nahian Sadique[1], Lei Wang[2], David Bock[2], Esther S. Takeuchi[1,2], Amy Marschilok[1,2] and Kenneth J. Takeuchi[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

The consistent delivery of clean electrical energy is a global challenge where the current electric grid infrastructure distributes electrical energy from the generation source to the end user.
Widespread integration of inherently intermittent renewable energy sources such as wind and solar into the electric grid electrical energy storage into the electric grid demands incorporation of energy storage. Further, energy storage would enable control over when the electrical energy is used improving grid reliability and resiliency. Thus, stationary energy storage for the electric grid is a critical and timely application for batteries.

Aqueous batteries are desirable candidates for stationary energy storage due to low cost and scalability. In addition, many electrode materials compatible with aqueous electrolytes
are earth abundant, and thus may be a cost effective alternative compared traditional lithium-ion battery materials. While batteries with aqueous electrolytes are less flammable than the non-aqueous organic electrolytes employed in lithium-ion battery technologies, they can still undergo problematic degradation processes. Thus, mechanistic understanding of promising aqueous battery chemistries is critical.

Rechargeable aqueous Zn/MnO_2 batteries have received attention for large-scale energy storage applications. Zn metal has a low redox potential (0.76 V vs. SHE) and under mild acidic
conditions exhibits an overpotential for hydrogen evolution, enabling a deposition and stripping charge storage mechanism when used as a battery anode. Zn is also non-toxic and has a high theoretical capacity (820 mA/g). Thus, the Zn/MnO2 system is a potentially high
energy density, low cost, and environmentally-friendly chemistry for stationary energy storage.

Advanced characterization approaches were used to investigate the Zn/a-MnO_2 system. The dominant Faradaic mechanisms were probed including determination of the structure and oxidation states of the discharge and charge products. Specifically, operando methods were applied to probe the system and will be discussed in detail.

EN03.03.09
Sodium Vanadium Oxide (NVO) Material Properties—Impact on Electrochemistry and Functional Properties in Zn-Ion Aqueous Batteries Gurpreet Singh[1], Christopher Tang[1], Lisa Housel[2], Sung Joo Kim[2], Lei Wang[2], Yimei Zhu[2], Esther S. Takeuchi[1,2], Kenneth J. Takeuchi[1,2] and Amy Marschilok[1,2]; [1]Stony Brook University, United States; [2]Brookhaven National Laboratory, United States

Implementation of intermittent renewable energy sources derived from wind and solar power provides interest in the development of safe, sustainable, low cost energy storage including batteries based on aqueous electrolytes. Zn as a negative electrode has a high theoretical capacity (820 mAh/g), low redox potential (-0.76 V vs. SHE), and low toxicity with a voltage window suitable for use with aqueous electrolytes
Vanadium based materials are appealing for aqueous electrochemical energy storage due to the multiple accessible redox states for the vanadium center. Layered vanadates are of interest for Zn-ion batteries as the vanadium redox center allows for high capacity and the layered structure promotes facile ion transfer. In particular, sodium vanadium oxides (NVO) show promise as cathode materials for Zn-ion aqueous batteries. Understanding the parameters that govern the charge storage mechanisms of the Zn/NVO aqueous systems remains of key interest where investigations that tune material properties can provide insight toward ultimately controlling electrochemical outcomes in Zn/NVO systems. Materials properties, their impact on functional electrochemistry such as capacity delivery and capacity retention were determined using methods including synchrotron based x-ray absorption analysis and will be discussed.

EN03.03.10

Ultrasmall $ZnMn_2O_4$ Cathodes for High-Energy and High-Power Aqueous Zinc-Ion Secondary Batteries Hiroaki Kobayashi[1], Yuto Katsuyama[2], Chie Ooka[1] and Itaru Honma[1]; [1]Tohoku University, Japan; [2]University of California, Los Angeles, United States

Current lithium-ion batteries are widely used for various energy storage devices. However, improvement of LIB performances such as high energy density, cost effective, and safety is urgently required, with increasing demand for lithium-ion batteries (LIBs) as energy storage devices. Rechargeable zinc-ion batteries, using aqueous electrolytes with mild acidity and zinc metal anodes, are promising for stationary power supply due to their environment-friendly, cost-effectiveness, and safety. For high energy density cathode materials, vanadium oxides and manganese oxides were widely developed. However, suitable cathode materials with high capacity and long cycling stability are still progressing. Spinel-type $ZnMn_2O_4$ is reported as highly cyclable cathode materials, though only one-electron reaction per Mn is available.[1] Theoretically, two-elecctron reactions using $Mn^{2+/4+}$can be utilized in spinel cathode materials.[2] Here, we apply the ultrasmall $ZnMn_2O_4$ spinel nanoparticle-graphene composite as cathode material to accelerate the fast Zn intercalation/deintercalation.
The ultrasmall $ZnMn_2O_4$ spinel was prepared by alcohol reduction process.[3] The Rietveld analysis of the X-ray diffraction (XRD) pattern suggests the obtained nanoparticles as tetragonal spinel. X-ray absorption spectroscopy (XAS) also shows the valence state of Mn as 3+. According to the Transmission Electron Microscope (TEM) image, primary particles of 5–10 nm were strongly aggregated into micron size secondary particles. The aggregation is effectively suppressed by dispersing graphene into the reaction solution. The $ZnMn_2O_4$-graphene composite cathode exhibits the reversible capacity of 450 mAh g^{-1} at 100 mA g^{-1}, a high value because of a reversible two-electron reaction, while $ZnMn_2O_4$ nanoparticle shows only 300 mAh g^{-1}. Downsizing particles is an effective way to enhance its specific capacity.

EN03.03.11
A Theoretical Investigation of Vanadium-Based Cathodes in Magnesium-Ion Battery Mai Nguyen; University of Texas at Austin, United States

Lithium-ion battery (LIB) technology, first commercialized in 1991 by Sony, has been explored extensively to accomplish many achievements in energy supply throughout past decades due to its high energy density and low self-discharge. Nevertheless, there are still challenges with LIB in cost and scarcity. In addition, the effort of using metal lithium as an anode to increase capacity compared to graphite is limited by the dendrite formation during deposition of Li-ion, which results in problematic and unsafe operation. Magnesium-ion battery (MIB), an alternative to LIB, has received huge interest in the field due to magnesium's higher abundance on Earth's crust, less expensive, a provision of high capacity on the account of two electrons transfer and the negligible dendrite formation on the anode compared to lithium. Despite that, one of the main challenges to MIB technology is the poor cathode cyclability caused by sluggish kinetics of Mg-ion resulting from the high charge density at most cathodes, which can affect the rate capability of the battery. In this work, we are looking at several vanadium oxides, one of the well-known cathode materials: V_2O_5, LiV_3O_8, and $V_2(PO_4)_3$. These materials have been widely studied in LIB showing great performance during cycling due to its layered and stable structure which indicates a promising material for improving the cathode's cyclability and the battery's rate capability for MIB. Here, we used density function theory (DFT) to predict the theoretical voltages and energy densities of MIB using the magnesium metal anode and the studied vanadium-based cathodes to compare with LIB technology. We found that the MIB's performance resulted in lower voltage but can be compensated by higher capacities in comparison to LIB; as a result, the energy densities of the two batteries can be commensurable. Furthermore, we constructed convex hull phase diagram to predict the process of intercalating Mg-ions into the studied cathodes and then predicted the voltage profile to study the phase boundaries which can affect the kinetics of intercalating ions within these cathodes in MIB. The result found that V_2O_5 and $V_2(PO_4)_3$ were developing phase boundaries during intercalation of Mg-ions while the flat voltage profile of LiV_3O_8 cathode looks more desirable for the kinetics of intercalating ions. Then, we will further investigate the kinetics characteristics of these vanadium-based cathodes by predicting the ionic conductivity and electrical conductivity which contribute greatly to the rate capability.

EN03.03.12
Mn Binary Nano-Spinel Oxides Toward Mg Rechargeable Battery Cathode with Room-Temperature Operation Reona Iimura, Hiroaki Kobayashi and Itaru Honma; Tohoku university, Japan

With the implementation of the decarbonization policies, the role and demand for storage batteries is significantly growing and changing. Therefore, further improvements for storage battery are required. Mg rechargeable batteries (MRBs), which use Mg metal as anode, are attracting attention as post-Li ion batteries. MRBs have been widely explored because of their high volumetric energy density, low cost and high safety. Regarding MRBs-cathode research, lots of issues such as low potential operation and low cyclability should be resolved. Recently, spinel oxide, MgM_2O_4 (M = Cr, Mn, Fe, Co), has come to draw a lot of attention as a cathode material because of its high potential operation. In particular, $MgMn_2O_4$ (MMO) is expected to be a high-energy cathode material as it can be used in both Mn^{2+}/Mn^{3+} and Mn^{3+}/Mn^{4+} redox reactions within the potential window of a standard electrolyte (< 3.5 V vs. Mg/Mg^{2+}). Nonetheless, oxide-type cathode materials show poor rate capabilities due to the sluggish diffusion rate of Mg-ion in solid derived from the large charge density of Mg^{2+}. One effective solution is to make cathode materials nanosized to reduce the diffusion distance in the solid. In our previous work, a cubic nano-spinel MMO was synthesized via alcohol reduction (AR) process and demonstrated the room-temperature operation at full-cell test. However, the observed capacity (100 mAh g^{-1}) is not close to the theoretical capacity (270 mAh g^{-1}), implying that nanosizing cathode materials is not adequate for room-temperature operation. In this study, we focused on changing the structural stability of the redox phase and conductivity using a different transition metal instead of Mg in MMO toward high capacity at room temperature.
Mn binary nano spinel oxides were synthesized by AR process. The appropriate amount of Bu_4NMnO_4 was added into the methanol dissolved with various transition metal salts and this reaction solution was vigorously stirred for an hour. After the reaction, the participants were washed with ethanol, dispersed into tert-butyl alcohol and freeze-dried. The crystalline phase and crystallite size of each spinel oxide were identified by X-ray diffraction and scanning transmission electron microscopy. The obtained sample was mixed with acetylene black and polytetrafluoroethylene at a weight ratio of 60/30/10. Then, these mixtures were pressed onto Al mesh to make a cathode. A coin-shaped full cell consisting of $Mg[B(HFIP)_4]_2$ / triglyme (HFIP: hexafluoroisopropyl) as electrolyte and a magnesium metal anode was prepared, and charge-discharge tests were conducted at room temperature.
All the synthesized A-Mn spinel (A = Cu, Ni, Co) by AR method showed a single phase of cubic structure from XRD measurements, suggesting that Jahn-Teller effect of Mn^{3+} is suppressed and the metastable cubic structure is obtained. In addition, TEM images revealed that all the synthesized samples have 5 nm-primary particles and electron diffraction patterns attributed to the spinel structure were obtained through Selected Area Electron Diffraction measurements. Regarding charge-discharge tests, Cu-Mn spinel showed much higher discharge capacity than MMO, implying that Mg-ion was easier to be inserted at room temperature. Furthermore, Galvanostatic Intermittent Titration Technique revealed that Cu-Mn spinel has smaller overpotential during discharge than MMO, demonstrating smaller particle resistance.
Therefore, we found that the cathode materials require not only nano-sizing but also smaller particle resistance toward room-temperature operation.

EN03.03.13
Ion-Selective and Chemical-Protective Interphase for Highly Durable Zinc Metal Anode Sangyeop Lee; POSTECH, Korea (the Republic of)

The development of sustainable energy sources such as wind, solar, and hydropower has been vigorously studied to overcome global energy crisis and climate change. However, they suffer from uncertainty and instability in power generation since they significantly depend on external environmental factors. As a result, additional energy storage systems are required to manage excess electricity efficiently and transfer energy timely. Rechargeable batteries that enable facile conversion and storage of energy produced, thus, have been extensively investigated as a rational solution for renewable energy sources. Among various candidates, aqueous zinc ion batteries (ZIBs) are studied as the most attractive system owing to the beneficial properties including insensitive manufacturing condition, low material cost, nonflammability, and environmental benignity. However, the practical application of ZIBs is under challenge due to dendritic growth and low electrochemical reversibility of Zn anode. Like other metals, Zn tends to form a dendritic architecture during plating/stripping processes due to inhomogeneous charge distribution. Furthermore, Zn dendrites with large surface area facilitate detrimental side reactions to induce insulating byproducts, corrosion, and hydrogen evolution reaction (HER) in mild acidic electrolytes. The detrimental side reactions incur local environmental change to accelerate dendritic growth and result in low Coulombic efficiency and subsequent capacity fading.
Several strategies reportedly enhance the electrochemical reversibility of Zn anode. In particular, introducing an artificial protective layer is an attractive method because it can be fabricated by a simple coating process and exhibits tunable electrochemical and mechanical properties according to its layer components. Additionally, an artificial protective layer can achieve homogeneous Zn^{2+} transfer through the interphase matrix and prevents direct contact between the aqueous electrolyte and the electrode surface, thereby increasing the lifespan of batteries. However, numerous artificial protective layers are designed with a thick structure to alleviate infinite volume expansion of Zn during the repetitive charge/discharge cycles, while these thick electrochemically inert layers negatively affect to the overall energy density. Also, studies on ion behavior inside the protective interphase still remain in the early stage, while it is required to develop advanced anode materials.
Herein, polystyrene-block-poly(ethylene-ran-butylene)-block-polystyrene-graft-maleic anhydride (SEBS-MA) is introduced as an artificial protective layer for the Zn anode through a simple spin-coating process. The 180 nm-thick SEBS-MA can withstand the volume change of Zn during repetitive charge-discharge processes due to its high stretchability and mechanical robustness. In the SEBS-MA layer, maleic anhydride groups attract Zn^{2+} dissolved in the electrolyte and form a cation transporting channel, leading to a smooth electrode surface without dendritic metal growth. Moreover, this SEBS-MA layer exhibits an ion-selective property, such that only Zn^{2+} can pass through the layer, whereas water molecules and SO_4^{2-} anions are highly restricted. The ion-selective layer could effectively suppresses HER and the formation of detrimental species. Consequently, based on the synergetic effects between the electrode surface stabilization and the uniform ion distribution, the SEBS-MA-coated Zn (Zn@SEBS-MA) symmetric cell demonstrates ultralong cycle life (>3,200 h) at a high current density of 3 mA cm^{-2} and an areal capacity of 1 mAh cm^{-2}. The beneficial effect of SEBS-MA was further investigated using Zn@SEBS-MA|MnO2 full cells and could realize durable cycle retention 80% after 2,500 cycles. This work provides a facile fabrication process and accessible analysis methods to rationalize the development of high-performance ZIBs.

EN03.03.14
Development of Zinc Ion Battery Anodes by Zinc Electrodeposition on Controllable Three-Dimensional Carbon Framework Shinnosuke Tachibana[1], Hiroaki Kobayashi[1], Yuto Katsuyama[2], Akira Kudo[1], Kazuyuki Iwase[1] and Itaru Honma[1]; [1]Tohoku University, Japan; [2]University of California, Los Angeles, United States

Lithium-ion batteries (LIBs) are widely used as energy storage devices, but their low level of safety, high cost, and unstable supply of lithium metal due to increased demand are challenging. Therefore, environmentally friendly and sustainable energy devices are required. In particular, rechargeable aqueous zinc-based batteries (ZIBs) are expected to be a new electrochemical energy storage device due to their low cost, non-toxicity, and high energy density. However, short circuits due to zinc metal dendrite formation at the anode and poor cycle characteristics due to reduced reversibility have hindered their practical application. Stable and dendrite-free cycling zinc anode with zinc electrodeposition confined in 3D carbon nanotubes network structure has been reported[1], hence zinc electrodeposition on dense 3D carbon frameworks is an effective approach. 3D printers are gaining attention among the methods for fabricating 3D carbon frameworks[2], [3]. The use of 3D printers for current collector fabrication allows for flexible form factors and scale control on the order of micrometers to centimeters. Therefore, the objective of this study was to develop a high-performance zinc anode material by zinc deposition on 3D carbon modeled by an LCD (Liquid Crystal Display) 3D printer.

3D carbon was designed using computer aided design (CAD). To avoid asymmetric structural parameters, a unit lattice with symmetric framework diameter and vacancies was used in the design. 3D polymer samples were fabricated using an LCD 3D printer (Mars3, ELEGOO) with photo-curing resin (ABS-like resin, SK hompo). The printed samples were rinsed with 2-propanol to remove the uncured resin, dried, and then pyrolyzed in a tube furnace under vacuum at 400 °C for 4 hours and then at 1000 °C for 4 hours. The 3D carbon was subjected to activation treatment (heating under CO_2 atmosphere), and the zinc electrodeposition behavior was evaluated pristine carbon and CO_2 activated carbon. For zinc electrodeposition, 3D carbon was fixed with Au mesh, and the electrolyte was 1M $ZnSO_4$ aqueous solution, and the current density was 1 mA cm^{-2}. The zinc electrodeposited 3D carbon samples were investigated by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDX), X-ray diffraction (XRD), and Raman spectroscopy. To evaluate the electrochemical properties, galvanostatic charge-discharge tests were conducted using a Zn foil and Zn/3D carbon in symmetrical cell.

Pyrolysis reduced it to a quarter of its original size, and even after pyrolysis, it retained its structure at the time of modeling. From the result of SEM observation, there was almost no zinc deposition on the carbon skeleton surface of pristine 3D carbon, but plenty of zinc was deposited on the surface of the carbon skeleton after CO_2 activation treatment. The CO_2 activation treatment was found to increase the specific surface area of the 3D carbon, thereby increasing the number of zinc nucleation sites and achieving uniform zinc deposition. Zinc deposition was also observed inside the CO_2 activated carbon structure, therefore the three-dimensional zinc metal anode was fabricated. Zn/CO_2 activated carbon showed similar low overpotential and long-term cycling stability compared with zinc foil, suggested to be promising as a zinc anode material.

High-Valence Metal-Ion-Preintercalated Vanadium Oxide as High-Capacity Aqueous Zinc-Ion Battery Cathode Material Sanna Gull, Chung-Sheng Ni, Hong-Jyun Huang, Jin-Wei Kang and Han-Yi Chen; National Tsing Hua University, Taiwan

The advantages of aqueous zinc-ion batteries (AZIBs) as high-safety and low-cost energy devices show increasingly large potential in grid-scale storage/supply applications. Nevertheless, finding suitable cathode materials is quite challenging for the further development of aqueous ZIBs. In this work, we design a layered porous structure of the chemically pre-intercalated high-valence metal ions into the interlayers of V_2O_5 (HM-VOH) with a large interlayer spacing of 11.4 Å by using a scalable hydrothermal method in order to improve the electrode performance of AZIBs. As a result, HM-VOH delivers a higher capacity of c.a. 400 mA h g^{-1} at a current density of 0.1 A g^{-1} and exhibits an excellent capacity retention of > 80% after 300 cycles at a higher current density of 5 A g^{-1}. In addition, we investigated the Zn^{2+} storage mechanism in this HM-VOH cathode material as well as its associated electrochemical kinetics by using *Operando* synchrotron X-ray diffraction, and operando synchrotron X-ray absorption near-edge spectroscopy.

Furthermore, the as-synthesized cathode material can maintain an energy density of > 280 W h kg^{-1} at a high power density of > 70 W $kg^{-1,}$ which is much higher than the pristine vanadium oxide material. Hence, we found that pre-intercalation of high-valence transition metal ion in the host material allowed rapid diffusion of Zn^{2+}, improved electrical conductivity, and excellent structural reversibility, which can be applied to other advanced battery systems.

EN03.03.17
Electrolyte Engineering for Zn-Ion Batteries—Concentration-Dependent Zn^{2+} Coordination Structure and its Implication on Zn Metal Anode Reversibility Dario Gomez Vazquez[1], Travis P. Pollard[2], Julian Mars[3], Ji Mun Yoo[1], Hans-Georg Steinrück[4], Sharon E. Bone[5], Michael F. Toney[3], Oleg Borodin[2] and Maria Lukatskaya[1]; [1]ETH Zurich, Switzerland; [2]DEVCOM Army Research Laboratory, United States; [3]University of Colorado Boulder, United States; [4]Universität Paderborn, Germany; [5]SLAC National Accelerator Laboratory, United States

Aqueous secondary zinc ion batteries (ZIBs) are promising systems for grid storage because of their high energy density, low cost, and low safety concern. However, ZIBs have major limitations at their Zn metal anode because it suffers from both, side reaction of water splitting and dendrite formation which affect their coulombic efficiency (CE) and long-term stability, respectively. Recent approaches in electrolyte engineering have shown promising improvements in the cyclic reversibility of Zn metal anodes, including water-in-salt (WIS) electrolytes. While WIS electrolytes effectively increase CE of Zn metal anode through unique solvation structure and suppressed water splitting, its high salt usage, and increased electrolyte viscosity put other limitations on advanced ZIB systems. To implement beneficial effects from WIS into realistic ZIB systems, additional fundamental understanding is required of the correlation between electrolyte concentration, Zn^{2+} coordination environment, electrolyte structure, and resultant Zn plating/stripping efficiency, which has not been properly addressed in the field. Herein, we investigate the electrochemical properties of Zn plating/stripping as a function of electrolyte concentration and structure using a mixed cation Zn^{2+}-K^{+} acetate (OAc) electrolyte: $Zn_{0.2}K_{0.8}OAc_{1.2}$ nH_2O where "n" was variated from 1.5 to 50. Upon increase in concentration, we observed a change in the Zn^{2+} coordination environment and bulk electrolyte properties (e.g. thermal, conductivity and viscosity). We identify optimal electrolyte composition at n=10. In this *salt-solvate* electrolyte state we benefit from both WIS-like Zn^{2+} coordination environment and high conductivity and enable high CE >99% during Zn plating/stripping.

EN03.03.19
Biomimetic Composite Architectural Cathode Material for Ultrahigh Rate Capability and Cycling Life of Na-Ion Battery Kang Ho Shin[1,2], Puritut Nakhanivej[3] and HoSeok Park[1]; [1]SungKyunKwan University, United States; [2]University of California, Los Angeles, United States; [3]University of Warwick, United Kingdom

$Na_3V_2(PO_4)_3$ is one of the excellent cathode candidates of sodium ion batteries owing to its high theoretical specific capacity (117 mA h g^{-1}) and operating voltage (3.4 V vs. Na/Na^{+}). However, the inferior intrinsic electronic conductivity of NVP limits facile charge transfer, resulting in poor rate capability and long-term cycle stability. In order to overcome these hurdles, studies are being conducted to improve electrical conductivity via forming a composite with a carbon material or doping/substitution of heteroatom. In this work, a composite with reduced graphene oxide (rGO) was fabricated to reduce particle size of NVP, organize a uniform 3D conductive network to minimize capacity loss, and greatly increase electrical conductivity. The composite, called 'BI-NVP', achieved excellent performance of a sodium ion battery and confirmed interfacial stability of NVP-rGO through various post-mortem analysis including HR-TEM and STEM-EELS.

EN03.03.20
Stable Zinc Anodes Enabled by a Zincophilic Polyanionic Hydrogel Layer Jin-Lin Yang and Hong Jin Fan; Nanyang Technological University, Singapore

The practical application of Zn metal anode for aqueous batteries is greatly restricted by the catastrophic dendrites growth, intricate hydrogen evolution and parasitic surface passivation. Herein, a polyanionic hydrogel film is introduced as a protective layer on Zn anode with the assistance of saline coupling agent (denote as Zn-SHn). The hydrogel framework with zincophilic $-SO_3^-$ functional group uniformizes the zinc ions flux and transport, and such hydrogel layer chemically bonded on Zn surface obviously suppresses the dendrites formation by guiding the 3D Zn accumulation. Consequently, very stable and reversible Zn stripping and plating at various currents and capacities is achieved. A full cell by pairing the Zn-SHn anode with a NaV_3O_8-1.5 H_2O cathode shows a capacity of around 176 mAh g^{-1} with a capacity retention around 67 % over 4000 cycles at 10 A g^{-1}. The presented polyanionic hydrogel film protection strategy paves a new way for future Zn anode design and safe aqueous batteries construction.

EN03.03.21
Study of Vanadium Oxides at Different Oxygen Flows Prepared by Reactive Magnetron Sputtering and its Evaluation as Cathodes for Lithium Batteries Mackarena Briceño, Juan Fernández, Dario Zambrano, Marcos Flores and Rodrigo Espinoza; Universidad de Chile, Chile

Vanadium pentoxide has intrinsic properties which allow it to obtain electrothermal and thermochemical stability [1]. One of the manufacturing techniques that allow obtaining low thicknesses, homogeneity, and control of the microstructure, is the reactive sputtering magnetron process which also allows to generate different stoichiometries of vanadium oxides and specifically V_2O_5 [1, 2]. The formation of different vanadium oxides mainly depends on the oxygen content of the system [3]. The aim of this work is the study of the effect of oxygen on argon plasma during the process of reactive sputtering and the further influence on the electrochemical performance as electrode. The samples were prepared by DC reactive magnetron sputtering using different oxygen flows and deposited over stainless steel at room temperature. The target was metallic vanadium, while the plasma was argon (15 sccm) combined with oxygen at 1.25, 1.75, 2.25, 2.5, 3.0 and 3.25 sccm. The deposition process was monitored by optical emission spectroscopy (OES), and the samples were characterized by XRD, EDS, Raman confocal spectroscopy, XPS and AFM. In the study of plasma at a constant power of 150W, the OES spectrum exhibited the emission lines of vanadium (458 nm), oxygen (777 nm) and argon (811 nm), showing that the intensity of the V and Ar lines decrease with the increase of oxygen. XRD results demonstrated that the samples were amorphous for all the different oxygen flows. Raman analysis indicated for the sample deposited at 3 sccm, the presence of the V-O-V bonding corresponding to a crystalline structure of the rhombohedral type of V_2O_5, by the vibrational stretching modes (143 cm^{-1}), and of the V=O bonding by the second flexion vibrational band (995 cm^{-1}). XPS established a correlation between the oxygen flow and the main V oxidation state: V^{+4} at 1.25 O-flow, V^{+4}/V^{+3} at 1.75 O-flow and V^{+5} over 2.5 O-flow. A capacity of 280 mAh/g at 1C is observed in the sample with higher oxygen flow in contrast to the samples with lower oxygen flow.

Grid Storage Batteries from Earth Abundant Elements Kyeongjae Cho[1], Fantai Kong[2], Denyce Alvarez[2], Nestor Solorio[2], Matthew Bergschneider[1], Youhwan Jo[1], Manifa Noor[1] and Taesoon Hwang[1]; [1]The University of Texas at Dallas, United States; [2]Hunt Energy Enterprises, United States

Over the last 3 decades, Li ion battery (LIB) production has grown rapidly driven by the mobile device applications and rapid expansion of electric vehicles. Along with these expansions of LIB production, large scale energy storage demands are also rapidly increasing, driven by the increasing renewable energy generation by solar and wind farms. . Recent projections of the global energy trends by the US National Academies require replacing the currently growing fossil fuel consumption by renewable energy sources (mainly solar and wind): 30% in 2030 and 50% in 2040. The intermittent and seasonal nature of solar/wind energy generation will require unusually large-scale energy storage capacity for long durations of 4-10 hours or longer. The global energy infrastructure is under rapid transition away from the fossil fuel economy toward renewable energy economy, and there are multiple challenges and opportunities for the current and emerging energy storage technologies. For the large-scale energy storage applications, fundamentally different electrochemistry with intrinsic safety is required based on earth-abundant elements (e.g., Na, K, Zn, Mg, Ca, Al, Fe, Mn) to avoid the competing demands of LIBs for mobile and EV battery applications
Among many emerging beyond LIB chemistries, aqueous zinc ion battery (AZIB) has recently attracted increasing research attentions due to high Zn energy density (5854 Ah l^{-1} and 820 Ah kg^{-1}), nonflammable nature, good durability, and low cost. Due to the water stability limits, the operating voltage of AZIB is lower that LIB (1.7 V vs. 4 V), but the overall theoretical energy densities are comparable to high ends of LIBs (300 Wh/kg and 500 Wh/L). With further research and development for performance improvements, AZIBs are very promising candidate for grid scale energy storage. The AZIB can be classified based on the electrolyte pH: strongly acidic electrolyte through acid addition, strongly basic electrolyte with alkaline solution, and mild acidic electrolyte with Zn salt solution. Different electrolyte pH leads to different proton electrochemical activity that leads to different electrolyte-electrode interactions, thus fundamental battery operation and degradation mechanism. AZIB with mild acidic electrolyte is an advantageous option due to better safety, lower corrosivity, higher durability, etc. While as both proton and OH- can be active at neutral pH, the fundamental chemistry tends to be more complex. In this work, combined modeling and experimental research progresses are presented to help deepen the understanding on AZIB systems.

9:00 AM *EN03.04.02
Comparisons of Li, Na, K and Mg-Ion Insertion into Layered and Spinel Intercalation Compounds Anton Van der Ven; University of California, Santa Barbara, United States

The electrochemical properties of intercalation compounds commonly used as electrodes in rechargeable batteries are very sensitive to the guest ion that is shuttled between the anode and the cathode. This talk will describe the results of a systematic first-principles statistical mechanics study of guest ion insertion into the layered and spinel forms of A_xMO_2 and A_xMS_2 where A = Li, Na, K, Mg and M = Co, Ti, Ni, Fe and Mn. Differences in the ionic radii and oxidation states of guest ions can lead to important differences in phase stability and diffusion mechanisms. The insertion of large guest ions such as Na and K into layered intercalation compounds, for example, causes a variety of stacking sequence phase transformations in which guest ion coordination by anions switches from octahedral to prismatic coordination. This leads to unique cation-vacancy ordering tendencies and new mechanisms of diffusion. We find that layered Na and K intercalation compounds at intermediate filling are susceptible to Devil's staircase orderings characterized by well-ordered domains that are periodically separated by anti-phase boundaries. The anti-phase boundaries are found to play a crucial role in mediating cation diffusion. The electrochemical properties of spinel are also strongly affected by the guest cation radius and oxidation state. Diffusion over the octahedral sites of spinel is mediated by vacancy clusters, a mechanism that can lead to highly correlated hop sequences. Kinetic Monte Carlo simulations show that correlated diffusion becomes more severe for cations such as Mg with high oxidation states.

9:30 AM EN03.04.03
An Extended Mixed Conduction Governs Cation Transport in Magnesium Cathode Hosts Aashutosh N. Mistry, Ian Johnson, Venkat Srinivasan and Brian Ingram; Argonne National Laboratory, United States

Magnesium batteries have been proposed to complement the existing Lithium-ion technology for the ever-growing battery market[1]. While several candidate cathode materials have been identified based on theoretical Mg-ion intercalation capacity, open circuit potential, and cation self-diffusion barriers[2], the electrochemical response of corresponding electrodes falls short of expectations and is not fully understood[3]. Of various mechanisms governing the electrochemical response, transport inside active particles is a plausible limitation. In this talk, based on careful electroanalytical measurements, we show that such bulk cation transport is indeed nontrivial, and does not agree with the conventional Li-ion understanding[4,5]. We propose an extended mixed conduction theory to explain these observations and characterize properties governing the transport behavior. We further discuss the implications of such an unusual behavior to engineering porous electrodes as well as screening new battery intercalation host materials.

Reactivity of Mg Electrolyte Species on MgV_2O_4 Cathode Surface Heonjae Jeong[1], Dan-Thien Nguyen[2], D B. Buchholz[3], Guennadi A. Evmenenko[3], Jinghua Guo[4], Feipeng Yang[4], Paul Redfern[1], Jian Zhi Hu[2], Justin Connell[1], Venkateshkumar Prabhakaran[2] and Lei Cheng[1]; [1]Argonne National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States; [3]Northwestern University, United States; [4]Lawrence Berkeley National Laboratory, United States

Understanding the interaction of electrolyte species and their reduction mechanism at electrode-electrolyte interface is essential for addressing electrolyte instability and surface passivation in multivalent batteries. In this work, reactivities of selected electrolyte species of magnesium bis(trifluoromethanesulfonimide) ($Mg(TFSI)_2$) in diglyme (G2) electrolyte on the surface of MgV_2O_4 cathode have been studied using a combination of first-principles calculations and experimental approaches such as soft landing of mass-selected electrolyte ions on MgV_2O_4 thin film and x-ray photoelectron spectroscopy analysis of softlanded interfaces. In this talk, we will focus on highlighting the key findings from the calculations of reactivity

and charge transfer of electrolyte species such as $Mg(TFSI)^+$, $Mg(TFSI)(G2)^+$, and $Mg(TFSI)(G2)_2^+$ complexes on MgV_2O_4 (001) cathode surface. Subsequently, their decomposition pathways were investigated by studying the cleavage of C-S bond of $TFSI^-$ that yields CF_3 species, and the cleavage of C-O bond of G2 that yields CH_3 or OCH_3. Our calculations showed that $Mg(TFSI)^+$ is the strongest adsorbing species on the MgV_2O_4 surface compared to other two. The decomposition reactions studied are generally much more favorable on the MgV_2O_4 surface *vs.* without the presence of the surface (gas phase) due to the strong stabilization effect of the surface to the decomposed fragments. The decomposition pathway of the $TFSI^-$ part to form CF_3 is the most favorable reaction for all three species, followed by the G2 decomposition to form CH_3. G2 decomposition that forms OCH_3 is endothermic for all three compounds. Our calculations are also corroborated well with the experimental results, wherein XPS analysis reveals the presence of final stable reaction products such MgF_2, metal oxyfluoride, SO_3^{2-} and C=O due to decomposition of TFSI and G2 part of softlanded electrolyte species. This work reveals the importance of interfacial charge transfer on electrolyte stability at cathode surface. of the influence of reacted products on the formation of interfacial layers are essential for understanding the design principle of stable electrolytes and cathodes in multivalent batteries.

Computational Studies of Ca-Ion Materials for Next Generation Multivalent Energy Storage Peter Zapol[1,2], Haesun Park[1,3], Robert F. Klie[4,2] and John T. Vaughey[1,2]; [1]Argonne National Laboratory, United States; [2]Joint Center for Energy Storage Research, United States; [3]Chung-Ang University, Korea (the Republic of); [4]University of Illinois at Chicago, United States

Development of multivalent energy storage with Ca2+ working ions shows theoretical promise of high energy density, however it faces numerous challenges. Finding high-voltage Ca cathode materials is a critical step to unleashing the full potential of high-energy-density Ca-ion batteries. First-principles calculations are used to evaluate different battery-related properties of cathode materials including thermodynamic stability, average voltage, energy density, synthesizability, ionic mobility, and electronic structure. To highlight recent advances in calcium-ion chemistry, the calculated properties are related to observed performance. Despite a significant advance in Ca-ion cathode development, the findings highlight the need for futher developments.

11:00 AM EN03.04.06
Plating and Stripping Ca-Metal Batteries Using Potassium Hexafluorophosphate in Hybrid Solid Electrolyte Interphases Paul A. Chando, Jacob Shellhamer and Ian Hosein; Syracuse University, United States

The use of calcium (Ca) metal anodes in batteries is currently challenged by the development of a passivation layer that forms in the Solid Electrolyte Interphase (SEI). The passivation layer is formed from the degradation of the electrolyte onto the surface of the calcium and produces either calcium fluoride (CaF_2) or calcium chloride ($CaCl_2$). This insulating phase significantly reduces cation movement while continually forming new layers with freshly plated calcium. Reversible plating and stripping of calcium in such systems has been possible but has required either large overpotentials or operating at elevated temperatures. The use of a hybrid SEI is a strategy to mitigate the uncontrolled production of the passivation layer and reduce the overpotentials needed for the plating and stripping of calcium. Here, we report the development of a hybrid Potassium (K) /Ca SEI using symmetrical Ca // Ca cells. The calcium symmetrical cells are cycled for 200 hours at a capacity of 0.15 mAh/cm^2 with a current density of 0.025 mA/cm^2. Throughout the lifetime of cycling, the symmetrical cells were able to maintain overpotentials below 2V. Ex-situ X-Ray Diffraction (XRD) of cycling reveals plating and stripping of both calcium and potassium. Scanning Electron Microscope (SEM) cross-sectional views of the calcium electrodes outline clear distinctions between the bulk electrode and the interphase formed from cycling while Energy Dispersive X-Ray (EDX) maps confirm the elements present in the XRD analysis.

11:15 AM EN03.04.08
Improving the Charge Storage of α-MoO_3 Electrodes in Zinc-Ion Batteries via Chemical Incorporation of Dopamine-Derived Carbon Darrell E. Omo-Lamai, Nazgol Norouzi, Farbod Alimohammadi, Timofey Averianov and Ekaterina Pomerantseva; Drexel University, United States

Orthorhombic molybdenum trioxide (α-MoO_3) is widely studied as an active electrode material for electrochemical energy storage devices, owing to its layered structure, which offers interlayer sites for cation intercalation, and high Mo oxidation state, which generates potential for multiple electron transfer during reversible intercalation of electrochemically cycled cations. However, one significant impediment to the electrochemical properties of α-MoO_3 is its low electrical conductivity, which prevents rapid charge transfer during electrochemical cycling and thus limits charge storage, particularly at high rates of operation. Thus, the attractive strategy to achieve advances in α-MoO_3 electrochemistry is the incorporation of an electrically conductive species to form an intimate heterointerface between the constituting materials.

In this work, a novel MoO_3-based electrode material containing carbon derived from chemically incorporated dopamine molecules shows an increased capacitance compared to reference α-MoO_3 electrodes in a 5M $ZnCl_2$ aqueous electrolyte. The material was synthesized *via* a hydrogen peroxide-initiated sol-gel reaction that entailed the oxidization of Mo powder in a dopamine hydrochloride (Dopa HCl) solution. A $(Dopa)_xMoO_y$ powder precursor was isolated from the metastable gel through freeze-drying, and subsequent hydrothermal treatment (HT) of this precursor at 180°C produced the new MoO_3 material with carbonized Dopa molecules, denoted as HT-MoO_3/C. The reference α-MoO_3 electrodes (α-MoO_3-ref) were synthesized similarly, but in the absence of Dopa HCl in the initial sol-gel reaction. The appearance of characteristic D and G bands in the Raman spectra and distinct vibrational modes in the FTIR spectra of HT-MoO_3/C confirm the presence of carbon in its structure. SEM images show a uniform nanobelt morphology with fragmentation due to interactions between interlayer Dopa and MoO_3 layers under the conditions of hydrothermal treatment. By means of four-point probe conductivity measurements, the electronic conductivity of rolled films containing 80 wt% HT-MoO_3/C, 15 wt% graphene nanoplatelets (GNPs), and 5 wt% PTFE was determined to be 5.9×10^{-1} S/cm, compared to 2.9×10^{-6} S/cm measured for α-MoO_3-ref films containing identical ratios of (GNPs) and PTFE, thus confirming improved electron transport in the material synthesized via integration with the dopamine-derived carbon.

HT-MoO_3/C delivered a second-cycle capacitance of 141.4 F/g when cycled at 2 mV/s in a -0.25–0.70 V vs. Ag/AgCl potential window in 5M $ZnCl_2$ electrolyte, while α-MoO_3-ref delivered a nearly two-fold smaller second-cycle capacitance of 76.1 F/g under the same conditions. Furthermore, HT-MoO_3/C retained greater capacitance compared to α-MoO_3-ref at each of the increasing sweep rates when cycled from 1 mV/s to 20 mV/s. The superior performance of HT-MoO_3/C prompted a study of the electrode in an expanded potential window, based on previous reports in which α-MoO_3 showed electrochemical activity at negative potentials vs. Ag/AgCl. The HT-MoO_3/C electrode exhibited a capacitance of 347.6 F/g (178 mAh/g) on the second cycle when cycled from -0.85–1.00V vs. Ag/AgCl at 2 mV/s in 5M $ZnCl_2$ electrolyte. The increased charge storage of HT-MoO_3/C compared to α-MoO_3-ref is attributable to facilitated electron transfer in HT-MoO_3/C due to the presence of a tight molybdenum trioxide/carbon heterointerface in its structure as a result of the bottom-up sol-gel approach adopted in its synthesis.
This work demonstrates a new strategy to improve the electrochemical performance of transition metal oxide electrodes for energy storage systems. Integration of oxides with carbon through wet chemistry synthesis approaches that involve carbonization of organic molecules can be used to create pathways for electron transport, leading to improved charge transfer and energy storage properties.

11:30 AM EN03.04.09
Modulation of Surface Chemistry to Overcome the Challenges in Zinc Ion Batteries Jiyun Heo and Hee-Tak Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Rechargeable aqueous zinc ion batteries (ZIBs) are considered promising candidates for large-scale energy storage systems by virtue of their high safety and low cost. Nevertheless, the application of ZIB has been hesitant because of the low cyclability caused by cathode dissolution, non-uniform Zn deposition, and unwanted hydrogen evolution reaction (HER). In this presentation, we present strategies to overcome the above-mentioned problems in ZIBs via modulating surface chemistry of electrode materials.
Manganese oxide (typically MnO_2) is acknowledged as one of the most promising cathode materials in ZIB due to its high voltage and high specific capacity. However, Mn^{2+} continues to dissolve from MnO_2, resulting in low capacity retention of MnO_2. The problematic Mn^{2+} dissolution originates from the charge disproportionation (CD) reaction of Mn^{3+}. Electrically degenerate Mn^{3+} has labile energy states and therefore participates in the relaxation process (CD reaction) producing non-degenerate Mn^{2+} and Mn^{4+}. Several works have notably improved the capacity retention of MnO_2 by coating the surface with physical barriers to prevent Mn^{2+} dissolution. However, these approaches do not address the fundamental cause of the Mn^{2+} formation and only physically suppress the Mn^{2+} dissolution. In order to properly target the underlying cause of Mn^{2+} dissolution, we propose a dicyandiamide-induced cooperative Jahn-Teller distortion (JTD) of Mn^{4+}. Triggering the cooperative JTD of Mn^{4+} alleviates lattice distortion and impedes the CD reaction of Mn^{3+}. Thus, the cycling stability of MnO_2 is improved by more than 170% compared to pristine MnO_2, and exhibits a 99.9% Coulombic efficiency at 1 C rate condition.
With the increasing demand on high current density and high areal capacity, several issues with negative electrode is also revealed to impinge the cycle life of ZIB. This is particularly true of uneven Zn deposition/dissolution reaction and H_2O decomposition reaction considering that these problems are aggravated under harsh operating conditions, consequently deteriorating the reversibility of Zn electrodes. Although numerous reports have challenged these issues by adopting various strategies, the positive effects have been limited to low current densities, low areal capacities, and low Zn utilizations. Here, we report a polymer of intrinsic microporosity (PIM-1) as an interface modulator and ion regulating layer, which reduces the HER and promotes a uniform Zn deposition/dissolution process. Experimental and computational methods are used to demonstrate that PIM-1 improves the reaction kinetics of Zn metal electrodes by altering the solvation structure of Zn^{2+} ions and increasing the work function of Zn surface. As a result, the PIM-1 coated Zn (PIM-Zn) electrode shows significantly improved cycling stability compared to the bare Zn electrode (1700 h and 340 h at 0.5 mA cm^{-2}, respectively). Moreover, PIM-Zn can operate for more than 200 h at 70% Zn utilization even under 10 mA cm^{-2} and 110 h at 95% Zn utilization of Zn metal electrode. The cycle life of the Zn||V_2O_5 full cell is also extended by more than 7 times compared to the cell using bare Zn by adopting the PIM-Zn.
Aqueous ZIB with high safety is an attractive battery system, and there is a persistent consensus that it can partake in the field of future energy storage system. However, it is true that the current technology level of ZIB is far below the level required for commercialization. We believe it is necessary to modulate the surface chemistry of the positive and negative electrode to build better ZIBs.

1:30 PM *EN03.05.01
Lithium- and Transition Metal-Free Fast-Charging Batteries Yan Yao; University of Houston, United States

Battery technologies available today that offer desirable energy density for transportation are based on lithium chemistry, most of which further require transition metals such as nickel and cobalt in their active materials. The availability of these critical commodity elements in the U.S. could soon be pressured due to the growth of the EV market. To enhance the energy supply chain security of the U.S., we herein propose a battery that will match lithium batteries in terms of energy and power densities without using lithium and transition metals in active materials. Our proposed battery will substitute lithium-based anodes with the energy-dense and abundant magnesium, of which metal the U.S. has a virtually unlimited reserve and has been the world's dominant producer. Transition metal-based cathodes will be replaced by organic materials obtained from oil refineries and biorefineries, of both the U.S. has the largest capacity in the world. The "magnesium-organic" batteries are thus a greener and more reliable domestically available alternative to lithium batteries. Our team's recent breakthrough in the technology has overcome the energy and especially power bottlenecks that have traditionally plagued magnesium batteries, resulting in material-level energy densities of up to 579 Wh/kg and fast charging-discharging capability at 20C. The new ARPA-E project will build on our latest discovery and advance the technology on multiple fronts, including electrode material and electrolyte optimization, cycle life extension, practical cell design, and scale-up of material production and cell fabrication. This work is supported by ARPA-E DE-AR0001548.

2:00 PM EN03.05.02
Cation Symmetry Breaking in Molten-Salt Electrolytes Enables Reversible, Long-Duration Storage in Al Batteries Regina Garcia-Mendez[1,2], Jingxu Zheng[3,1], David C. Bock[4,5], Cherno Jaye[4], Daniel A. Fischer[4], Amy Marschilok[4,5], Kenneth J. Takeuchi[4,5], Esther S. Takeuchi[4,5] and Lynden A. Archer[1,2,1]; [1]Cornell University, United States; [2]Cornell Energy Systems Institute, United States; [3]Massachusetts Institute of Technology, United States; [4]Brookhaven National Laboratory, United States; [5]Stony Brook University, The State University of New York, United States

Aluminum is the most earth-abundant metal, is trivalent, and offers a volumetric energy density more than twice that of lithium. It has emerged in recent years as among the most promising candidate materials for cost-effective, long-duration storage of electrical energy in batteries. Scientific discoveries in the past decade have established that rechargeable Al batteries can be created by pairing an Al metal foil with a graphitic carbon sheet in imidazolium-based ionic-$AlCl_3$ electrolytes. Although such cells are of increasing scientific interest, their utility remains limited by the high cost and environmental sensitivity of the ionic liquid, as well as by the surprisingly poor reversibility of Al electrodes in other electrolyte chemistries. We report that application of *Carnelley's rule* to short-chain alkylammonium chlorides enables design of new families of low-cost alkylammonium chloride-$AlCl_3$ molten-salt electrolytes that support highly reversible redox reactions at an Al electrode. Through straightforward manipulation of the composition of $[AlCl_4]^-$ and $[Al_2Cl_7]^-$ species in electrochemical cells, we achieve near-unity efficiency for thousands of charge/discharge cycles and conformal Al electrodeposit morphology at a planar substrate. As a first illustration of the practical relevance of our findings, Al||graphite full cell batteries are created and reported to support stable charge/discharge cycling for more than 1000 cycles. Further, the successful development of this new group of electrolytes creates a robust platform to study in detail the working mechanisms of the electrodes using advanced characterization tools. Our findings open up new opportunities for developing simple, cost-effective, room-temperature Al batteries that enable long-duration electrical energy storage.

2:15 PM EN03.05.03

Anodic Hydration V_2O_3@C for Mg-Ion Battery Cathode Jang Gun and HoSeok Park; Sungkyunkwan University, Korea (the Republic of)

Magnesium-ion batteries are a promising candidate as a next-generation energy storage systems due to high working voltage, high abundance of magnesium metal, and multivalent nature of magnesium-ion. However, finding a suitable cathode material presents a major challenge: low practical capacity and low power density. Due to the strong interaction of the Mg^{2+} ions with the metal oxides commonly used in the cathode. To solve these issues, we demonstrated a novel Mg ion storage mechanism using the in-situ anodic hydration reaction of V_2O_3@C. Through In-situ XRD and Solid-state NMR, we observed the development of V_2O_3@C as a high-power energy storage material during anodic hydration of crystal, which displayed a capacity of more than 381.0 mA h g^{-1} at 0.2 A g^{-1} and 130.4 mA h g^{-1} at 50.0 A g^{-1}. This work not only provides a new type of cathode material for the magnesium-ion system, but also suggests a new mechanism to prevent the loss of active cations due to irreversible reaction (i.e. formation of solid electrolyte interface (SEI) layer) that occurs in the cathode material during the first charge and discharge.

2:30 PM EN03.05.04
Advanced Investigation of the Electrolyte-Mg Anode Interphase for the Development of Mg-Ion Batteries Martina Romio[1], Yuri Surace[1], Nicolas Eshraghi[1], Benedikt Herzog[2], Bruno Eckmann[2], Damian M. Cupid[1], Johannes Hoffmann[2] and Marcus Jahn[1]; [1]Austrian Institute of Technology, Austria; [2]Federal Institute of Metrology METAS, Switzerland

Magnesium-ion batteries (MIBs) represent a promising chemistry to potentially substitute Li-ion technologies in the e-mobility and stationary energy storage applications. This is due to the favourable properties of metallic Mg, such as: abundancy, non-toxic nature, high recycling rate[1], low redox potential (-2.37 vs SHE), safety (smooth Mg^{2+} electrodeposition), as well as divalent character of Mg^{2+} cations which leads to higher theoretical volumetric capacity (3833 mAh/cm^3) than Li (2046 mAh/cm^3) and commercial graphite (760 mAh/cm^3).[2]
However, the major obstacle in the development of MIBs is the incompatibility of Mg anode with electrolyte formed by mixing simple Mg-based salts (e.g $Mg(TFSI)_2$, etc.) and polar aprotic solvents (e.g. acetonitrile, etc.). These solutions decompose at the Mg surface forming an electronic and ionic insulating layer, which blocks the electrochemical activity of Mg anode. Conversely, organoborate (Mg-tetrakis(hexafluorosisopropyloxy)borate in monoglyme, MgBOR)[3] or organoaluminate (1:2 $AlCl_3$:PhMgCl in THF, APC)[4] ethereal solutions are known to prevent the passivation of the Mg metal anode, allowing the reversible Mg^{2+} electrodeposition.
Despite a great effort has been done in the development of MIB,[5] very little is known about the formation, evolution and degradation of the solid electrolyte interphase (SEI) formed at the interface between metallic Mg and electrolyte. This work, therefore, aims to investigate the interactions between Mg metal and passivating ($Mg(TFSI)_2$ in monoglyme:diglyme, $Mg(TFSI)_2$ in M:D) and non-passivating (MgBOR and APC) electrolytes combining *ex-situ* and *in-situ* spectroscopic and microscopic techniques with electrochemical testing (cyclic voltammetry, galvanostatic cycling with potential and electrochemical impedance spectroscopy).
As the first step, a successful polishing method was developed to remove the native oxide layer form the surface of Mg discs allowing to expose a bare Mg metal to the electrolyte solutions. The polishing method also enabled to perform scanning microwave microscopy imaging[6,7] of the Mg metal since a roughness between 1-2.5 µm was achieved. This method was applied to MIB technologies for the first time in this work. The Mg discs were then immersed in the electrolyte solutions and an initial deposition of interfacial species (few nm thickness) was observed by SEM when $Mg(TFSI)_2$ in M:D was used, whereas a smooth surface was detected with MgBOR and APC electrolytes. This resulted in different electrochemical behaviours. In fact, symmetric cells (Mg|Mg) with MgBOR electrolyte showed a significantly higher cycling stability (> 250 h) than those with $Mg(TFSI)_2$ in M:D solution. In addition, when the latter electrolyte was used, fluorinated by-products were identified by X-ray photoelectron spectroscopy. To study the SEI formation and growth further, *in-situ* Raman and was employed to establish a correlation between the chemical composition of the electrolyte, the voltage range of the electrochemical tests and cycling time.

π-Bridge Spacer Embedded Electron Donor-Acceptor Polymer for Flexible Electrochromic Zn-Ion Batteries Jiyoung Lee[1], Tae Gwang Yun[2] and Il-Doo Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Myongji University, Korea (the Republic of)

Zinc ion batteries (ZIBs) have drawn much attention as an alternative to conventional lithium ion batteries due to the high gravimetric/volumetric energy capacities (820 mAh/g, 5855 mAh/cm^3), non-explosiveness, and cost-effectiveness. However, most ZIBs are insufficient to achieve both high energy capacity and multi-functionality (e.g., mechanical flexibility and color visualization), making them undesirable for futuristic smart energy storage systems. In this work, we proposed a π-bridge spacer embedded electron donors-acceptors alternative polymers as cathode materials for multifunctional flexible-ZIBs with high electrochromic and electrochemical performances. This π-bridge spacer endows polymeric skeleton with improved physical accessibility of Zn^{2+} ions and sensitive color variation along the charging–discharging cycles, exhibiting extremely stable cyclability with high specific capacity (95 mAh/g) at very fast rates (8A/g) and large coloration contrast (40%) under severe mechanical deformation and long-period of time (~ 14 days). These results are markedly outstanding than the topological analogue without π-bridge spacer (70 mAh/g at current density of 8 A/g and coloration contrast of 30%) and previously reported other ZIBs. Our strategy to incorporate π-bridge spacer into a polymer network realizes significant electrochromism and electrochemical performance in ZIBs, which paves the way for the future development of smart and stable flexible/wearable electronics.

Dendrite-Free Zn-Ion Energy Storage Using Hybrid Electrolyte and 3D Printed Electrodes Nagaraju Goli, Stefano Tagliaferri, Apostolos Panagiotopoulos, Mauro Och, Rachael Q. Baxendale and Cecilia Mattevi; Imperial College London, United Kingdom

The rapid growth of miniaturized and customized electronics has initiated constant drive towards efficient energy storage systems, featuring high safety, cost-effective fabrication, and innovative design. Among the various energy storage devices, eco-benign zinc (Zn)-ion capacitors with natural abundancy, intrinsic safety, high electrochemical performance, and great compatibility, has nowadays been widely conceded as the most promising power supply for

various portable electronic devices. Nevertheless, the formation of Zn dendrites and unsatisfactory cycling lifetime ascribed by the localized electric field/undesired side reactions on Zn led to an internal short-circuit and dimnished electrochemical performance. Various methods have been designed to inhibit the Zn dendrite formation, which include surface modification and electrolyte optimization. Additionally, compared to the planar/thin film cathodes, design of three-dimensional (3D) electrodes with large surface area could be a promising approach to increase energy density of the Zn-ion capacitor. Recently, Direct Ink Writing (DIW) based 3D printing technology is emerging as a novel platform for the scalable development of 3D architectured electrodes for high-performance energy storage devices. The 3D printed porous electrodes holds several advantages, including large surface area and can be printable in customized shapes within small footprint areas. Herein, we designed DIW-based 3D printed graphene-carbon nanotubes (Gr-C) electrodes as cathode and hybrid electrolyte for high-energy density and dendrite-free Zn-ion capacitors. The hybrid electrolyte provides two key beneficial features on the anode and cathode, which are: a dynamic electrostatic shield layer and a pH regulating effect which reduces the irreversible side reactions and dendrites. In addition, the high surface area and the good electrical conductivity of the 3D printed 6L Gr-C cathode enable a dual-ion electrochemical mechanism with the hybrid electrolyte, which leads to a maximum capacity of 0.84 mAh cm^{-2} and energy density of 0.87 mWh cm^{-2} with good cycling stability. The rate performance of the 3D Gr-C//Zn cells are also evaluated using advanced electrochemical methods. This work demonstrates a pathway towards the cost-effective development of efficient electrolytes and highly conductive 3D electrodes for sustainable energy storage devices.

Do Solvent Exchange Rate Drives Electrochemical Performance of Multivalent Ions? Ying Chen, Karl T. Mueller and Vijayakumar Murugesan; Pacific Northwest National Laboratory, United States

Solvation structures of metal ions have been considered as one of the key components that influence battery performances. Our work here reports that the solvation dynamics, i.e., how fast the solvents and anions exchange between the free and coordinating states, matters more in multivalent electrolytes due to the stronger interaction between the multivalent cations and the solvents/anions compared to monovalent cations. Based on our previous work on magnesium bis(trifluoromethanesulfonyl)imide ($MgTFSI_2$) in 1,2-dimethoxyethane (DME), where Mg^{2+} ions form stable fully solvated clusters $[Mg(DME)_3]^{2+}$ at ≥ 0.1 M, we prepare a variety of mixed-solvent electrolytes by maintaining a Mg : DME molar ratio of 1:3 while varying cosolvents ranging from tetrahydrofuran (THF), 2-methyltetrahydrofuran (MeTHF), bis(2,2,2-trifluoroethyl) ether (BTFE), propylene carbonate (PC) to acetonitrile (ACN), trimethylsilyl imidazole (TMSI) and 2-Methoxyethylamine (MEA). Multinuclear (^{1}H, ^{13}C, ^{19}F, and ^{17}O) NMR studies of these $MgTFSI_2$-3DME-cosolvents reveal a wide range of solvation structures with a fraction of DME, cosolvent or $TFSI^-$ forms stable first solvation sheath with Mg^{2+}. The residence time of coordinating DME or cosolvent can be estimated from ^{1}H-^{1}H 2D EXSY NMR, and the coordination power of the cosolvents can be evaluated accordingly and correlated to the physicochemical properties of the cosolvents (coordination asymmetry, donor number, relative permittivity, viscosity, electrostriction, etc.). Furthermore, cyclic voltammograms of these cosolvent electrolytes demonstrate that a shorter-lived solvation shell with faster exchange between coordinating and free solvent/anions can facilitate cation transport, reduce desolvation energy and promote fast charge transfer at the interface, and therefore leads to better reversible magnesium platting and stripping.

Conducting Polymer and Zinc-Ion Co-Intercalated Vanadium Oxide Nanofibers for High-Performance Stretchable Zinc-Ion Micro-Battery Jeonguk Hwang, Se Hun Lee, Sucheol Kim and Heejoon Ahn; Hanyang University, Korea (the Republic of)

The form of next-generation digital electronic devices has been changed to a wearable design that can be worn or attached to the human body to provide super-connection between people and devices using wireless systems. The wearable electronic device is designed in a stretchable form without shape restriction to secure functionality and wearability. In addition, it is necessary to develop a stretchable battery that can be integrated into a stretchable electronic device to drive a wearable electronic device. Lithium-ion batteries, which are currently the most commonly used batteries, are not suitable as stretchable batteries for wearable electronics due to their flammability and toxicity, which may pose a potential risk to human health. Furthermore, since lithium-ion batteries are manufactured under inert conditions, it is difficult to apply manufacturing processes for stretchable batteries. Recently, aqueous zinc-ion batteries, which have excellent capacity, low price, high safety, and are harmless to the human body, have attracted attention as energy supply devices for wearable electronics. In addition, the aqueous zinc-ion battery has the advantage of being manufactured under ambient conditions where various methods are easily applied, unlike a non-aqueous lithium-ion battery. A wavy-structure strategy has been known as one of the methods for imparting elasticity to objects, and in this strategy, the flexibility of the battery component is inevitably required. However, metal oxides, generally used as the active material for battery electrodes, lack elasticity and flexibility and break easily. As a result, it is difficult to maintain the intrinsic electrochemical performance of the device under repeated deformation. In this study, we developed a stretchable zinc-ion micro-battery with excellent mechanical properties and battery performance. Various strategies such as synthesis of cathode material with improved elasticity and flexibility, pre-zincification, wavy structural design, and assembly technique were applied together to achieve excellent electrochemical performance and mechanical properties of the stretchable zinc-ion micro-battery. Vanadium oxide nanofiber, which is co-intercalated with Zn^{2+} ions and poly 3,4-ethylene dioxythiophene (PEDOT), was synthesized as an active material of the cathode using a facile sonochemical method. The vanadium oxide nanofiber co-intercalated with Zn^{2+} ions and PEDOT showed improved mechanical properties, electrical conductivity, and specific capacity than the vanadium oxide intercalated with only Zn^{2+} ions. In addition, the pre-zincification of the cathode extended the cyclic stability of the stretchable zinc-ion micro-battery. As a result, the stretchable zinc-ion micro-battery exhibited a high areal capacity of 0.15 mAh cm^{-2} and maximum energy density of 0.12 mWh cm^{-2} at a power density of 0.12 mW cm^{-2} and retained 83% of initial capacity over 500 cycles. In addition, the excellent mechanical performance of the stretchable zinc-ion micro-battery was demonstrated while maintaining a capacity of 78.9% during 7000 simultaneous stretching and bending tests. The strategy proposed in this study for fabricating stretchable zinc-ion batteries is expected to contribute to the development of wearable energy storage devices.

Correlating Solvation Structure and Interphase Chemistry in Emerging Multivalent Battery Electrolytes Scott A. McClary, Alan Landers, Kathryn A. Small, Paul G. Kotula, Nathan Hahn and Kevin R. Zavadil; Sandia National Laboratories, United States

Multivalent (MV) metals such as Mg and Ca are promising beyond-Li-ion anode materials due to their high gravimetric and volumetric capacities, high abundance in Earth's crust, minimized dendrite formation, and low reduction potentials [1,2]. However, implementing MV metal anodes is challenging because electrolyte constituents spontaneously decompose when in contact with the metal surface, leading to products that are typically ionically insulating. To achieve high-efficiency cycling with a metal anode, a robust solid-electrolyte interphase (SEI) that simultaneously permits sufficient cation transport and blocks electron transport is required. Studying MV SEIs is challenging due to reactivity of metallic anodes with trace contaminants, and little is known about relationships between electrolyte speciation, SEI composition and structure, and electrochemical performance in exemplar electrolytes [3,4]. Our group recently used cryogenic focused ion beam (FIB) and transmission electron microscopy (TEM) to demonstrate that a nanocrystalline CaO layer containing minority calcium borate and carbonate species is an effective SEI for Ca anodes [5]. Supplemental density functional theory (DFT) calculations showed that the unique interfacial solvation structure is key in forming the heterogeneous SEI.

In this contribution, we employ a suite of multimodal characterization techniques to establish correlations between cation solvation structure, SEI chemistry and structure, and electrochemical performance in exemplar Ca and Mg electrolytes. We first quantify Ca^{2+} and Mg^{2+} solvation in ether-based electrolytes

using Raman, nuclear magnetic resonance, and dielectric relaxation spectroscopies in tandem with complementary DFT calculations. We demonstrate control over bulk and interfacial electrolyte speciation via co-salt addition to $Ca(BH_4)_2$ and $Mg(Bhfip)_2$ electrolytes. We then characterize the chemistry and microstructure of electrodeposited Ca and Mg using analytical electron microscopy, X-ray photoelectron spectroscopy, and time-of-flight secondary ion mass spectrometry. We finally conduct chemical and structural mapping of cation-transmissive SEIs using cryo-FIB and TEM, revealing that heterogeneous films are key in enabling MV cation transport. In all cases, we correlate changes in liquid electrolyte speciation and SEI chemistry with improvements in electrochemical performance. Our results provide critical knowledge that will inform design of practical electrolytes and SEIs for rechargeable MV batteries.

Spatially Controlled Li Electrodeposition on 3-D Patterned Cu Current Collectors Through Nanometer-Scaled Surface Roughness in Li-Metal Batteries Taegyu Jang, Jin-Hyuk Kang, Sujung Kim, Minyoung Shim and Hye Ryung Byon; KAIST, Korea (the Republic of)

Ever-growing demands for electric vehicles and unmanned aerial vehicle systems require higher energy density of energy storage. The metallic lithium (Li) has been considered a promising negative electrode in lithium-ion batteries, owing to its high specific capacity (3860 mAh/g) and a negative electrochemical reduction potential (-3.04 V vs. SHE). Recently, the Li-free copper (Cu) current collectors have also been developed, called anode-free Li batteries, to improve gravimetric energy density further. However, the dendritic growth of Li during the plating process has caused an electric short-circuit and risk of catching fire for both batteries. Various strategies have been suggested to mitigate this detrimental Li deposition. One of the ideas is to utilize three-dimensional (3-D) current collectors, comprised of alternate receding and protruding parts, to induce selective Li deposition into the receding space. However, many studies showed the preferential Li deposition on the protruding area or edges, which rather promoted vertical Li growth and the electric short-circuit.
Here we show that the nanometer-scale surface roughness of the Cu current collector aided the Li plating at the receding space, which improved cell performance. We designed a 3-D Cu pattern through photolithography, followed by chemical etching using 3.5 mol/kg ammonium persulfate solution. The resulting Cu foil had square patterns of the receding and protruding parts, where the former had ~10 μm of offset from the latter surface. They also had a similar Cu oxidation state and surface crystallinity to the pristine Cu foil. However, due to the chemical etching process, the receding area had a rougher surface than the protruding one, measured to be <10 nm of surface roughness. This nanometer-scale roughness in the 3-D Cu foil contributed to two-fold higher capacitance than the flat and pristine Cu foil. In addition, the surface roughness determined the exchange current-density. COMSOL simulation for the 3-D patterned Cu predicted superior local current density at the receding area compared to the protruding part where the enhanced electric field was typically expected. Experimentally, we also observed the selective Li deposition at the receding space thanks to the high surface roughness, better wettability, and high surface energy. COMSOL simulations also indicated that the surface roughness should be dependent on the depth of the receding area if we intended to more intense local current density in this space. Namely, deeper receding areas need more significant roughness. We demonstrated improved Li|Cu cell performances using the resulting 3-D Cu current collectors. This concept guides the design of selective Li deposition in the Li metal and anode-free Li batteries.

EN03.06.02
Dual-Type Gel Polymer Electrolyte for High-Voltage Lithium Metal Battery with Excellent Cycle Life A-Hyeon Ban[1], Su-Jin Pyo[1], Jin-Ah Roh[1], Woo Jin Bae[2], Hyun-Sik Woo[2], Jongseok Moon[2] and Dong-Won Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Samsung SDI R&D center, Korea (the Republic of)

Rechargeable lithium metal batteries (LMBs) using lithium metal as an anode are attractive candidates for high energy density power sources in portable electronics and electric vehicles, because the lithium metal offers the highest specific capacity. However, the development of rechargeable lithium metal batteries has been hindered by the high reactivity of lithium metal toward liquid electrolytes and the occurrence of dendrite growth during charge and discharge cycles. Herein, we report a dual-type gel polymer electrolyte composed of anolyte and catholyte, which improves the cycling stability of LMBs. Anolyte is a poly(ethylene oxide) (PEO)-based hybrid electrolyte that can prevent direct contact between lithium metal anode and liquid electrolyte as well as suppress lithium dendrite growth. As a catholyte, the cross-linked gel polymer electrolyte with high ionic conductivity and oxidative stability was used. The $Li/LiCoO_2$ cell was assembled with dual-type gel polymer electrolyte, and its cycling performance was investigated in the voltage range of 3.0 - 4.48 V at 0.5 C rate. The cell exhibited excellent cycle life with a capacity retention of 87% after 500 cycles, suggesting that dual-type gel polymer electrolyte is promising electrolyte for high-voltage lithium metal batteries.

EN03.06.03
Gel Polymer Electrolyte Based on Localized High-Concentration Electrolyte for Enhancing Cycle Life of Lithium Metal Batteries Ji-Wan Kim[1], Myung-Keun Oh[1], Yeon-A Kim[1], Eun-Ji Kwon[2], Samuel Seo[2], Won-Keun Kim[2], Kyoung-Han Ryu[2] and Dong-Won Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Hyundai Motor Company, Korea (the Republic of)

Lithium metal with high theoretical capacity and low redox potential is one of the promising anode materials for high energy density batteries. However, use of Li metal in conventional liquid electrolyte generates unstable solid electrolyte interphase (SEI) layer on Li metal due to the deleterious reactions between liquid electrolyte and Li metal, which degrades the cycling performance of the battery. To improve the cycling stability, the Li^+ ion-conductive and stable SEI layer should be formed on Li metal. Recently, high-concentration electrolyte (HCE) or localized high-concentration electrolyte (LHCE) have been studied to form the stable SEI on Li metal, because increasing coordination between Li^+ and anion is advantageous for forming stable SEI layer. In our study, we synthesized LHCE-based gel polymer electrolyte for forming stable SEI layer and enhancing cycling stability. Dimethoxyethane (DME)-based LHCE containing small amount of cross-linking agent and lithium nitrate ($LiNO_3$) was used to prepare the cross-linked gel polymer electrolyte. The acrylate groups in cross-linking agent changed the solvation structure of lithium nitrate in LHCE, and increased Li^+ and nitrate anion coordination, resulting in formation of the inorganic-rich SEI layer composed of Li_3N and Li_2O. The electrochemical characterization of gel polymer electrolyte was performed by linear sweep voltammetry and DC polarization. Spectroscopic analyses such as FTIR, Raman, NMR and XPS were used to investigate solvation structure and SEI layer composition. The Li/NCM cells were assembled with LHCE-based gel polymer electrolyte, and their cycling performance was investigated.

EN03.06.05
Nitrate Additive-Chelate BlockNitrate Additive-Chelate Block Copolymer Micelles Enable Stable Lithium Metal Batteries in Universal Carbonate Electrolytes Copolymer Micelles Enable Stable Lithium Metal Batteries in Universal Carbonate Electrolytes Sungjin Cho; Postech, Korea (the Republic of)

The inherent instability of lithium (Li) metal anodes against conventional carbonate-based electrolytes (denoted as carbonates) preclude practical Li-metal batteries (LMBs) delivering high-energy and high-power densities. Herein, we propose an innovative strategy based on a thin micelle layer conjunct with Li nitrate ($LiNO_3$) to enable Li-metal anodes in carbonates without additives. Ionized $LiNO_3$ is linked with polystyrene-block-poly(2-vinyl pyridine) (S2VP) block copolymer micelles via electrostatic interaction, and planted directly on a Li-metal surface. The rational union between S2VP and $LiNO_3$ acts effectively to control the deposited Li morphology and to construct a unique solid electrolyte interface layer having a Li-ion conductivity gradient. The use of S2VP/$LiNO_3$-electrodes enables average high-efficiency (92.6 %) of Li plating/stripping after 100 cycles even at high-temperature. Moreover, S2VP/$LiNO_3$-Li//$LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ full cells achieve long-stable cycling and high-energy-density (~300 Wh kg^{-1}) under limited-excess Li, high capacity, high current density, and lean carbonates without any additives.

EN03.06.06
"Salt-in-Fiber" Electrolyte Enables High-Voltage Solid-State Supercapacitors Nageh K. Allam[1], Loujain G. Ghanem[1] and Basamat Saif[2,1]; [1]American University in Cairo, Egypt; [2]University of California Santa Barbra, United States

The design of functional solid electrolytes is crucial to developing flexible non-sealing supercapacitors for lightweight, wearable, and portable electronics. Herein, an innovative method was used to fabricate LiCl electrospun electrolyte. A solid-state supercapacitor was assembled using LiCl-containing nanofibers as both an electrolyte and separator, and commercial activated carbon as the positive and negative electrodes, respectively. The morphology and chemical composition of the novel electrolyte was revealed using scanning electron microscopy, energy-dispersive X-ray, Fourier transform infrared, and Brunauer–Emmett–Teller analyses. The electrochemical properties of the solid-state supercapacitor were characterized by cyclic voltammetry, galvanostatic charge-discharge, and electrochemical impedance spectroscopy techniques. Additionally, the performance of the supercapacitor device with the nanofiber electrolyte was compared with that of the aqueous electrolyte-based and hydrogel-based devices. The supercapacitor with the LiCl nanofiber electrolyte exhibited an extended potential window of 2.3 V compared to 1.8 V for the aqueous-based device and 2 V for the hydrogel-based device. Consequently, the specific capacitance and energy density were increased by 9.6 and 44.6%, respectively, when both devices are measured at 1 A/g.

EN03.06.07
Three-Dimensional Si/C Composite Thin Films with Helium-Induced Nanostructures for Use as Anode Materials for Next-Generation LIBs Atsushi Hiramatsu, Kenzo Ibano, Heun T. Lee and Yoshio Ueda; Osaka University, Japan

Lithium-ion batteries are widely used as power sources for portable electronic devices such as PCs and smartphones because of their high voltage and high energy density. Recently, they have also begun to be used in electric vehicles (EVs) and as back-up power sources in times of disaster. In particular, EVs, which have been attracting attention in recent years, require high-output, high-capacity batteries, and there is a need to further increase the capacity of lithium-ion batteries. Silicon (Si) anode (Li15Si4 chemical composition, capacity density: 4200 mAh/g) is attracting attention as an anode material expected to have higher capacity, replacing graphite (LiC6 chemical composition, capacity density: 370 mAh/g), which has been used in the past. However, it has been reported that Si anode undergoes large volume changes due to insertion and desorption of Li during charging and discharging, and that the cycle life is shortened due to pulverization [1]. In addition, mechanical crushing of the Si anode during the alloying/de-alloying process during charging/discharging may cause rapid and irreversible capacity reduction and low Coulomb efficiency. One of the methods to solve these problems is the nanosizing of active material particles. Nanoparticles can adapt to large stresses without cracking and shorten the transport distance of electrons and ions. Previous studies have shown that for particle sizes <150 nm, the strain energy stored by electrochemical reactions is insufficient to cause crack propagation in silicon nanoparticles [2]. Another approach to solve the problem of volume change during charging and discharging is the use of composite materials. Since matrix materials do not undergo significant volume changes, they may reduce silicon agglomeration or electrochemical sintering, thereby reducing silicon expansion, maintaining electrode structure, and improving stability. One approach is silicon-carbon composites, the benefits of which include improved electrical conductivity and the buffering effect of the carbon matrix. In addition, carbon additives have the added advantages of excellent ionic conductivity and lithium storage capacity. Based on the above background, in this study, copper was deposited on stainless steel by pulsed laser deposition, and then nano-order Si thin films were fabricated on the copper films by sputtering. The Si nanostructure was then irradiated with helium plasma, and carbon was sputtered onto the surface to create a three-dimensional Si/C thin film. The evaluation of crystal structure properties and the effect on electrochemical performance are reported for these thin films.

EN03.06.08
Improving the Initial Coulombic Efficiency and Cycle Stability of Prelithiated SiO Anode Materials by Topological Optimization Ji Young Kim, Dong Jae Chung, Donghan Youn, Won Joon Jeong, Donghyeok Ma, Tae Rim Lee, Seung Tae Kim and Hansu Kim; Hanyang University, Korea (the Republic of)

Silicon monoxide (SiO) is one of the promising anode materials for lithium-ion batteries. However, some chronic problems remain hindering the commercialization of the SiO such as the low initial Coulombic efficiency (ICE) and the poor cyclability. Many efforts were proceeded to solve these problems by prelithiation or coating the surface. In this work, we demonstrated that the ICE and cycle stability of prelithiated SiO can be improved simultaneously by topological optimization of the prelithiated SiO. We identified phase transformation, microstructural evolution and four exothermic reactions during prelithiation of SiO with LiH through X-ray diffraction, NMR, Raman spectroscopy and TG-DSC. We visualized the microstructure of the prelithiated SiO by laser-assisted atom probe tomography and scanning transmission electron microscopy. The prelithiated SiO, heated at 650°C, exhibits a capacity of 1164 mAh g^{-1} with an ICE of ≈90% and shows remarkable capacity retention of 73.4% after 300 cycles compared to non-optimized homologs. The outstanding electrochemical performances were attributed to the modulated topological arrangement of active Si phase and Li_2SiO_3 inactive buffer phase. Further description of the reaction mechanism will be discussed in the presentation.

EN03.06.10
High Performance Biphasic SiO_x Nanocomposite Anode Material for Lithium Ion Batteries Seungeun Kim[1], Eunjun Park[1], Yeong Eun Kim[1], Juhye Song[1], Da Young Ko[1], Min-Sik Park[2] and Hansu Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of)

Silicon oxides(SiO_x) have gained attention as potential candidate of high capacity anode materials for lithium-ion batteries(LIBs) due to their enhanced cycle performance compared to other Si-based materials. However, these materials are insufficient for commercial use owing to poor electrochemical properties and reliability. We propose a biphasic SiO_x composite with a core-shell structure composed of a silicon monoxide(SiO) as core material and Si nanocrystals embedded in SiO_x(Si/SiO_x) as shell material to improve electrochemical performance. Since the Si/SiO_x shell accommodates the volume expansion of the SiO core material during cycling, the long-term cycle performance is improved for up to 350 cycles. More detailed electrochemical properties of biphasic SiO_x composite will be discussed further in the presentation.

EN03.06.14
Analysis of Doped Silicon Anodes in Lithium-Ion Batteries Alexander Suen, Colin Chu, Aaron Hsi, Shyam Annamalai and Neelima Sangeneni; Aspiring Scholars Directed Research Program, United States

Although graphite-based anodes in lithium-ion batteries have been widely accepted as the primary anode material in rechargeable batteries for several decades, we have reached the limit for further exploration, and finding alternative materials is necessary as sustainable battery solutions increase in demand. The abundance and low cost of silicon present silicon anodes as an energy-dense, sustainable alternative to graphite anodes in lithium-ion batteries with a higher reported theoretical capacity of 4200 mAh/g. However, challenges such as significant volume expansion, rapid pulverization, relatively poor conductivity, and unstable SEI layers formed with the use of silicon anodes hinder practical applications. Micro silicon and nano silicon particles under 150 nm in size show promise regarding the challenges while still utilizing the unique energy characteristics of silicon. Due to a larger surface area with smaller particle sizes, this allows for greater charge intercalation with the anode material and the electrolyte without causing significant volume expansion. In order to test micro silicon and nano silicon, we combined them with Nafion and activated Carbon, and sonicated them into inks before depositing them onto our nickel foam electrode. We also created samples with varying amounts of nano silicon with graphite and tested those as well. Then, we analyzed the current against varying voltages using cyclic voltammetry (CV), which was then used to computationally identify the theoretical capacity of the different micro and nano-silicon. Through our computational analysis, we found the theoretical values of our micro silicon and nano silicon anodes. For nano silicon doped with 20% graphite, the areal capacity turned out to be 245 mAh/cm^2 while the 30% graphite had an areal capacity of 125 mAh/cm^2. Comparatively, pure nano silicon had an areal capacity of 181 mAh/cm^2. Nano silicon doped with 10% graphite is still being analyzed and run through CV to determine the areal capacity. We have also analyzed the voltage of our inks over time using an experiment known as galvanostatic charge-discharge (GCD) on our non-doped silicon inks. This will allow us to measure the longevity of our batteries to ensure sustainability and repeatability. In the future, we will continue testing different ratios of micro silicon and nano silicon with new doping materials to find the true optimum combination, wrap up the remaining CV and GCD's to complete the results, and begin testing our materials in coin cell batteries to confirm real-world applications.

Borohydrides for Use as Solid-State Electrolytes in Battery Applications Tabbetha A. Dobbins; Rowan Univ, United States

This abstract is based on a review article written to describe the status of borohydrides for use as solid-state electrolytes. In it, crucial breakthroughs are highlighted in solid-state ionic conduction in borohydrides for battery applications. Borohydrides, $M^{z+}B_xH_y$, form in various molecular structures, for example, nido-$M^{+}BH_4$; closo-$M^{2+}B_{10}H_{10}$; closo-$M^{2+}B_{12}H_{12}$; and planar-$M^{6+}B_6H_6$ with M = cations such as Li^+, K^+, Na^+, Ca^{2+}, and Mg^{2+}, which can participate in ionic conduction. Key parameters which optimize these materials as solid state electrolytes, such as ionic conduction, electrochemical window, high energy density, and resistance to dendrite formation, are discussed. The full phase space of boron–hydrogen chemistry is described. The open structures (for closo-boranes) leads to rapid ionic conduction. The ability to undergo phase transition between low conductivity and high conductivity phases is also described. The remaining challenge of low electrochemical stability of borohydrides is described– with suggestions to mitigate this issue. This poster provides an overview of the current status of borohydrides for solid state electrolyte applications. It additionally recommends approaches which could further expand computational and experimental research efforts.[1]

Layered Oxides for High-Power and Durable Na Battery Applications Naoaki Yabuuchi; Yokohama National University, Japan

The urge for the worldwide development of renewable energy production has shed light on the crucial role played by energy storage devices. Among them, Li-ion batteries certainly improved our lives with their high energy density which led them to be widely used in consumer electronics, hybrid and electric

vehicles, and renewable energy storage in grids. However, to guarantee the earth environment sustainability through this worldwide energetic transition, the technological answer should be based on abundant materials. In this context, Na-ion battery arises as the ideal solution, and layered oxides are potentially used for positive/negative electrode materials. Although reversible capacity of Ti-based oxides is small compared with hard carbon, quick charge is possible for Ti-based materials without the sacrifice of safety issues related to Na plating. Moreover, excellent cyclability is achieved as electrode materials.[1-3] In addition, large reversible capacity, which is competitive to layered materials used for Li-ion batteries, is obtained for Mn-based layered oxides.[4] Long-term electrode reversibility is effectively improved by avoiding Jahn-Teller distortion on electrochemical cycling. From these results, we discuss the possibility to design practical and durable sodium ion batteries with high power density.

A Universal Principle of Anionic Redox Chemistry in Li/Na Batteries Donggun Eum and Kisuk Kang; Seoul National University, Korea (the Republic of)

Oxygen redox chemistry provides a novel way to realize the high energy density of electrodes for Li/Na batteries. However, the reaction is accompanied by undesirable structural transformations and electrochemical degradation, which limits its practical use. In this regard, we explore the intimate interaction between local structural changes and oxygen redox chemistry during dynamic battery operation. It is demonstrated that the distinct evolution of oxygen-redox activity and reversibility is governed by the different cation migration mechanisms available within the structure of materials. We found that these cation mechanisms play an important role in determining the stabilization pathway of oxygen oxidation. Although π stabilization of oxygen in the absence of cation migration enhances the reversibility of oxygen chemistry, π-interacting oxygen is gradually replaced by σ-interacting oxygen as the electrochemical cycle progresses, resulting in significant structural changes with O–O dimer formation. These findings provide a unified picture for understanding the interplay between structural evolution and anionic redox chemistry and provide further guidance for designing high-energy Li/Na battery electrodes.

Designing Hysteresis Free High-Valent Redox Cathode Materials for Electrochemical Application Iwnetim I. Abate[1] and William C. Chueh[2]; [1]Massachusetts Institute of Technology, United States; [2]Stanford University, United States

Advances in electrochemical devices such as batteries, fuel cells, and water-splitting membranes are making global transition towards clean and renewable energy more possible than ever. Foundational to (electro)chemical and catalytic transformations in these devices are a stable and reversible high-valent redox couples. In particular, the phenomenon of high-valent oxygen redox (anionic redox) in lithium- and sodium-ion positive electrodes has the potential to significantly improve cell energy density by providing additional high voltage capacity beyond that of most transition metal redox couples. However, the additional capacity from (anionic redox) has come at the expense of reduced reversibility in the form of voltage hysteresis and voltage fade. As a result, high valent redox couples have been historically avoided. In this talk, first, I will outline the mechanism and the framework for understanding the source of poor electrochemical reversibility in high valent redox. Second, I will demonstrate a mechanism where structural disorder and voltage hysteresis can be completely avoided. I will finish my talk by discussing a set of actionable design rules to engineer materials for different applications that involve high valent redox couple.

A New Differential Electrochemical Mass Spectrometry (DEMS) Setup and Its Application in Sodium Ion Batteries Jonas Geisler[1], Lukas Pfeiffer[2], Peter Axmann[2] and Philipp Adelhelm[1]; [1]Humboldt Universität zu Berlin, Germany; [2]Center for Solar Energy and Hydrogen Research Baden-Württemberg (ZSW), Germany

Many processes in alkali ion batteries lead to the formation of gases. These can be SEI formation, electrolyte decomposition, oxygen release from certain cathodes to name some. These gas formations are relevant for lifetime and safety of the battery cells. Having information about these side reactions is important to fully understand the cell chemistry. This can be the behavior of single parts, like electrode materials or electrolyte solvents, or the more complex interplay in a full cell.

Differential electrochemical mass spectrometry (DEMS) is a powerful method to understand these processes. By measuring the electrochemical behavior and the gases evolving from the cell at the same time, information is gained under which conditions side reactions occur [1]. This can be state of charge, resting times or temperature changes. While it is such a powerful method, not many DEMS studies have been made on sodium ion batteries (NIBs) [2]. A better understanding of these side reactions in NIBs is still needed. Therefore, we developed a new DEMS system in our group.

This setup was designed to be comparable to other lab scale cells. So, the results would be comparable over different systems. To do so we took the carrier gas based design of Berkes *et al.* as a starting point for our design [3]. From there we did some optimizations to make the system suit our requirements.

In the first part of the talk, we want to present the new DEMS system. Here we want to go into detail about the setup and highlight some key features, which can be advantageous compared to other systems. Besides the instrument the way we analyze our measurement data to calculate the gas evolution from full mass spectra is new in the field of DEMS for batteries. This data evaluation algorithm leads to a better signal to gas attribution and more possibilities to verify the results [4].

In the second part of the talk, we will present results measured with the new system. Here we will show our work on sodium manganese nickel oxide cathodes and hard carbon anodes in half cells and full cells thereof. Comparing the results from half to full cells gives insight into the interplay of the whole cell. The stepwise oxidation of the electrolyte solvent, as well as the cross talk of side products between the electrodes, leads to a complex reaction behavior. To show similarities and differences for different electrolytes, we will present data on carbonate and glyme based electrolytes [4].

Probing Interfacial Reactivity in K Batteries with Nuclear Magnetic Resonance Techniques Lauren Marbella; Columbia University, United States

Beyond Li-ion technologies have the potential to diversify the suite of chemistries that can address our energy storage needs in the next few decades. However, we still do not know if the decades of research dedicated to optimizing Li-ion battery performance is transferable to more earth abundant chemistries, such as K-ion batteries. In this talk, I will discuss our research results that show the addition of fluoroethylene carbonate (FEC), a well-known additive used in Li-ion systems, to K-ion batteries led to a drastic decrease in capacity and cell failure in only two cycles. This performance loss in the K system was attributed to the formation of KF and K_2CO_3 species seen in ^{19}F NMR and XPS on the hard carbon anode surface and was correlated with increased resistance in the cell. The high internal resistance is likely due to the fact that binary K compounds exhibit lower dielectric constants than their Li counterparts and higher activation barriers to ion diffusion. Insight from these results underscore the importance of developing experimental tools to screen potential K-ion conductors to design a solid electrolyte interphase (SEI) layer that facilitates K transport.

Extremely High-Capacity Design of Hard Carbon for Na- and K-Ion Batteries Yoko Tanaka, Daisuke Igarashi, Kei Kubota, Ryoichi Tatara, Tomooki Hosaka and Shinichi Komaba; Tokyo University of Science, Japan

Non-graphitizable carbon, also known as hard carbon (HC), is a promising candidate for a negative electrode material for Na-ion and K-ion batteries because of its high capacity and good cyclability.[1] The electrochemical properties of HC are significantly affected by the carbon source and synthesis conditions.[2, 3] We have recently synthesized a new type of HC, which delivers a capacity of 478 mAh g^{-1}, by using a freeze-dried precursor of Mg gluconate and glucose mixture.[3] In this study, we synthesized HC samples from Mg, Zn, and Ca gluconates (HC-Mg, HC-Zn, and HC-Ca) and electrochemical performance.

The reversible capacities in Na-ion batteries obtained with HC-Mg, HC-Zn, HC-Ca were 383, 418, 258 mAh g^{-1}, respectively. Different reversible capacity obtained could originate from the changes in the size of the micropores in HCs derived from different templates. The irreversible capacities observed at the 1st cycle increased as follows: HC-Zn < HC-Mg < HC-Ca. We also conducted CV to examine the electric double-layer capacitances of the HC-based anodes, and their capacitances were consistent with the trend of variation in irreversible capacities. This suggests that the lower irreversible capacity of HC-Zn was ascribed to lower specific surface area. The charge and discharge behaviors are also examined in K-ion batteries. HC-Zn delivers a larger reversible capacity of 357 mAh g^{-1}, which is much higher than that of graphite (K-GIC).

11:15 AM EN03.07.07
Sodium and Potassium Superconcentrated Aqueous Electrolytes for 2 V-Class Aqueous Batteries Tomooki Hosaka, Ayumi Noda, Kento Chiguchi, Rie Takahashi, Kei Kubota and Shinichi Komaba; Tokyo University of Science, Japan

Recently, superconcentrated aqueous electrolytes have attracted significant attention because of their wide potential window compared with conventional aqueous solutions. According to the literature, 21 mol kg^{-1} $LiN(SO_2CF_3)_2$ (LiTFSA)/H_2O and 27.8 mol kg^{-1} $Li(TFSA)_{0.7}[N(SO_2C_2F_5)_2$ (BETA)$]_{0.3}/H_2O$ electrolytes show potential window of ~2 V and ~3.5 V, respectively.[1, 2] As well as the Li electrolytes, superconcentrated aqueous Na and K electrolytes have been recently studied. In general, aqueous Na and K solutions show higher ionic conductivity than Li counterparts because of their weak Lewis acidity, i.e. weak interaction between the cations and solvents/anions, and consequent small Stokes radii of Na^+ and K^+ ions.[3] Moreover, these cations with weak Lewis acidity stabilize $N(SO_2F)_2^-$ (FSA^-) anion in highly concentrated aqueous solutions.[4, 5] In order to prepare superconcentrated solutions, both anionic mixing and cationic mixing are effective because larger entropy increase from the solid mixtures to the liquid mixtures at the eutectic mixture makes the liquid phase more stable.
Based on the dual cation and dual anion strategy, we recently reported superconcentrated electrolytes of 33 mol kg^{-1} $Na_{0.45}K_{0.55}FSA/H_2O$ [6] and 55 mol kg^{-1} $K(FSA)_{0.6}(OTf)_{0.4}/H_2O$ electrolytes, [7] showing the wide potential windows of close to 3 V. In this presentation, we present electrochemical performance and charge-discharge mechanism of aqueous Na- and K-ion batteries using the superconcentrated solutions.
Using the $Na_{0.45}K_{0.55}FSA$ electrolyte, we designed Na/K dual-ion batteries with $K_2Mn[Fe(CN)_6]$ (KMnHCF) positive electrode material and the NASICON-type polyanionic compounds, $NaTi_2(PO_4)_3$ (NTP) or $Na_3V_2(PO_4)_3$ (NVP), as negative electrode materials. The NTP||$K_2Mn[Fe(CN)_6]$ cell shows reversible charge-discharge curves with mainly two discharge voltage plateaus located at 1.7 V and 1.3 V and excellent capacity retention. Furthermore, the NVP||$K_2Mn[Fe(CN)_6]$ cell demonstrated a 2 V-class operation.
In the 55 mol kg^{-1} $K(FSA)_{0.6}(OTf)_{0.4}$ electrolyte, we evaluated $K_2Mn_{0.5}Fe_{0.5}[Fe(CN)_6]$ (KMnFeHCF) positive and PTCDI negative electrodes, which have been utilized for aqueous K-ion batteries using with 22 mol kg^{-1} KOTf electrolyte.[8] Both positive and negative electrodes achieved highly reversible charge-discharge for 200 cycles. The cycle performances were much better than either 31 mol kg^{-1} KFSA or 20 mol kg^{-1} KOTf electrolytes. Similar to the half cell, the full cell of PTCDI |55 mol kg^{-1} $K(FSA)_{0.6}(OTf)_{0.4}|$ $K_2Fe_{0.5}Mn_{0.5}[Fe(CN)_6]$ delivered highly reversible charge-discharge curves for 200 cycles, achieving capacity retention of 96 %.
We will discuss the impact of mixed anions and cations on the electrode reaction, including mobile ionic species and the surface layer of the electrode in the presentation.

11:30 AM EN03.07.08
High Voltage Potassium Intercalation Cathode Young-Woon Byeon[1], Minjeong Gong[2], Dong-Hwa Seo[2] and Haegyeom Kim[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Alkali-ion intercalation compounds are the most common cathode materials for rechargeable batteries, including Li-, Na-, and K-ion batteries. For several years, layered oxide cathode materials have been considered promising cathode materials for Na- and K-ion batteries because of their high reversible capacity and high working voltage in Li-ion technology. However, our recent findings demonstrated that the layered oxides may not be good candidates for Na and K intercalation cathodes.[1] Na and K transition metal oxide compounds have alkali ion deficient composition ($x<1.0$ in A_xMO_2, A= Na and K), which leads practical difficulty of realizing Na- and K-ion batteries. This is because all the Na and K ions should come from the cathode in rocking-chair batteries. As the insertion ion size increases, the voltage curve becomes much sloped and the sloped voltage curves cause low specific capacity and low average voltage. Both the problems are attributable to much stronger Na^+-Na^+ and K^+-K^+ interaction than Li^+-Li^+ in the layered oxide structure. In this respect, we propose that polyanion compounds will be better candidates because they have 3 dimensional arrangements of Na and K ions, resulting in longer Na^+-Na^+ and K^+-K^+ distance and reduced effective interaction between them. We proved this concept using $KVPO_4F$ as a model system of polyanion compounds, which has stoichiometric composition and provides a high average voltage of ~4.3 V (vs. K/K^+) with a reversible capacity of ~105 mAh/g.[2]
In this presentation, we will discuss (1) why polyanion frameworks can provide high K intercalation voltages (vs. the layered oxides)[1-3] and expand our discussion to understand (2) how local structure factors, such as cation and anion substitutions, affect K storage properties and performance with the $KVPO_4F$ model system.[4]

Effects of Ti-Substitution on Electrochemical Properties of $KVPO_4F$ for K-Ion Batteries Xiaoran Yang and Jae Chul Kim; Stevens Institute of Technology, United States

For large-scale energy storage applications, the potassium (K)-ion battery system consisting of electrodes that reversibly intercalate potassium (K) ions have received recent research interest due to the earth-abundance of K resources.[1-3] To design K-ion cathodes, materials with open and rigid frameworks are considered desirable due to the large ionic radius of potassium.[1, 2, 4-8] Particularly, $KVPO_4F$ with a tetrahedral phosphate framework has the potential to achieve effective K storage.[1, 2, 5] In this presentation, we will demonstrate the impact of partial titanium (Ti) substitution for vanadium (V) on the structure and electrochemical properties of $KVPO_4F$. We found that kinetics and reversibility of K intercalation and the associated physicochemical properties of Ti-substituted $KVPO_4F$ are strongly coupled with local coordination of K. Ti-substituted $KVPO_4F$ delivers a reversible discharge capacity of ~ 97 mAh/g at an average working voltage at 4 V over the extended number of cycles. Our results suggest that understanding the K environment can be an effective approach to designing K-ion cathode materials.

Liquid and Polymer Electrolytes for Potassium-Ion Battery Shinichi Komaba, Tomooki Hosaka, Ryoichi Tatara and Daisuke Igarashi; Tokyo University of Science, Japan

Nonaqueous K-ion batteries have attracted much attention as a potential high-voltage secondary battery owing to the lower standard electrode potential of K+/K than that of Li+/Li.1 Our group has demonstrated a 4 V-class KIB of graphite//K2Mn[Fe(CN)6] (KMnHCF) with 0.7 mol dm-3 KPF6/EC:DEC electrolyte.2 Because of the wide operating potential range, developing nonaqueous electrolytes with higher oxidation stability and the ability to passivate low-potential negative electrodes is one of the major challenges. We will present our recent studies on nonaqueous electrolyte solution, electrolyte additive, and solid polymer electrolyte for KIBs. Based on these results, we provide a design strategy for KIB electrolytes.

KPF6 and KFSA can be used as electrolyte salts because of their sufficient solubility in nonaqueous solvents and their electrochemical stability.3 Highly concentrated KFSA/glyme 4, 5 or KFSA-based ionic liquid (IL)6 electrolytes showed high oxidation stability, good passivation ability toward the Al current collector, and stable solid electrolyte interphase (SEI) formation on the negative electrodes. The KPF6-KFSA binary salt electrolyte allows both Al passivation and suitable SEI formation.7

Electrolyte additives are critical for the long life of K cells. We found that 1,3,2-dioxathiolane 2,2-dioxide (DTD) successfully passivates the K metal surface.8 The DTD addition into nonaqueous electrolytes enables the highly reversible operation of K//KMnHCF cells. Moreover, pretreatment of K metal by a DTD-containing solution enabled the fabrication of 3 V-class all-solid-state K polymer batteries.9

2:00 PM EN03.08.02
Structural Complexity of K-Ion Prussian Blue Analogue Cathodes John Cattermull, Mauro Pasta and Andrew Goodwin; University of Oxford, United Kingdom

Prussian blue analogues (PBAs) are a framework material that are of great interest for use as cathode materials in Na- and K-ion batteries. Whilst Na-ion PBA batteries have been commercialized for use in stationary storage, the high operating potential of some K-ion PBAs offers the exciting prospect of use in electric vehicles where high specific energy density is critical.

Attempts to maximise the specific capacity of PBA cathodes have been made by eliminating $[Fe(CN)_6]$ vacancies. Whilst making these low-vacancy materials has been made possible by altering the synthesis, optimising the electrochemical performance has proved more challenging. Accessing the full capacity with high retention on cycling is one problem, and achieving the same excellent rate capability of the high vacancy PBAs is also non-trivial.

High-vacancy PBAs have an apparent simple cubic structure, but the low vacancy PBAs with high K-ion content have structural distortions. The subsequent phase transitions on cycling these low-vacancy materials are believed to be responsible for poor capacity retention and rate capability.

PBAs have a parent cubic structure with MN_6 (M = Mn, Fe, Co, Ni, Cu) and FeC_6 octahedra decorating a framework, with K^+ ions occupying the channels within. At high concentrations of K^+ in the discharged state of the cathode, the cubic structure is distorted by off-centering of the K^+ ions in the form of sliding alternate layers. High vacancy PBAs with Jahn-Teller active metals at the nitrogen-coordinated site have a cubic structure, as there is no cooperative alignment of the Jahn-Teller axes. Whereas the same PBAs with a lower vacancy content have a cooperative Jahn-Teller distortion. In fact, it is these two distortions – the slide, and the Jahn-Teller – which are most often responsible for phase transitions on cycling and subsequent structural degradation and/or capacity fade.

To explore the impact of these distortions on the functionality of PBAs we synthesised a material that displayed all of these distortions at once, $K_2Cu[Fe(CN)_6]$. From a structural perspective, this is the most complex PBA yet characterised: its triclinic crystal structure results from an interplay of cooperative Jahn-Teller order, octahedral tilts, and a collective slide distortion involving K-ion displacements. These different distortions give rise to two crystallographically-distinct K-ion channels with different mobilities. The crystal structure was solved by Rietveld refinement of synchrotron X-ray powder diffraction (XRD) pattern using ISODISTORT in combination with TOPAS. The low symmetry can be explained in theory by the combination of the aforementioned distortion modes, and is justified from good fit to data in the diffraction pattern (Rwp = 1.95%).

Variable-temperature X-ray powder diffraction measurements show that K-ion slides are the lowest-energy distortion mechanism at play, as they are the only distortion to be switched off with increasing temperature. At higher temperatures we propose a decomposition pathway to form a different Prussian blue material from exsolving the copper ions in the framework.

Electrochemically, the material operates as a K-ion cathode with a high operating voltage, and an improved initial capacity relative to higher-vacancy PBA alternatives. On charging, K^+ ions are selectively removed from a single K-ion channel type and the slide distortions are again switched on and off accordingly.We discuss the functional importance of various aspects of structural complexity in this system, placing our discussion in the context of other related PBAs.

2:15 PM EN03.08.03
Manganese Oxides as Versatile Hosts for Beyond Lithium Ion Electrochemistry Amy Marschilok[1,2], Esther S. Takeuchi[1,2] and Kenneth J. Takeuchi[1,2]; [1]Stony Brook University, The State University of New York, United States; [2]Brookhaven National Laboratory, United States

Future advances in energy storage systems rely on identification of appropriate target materials and deliberate synthesis of the target materials with control of their physiochemical properties in order to disentangle the contributions of distinct properties to the functional electrochemistry. This goal demands systematic inquiry using model materials that provide the opportunity for significant synthetic versatility and control. Ideally, a material family that enables direct manipulation of characteristics including composition, defects, and crystallite size while remaining within the defined structural framework would be necessary. Accomplishing this through direct synthetic methods is desirable to minimize the complicating effects of secondary processing. This presentation will describe synthetic control of manganese oxide composition and structure with resulting impact on electrochemistry. Attributes specific to beyond lithium ion electrochemistry will be highlighted, including comparisons of function in aqueous and nonaqueous electrolyte systems.

Oxygen Redox Activity in P2 Layered Oxides as High Energy Cathodes in Na-Ion Batteries—New Design Hints from First-Principles Michele Pavone, Arianna Massaro and Ana B. Muñoz-Garcia; University of Napoli Federico II, Italy

Na-ion batteries (NIBs) are rapidly emerging as promising post-Lithium technology for large-scale applications, thanks to the wide availability and low cost of raw materials [1]. Design and optimization of highly efficient active materials are major issues for their effective deployment [2]. Layered transition metal oxides (NaxTMO2) have shown outstanding performances as high-energy cathode materials in NIB cells and exhibited the chance to attain larger specific capacity by enabling anionic reactions at high operating voltage [3, 4]. This represents a new paradigm in the development of positive electrodes, but the O2-/O2n-/O2 redox processes need to be finely controlled to prevent the release of molecular oxygen and thus huge capacity loss. We report a first-principles investigation of P2-type Mn-defective layered oxides with different metal doping at the TM site by means of PBE+U-D3(BJ) calculations. Structural and electronic features are dissected for each redox-active element in NaxTM0.25Mn0.68O2 (TM = Ni, Fe) materials as function of sodiation degree corresponding to different states of charge. We address the oxygen redox activity by considering the formation of oxygen vacancies and dioxygen metal complexes at low Na loads (i.e., high voltage range). Low-energy superoxide moieties with different coordination geometries are predicted to be formed at x Na = 0.25 in Mn-deficient sites, while the x Na = 0.125 content enables the release of molecular O2 via preferential breaking of Ni-O bonds. Mechanistic insights show that dioxygen formation is driven by the TM-O covalency and unveil that O2 loss can be effectively suppressed by Fe and Ru doping. Our findings pave the route for the rational design of high-energy NaxTMO2 cathodes that feature enhanced reversible capacity and thus boost the development of efficient NIB devices. These outcomes are subject of our recent publications on ACS Energy Letters and Journal of American Ceramic Society [5, 6].

Tape/Freeze-Cast PVDF-HFP/Silica Composite Membranes for Separators in Na-Ion Batteries Chun-Wei Wu[1], Katherine T. Faber[1], Xiaoping Lin[2] and Hansan Liu[2]; [1]California Institute of Technology, United States; [2]Talos Tech LLC, United States

Separators for Na-ion batteries benefit from directionally aligned pores for shorter transport paths, high porosity, and hydrophilicity for greater electrolyte uptake. This can be achieved by tape/freeze casting of polymeric solutions with ceramic fillers as reinforcements. In this study, the introduction of silica particles from the sol-gel reaction of tetraethoxysilane (TEOS) into poly (vinylidene fluoride-hexafluoropropylene) (PVDF-HFP) membranes is attained by a co-solvent method in conjunction with dimethyl sulfoxide (DMSO). The effects of TEOS on the microstructure, crystal structure, hydrophilicity and mechanical properties of tape/freeze-cast membranes have been investigated. In addition, the effects of silica reinforcement in the composite membrane separators on ionic conductivity, MacMullin numbers and electrochemical performance of NVP/NTP coin cells have been studied. The tape/freeze-cast PVDF-HFP membranes fabricated with DMSO as the solvent exhibit directionally aligned and dendritic pores, while a hierarchical pore morphology with spherical pores on the aligned pore walls is found in membranes fabricated with the addition of TEOS. With the introduction of silica, as confirmed by EDX and FTIR, composite PVDF-HFP/SiO_2 membranes exhibit similar porosities but greater tensile strengths and a noticeable increase in electrolyte uptake and hydrophilicity compared to its unreinforced polymer counterpart. Due to the incorporation of silica, the composite membrane separators show higher conductivities and lower MacMullin numbers. Furthermore, the coin cells with composite membrane separators outperform those with polymer membrane separators and filter papers as separators in capacity retention from charge-discharge and cycling performance tests.

Impact of Electrolyte Additives on Interphase Chemistry and Performance in Potassium-Ion Batteries Zachary T. Gossage, Tomooki Hosaka, Tatsuo Matsuyama, Ryoichi Tatara and Shinichi Komaba; Tokyo University of Science, Japan

Potassium-ion batteries are an emerging energy storage technology with promising aspects including high access and good distribution of potassium sources, earth-abundant electrode materials, and voltages comparable to lithium-ion batteries.[1] At the forefront for electrode materials are graphite, as the negative electrode, and Prussian blue analogues, for the positive electrode. While these materials offer good theoretical capacities and redox potentials, their high performance is often achieved in relatively expensive electrolytes based on potassium bis(fluorosulfonyl) amide (KFSA) and potassium bis(trifluoromethanesulfonyl) amide (KTFSA). As an alternative, the costs of the electrolyte could be minimized through low concentration additives in an inexpensive electrolyte, such as potassium hexafluorophosphate (KPF_6) in a carbonate ester solvent.[2] In this work, we explored fluorosulfonyl-type additives that have a similar structure to the electrolyte KFSA, among others, at low concentration (below 10 weight %). We focused on the impact of these additives on graphite and manganese Prussian blue ($K_2Mn[Fe(CN)_6]$) performance within KPF_6 electrolytes. We found the use of even 1 weight percent of KFSA or dimethyl sulfamoyl fluoride additives could improve the initial charge/discharge coulombic efficiency and subsequent capacity access. We further explored the additive impact on rate performance and charge transfer properties. Lastly, we evaluated the resulting interphase chemistry through surface techniques (e.g. XPS) and other analyses to understand how the additives react at the electrode surfaces. Alike to the additives applied in lithium-ion batteries,[3] we found evidence that small differences in the additive structure can strongly impact the resulting degradation reactions and their subsequent impact on cell performance.

Interfacial Science and Engineering in all Solid-State Batteries—A Comparison Between Li SSB and Na SSB Y. Shirley Meng[1,2,3]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States; [3]University of California, San Diego, United States

Compared with their liquid-electrolyte analogues, Solid state electrolytes SSEs have drawn increased attention as they promote battery safety, exhibit a wide operational temperature window, and improve energy density by enabling pure metals as anode materials for next-generation rechargeable batteries. Despite suitable mechanical properties to prevent metal dendrite penetration, relatively wide electrochemical stability windows, comparable ionic conductivities, and intrinsic safety, most SSEs are found to be thermodynamically unstable against reactive metals such as Li and Na, where SSE decomposition produces a complex interphase, analogous to the SEI formed in liquid electrolyte systems. An ideal passivation layer should consist of ionically conductive but electronically insulating components to prevent the SSE from being further reduced. Study of the buried interfaces in solid state electrolytes has been challenging. Originating from the structural biology field, cryogenic focused ion beam (cryo-FIB) and cryogenic electron microscopy (cryo-EM) have recently been introduced to battery research, and have proven the ability to preserve and probe reactive metals for quantitative structural and chemical analysis. I will do a comparative study for lithium based and sodium based all solid state battery platforms.

Room-Temperature Electrochemical Fluoride (De)Insertion into $CsMnFeF_6$ Jessica Andrews, Eric McClure, Michael J. Brady and Brent Melot; University of Southern California, United States

Understanding the structural changes induced by cation intercalation has proven crucial to augmenting the performance of Li-ion batteries. However, little work has been done to understand the mechanism of anionic intercalation and its effects on host structures. The possibility of anions serving as charge carriers for electrochemical energy storage provides an alternative frontier to explore a variety of new rechargeable battery materials. Systems that leverage fluoride intercalation have recently been reported, but the solid electrolytes utilized in these cells suffer from low room temperature fluoride conductivity, thereby requiring high operating temperatures and limiting practical use. Recent advancements in liquid electrolytes include salt and solvent combinations that exhibit significant fluoride ion shuttle at room temperature and relatively large electrochemical windows. We will present on the reversible, electrochemical (de)fluorination of $CsMnFeF_6$ at room temperature using a liquid electrolyte. $CsMnFeF_6$ can be synthesized via three methods (hydrothermal, ceramic, and mechanochemical), each of which yield products in a defect pyrochlore structure with varying particle sizes and phase purities. After three galvanostatic cycles, approximately one fluoride ion can be reversibly (de)inserted into mechanochemically synthesized $CsMnFeF_6$ for multiple cycles. Ex-situ X-ray absorption spectroscopy confirms that both Mn^{2+} and Fe^{3+} are redox active. The cell impedance decreases after one cycle, suggesting the formation of fluoride vacancies in early cycles generates mixed-valent Fe and enhances the material's conductivity. Ex-situ synchrotron diffraction shows subtle expansion and contraction of the $CsMnFeF_6$ cubic lattice on insertion and removal, respectively, during the first two cycles. New reflections intensify in the cycle 3 ex-situ diffraction, corresponding to the formation of a new phase from the topotactic transformation of $CsMnFeF_6$ in the pyrochlore structure into an orthorhombic polytype that continues cycle reversibly cycle fluoride ions for up to 10 cycles.

EN03.10.02
Polymeric Anchor-Driven Multilinked Graphite Electrode for High-Performance Durable Anion Storage Jieun Kang; Pohang University of Science & Technology (POSTECH), Korea (the Republic of)

A booming market for electric vehicle and stationary energy storage systems has contributed to explosive research efforts to realize impeccable rechargeable batteries. Lithium-ion batteries (LIBs) with high energy density and long lifespan have led the new renaissance of the rechargeable battery market for the past few decades, but their limited theoretical energy density and expensive/finite resources (e.g., lithium (Li), cobalt, nickel) call for the development of next-generation rechargeable batteries with advanced battery chemistry. Among the feasible alternatives, anion intercalation-type batteries such as dual-ion batteries (DIBs) and aluminum-ion batteries (AIBs) have emerged as promising energy storage systems utilizing the inexpensive transition metal-free host materials (e.g., graphite) and anion redox chemistry while delivering compatible energy/power density, cycle life, and safety of rechargeable batteries. Particularly, DIBs have achieved energy density close to commercialized LIBs (~250 Wh kg^{-1}) despite a short research history due to the high-voltage redox reaction of anions (>5.0 V *vs.* Li/Li^+). The Li-ions and counter ions (i.e., anions) in the electrolyte are simultaneously stored inside the anode and cathode host during charge-discharge, respectively, and thus shortened diffusion length of each charge-carrier ion significantly improves the rate capability of the DIBs.
High-voltage anion-intercalation into the graphite cathode increases the operating voltage of batteries but entails inevitable structural deterioration (~200% of volume expansion) in repeated anion (de-)intercalation of large-radius anions (e.g., PF_6^-, FSI^-, $TFSI^-$) into the graphite. Analogous to high-capacity alloying-type anode (e.g., Silicon) in LIBs, such structural issues cause electrically isolated "dead" graphite, electrical contact loss between graphite particles, and the formation of unstable/thick cathode electrolyte interphase (CEI) that blocks the anion diffusion pathway, resulting in the material and/or electrode-level collapse and failure of sustainable anion storage. . Based on studies of large-volume-change materials, several material designs have been proposed to mitigate the degradation of graphite electrodes: (i) Introducing electrochemically anion-inactive inorganic coating layers (e.g., Al_2O_3) that physically encapsulate graphite; (ii) Using porous micro/nanoflake or nanoribbon morphologies to accommodate volumetric expansion during anion (de-)intercalation; (iii) To extend the interlayer spacing of graphite; (iv) Interlayer binding design directly connecting graphene layers with a carboxylic anhydride functionality. Such approaches have achieved significant improvements in battery cycle stability and rate capability. However, adding an electrochemically anion-inactive material lowers the energy density of the battery. Also, the excessively widened specific surface area of the host material causes excessive electrolyte decomposition and CEI generation. Therefore, there is a need for an effective strategy for simply mitigating graphite electrode degradation while overcoming the limitations of existing methods.
Here, we report a high-performance durable graphite electrode using polymeric binders, which are essential for electrodes. A designed high-voltage polymer strongly holds the graphite integrity through the formation of a direct covalent bond with graphite. The graphite electrode with the designed binder shows remarkable rate capability and long-term performance of DIBs and dual-graphite batteries. In addition, it shows superb cell performance even when used for existing LIB graphite anodes. The binder design presented here offers guidelines for further designs of the advanced binder for carbonaceous host material with anion intercalation-type redox chemistry.

EN03.10.03

Changes of Charge Storage Mechanism of Aqueous Battery Depending on pH Youngjae Hong, Changmin Lee and Sung-Yoon Chung; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Aqueous zinc-ion batteries (AZIB) are the promising candidates for the next-generation energy storage system due to their inherent safe, eco-friendly, and cost-effective characteristics. However, the development for high performance is hindered by the lack of understanding on the charge storage mechanism of AZIB. In fact, there is an ongoing debate on which of the two cations, Zn^{2+} and H^+, dominantly works as major charge carriers and how much of those contribute to the charge storage of AZIB. Here, we visualized that the charge storage mechanism varies depending on electrolyte pH in AZIB system consist of the orthorhombic α-V_2O_5 cathode. Proton is major charge carrier in acidic (pH=1~2) electrolyte, meanwhile, Zn^{2+} ion is major carrier in near-neutral condition (above pH=4). Furthermore, pH dependency exists not only in zinc ions, but also in other aqueous electrolyte systems such as Na^+, Mg^{2+}, and Al^{3+}. Finally, we tried to conclude the discussion about Zn^{2+}/H^+ insertion chemistry to some extent by confirming that not only the pH but also the absolute amount of proton can affect the storage mechanism. Through this study, we enable to design an insertion carrier for the aqueous battery system by tuning the salt, concentration, etc.

EN03.10.05
Study of Lithium-Excess Manganese Oxyfluorides with Mn^{2+}/Mn^{3+} Ions for Li Storage Applications Asuka Kanno[1], Naoaki Yabuuchi[1], Issei Ikeuchi[2], Mitsuhiro Hibino[2] and Kensuke Nakura[2]; [1]Yokohama National University, Japan; [2]Panasonic Energy Co., Ltd., Japan

To further increase energy density of rechargeable Li batteries, the development of high-capacity positive electrode materials is required. Recently, our group has reported that the use of anionic redox in Li-excess Mn-based oxides as high-capacity positive electrode materials. [1)] In this study, this concept is extended to Li-excess Mn-based oxyfluorides, in which higher operating voltage is expected for anionic redox associated with the incorporation of fluoride ions with higher electronegativity. [2)]
Synthesis of oxyfluoride with different compositions has been conducted on the basis of a triangular phase diagram consisting of LiMnOF, Li_2MnO_2F, and Li_2MnOF_2. Single-phase samples are obtained for Li_2MnO_2F with Mn^{3+} ions and $Li_2Mn^{2+}O_{3/2}F_{3/2}$ with Mn^{2+}:Mn^{3+} = 1:1, synthesized by mechanical milling. These samples are crystallized into the cation-/anion-disordered rocksalt-type structure with low crystallinity. On the other hand, a single phase sample cannot be obtained for Li_2MnOF_2 with Mn^{2+} ions. Although Li_2MnOF_2 was electrochemically inactive, Li_2MnO_2F and $Li_2Mn^{2+}O_{3/2}F_{3/2}$ deliver a large reversible capacities of >250 mA h g^{-1}. Note that the capacity retention is partly improved by the enrichment of Mn^{2+} ions with less anionic redox. Based on these results, we will further discuss the possibility of Li-excess manganese-based oxyfluorides with different chemical compositions for Li storage applications.

EN03.10.06
Scaled-Up Synthesis of High-Energy Vanadyl Phosphate LIB Cathode Material Jonathan Miller, Krystal J. Lee, Hui Zhou and Stanley Whittingham; M.S. Whittingham Group, United States

Lithium-ion batteries (LIBs) have rapidly become the focus of renewable energy storage over the past decade due to their high cycle life, energy density, and capacity. With the automobile industry preparing for a significant increase in electric vehicle (EV) production, it is more important than ever to develop high-energy cathode materials. These materials should ideally be cobalt and nickel-free. Vanadium is the fourth most abundant transition metal, and moreover can undergo a two redox reaction, from V 5+ to V 3+ . Vanadyl phosphate (VOPO 4) has shown increasing promise as a viable cathode material for lithium-ion batteries as it is capable of intercalating up to 2 Li + ions reversibly, reaching a capacity that exceeds 300 mAh/g and an energy density higher than commercial NMC cathodes. However, an underlying issue surrounding this material is that it is not commercially available so must be made in-house. ε- VOPO 4 with excellent electrochemical performance, reported by our team, was synthesized via a solvothermal method which normally gives a low (~1.5 g) product yield for one batch synthesis. The primary focus of this work is to increase the yield without sacrificing the electrochemical performance. By increasing the concentration of reagents while keeping the amount of solvent
constant, VOPO 4 synthesis has been successfully scaled up by a factor of five. Although some particle morphology changes occurred with increased reagent concentration, possibly due to pressure changes inside the reaction vessel, there is no discernible influence on electrochemical performance. By monitoring the physical properties of each synthesis, an optimal procedure will be developed to scale up the production of VOPO 4 to 100 g per batch. This work was supported by the NorthEast Center for Chemical Energy Storage (NECCES).

EN03.10.07
Study of Factors Affecting the Reversibility of Anionic Redox in Mn-Based Li-Excess Layered Oxides Kazuki Yukishita[1], Naoaki Yabuuchi[1] and Tokuhiko Handa[2]; [1]Yokohama National University, Japan; [2]BMW Japan Co., Japan

$Li_{1.2}Co_{0.13}Ni_{0.13}Mn_{0.54}O_2$, a solid solution sample between Li_2MnO_3 and $LiCo_{1/3}Ni_{1/3}Mn_{1/3}O_2$, delivers a large reversible capacity exceeding a theoretical capacity based on cationic redox of transition metal ions by using charge compensation of oxide ions, *i.e*., anionic redox. However, continuous oxygen loss on charging results in a decrease in average operating voltage, which is known as a critical issue for practical use.[1] In this study, to retain high energy density for $Li_{1.2}Co_{0.13}Ni_{0.13}Mn_{0.54}O_2$, the impact of the substitution of transition metal ions with Al^{3+} ions, which have high ionic bonding characters with oxygen on reversibility of anionic redox and oxygen loss is systematically examined. For comparison, Co-free and Al-substituted Li-excess layered oxides are synthesized and tested as positive electrode materials. Based on these results, we will further discuss the factors affecting the reversibility of anionic redox and the possibility of anionic redox for practical battery applications.

EN03.10.08
Systematic Studies on Li-Excess Mn-Based Oxides with Disordered Rocksalt Structure Nanaka Shimada and Naoaki Yabuuchi; Yokohama National University, Japan

Demand for lithium-ion batteries with higher energy density is rapidly growing all over the world to realize a carbon-free society in the future. Li-excess Mn-based materials based on abundant Mn ions are attracting research interest as cost-effective and high performance electrode materials, and our group has reported that solid solution materials of $LiMnO_2$ and Li_2TiO_3 ($Li_{1.33}Ti_{0.67}O_2$) with disordered rocksalt structure.(1) The solid solution materials deliver a large capacity with reversible cationic/anionic redox. However, the improvement of electrode reversibility is necessary to use anionic redox in practical battery applications. Therefore, in this study, the optimization of chemical compositions and particle sizes in $LiMnO_2$–Li_2TiO_3 solid solution samples has

been conducted. Through electrochemical and structural characterizations for the optimized materials, we will discuss factors affecting the activation and reversibility of anionic redox for Li-excess Mn-based oxides with the disordered rocksalt structure for lithium-ion battery applications.

EN03.10.09
Crosslinked Polyacrylate Binder and Electrode Maturation for Si-Based Composite for LIB Shogo Yamazaki[1], Ryoichi Tatara[1], Tomooki Hosaka[1], Hironori Mizuta[2], Kei Kawano[2] and Shinichi Komaba[1]; [1]Tokyo University Of Science, Japan; [2]FUJIFILM Wako Pure Chemical Co. Ltd., Japan

SiO has attracted significant attention as a high-capacity electrode material for Li-ion batteries. The mechanical stability of composite electrodes is critical for ensuring a long-term cycle life because Si exhibits large volume changes during lithiation-delithiation process. The use of partially neutralized crosslinked sodium polyacrylate (CLPA) as a binder for Si electrodes was previously shown to improve the capacity retention[1]. Moreover, Hernandez et al. reported that a maturation process, wherein the Si electrode slurry was cast onto a Cu foil, following which the pre-dried electrode was stored in a humid atmosphere, improved the cycling performance of the electrode[2]. Building on these studies, a new CLPA binder was applied; this binder could suppress the electrode volume changes inherent to SiO, which exhibits smaller volume changes than Si. Subsequently, the SiO electrodes were subjected to maturation treatment and its effects on the electrochemical properties and performance were evaluated.
Three kinds of CLPA-based binders were used herein. The carboxyl groups of CLPA were modified by the covalent attachment of functional groups to enhance the mechanical flexibility of the electrode. The modified CLPA samples, with carboxyl functional group contents of 0%, 20%, and 50%, were denoted as CLPA, CLPA-20, and CLPA-50, respectively. Polyvinylidene fluoride (PVdF) or the CLPA-based binders, carbon-coated SiO, and acetylene black were mixed into a slurry, which was subsequently casted onto a Cu foil substrate to prepare negative composite electrodes. The cast electrodes were stored under 92% RH for two days before vacuum drying at 100 °C as part of the maturation process. These electrodes were analyzed using 2032 coin cells with Li metal counter electrodes and a 1 mol dm^{-3} $LiPF_6$/ethylene carbonate:dimethyl carbonate (1:1, (v/v)) with 2 vol% fluoroethylene carbonate (FEC) electrolyte under charge-discharge cycling in the voltage range of 0.002–1.0 V.
Among the three different binders, the SiO electrode prepared with CLPA-20 showed the highest discharge capacity after 90 cycles. The maturation process increased the discharge capacity and efficiently suppressed the capacity decay. The dispersibility of the electrode constituents was likely improved through changing the chemical structure of the binder polymers and maturation treatment. Thus, the mechanical stability of the electrode was improved and electrolyte decomposition at the active material surface was suppressed.

EN03.10.11
Effect of Carbon Properties on the Lithium-Sulfur Battery Performance H. Merve Bilal, Kagan Yuksel and Damla Eroglu; Bogazici University, Turkey

Lithium-Sulfur (Li-S) batteries have attracted great attention as a beyond Li-ion chemistry because of their high theoretical specific capacity in addition to the natural abundance and low cost of sulfur, the active material in the cathode. Yet, due to the highly complex reaction and shuttle mechanisms in the cell, cell design, specifically the design of cathode materials, is highly determinative of the Li-S battery performance. For instance, the battery performance is vastly sensitive to the type and properties of the carbon in the cathode since Li-S batteries typically use an excess of carbon in the cathode to achieve high electronic conductivity and surface area. In this study, the impact of carbon type and properties on the electrochemical, cell- and system-level performance of the Li-S battery was investigated by combining experimental and modeling techniques. First, the influence of carbon properties on the discharge behavior and cycling performance of Li-S batteries were inspected experimentally for cathodes prepared at different thicknesses (in other words, different S loadings) with three different carbons exhibiting various pore volumes, particle sizes, and specific surface areas: Acetylene Black (AB), Ketjen Black (KB), and Carbon Black (Super C65). Moreover, the influence of S loading on the battery performance was studied for these three different carbons. Following experimental characterization, a system-level performance model projecting the specific energy and energy density of the battery pack as a function of the carbon type and S loading was proposed by modifying the publicly available Battery Performance and Cost (BatPac) model. The performance model considers the experimental dependence of the discharge capacity on the carbon type. It also includes a one-dimensional electrochemical model predicting the area-specific impedance (ASI) and overpotential for each cell component. Subsequently, the variance of the current-voltage relation with the carbon properties was also reflected in the model.
The cycling behavior of Li-S cells with varying sulfur loadings indicates that the carbon used in the cathode has a decisive impact on how the S loading affects battery performance. For instance, Li-S cells with AB present no significant dependence on the S loading, whereas Li-S cells with Super C65 show higher capacity retention at higher S loadings. On the other hand, Li-S cells with KB cannot achieve high performance at higher S loadings, which is quite unexpected due to its considerably higher surface area. The inhomogeneous distribution of S in the cathode may cause this inferior performance. Our results also suggest that carbon properties are more determinative of the cycling performance at higher S loadings. Moreover, the highest pack performance is predicted for Super C65. Interestingly, Li-S cells with both AB and Super C65 cathodes achieve the highest system-level metrics at medium S loadings, where the discharge capacities are maximized. This suggests that the decrease in the cell weight and volume with increasing S loading has a less dominant effect than improving the cell capacity. Our results clearly show that maximizing the energy density and specific energy of the battery pack is critical, and optimizing Li-S cell design based solely on the discharge performance may be misleading.

EN03.10.12
Build a High Energy Density Li-S Battery with Long Lifespan Xiaowei Wang[1], Bhargav Bhamwala[1], Saurabh Parab[1], Bingyu Lu[1], Darren H. Tan[1] and Y. Shirley Meng[2,1]; [1]University of California San Diego, United States; [2]The University of Chicago, United States

Commercialization of high energy lithium-sulfur battery is hampered by bottlenecks like low sulfur loading, high cathode porosity, low cycling stability. Herein, we developed a tool box of quantification to identify the limiting factors in Li-S batteries under practical lean Li and electrolyte conditions. As guided by the root reasons identified, we strategically synthesized densely stacked redox-active hexaazatrinaphthylene (HATN) polymer with a surface area of 302 m^2 g^{-1} and a very high bulk density of ~1.6 g cm^{-3}. Uniquely, HATN polymer has a similar redox potential window to S, which facilitates the binding of Li_2S_x and its transformation chemistry within the bulky polymer host, leading to fast Li_2S/S kinetics. For another, we designed and synthesized a non-sacrificial NewEle to replace the decomposition-based $LiNO_3$ to achieve long cycle lifespan of Li-S battery. The compact polymer/S electrode presents a high sulfur loading of ~10 mg_s cm^{-2} with a low cathode porosity of 30%. It delivers a high areal capacity of ~10 mAh cm^{-2} and good cycling stability

(500+ cycles) at electrolyte-sulfur (E/S) ratio of 5 µl mg_s^{-1}. This works paves the way for achieving practical high energy Li-S battery with long lifespan.

EN03.10.13
Hybrid Supercapacitors—A simple Electrochemical Approach to Determine Optimum Potential Window and Charge Balance Manar M. Hazaa, Nageh K. Allam, Doha M. Sayed and Loujain G. Ghanem; The American University in Cairo, Egypt

In this work, we introduced novel, and simple electrochemical principles to guide the choice of the safe and valid operating potential window profile for carbon-based hybrid supercapacitor. The start vertex potential of the cyclic voltammograms (CVs) is set as the potential of zero charge (PZC). However, the final potential limit is chosen after elucidation of the storage mechanism using the CVs measured at various potential scan rates across the overall examined potential window. In addition, the mass and charge balance of the fabricated hybrid electrodes are rationally designed after evaluation of the potential window of the two separate electrodes. Using those strategies, a record performance merits are achieved of a hybrid device made up of carbon derived from biomass and carbon derived EDTA salt. The assembled device exhibits a specific capacitance 265 F/g at 5 mV/s and 221 F/g at 1 A/g with a high capability rate. Moreover, the device shows exceptional stability over 10,000 cycles with 100% capacitive retention and near 100% columbic efficiency. Most importantly, attaining a battery-like energy level of 99.2 W h/kg is a proof of concept that validates the proposed electrochemical fundamental methods for monitoring the mass ratio balancing of the hybrid cell electrodes.

EN03.10.14
Predicting Electrochemical Stability Window of Polymer Electrolytes with First-Principles Approaches Pax E. Makhura and Qing Zhao; Northeastern University, United States

Polymer electrolytes in lithium-ion batteries represent an emerging paradigm for energy storage by offering numerous advantages over liquid or solid electrolytes through enhanced resistance to variations in volume of electrodes during charge/discharge process, safety, flexibility, and processability. Overcoming the current limitations of polymer electrolytes necessitates a fundamental understanding of their electrochemical stability window (ESW), which controls polymer electrolyte performance and degradation during charge/discharge cycles. First-principles simulations can provide valuable insights into such properties. However, the widely used density functional theory (DFT) unfortunately engender foundational errors, resulting in incorrect frontier-orbital and band gaps. Here, we carry out a systematic study to accurately and efficiently predict ESW of selected polymer electrolytes. We first identify the most accurate correlated wavefunction (CW) theory methods in predicting ESW of polymers of which experimental data is available. We then develop DFT approximations with enhanced predictive capabilities validated using the CW-predicted properties. These efforts pave the way to reconcile DFT against more computationally demanding approaches and thereby retrieve higher level of accuracy with low computational cost. Our work also assists in the rational design of novel polymer electrolytes with improved electrochemical and physical properties.

EN03.10.15
Unveiling the Charge Storage Behavior in Flower-Like $MnMoO_4$/Mn-MoS_2 Nanosheet Anode Material by *Operando* Spectroscopy Wan-Ju Yu, Han-Yi Chen and Ruey-An Doong; National Tsing Hua University, Taiwan

Transition metal disulfides (TMDs) have recently attracted considerable attention on serving as the promising electrode materials for energy storage devices like Li-ion batteries (LIB) due to their rich reaction sites and unique structural features. Molybdenum disulfide (MoS_2) has a high theoretical capacitance (669 mAh g^{-1}) and a low volume expansion rate, which is a promising material for LIB. However, the low cycling stability (<30 cycles) as well as high electric resistance have limited the practical application. Therefore, the combination of TMD with metal oxide such as $MnMoO_4$ is a possible solution to enhance the cyclability and conductivity of electrode materials for LIB applications. Herein, a binary transition-metal sulfide/oxide, $MnMoO_4$/Mn-MoS_2 nanosheet (MMSO) grown on nickel foam was developed as the anode material for LIB application. The MMSO electrode was prepared by a two-step hydrothermal method, and the well-distributed sheet structure of $MnMoO_4$ can freely deposit onto the Mn-MoS_2 surface to form the flower-like heterostructures, which can separately stand onto Ni form substrate to significantly enhance the electrochemical performance of the active material by increasing the number of active sites as well as by shortening the diffusion path for Li^+ ions. The electrode exhibits both large mass and areal capacities (1885 mA h g^{-1} and 3.56 mA h cm^{-2}) at a current density 0.5 mA cm^{-2} and an outstanding rate capability (2.5 mA h cm^{-2}) at a current density 3 mA cm^{-2}. Moreover, the energy storage mechanism of Mn-MoS_2 nanosheet was unveiled systematically by *operando* synchrotron X-ray absorption near edge structure (XANES) and *in operando* synchrotron X-ray diffraction (XRD) by continuously analyzing the crystal phase and valence state of the material during the charging and discharging process. Based on these observations, the anode material exhibits the conversion-type reaction by reducing Mn-MoS_2 to molybdenum metal (Mo) and Li_2S during lithiation process, and some of Li_2S would be oxidized to elemental sulfur (S_8^0 or S_4^{2-}) at the delithation process. This reaction leads to the formation of elemental sulfur at about < 1.0 V, and the released sulfur would be further utilized in subsequent reactions to enhance the electrochemical performance greatly. Results in this study have clearly clarified the charging-discharging behaviors of TMD-based materials as the anode of LIB, which can provide a gateway to develop a platform for the utilization of 2-D sulfide materials for energy storage applications.

EN03.10.16
Dual-Single-Atom Enables Bidirectional Catalytic Effect for SRR and SOR in Lithium-Sulfur Battery Jin-Lin Yang and Hong Jin Fan; Nanyang Technological University, Singapore

Lithium-sulfur battery has been widely considered as one of the most potential candidates for traditional lithium-ion battery owing to its high theoretical capacity (1675 mAh g^{-1} for sulfur), high energy density (2500 Wh kg^{-1}) and low cost. However, the shuttle effect of lithium polysulfides (Li_2S_x x=4, 6, 8), the low electrical conductivity of the final products (S_8 and Li_2S), and sluggish redox kinetics greatly impede the practical application of lithium-sulfur battery. Herein, we fabricated a novel hierarchical bidirectional electrocatalyst for sulfur cathode based on single atom engineering. In this structure, hollow carbon polyhedrons with a high specific surface area were modified with Ni-N_4 and Fe-N_4 single atomic sites simultaneously and served as the host for sulfur. From the experimental and DFT calculation results, Ni-N_4 sites could accelerate the liquid-solid conversion ($Li_2S_4 \rightarrow Li_2S$) while the Fe-$N_4$ center makes more contribution to the Li_2S oxidation process. Based on such bidirectional catalytic effect, the as-prepared catalyst with dual single atom sites exhibited outstanding rate performance (566 mAh g^{-1} at 4 C) and remarkable capacity retention in the long-term cycling test (713 mAh g^{-1} at 1 C after 600 cycles). More importantly, when the sulfur cathode was thickly coated with an areal sulfur loading of around 6 mg cm^{-2}, a high energy density over 4 mAh cm^{-2} (commercial lithium-ion battery) can still be maintained during the cycles. We believe this work could pave a way for the next generation energy storage system investigation.

EN03.10.17
Advanced Electrolyte Development for Next-generation Lithium Batteries Laisuo Su and Arumugam Manthiram; University of Texas at Austin, United States

Electrolytes connect the two electrodes in a lithium battery by providing Li^+ transport channels between them. Advanced electrolytes are being explored

with high-Ni cathodes and lithium-metal anodes to meet the high energy density and cycle life goals, but the origin of the performance differences with different electrolytes is not fully understood. In this study, we explored the effect of electrolyte on Li plating morphology and its crystallinity, interphase chemistry on both electrodes, and surface degradation of high-Ni cathodes. We found that advanced electrolytes help form close-packed homogeneous Li morphology on the anode, generate thin and inorganic-rich interphase layers on both electrodes, and reduce surface degradation into spinel and rock-salt phases of high-Ni cathodes, leading to superior cycling performance of lithium batteries. Based on these understandings, we proposed a new concept of electrolyte, namely localized saturated electrolyte (LSE), which can increase the cycle life of lithium batteries based on the Co-free $LiNiO_2$ cathode by almost an order of magnitude. For example, compared to the conventional electrolyte that retains only 55% of the initial capacity after 200 cycles, the LSE retains a record 81% of the initial capacity after 600 deep cycles at 4.4 V (versus Li/Li^+). Our work highlights the importance of developing advanced electrolytes for next-generation batteries.

Apply Machine Learning for Post Li-Ion Batteries—From Research to Engineering Problems Chen Ling; Toyota Research Institute of North America, United States

Batteries dominate the power source of portable electronic devices. Yet in large scale applications the requirement remains to improve the battery performances and reduce the cost. It urges the research of new battery chemistries as well as seeking better strategies for the deployment and recycling. The traditional simulation and experiment methods in battery research usually requires large resources in combination with sophisticated domain knowledge and/or experience to enhance the effectiveness of trial-and-error approaches. In recent years, data-driven approaches have made the way into the research of materials science domain. It is widely recognized that machine learning based technologies offer a fourth paradigm of materials research in parallel to empirical, model-based and computation-based science with the promise of solving challenges intractable through traditional means.

In this talk, we will share our experience on the usage of machine learning in various aspects of battery research and engineering problems. In particular, we show the combination of conventional computational materials science with the emerging data science facilitates the exploration of novel functional materials for all-solid-state batteries. We will also discuss the difference between battery research and battery engineering for the employment of machine learning techniques. Our talk highlights the great potential of machine learning in the development, deployment and management of new battery technologies as a new tool in the arsenal towards the carbon neutrality and electrification.

9:00 AM *EN03.11.02
On the Connections of Thermal and Ionic Transport in Solid Ionic Conductors Wolfgang Zeier; University of Muenster, Germany

The advent of solid-state batteries has spawned a recent increase in interest in lithium and sodium conducting solid electrolytes, especially in the lithium thiophosphates. However, many open questions remain when trying to optimize electrolytes and understand solid state battery chemistries, especially pertaining to the fundamentals of ionic transport.

In this presentation, we will show that single series of substitutions are not sufficient to understand ionic transport bottlenecks and that there is a tremendous influence of lattice dynamics on ionic conductors. By introducing a different approach to understanding ionic motion using phonon occupations, we try to explain so far unexplained behaviors of physical ionic transport and by extending this work we will try to compare ionic and thermal transport properties of solid electrolytes.

9:30 AM EN03.11.03
Computational Understanding of the Role of Local Structures in Superionic Conductivity of Solid-State Electrolytes Bin Ouyang[1,2], Yingzhi Sun[2], Yan Zeng[3], Yan Eric Wang[4], Haegyum Kim[3] and Gerbrand Ceder[2,3]; [1]Florida State University, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States; [4]Samsung Research America, United States

The past decades have witnessed a rapid growth of computational aided discovery of novel solid-state superionic conductors. Most advancements have been achieved in discovering novel crystalline frameworks that offer the right bond topology for Li/Na diffusion. However, optimal superionic conductors identified so far in many cases only work with specific stoichiometry and chemical compositions. Such limitation of expanding chemical space in known conductor framework requires a more thorough understanding of the key local structures that evolves when we bring composition modification. In this presentation, we will demonstrate how to control the ionic conductivity by engineering the behaviors of two types of local structures, e.g., cluster ion rotation and local site occupancy conservation. The capability of manipulating cluster ion rotation will be demonstrated with cluster ion substitution of halide-based ionic conductor framework, followed by a high throughput screening and prediction of more halide-based superionic conductors with cluster ion substitution. On the other hand, oxide-based superionic conductors will be used to demonstrate the correlation between local site occupancy conservation and ionic conductivity. It has been found that the need for local site occupancy conservation can lead to very different ion diffusion mechanisms.

9:45 AM EN03.11.04
Minimizing Cathode Volume Change via Design of Microstructure and Mechanical Properties Howard Qingsong Tu, Taylor Kranbuhl and Shafee Farzanian; Rochester Institute of Technology, United States

Integrating the NCM material (high capacity and working voltage) into the composite cathode of solid-state batteries (SSB) is the crucial step for the development of SSBs with high energy density. However, the poor rate capability and the inferior cycling stability of the composite cathode have been observed, which seriously bottleneck its practical implementation. It has been reported these drawbacks are mainly attributed to the contact loss between the cathode particles and solid electrolyte (SE) particles under the random volume expansion-contraction cycles of primary particles inside secondary particles. [1-2]
The systematic theoretical investigations in this work enable the understanding of the cathode volume change affected by the SE plastic deformation, the

particle size dispersion, and the stress evolution inside the composite. Strategies to minimize the overall volume change and to prevent SE fracture from the modeling will provide important guidance for the experimental optimizations of the composite cathode, and therefore for the final commercialization of the solid-state batteries.

10:30 AM EN03.11.05
Multi-Layer Graphene Mash Membrane Decorated with ZnO Rods for Controlling Dendritic Growth in Lithium Metal Anodes Dae Yeop Jeong and Won Il Park; Hanyang University, Korea (the Republic of)

Despite an ultimate capacity of ~3,860 mAh g^{-1} and the lowest negative electrochemical potential (−3.040 V vs. the standard hydrogen electrode) of Li metal anode, it suffers from potential safety hazard and poor cycle lifetime by Li dendrite growth. Here we present a new design strategy for Li metal anode that can circumvent the issues regarding the unwanted Li dendrite growth by inducing position-selective and direction-selective deposition of Li. Deposition of Li is induced by disposing lithiophilic ZnO rods under lithiophobic multi-layer graphene. Owing to the geometric configuration, Li continues to grow in the opposite direction of the counter electrode, that is, toward the current collector. This unusual Li growth depresses the formation of dead Li and prevents a short circuit occurring between the anode and cathode. As a result, the proposed anode showed a significant improvement in cycling performance with no capacity loss over 1400 hours, superior rate characteristics with a Coulombic efficiency higher than 99.9%, and a low overpotential at high current density.

10:45 AM EN03.11.06
Improved Electrochemical Performance of Lithium Metal Batteries with Fluorine Doped SO_2 Based Nonflammable Inorganic Electrolytes Seong Hoon Choi, Jiwhan Lee, Seung Do Mun, Seungeun Kim and Hansu Kim; Hanyang University, Korea (the Republic of)

Lithium metal batteries (LMBs) are one of the most promising candidates for next generation energy storage systems owing to their high energy density. However, the growth of undesired lithium dendrite and low Coulombic efficiency during cycling of LMBs inhibit their commercial applications. The safety issues such as thermal runaway due to lithium dendrite growth must also be addressed for commercialization of LMBs. Herein, we demonstrate LMBs with fluorine doped SO_2 based nonflammable inorganic electrolyte, $LiAlCl_{4-x}F_x$-$3SO_2$. The $LiAlCl_{4-x}F_x$-$3SO_2$ electrolyte showed enhanced electrochemical performance than that of $LiAlCl_4$-$3SO_2$ electrolyte, which could be attributed to more stable solid electrolyte interface induced by the presence of $AlCl_3F^-$ anions. Detailed mechanism of LMBs with $LiAlCl_{4-x}F_x$-$3SO_2$ inorganic electrolyte will be discussed in the presentation.

11:00 AM EN03.11.08
Fluorinated Ether Co-Solvents for Lithium-Metal Batteries Lina Kim and Hye Ryung Byon; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Lithium (Li)-metal batteries (LMBs) have been developed for next-generation energy storages with higher energy density than the current lithium-ion batteries (LIBs). It is attributed to the metallic Li having around a ten-fold higher specific capacity (3,860 mAh g^{-1}) than the graphite. However, interfacial reactions at Li surface are complicated and significantly depend on electrolyte solutions. Carbonate-based electrolyte solutions, which were generally used in the LIBs, were incompatible with the Li and remained poor solid electrolyte interphase (SEI).[1]. Alternatively, Ether-based electrolyte solutions, for example, dimethoxyethane (DME), showed better performance owing to their high reductive potential (< 0.5 V vs. Li/Li^+) and chemical stability against the metallic Li.[2],[3] Nonetheless, the low oxidative potential (< 4 V vs. Li/Li^+) of ether-based electrolyte solution was not applicable for the NCM cathode requiring chemical and electrochemical stability over 4.5 V vs. Li/Li^+. These limitations have restricted the development of LMBs toward high energy density.
We investigated the improved oxidative stability of electrolyte solutions using fluorinated ethers in the LMBs. Recently, fluorinated 1,4-dimethoxylbutane (FDMB) was designed and tested for the LMBs and anode-free Li batteries.[4] The inductive effect of fluorine in FDMB significantly raised the oxidative potential up to 6.14 V vs. Li/Li^+ at the Al electrode, which was correlated with the low HOMO energy level (-7.75 eV).[4] However, the ionic conductivity of FDMB was lower (5.0 cp at 25 ºC) than DME with 1 M LiFSI due to the high intrinsic viscosity and the weak Li^+ solvation affinity of fluorines. We added 1,2-diethoxyethane (DEE) solvents to FDMB with different ratios and investigated their ionic conductivities, oxidative potentials, and chemical stability with Li. The ionic conductivities and voltage polarizations of symmetric Li cells were improved with increasing DEE concentrations. However, the oxidative potentials shift more positively at a higher FDMB amounts. In this presentation, I will show physicochemical properties of FDMB with different DEE ratios and their feasibility for symmetric Li cells, Li|LFP, and Li|NCM full cells.

Disentangling the Complexity of Sodium-Ion Transport in Mixed Polyanion Solid Electrolytes and Electrodes Pieremanuele Canepa; National University of Singapore, Singapore

Rechargeable Li-ion batteries have performed admirably as the linchpin technology enabling today's mobile electronics industry, currently powering hundreds of millions of laptops, cameras, and phones worldwide.However, the energy density required for stationary energy storage devices and electric vehicles are quickly exceeding the limits of commercial Li-ion batteries. Finding alternatives to the Li-ion battery appears a crucial priority in the diversification and modernization of energy storage technologies. Indeed, when life-cycle analysis is examined in the design of batteries, sodium (Na) appears attractive because it can be "harvested" directly from seawater, making Na ~50 times lower in cost than Li.
An important class of phosphate electrodes and electrolytes discovered by Hong and Goodenough is the Natrium Super Ionic CONductors (NaSICONs), with chemical formula $Na_xMM'(XO_4)_3$, where M and M' are transition metals and X = Si, P and/or S. NaSICON electrode materials and electrolytes typically display significant Na-ion mobility. In this talk I will show that computational materials science, in particular first principles methodologies, can guide the design of better NaSICON electrode and electrolyte materials, with superior energy densities and improved ion transport. For example, our predictions indicate that suitably doped NASICON compositions, especially with high silicon content, can achieve high Na^+ mobilities.
These findings are relevant for the optimization of mixed polyanion solid electrolytes and electrodes, including sulfide-based polyanion frameworks, which are known for their superior ionic conductivities.

2:00 PM EN03.12.02
Relating Critical Phonon Occupation to Activation Barrier in Fast Lithium-Ion Conductors Matthias T. Agne, Joop Frerichs, Michael Hansen and Wolfgang Zeier; WWU Münster, Germany

The families of $Li_{10}(Ge/Sn)P_2S_{12}$ and $Li_6(P/Sb)S_5X$ (X = Cl, Br, I) are, so far, the only Li^+ compounds exceeding 10 mS cm^{-1} at room temperature. The structure and transport of these materials has been widely investigated, and the ionic conductivities have been pushed continually higher, reaching values reasonable for solid state battery operation. From a structural perspective, however, they are markedly different, making them excellent model systems to compare in fundamental investigations. For example, if isotopic substitutions have any impact on ionic transport, known as kinetic isotope effects.

By using a combination of nuclear magnetic resonance spectroscopy and ab initio molecular dynamics to characterize temperature-dependent ion transport, it is demonstrated that the isotopic substitution of ^6Li for ^7Li increases the thermodynamic activation barrier for Li-ion transport in $Li_{10}SnP_2S_{12}$ and Li_6PS_5Cl. Although previous studies in Li^+ conductors have indicated that lower vibrational frequencies generally result in lower activation barriers, we find that the lower average vibrational frequency of the $^7Li^+$ ions results in a larger thermodynamic activation barrier. Unlike the case of proton conductors, the magnitude of the kinetic isotope effect cannot be explained by changes in the zero-point vibrational energy. We propose that the observed changes in activation barrier are related to the differences in critical phonon occupation needed to overcome the local barrier to transport. Our hypothesis is supported by an analytical model, based on the physics of quantum harmonic oscillators, that gives good agreement with experiment. Thus, the kinetic isotope effect provides unique insights into the vibrational perspective and frequency dependence of the activation barrier in these fast Li^+ ionic conductors.

2:15 PM EN03.12.03
Understanding the Role of Charge Carrier Transport in High Performance Silicon-Based Anode Composite for Solid State Lithium-Ion Battery Moumita Rana; University of Münster, Germany

Solid state lithium metal batteries are promising as the next-generation energy storage system due to their high energy density, thermal stability, and volumetric miniaturization.[1] However, the use of Li metal anode is detrimental in terms of catastrophic dendrite formation and Li deposition in the solid electrolyte layer that causes short-circuit, thereby limits the battery cyclability. Besides, the chemical and mechanical instability of the Li-anode-SE interface, and the low earth abundance of lithium establish the need for alternative high-capacity anode development. In this regard, silicon is a potential alternative due to its high theoretical capacity of 4200 mAh/g and formation of lithium-rich alloy ($Li_{15}Si$) at low electrode potential (<0.35 V vs. Li/Li^+). However, one of the main bottlenecks to achieve electrochemically stable and high-performance Si based anode is limited electronic and ionic conductivity of silicon. [2, 3] Despite appreciable advances in achieving stable Si based anode, the influence of the transport properties on the rate capability and long-term stability remains unclear.

In this study, we aim to understand the role of effective ionic and electronic conductivity in modulating the electrochemical performance of Si based anodes. First, we have developed Si-based composite anodes with a sulfide solid electrolyte and carbon additive, which significantly improved the ionic and electronic conductivity of the electrode composite, respectively. By systematically varying the ratio of the ion/ electron conducting phases in the silicon anode composite and relating corresponding cell performance with effective transport coefficients we can estimate the limiting conductivity values. The particle size of silicon is also found to significantly influence the effective transport properties, which in turn modulate the rate performance as well as the long-term stability of these anode composites. This study provides a comprehensive understanding on the role of charge carrier transport in achieving high-performance silicon based anode composites for solid-state batteries.

A General Mechanism to Increase Ionic Conductivity by High Entropy Yan Zeng[1], Bin Ouyang[2,3] and Gerbrand Ceder[2,1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Florida State University, United States

There is increasing interest in high-entropy ceramics due to their successful use to enhance properties in Li-ion cathodes, catalysts, thermal barrier coatings, and thermoelectrics. Attractive because of their good synthesizability and reduced reliance on specific chemistries, it has been unclear whether and how a high-entropy design would be beneficial for developing new and better ion alkali-ion conductors for all-solid-state batteries. In this work, we combine first-principles modeling and experiments to demonstrate the mechanism by which a mixture of multiple principal elements boosts ionic conductivity, regardless of the alkali metal content and crystal framework. We validated our conceptual models and first principles results with experiments that show several orders of magnitude enhancement in the ionic conductivity in oxide materials when the mixing entropy of the metals is increased. This work unveils new opportunities in the vast design space of high-entropy materials and adds a new strategy to the development of novel superionic conductors.

2:45 PM EN03.12.05
Homogenization of Lithium Ion Flux by Utilizing a Solid-state Electrolyte Composite Coupled with a Three-Dimensional Porous Framework for Highly Stable Lithium Metal Batteries Jooyoung Lee, Hyunji Park, Jieun Hwang, Juran Noh and Choongho Yu; Texas A&M University, United States

Lithium metal (Li) has been acknowledged as a holy-grail anode material for the next-generation rechargeable battery due to the high specific capacity (3,860 mAh g^{-1}) and low electrode potential (-3.04 V vs. SHE) over all possible alternatives. However, the non-even dendrite growth on the Li surface and the related rapid capacity fading prevent the commercialization of two dimensional (2D) Li metal itself as an anode. Here we suggest a feasible route of utilizing Li metal as an anode without modifying the other components including cathode and electrolyte by investigating the root cause of the failure when employing the conventional separator and 2D Li metal. In detail, we propose both a highly porous solid-state electrolyte (SE) composite separator which provide more preferential lithium ion (Li^+) passages through the percolated SE and pore networks and a porous three-dimensional (3D) carbon nanotube (CNT) lithium metal host framework with a large surface area. The proposed SE composite separator showed both a high ionic conductivity (~1.7 mS cm^{-1}) and a high lithium-ion transference number (0.68), which induced the compact and uniform Li plating on the anode side. This could overcome the non-even Li plating issue of the conventional separator. Our in-operando study showed that both the non-uniformly distributed Li^+ flux through the non-even pores of the conventional induced the localized Li plating and detrimental side effects during large volume changes during the cycling, which give rise to the irreversible capacity fading. By exploiting the SE composite, the homogenized Li^+ flux was contributed to the compact and uniform Li plating with robust inorganic-rich solid-electrolyte-interphase (SEI) layers. Moreover, by utilizing the large surface area of the 3D CNT framework, both a low Li nucleation overpotential and a low interfacial contact impedance during Li plating compared to the 2D Li metal anode were confirmed. Further comparative tests with the conventional separator/anode corroborated the importance of the synergistic effect between the homogeneous Li^+ flux and low current density near the anode surface. By coupling the proposed SE composite separator and the 3D CNT anode, full cell tests with conventional cathodes, $LiFePO_4$ (LFP) and $Li[Ni_{0.8}Mn_{0.1}Co_{0.1}]O_2$ (NMC811), were conducted. Both LFP and NMC811 full cell represented a long and stable cycling behaviors, ~80% capacity retention at the 750th cycle and 235th cycle for LFP and NMC811, respectively. Finally, the full cell test with a NMC811 cathode with a high active material loading (~4mAh cm^{-2}) displayed maximum electrode level-energy densities of 456 Wh kg^{-1} and 794 Wh L^{-1}, which surpass those of commercial Li-ion batteries based on the conventional separator with a graphite anode pair. This work proposes a readily utilizable solution for raising energy density of the Li battery, which could be a viable option considering only incremental advancement in the conventional cathodes lately.

Multi-Functional Liquefied Gas Electrolytes for Lithium-Metal Batteries Yijie Yin[1], Yangyuchen Yang[1] and Y. Shirley Meng[2]; [1]University of Californa, San Diego, United States; [2]The University of Chicago, United States

High-energy density, improved safety, temperature resilience, and sustainability are desirable properties for lithium battery electrolytes, yet these metrics are rarely achieved simultaneously. Inspired by the compositions of clean fire extinguishing agents, we demonstrate inherently safe liquefied gas electrolytes based on 1,1,1,2-tetrafluoroethane and pentafluoroethane that maintain > 3 mS cm^{-1} ionic conductivity from –78 to +80 ºC. As a result of beneficial solvation chemistry and a fluorine-rich environment, Li cycling at > 99% Coulombic efficiency for over 200 cycles at 3 mA cm^{-2} and 3 mAh cm^{-2} was demonstrated in addition to stable cycling of Li/NMC622 full batteries from –60 to +55 ºC. Additionally, we demonstrate a one-step solvent recycling process based on the vapor pressure difference at different temperatures of LGE, which promises sustainable operation at scale. This work provides a route to sustainable, temperature-resilient lithium metal batteries with fire-extinguishing properties that maintain state-of-the-art electrochemical performance.

3:45 PM EN03.12.07
Three-Dimensional Current Collector Construction via Electro-Writing for Reversible Li Plating/Stripping in Anode-Free Li Batteries Yazhou Zhou, Lauren P. Chew and Jae Chul Kim; Stevens Institute of Technology, United States

As one of the promising next-generation energy storage systems, anode-free batteries can have the potential to deliver high energy density with low manufacturing costs compared to conventional lithium batteries[1]. However, the practical use of anode-free batteries faces obstacles due to inevitable problems associated with Li dendrites such as substantial volume change at the anode side and poor Coulombic efficiency from the continuous formation of solid-electrolyte interphases (SEI)[2, 3]. The key to unlocking the true potentials of energy-dense anode-free batteries can be employing functional current collectors that can stabilize SEI and the associate interfaces Li plating and stripping electrochemically and mechanically[4, 5].
Herein, we introduce an electro-writing technique that can fabricate flexible three-dimensional (3D) structures on the Cu current collector. We will demonstrate how the 3D structure can stabilize cycling electrochemically and mechanically in an anode-free battery by engineering the construction materials. Specifically, this presentation will show how the composition, porosity, and thickness of the 3D current collector affect the Li plating/stripping. Our results show that elaboration of the 3D structure leads to stable extended cycle life at 1 mA/cm2 against Li metal (>150 times) and at C/5 against LiCoO2 (>100 times), outperforming conventional anode-free batteries with a planar Cu current collector. We believe that our approach to developing 3D current collectors can promise great opportunities for inexpensive, scalable, and safe anode-free batteries.

Baird[2,1], Tofunmi Ogunfunmi[2], Xinxing Peng[1], Young-Woon Byeon[1], Haegyum Kim[1], Mary Scott[2] and Brett A. Helms[1]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States

Electric aircraft require battery systems with stringent demands for both power and energy density to enable, e.g., vertical take-off and landing (eVTOL), passenger and cargo loading, or long-range flight. Energy density is largely defined by the cell components, as well as the extent to which the full capacity of the cathode is stored on charge and utilized on discharge. For high nickel NMC cathodes (e.g., NMC-811), areal capacities of >5 mAh/g are needed, as are electrolytes that enable charging to >4.2 V vs. Li/Li^+. Lacking, however, is a deep understanding of electrolyte design rules for minimizing impedance rise (i.e., due to the formation of the cathode-electrolyte interphase, CEI) and cathode fracturing under those criteria. Similarly, for thin Li metal anodes and for anodeless cells, electrolytes that enable high areal ion flux are needed for both power on take-off and landing as well as for fast charge. If realized, then cells for electric aviation with specific capacities of 400–500 Wh/kg would be groundbreaking for the emerging industry. Here, we will discuss design rules for liquid electrolytes that realize the stable operation of Li metal batteries for electric aircraft operating under 3.8 C discharge and a charge cut-off voltage of 4.2 V and 4.35 V. Top performing electrolytes with specific additives enable ~90% and ~70% capacity retention after 500 cycles at a charge cut-off voltage of 4.2 V and 4.35 V, respectively, with Li metal anodes and >50% capacity retention after 100 cycles in anodeless cells. We find that the additives responsible for these gains in performance function not by improving anode reversibility, but instead on cathode reversibility. By using FIB-SEM and TEM analysis, we show that the additives promote the formation of unique CEI that minimizes impedance growth and significantly reduces the rate of self-discharge. Our strategy may be general to other battery chemistries featuring NMC cathodes, thus accelerating their parallel development to similar gains.

4:15 PM EN03.12.09
The Understanding of Solvation Structures of Localized High Concentration Electrolytes Bin Li; Idaho National Laboratory, United States

Due to its low density (0.534 g/cm^3), high theoretical capacity (3,860 mAh/g), and low electrochemical potential (-3.04 V vs. SHE), lithium metal is the ideal anode for electrochemical energy storage to support the transition to cleaner energy technologies. However, there are still key materials issues that inhibit lithium metal from being commercialized for rechargeable battery applications. The chemical and morphological (e.g., grain distribution, surface roughness, etc.) non-uniformity, coupled with the high reactivity of lithium drive heterogeneous solid-electrolyte interphase (SEI) formation, poor ionic flux distribution, active material consumption, and rapid dendrite growth.
The SEI, formed through reaction between electrolyte and electrode, is an inherently passive barrier to continuous consumption of active material that extends the operating voltage window. The ideal SEI should have high ionic conductivity while being electrically insulating to ensure good diffusion kinetics and ion permeability by plating at the SEI/foil interface rather than be consumed at the SEI/electrolyte interface. The SEI must also have good mechanical properties, such as high strength and good flexibility when inevitable non-uniform volume expansion and contraction occurs. One of promising pathways to improve SEI properties and thus harness the highly reactive, yet energetic Li-metal anode is by regulating electrolyte solvation structures beyond that of conventional low-concentration electrolytes (LCEs). Increasing the salt concentration to form high-concentration electrolytes (HCEs) is an effective approach to enable high-performance Li-metal batteries by forming more stable inorganic-rich SEI from anion reduction and reducing parasitic reactions of free solvent molecules. However, increasing salt concentration results in increasing electrolyte viscosity and decreasing ionic conductivity. To mitigate this issue, low viscosity diluent was added to form localized high-concentration electrolytes (LHCE). It was demonstrated that the LHCE formulation largely prevents the formation of Li dendrites due to the formation of inorganic-rich, monolithic SEI and shows excellent cycling performance for Li-metal batteries under practical conditions.
However, the current descriptions on LHCE solvation structure cannot well explain most of experimental phenomena. In our work, the new solvation structure of LHCE was proposed and validated with experiments. The pathways to rationally design LHCE formulation with higher performances based on the new solvation structure were highlighted.

Batteries with Earth-Abundant Elements Ju Li; Massachusetts Institute of Technology, United States

Low-cost, earth-abundant and easy-to-recycle battery chemistries are key for the impending global energy transition. We provide some examples of proton solid-state battery, Zn-metal battery with aqueous electrolyte, and lithium-sulfur batteries that may compete successfully with lead–acid battery and Li-ion batteries. Full-cell performance evaluation and techno-economic assessment are essential for judging different battery chemistries.

9:00 AM *EN03.13.02
Engineering the Metal Dissolution/Redeposition Dynamics to Control the Structural and Electrochemical Evolution of Battery Electrodes Yuxin Zhang, Anyang Hu and Feng Lin; Virginia Tech, United States

The solid-liquid electrochemical interface offers a two-dimensional environment for geometrically confined interfacial reactions to tailor electrode surface chemistry under operating conditions. Herein, we demonstrate that the dissolution and redeposition kinetics of transition metal cations, a ubiquitous phenomenon at the electrochemical interface, can be manipulated to regulate the chemical composition and crystal structure of the electrode surface as well as the overall electrochemical performance. The presentation will focus on aqueous electrolyte-based battery systems. Foreign cations, either added as electrolyte additives or dissolved from surface coatings, can rapidly participate in the electrode dissolution-redeposition process, and facilitate the establishment of the dissolution-redeposition equilibrium. Furthermore, some ionic polymers, present at the surface of active particles, have strong coordination with dissolved TM cations, reduce the proton transport at the interface and help establish the D/R equilibrium. Our work expands the control over the electrochemical reactions at the solid-liquid interface and provides new insights into interfacial studies in electrochemistry and surface science.

NMR Studies of Concentrated Aqueous Electrolytes for Low Temperature Batteries Mounesha Garaga[1], Sarah Whittle[1] and Steven G. Greenbaum[1,2]; [1]Hunter College-CUNY, United States; [2]CUNY Graduate Center, United States

Concentrated aqueous electrolytes have received much attention in recent years due to their high ionic conductivity, electrochemical window that significantly exceeds the water electrolysis limit, and surprisingly low freezing point. We present here two projects. In collaboration with Fudan University in China (Fei Wang, Ziyue Li) we have investigated phosphoric acid solutions being considered for proton-based batteries capable of operating at low temperature. ^{31}P and ^{1}H NMR self-diffusion coefficient as well as spin-lattice time relaxation measurements were performed on acid concentrations ranging from 1.25 to 16.6 M. The observed maximum in conductivity at the 5.9 M concentration is attributed to changes in solvation structure and transport mechanism in addition to the usual trade-off between solution viscosity and carrier concentration.

In a second collaborative project with Oregon State University (Alexis Scida, David Ji) we examine concentrated (up to 7 M) aqueous lithium chloride solutions from room temperature down to -40C using a combination of self-diffusion measurements and 1D ^{1}H, ^{7}Li, ^{17}O, and ^{35}Cl NMR spectra. Along with Raman Spectroscopy and first-principles MD simulations we observe a tendency toward less hydration of the Li^+ ions and more Li^+ - Cl^- pair formation accompanied by ice-like water clusters upon cooling.

High-Performance Zinc−Air Batteries with Scalable Metal−Organic Frameworks and Platinum Carbon Black Bifunctional Catalysts Juntao Li, Ivan P. Parkin, Paul Shearing and Srinivas Gadipelli; UCL, United Kingdom

Metal−organic framework (MOF)-related derivatives have generated significant interest in numerous energy conversion and storage applications, such as adsorption, catalysis, and batteries. However, such materials' real-world applicability is hindered because of scalability and reproducibility issues as they are produced by multistep postsynthesis modification of MOFs, often with high-temperature carbonization and/or calcination. In this process, MOFs act as self-sacrificial templates to develop functional materials at the expense of severe mass loss, and the resultant materials exhibit complex process−performance relationships. In this work, we report the direct applicability of a readily synthesized and commercially available MOF, a zeolitic imidazolate framework (ZIF-8), in a rechargeable zinc−air battery. The composite of cobalt-based ZIF-8 and platinum carbon black (ZIF-67@Pt/CB) prepared via facile solution mixing shows a promising bifunctional electrocatalytic activity for oxygen evolution reaction (OER) and oxygen reduction reaction (ORR), the key charge and discharge mechanisms in a battery. ZIF-67@Pt/CB exhibits long OER/ORR activity durability, notably, a significantly enhanced ORR stability compared to Pt/CB, 85 versus 52%. Interestingly, a ZIF-67@Pt/CB-based battery delivers high performance with a power density of >150 mW cm−2 and long stability for 100 h of charge−discharge cyclic test runs. Such remarkable activities from asproduced ZIF-67 are attributed to the electrochemically driven in situ development of an active cobalt-(oxy)hydroxide nanophase and interfacial interaction with platinum nanoparticles. This work shows commercial feasibility of zinc−air batteries as MOF-cathode materials can be reproducibly synthesized in mass scale and applied as produced.

10:45 AM EN03.13.07
Improved Reversibility of Discharging and Charging Processes in CO_2-Containing Lithium-Oxygen Cells at Low Temperature Jin-Hyuk Kang, Jiwon Park, Moony Na and Hye Ryung Byon; KAIST, Korea (the Republic of)

Lithium-oxygen (Li–O_2) cells suffer from undesired reactions by superoxide radical ($O_2^{\bullet-}$) intermediate and oxidations at high charging potential. Lithium carbonate (Li_2CO_3) as the main side product was irreversibly deposited over electrodes and only partially decomposed at 4.5 V vs. Li/Li^+, which caused rapid capacity fading. Interestingly, adding CO_2 gas alters electrochemical and chemical routes in the Li–O_2 cells and allows improving reversibility in galvanostatic discharging-charging processes. The desired reaction is forming a soluble peroxodicarbonate dianion ($C_2O_6^{2-}$). Cycling performances of the Li-O_2/CO_2 cells are associated with the preserved $C_2O_6^{2-}$ without chemical transformation to Li_2CO_3 because the oxidation potential of $C_2O_6^{2-}$ is ~3.75 V vs. Li/Li^+ at 25 °C, far lower than Li_2CO_3. However, these Li–O_2/CO_2 cells still exhibited low cyclability due to the swift deposition of Li_2CO_3 converted from $C_2O_6^{2-}$ at 25 °C.[1]
Here we showed that temperature and aprotic solvents determined the stability and molecular structure of $C_2O_6^{2-}$. The life of the $C_2O_6^{2-}$ species lengthened at low temperatures due to their poor thermal stability. A low temperature below 0 °C was necessitated to preserve the stability of $C_2O_6^{2-}$, while the electrolyte solution should have high ionic conductivity. In addition, the solvents determined the molecular structures of $C_2O_6^{2-}$. The Li^+ solvating powers of the aprotic solvents explained by the dielectric constants and Gutmann donor numbers caused distinct molecular structures of the $C_2O_6^{2-}$. We observed the anhydride-linkage $C_2O_6^{2-}$ in the tetraglyme. However, the low ionic conductivity of tetraglyme caused large voltage polarization and rapid capacity fading. By contrast, DMAc rendering better Li^+ solvation produced the peroxo-linkage $C_2O_6^{2-}$ and provided the sufficient ionic conductivity even at -10 °C. Our in-depth study revealed the best cyclability of the Li–O_2/CO_2 (90/10 v/v%) cells with 0.5 M $LiNO_3$/DMAc at –10 °C. The first charging plateau at 3.75 V (vs. Li/Li^+) belonging to the $C_2O_6^{2-}$ oxidation process was elongated during the cycles. In addition, the limited amount of Li_2CO_3 was entirely decomposed upon the second charging process, resulting in no capacity fading over 100 cycles. Our positive results encourage us to develop future Li–O_2/CO_2 batteries and Li-air batteries with improved cyclability.

Modeling the Cathode Area to Predict Lithium-Sulfur Battery Performance as a Function of Materials and Cell Design Busra Abdulkadiroglu, Hilal Bektas and Damla Eroglu; Bogazici University, Turkey

Beyond lithium-ion batteries have attracted significant attraction recently. The lithium-sulfur (Li-S) battery is perhaps the most commonly investigated example as it has a significantly high theoretical energy density. Furthermore, sulfur, which is the active material in the cathode, is an abundant, cheap, and environmentally friendly material. The design of lithium-sulfur batteries affects the performance significantly; both materials properties, such as the conductivity and surface area of the carbon, and cell design factors, such as the carbon-to-sulfur ratio, electrolyte-to-sulfur ratio, and sulfur loading, play an essential role in the discharge performance of the Li-S batteries.
There is an immense effort to model the electrochemical performance of the Li-S batteries in the literature. However, the importance of defining the electrochemically active cathode area has not been considered in the previous reports. This study offers a one-dimensional model for the Li-S battery projecting the initial discharge profile. In the model, the electrochemically active cathode area is defined in a novel way based on the weight fraction of the carbon in the cathode and a reference porosity. The effect of key materials and cell design parameters on the discharge performance is captured

successfully by employing this novel area definition. The results of the model are compared with that of two different models, which use two different electrochemically active area formulas. Furthermore, a mechanistic explanation of the effect of critical design parameters on the battery performance is proposed by investigating the change of the electrochemically active cathode area with carbon properties, carbon-to-sulfur ratio, electrolyte-to-sulfur ratio, and sulfur loading.
The model predictions for the effect of the carbon-to-sulfur ratio on the discharge profile of a Li-S cell present that increasing the carbon-to-sulfur ratio increases the discharge capacity and cell voltage up to a point. However, a further increase in the carbon-to-sulfur ratio does not affect the cell voltage and diminishes the discharge capacity. Considering the experimental findings in the literature, the model successfully predicts the effect of the carbon-to-sulfur ratio on the discharge profile due to the proposed definition of the electrochemically active area. As a result of including a reference porosity in the description of the electrochemically active cathode area in the model, we observe the following trend. The electrochemically active cathode area increases with increasing carbon-to-sulfur ratio up to a point; however, due to the decreasing porosity with increasing carbon-to-sulfur ratio, the increase in the active area stops at high C loadings. This expected trend can only be captured with the proposed cathode area. Similarly, the model successfully projects the impact of electrolyte-to-sulfur ratio and sulfur loading on the discharge behavior of a Li-S cell with the proposed cathode area definition.
The properties of carbon in the cathode have a determinative influence on the discharge performance of the Li-S battery. The offered model can successfully capture the impact of both the carbon surface area and electronic conductivity on the discharge behavior. The carbon surface area controls the electrochemically active area in the model; consequently, the predicted discharge capacities are highly sensitive to this property.

Room Temperature Electrochemical Cycling of Fluoride in $CsMnFeF_6$ Brent C. Melot; University of Southern California, United States

This talk will present our group's recent work that reports the first example of a reversible battery based on the electrochemical (de)insertion of F-ions at room temperature. We demonstrate that after three cycles, one full equivalent of F-ions can be reversibly cycled in $CsMnFeF_6$. Electrochemical impedance spectroscopy and Mössbauer spectroscopy suggests the formation of fluoride vacancies in early cycles generates mixed-valent Fe that enhances the electrical conductivity of the electrode. Furthermore, *ex situ* powder diffraction reveals a subtle expansion and contraction of the cubic lattice during oxidation (insertion) and reduction (removal) respectively, that eventually leads to the evolution of new reflections corresponding to a closely related orthorhombic polytype in later cycles. This topotactic transformation suggests that structural derivatives of the fluorite structure offer a promising class of materials for creating high-performance F-ion insertion electrodes.

First Principles Study of Proton Insertion in Aqueous Li- and Na-Ion Battery Cathodes Geoffroy Hautier[1,2], Sergi Posada[1] and Gian-Marco Rignanese[1]; [1]University Catholique de Louvain, Belgium; [2]Dartmouth College, United States

Li- and Na-ion batteries are effective energy storage technologies. Nonetheless, currently used organic-electrolyte batteries present well-known safety problems. Among the alternatives, aqueous batteries could be an interesting choice since they are safe and environmentally benign. However, working with aqueous electrolytes brings new detrimental mechanisms such as proton intercalation. I will report on our recent work aiming at understanding the (de)intercalation chemistry of protons and alkali is one of the keys for designing cathode materials in such aqueous electrochemical cells. We study through first principles computations the competition between alkali and proton intercalation and use these results to rationalize experimental knowledge. I will report mainly on LiCoO2 and NaCO2 but discuss also other cathode materials.

2:00 PM EN03.14.03
High-Rate, High-Capacity Electrochemical Energy Storage in Hydrogen-Bonded Fused Aromatics Tianyang Chen, Harish Banda and Mircea Dinca; Massachusetts Institute of Technology, United States

Growing demand for electrifying the transportation sector and decarbonizing the grid requires the development of electrochemical energy storage (EES) systems that cater to a wide variety of energy and power needs. As the dominant EES devices, lithium-ion cells (LICs) and electrochemical capacitors (ECs) typically only offer either high energy or high power. This creates a strong incentive to develop electrode materials that combine the high charge capacity of LICs with the fast charging and long cycling life of ECs, mandating that the material possesses abundant redox-active sites, facile pathways for rapid transport of electrical and ionic charges throughout the electrode bulk. This charge storage mechanism, commonly known as pseudocapacitance, has primarily been identified in redox-active transition metal oxides/nitrides/carbides.
Organic materials offer an alternative, more compositionally diverse materials space for designing pseudocapacitive electrodes from earth-abundant elements. Here, we report bis-tetraaminobenzoquinone (BTABQ) and its polymeric analogue (pBTABQ) as new pseudocapacitive organic materials for EES. They exhibit a high density of redox-active quinone and imine groups and aromatic backbones with extended conjugation. Owing to strong intermolecular hydrogen bonding and donor-acceptor (D-A) π-π interactions, they are insoluble in both organic and aqueous media. They can store up to 310 mAh g^{-1} and charge in as little as 33 seconds. Charge storage and transport occurs throughout the electrode bulk, even at practical mass loadings, due to extended electronic delocalization and facile ion transport.

2:15 PM EN03.14.04
Cu Based Metal Organic Framework as Electrocatalyst for High Performance Lithium-Sulfur Batteries Aqsa Nazir and Wonbong Choi; University of North Texas, United States

Lithium-Sulfur (Li-S) batteries with high energy and power densities have arisen as one of the most promising secondary batteries but due to Li-polysulfide (LiPSs) shuttle effect, declining discharge capacity and unstable cyclability are main problems. Implementing an effective catalyst which can not only reduce the LiPSs shuttle effect but also increase the conductivity of Li-S battery cathode is prime requirement. Here for the first time, we have

implemented conductive Cu metal-based Metal organic framework (Cu-MOF) as a Li-S battery cathode material.
Cu-MOF with tunable pore structure and thread like interwoven morphology has proven itself more efficient electrocatalysts for boosting sulfur conversions, and the innate pores of conductive Cu-MOF helps to trap the LiPSs product towards the cathode side. The well-defined architecture of organic ligands of Cu-MOF also participate to explicate the involved surface-binding mechanisms of S and polysulfide products. Conductive Cu-MOF improve the diffusion rate of Li ions, shackling LiPSs, upsurging conduction of electrons/ions, and regulating the deposition of Li_2S_2/Li_2S towards cathode side.
The Li-S battery having sulfur percolated inside the pores of conductive Cu-MOF shows outstanding long-cycling performance. In this presentation, we will discuss the experimental data and mechanistic understanding of the outstanding battery cell performance. It is believed that introducing sulfur in conducting Cu-MOFs open up new gateways to further utilize other conductive MOFs in the Li-S batteries arena.

Real-Time In-Situ Raman Spectroscopy Investigation of Lithium-Sulfur Battery Mechanism Under Lean Electrolyte Condition Pashupati R. Adhikari, Anil D. Pathak and Wonbong Choi; University of North Texas, United States

Lithium-sulfur batteries, which possess high theoretical capacity and energy density (1672 mAh/g and 2500 Wh/kg, respectively) have emerged as the next-generation energy storage systems due to recent developments in electric vehicles (EVs) and portable electronics. However, their development is still hindered due to an incomplete understanding of the complicated reaction mechanism that takes place during charge-discharge. In this work, the underlying mechanism of lithium-sulfur battery during charge-discharge is investigated using LiTFSI-DOL-DME as the electrolyte system. The conversion of elemental sulfur to higher/lower order polysulfides during discharge mainly depends on operating potentials. In-situ Raman spectroscopy is performed at various charge-discharge potentials to investigate such conversion reactions of lithium polysulfides, especially under lean electrolyte condition. In addition, the effect of sulfur loading and E/S ratio in the conversion of elemental sulfur to lithium polysulfides is also investigated. Furthermore, the reaction mechanism, self-discharge reactions, and rates of polysulfide formation and diffusion during the charge-discharge are thoroughly investigated using the in-situ Raman spectroscopy in real-time. The mechanistic understanding of lithium-sulfur battery operation from this study will help the researchers in the future development of electrolyte and electrode materials for lithium-sulfur batteries and beyond.

3:15 PM EN03.14.06
Highly Reversible Lithium Phosphorothioate Complexes Catholytes for High Performing Lithium-Sulfur Batteries Peiyu Wang[1], Nick Kateris[2], Yiwen Zhang[1], Chuanlong Wang[1], Jianmin Luo[1], Hai Wang[2] and Weiyang Li[1]; [1]Dartmouth College, United States; [2]Stanford University, United States

Beyond lithium-ion technologies, lithium-sulfur batteries stand out because of their multielectron redox reactions and high theoretical specific energy density (2500 Wh kg^{-1}). However, major challenges in realizing this potential lie in the uncontrollable precipitation of solid Li_2S_2/Li_2S and irreversible cyclic liquid-solid phase transitions, which cause sluggish reaction kinetics and poor cycle life. This work presents a series of lithium phosphorothioate complexes dissolved in organic solvent as battery catholytes to anchor and store the solid discharge products without precipitation. Such highly reversible and fast all-liquid electrochemical conversion enables superior battery performance with wide-ranging temperature operability (down to -40 °C). Coupled experimental characterizations and density functional theory calculations are utilized to reveal the molecular structures of complexes, the complexation mechanisms, and associated electrochemical reaction mechanisms. This novel complexation chemistry holds great potential for lithium-sulfur batteries as the next-generation energy storage solution to overcome the capacity limitation of intercalation-based chemistries.

3:30 PM EN03.14.07
Data-Driven Prediction of Structure and Dynamic Features of Lithium-Sulfur Electrolytes with an Automated Multi-Scale Computational Infrastructure Rasha Atwi and Nav Nidhi Rajput; Stony Brook University, The State University of New York, United States

Lithium-sulfur (Li-S) batteries continue to be considered promising “beyond lithium-ion” technologies owing to their low cost, natural abundance of elemental sulfur, and high theoretical energy density. However, the dissolution of lithium-polysulfide (LiPS) species formed during cycling in the electrolyte, combined with the insulating properties of sulfur and LiPS are among the most critical factors that impair the achievable specific energy. Many of these challenges are related to the nature and properties of the Li-S electrolyte. The composition and stability of the solid-electrolyte interphase (SEI) layer is also inherently dependent on the electrolyte and its intimate interaction with the Li anode. The selection of solvent in particular plays a crucial role in the transportation of ions and determines the polysulfide solubility and the Li anode stability.

Despite the significant body of work on Li-S electrolyte systems, there is much that is still not understood in terms of the structure-property relationships of Li-S electrolytes and the contribution of the speciation to the overall ionic transport properties. Here, we seek to understand how the replacement of conventional ether solvents with different classes of commonly reported Li-S solvents alters the structure and dynamics of Li-S electrolytes. To do so, we leverage our recently developed high-throughput computational framework (MISPR; https://github.com/molmd/mispr) to construct a database of Li-S electrolyte properties from a series of automated density functional theory and molecular dynamics simulations. We find that there is no single descriptor that explains the trends in the polysulfide solubility. We also utilize the output database to highlight on the unique behavior of each solvent class, develop a quantitative model for the primary speciation in solution and its relation to the dynamics, and unravel the underpinnings governing the polysulfide dissolution. This work provides guidelines and crucial information that can accelerate our rational selection of solvents that enable optimal compromise between the solubility of PS species and the transport properties.

High-Performance Rechargeable Zinc Sulfur Battery with Deep Eutectic Solvents Shu-Chi Wu, Shin-Yi Tang, Hsiang-Ju Liao, Kuangye Wang, Tzu-Yi Yang, Ling Lee, Ying-Chun Shen and Yu-Lun Chueh; National Tsing-Hua University, Taiwan

Zinc is an attractive anode material due to it possesses the merits of high theoretical capacity, proper redox potential (−0.76 V vs standard hydrogen electrode) and low cost. However, when used in a zinc–sulfur battery, polysulfide rapidly reacts with zinc to form a passivating zinc sulfide (ZnS) film on the zinc metal surface, leading to the capacity decays rapidly. Up to date, it remains challenging to develop high-performance Zn–S batteries. To overcome these issues, non-aqueous electrolyte system composed of deep eutectic solvent (DES), which is combined by choline chloride, ethylene glycol and zinc chloride, is developed in this study. This DES electrolyte provides a wide electrochemical window of 1.8 V, which can stabilize the side reaction during the charge–discharge process. By applying carbon nanotube (CNT)/sulfur composite as cathode material and zinc foil as anode, the battery delivers a specific capacity of 450 mAh g^{-1} with a flat discharge voltage of 0.8 V and a long-term stability. *Ex-situ* characterization of XRD, XPS, Raman and SEM-EDS mapping reveal that the working mechanism based on the reversible conversion reaction of the Zn–S alloying processes. The utilization of DES on electrolyte for rechargeable battery system opens a new route for high-performance zinc-sulfur batteries.

4:00 PM EN03.14.09

Coarsening Regulated Preventive Magnesiation of SiO for High-Performance Lithium Storage Materials Donghan Youn, Nam Gyu Kim, Won Joon Jeong, Dong Jae Chung, Ji Young Kim and Hansu Kim; Hanyang University, Korea (the Republic of)

Silicon monoxide (SiO)-based materials have been intensively investigated as an anode material for high energy density lithium-ion batteries (LIBs) because of their high capacity and superior cycle performance. However, these materials have chronic problems of low initial Coulombic efficiency (ICE), which decreases the energy density of the full cell. Magnesiation of SiO is one of the promising candidates for increasing the ICE of SiO-based anode materials. Here, we propose Si/Mg_2SiO_4 nanocomposite materials prepared by endothermic dehydrogenation-driven magnesiation of SiO using MgH_2 to improve both ICE and cycle stability. The proposed material shows a much increased ICE up to 89.5% and enhanced long-term cycle performance over 300 cycles compared with pristine SiO and the Si/Mg_2SiO_4 nanocomposite prepared by magnesiation of SiO with Mg. The endothermic dehydrogenation of MgH_2 suppressed the abrupt temperature rise during magnesiation of SiO, thereby regulating the coarsening of the Si phase in Si/Mg_2SiO_4 nanocomposite, which was revealed by high-resolution transmission electron microscopy with thermogravimetry-differential scanning calorimetry. More detailed material characterizations and electrochemical analysis of the Si/Mg_2SiO_4 nanocomposite material will be discussed in this presentation.

4:15 PM EN03.14.10
Si Microparticles Embedded within Wrinkled-Multilayered-Graphenes for High-Areal-Capacity Lithium-Ion Batteries Incheol Heo, Chanyoung Lee and Won Cheol Yoo; Hanyang University, Korea (the Republic of)

Even nanostructured Si electrodes have demonstrated stable electrochemical performances in lithium-ion batteries (LIBs), complex process and high-cost of nanostructured Si electrodes are far from industry standards. Thus, utilization of commercially available low-cost Si microparticles with high-performance is highly necessary for high-energy-density LIBs. In this presentation, we demonstrate a simple and scalable method to utilize commercially available Si microparticles (*ca.* 7 μm) with wrinkled-multilayered-graphenes (Si-WMGs) for high-areal-capacity LIBs. The WMGs provide not only mechanical flexibility for mitigating large volume change of Si microparticles during deep charge/discharge processes, but also good adhesion property to effectively coalesce Si microparticles, and high electrical conductivity, resulting in binder- and conductor-free thick electrodes. The Si-WMG electrodes showed high initial areal capacities of 12.5 mAh cm^{-2} at 0.1 C and 7.1 mAh cm^{-2} even at a very high rate of 2 C, with outstanding long-term stability with 5.3 mAh cm^{-2} at 2 C for over 240 cycles. Furthermore, a full cell composed of Si-WMG and lithium cobalt oxide presented 3.13 mAh cm^{-2} and a stable cycling performance (90.3% retention after 100 cycles) in a practical cell setting, clearly demonstrating the practical applicability of Si-WMG electrodes. Therefore, the WMG as a binder and conductor could be applicable to other electrodes with a large volume change and high mass-loading for high-areal-capacity LIBs.

4:30 PM EN03.14.11
Microgrid-Patterned Silicon Electrode as an Electroactive Lithium Host for Stable and High-Energy Lithium Batteries Seung-Hyeok Kim[1,2], Myeong-Hwa Ryou[1] and Sang-Young Lee[1]; [1]Yonsei University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

The ongoing surge in the demand for smart portable electronics, electric vehicles, and large-scale stationary energy storage systems has necessitated the development of high-energy-density lithium (Li) batteries with electrochemical longevity. Li metal has garnered considerable attention as a promising battery anode to achieve this goal owing to its high theoretical gravimetric capacity (3,860 mAh g_{Li}^{-1}) and low redox potential (-3.04 V vs. standard hydrogen electrode). However, the unstable Li plating/stripping cyclability of Li-metal anode has restricted its practical application. To address this issue, Lithium (Li) hosts, which can electrochemically accommodate Li in preformed pores of three-dimensional frameworks, have been investigated as an advanced electrode architecture for high-energy-density Li-metal batteries. However, most of the previous studies on Li hosts utilized electrochemically inert materials for their framework constituents, resulting in the undesired loss of gravimetric/volumetric energy densities of the resulting batteries. Here, we present a microgrid-patterned Si (MPS) electrode as a new electroactive Li host concept (denoted as MPS host). The MPS host is composed of a microgrid-patterned Si electrode active layer on a lithiophilic conductive substrate (*lc*-substrate). The *lc*-substrate is fabricated by electrospraying a suspension solution (Si nanoparticles/single-walled carbon nanotubes (SWCNTs)) onto a Cu foil. Subsequently, an electrode ink consisting of Si/carbon black/polymeric binders is printed on top of the *lc*-substrate using a microscale direct ink writing (DIW) technique to produce the MPS host. The DIW technique is considered as a facile method for constructing on-demand and complex architectures on arbitrary substrates with high throughput. The underlying design concept of the MPS host is described as follows: (i) owing to its high specific capacity (>3,000 mAh g_{Si}^{-1}), the Si embedded in the microgrids enables the redox capacity of the microgrid frameworks; (ii) a lithiated Si (Li_xSi), which acts as a lithiophilic site, guides the uniform flux of Li-ion toward the MPS host; (iii) the difference in the electronic conductivity of the microgrids and *lc*-substrate regulates the magnitude and direction of the applied electric field, thereby enabling the preferential deposition of Li on the *lc*-substrate; (iv) the ordered pore space formed between the microgrids contributes to the uniform and stable deposition of Li. The resulting MPS host enables a stepwise sequential Si lithiation/delithiation (from the Si in the microgrid frameworks) and Li plating/stripping (inside the pore space between the microgrids) reaction, verifying its unique behavior as an electroactive Li host. In addition, a full cell assembled with the MPS host and $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ (NCM811) cathode (areal capacity = 3.8 mAh cm^{-2}) exhibits high cell energy densities (644 Wh kg_{cell}^{-1}/1,538 Wh L_{cell}^{-1}) and reliable cyclability.

Solid-State NMR Guided Discoveries of Low-Cost, High-Performance Solid Electrolytes Yanyan Hu; Florida State University, United States

Developing low-cost and high-performance solid electrolytes is key to producing inexpensive solid-state batteries. Leveraging cost-effective precursors for synthesizing highly conductive and stable solid electrolytes under mild conditions is a promising approach. We have demonstrated the feasibility of such an approach in several cases, including thiophosphate-, phosphate-, and halide-based solid electrolytes. Solid-state NMR investigations of structure-ion transport correlation have been critical to guiding the synthesis and optimization of these solid electrolytes. In particular, we have employed high-resolution NMR spectroscopy complemented by diffraction techniques to determine long- and short-range structures, NMR relaxometry to probe ion dynamics, NMR diffusometry to measure tracer diffusivity, and electrochemically driven tracer-exchange NMR to map out ion transport pathways. Such a systematic investigation allows for a fundamental understanding of how structural attributes affect different aspects of ion transport properties. In conduction with *in situ* NMR, we can establish synthesis-structure-property relationships, which we use to advise synthesis strategies.

Self-Supporting Negative Electrode of Silicon Monoxide Held by Carbon Nanotubes for Stable and High-Capacity Secondary Batteries Tomotaro Mae, Kentaro Kaneko, Mochen Li and Suguru Noda; Waseda University, Japan

Silicon monoxide (SiO) is a promising anode material having high theoretical capacity (>1710 mA h/g_{SiO}) with superior stability. However, SiO is used with polymeric binder, conductive filler and heavy current collector of metal [1,2], resulting in low delithiation capacity per electrode mass. Herein, we propose self-supporting SiO-carbon nanotube (CNT) electrode without metal foils nor polymeric binders, being expected to have high delithiation capacity based on electrode mass because CNT is light weight.
Self-supporting electrode was prepared by simple co-dispersion and filtration process [3] using ~1 μm-sized SiO particles coated with carbon (SiO/C) and submillimeter-long few-wall CNTs synthesized by our fluidized bed [4] having large specific surface area of ~300 m^2/g. The SiO/C-CNT (~1.9 mg_{SiO}/cm^2 and ~3.2 mA h/cm^2) was evaluated by half-cell test with a Li foil counter electrode, a polypropylene separator, and an electrolyte (1 M LiTFSI + 0.6 M $LiNO_3$, DOL:DME=1:1, v:v). As a condition of electrochemical measurement, the SiO/C-CNT electrode was fully lithiated, fully delithiated, fully lithiated, and then the following cycles were performed with SiO utilization ratios of 42%, 67%, or 100% (1.5, 2, or 3.2 mA h/cm^2). The 1st delithiation capacity per electrode mass achieved >1200 mAh/$g_{electrode}$ at the optimum SiO/C content of 85-90 mass%. The delithiation capacity faded rapidly with the high SiO utilization of 100% and 67% while remained high and stable at 709 mA h/g_{SiO} and 584 mA h/$g_{electrode}$ for 236 cycles with the moderate SiO utilization of 42%. This is because the moderate SiO utilization keeps the volume change of SiO particles moderate, preventing damage to and regeneration of the solid-electrolyte interphase. And the flexible CNT sponge enabled reversible volume/thickness change of the electrode and retained the electrode structure even after 51st lithiation as evidenced by electron micrographs.

Enhancement in Battery Performance of $Na_2Ti_3O_7$ Through Vanadium Doping for Sodium-Ion Batteries Akshita Sharma[1], Katchala Nanaji[2] and Ashok K. Ganguli[1]; [1]Indian Institute of Technology Delhi, India; [2]International Advanced Research Centre for Powder Metallurgy and New Materials, India

Sodium-ion batteries are a next-generation and cost-effective alternative to rechargeable lithium-ion batteries. However, there is a substantial reduction in volumetric and gravimetric capacity using sodium ion as a charge carrier. $Na_2Ti_3O_7$ (Sodium titanate oxide-NTO) has a wide direct band gap of 3.07 eV leading to poor performance and high capacity fading after prolonged galvanostatic cycling, limiting the mobility of ions between vacant sites of the structure, which results in low intrinsic electrical conductivity across the material. The above drawback of NTO can be improved by incorporating vanadium into the NTO crystal lattice. This work investigates the varying percentage of doping of vanadium ions in NTO and its overall effect on cell performance with sodium ias a charge carrier. Various concentration of vanadium ions were substituted in sites of Ti^{4+} sites and the phases were well-characterized by powder XRD, TEM-EDX, HRTEM, ICP, and XPS. Likewise, electrochemical measurements, i.e., EIS, CV, galvanostatic cycling, etc, were carried out in the swagelok cell in two-electrode configuration. The charge-discharge profile has been comparatively analyzed with the varied amount of vanadium in $Na_2Ti_{3-x}V_xO_7$ at different C-rates to investigate performance and capacity retention. The initial discharge capacity of the V-doped NTO half-cell was improved to 119.46 mAh/g compared to NTO with 98.61mAh/g at a 0.5 C-rate. Also, there was a significant reduction of 57% in the internal resistance of V-doped NTO half-cell when EIS was recorded between 10 MHz-100 kHz. Cyclic voltammetry study exhibits an increase in the maximum peak current with increasing scan rate, leading to high diffusivity (D_{Na^+}) in the case of $Na_2Ti_{3-x}V_xO_7$ when compared against $Na_2Ti_3O_7$. The very identical nature of CV profiles of both samples, from 0.1 mV/s to 2 mV/s, is indicative of the pseudocapacitive behaviour of the electrode. The presence of two anodic peaks-0.33V and 0.51V in the cyclic voltammetry of V-doped NTO suggests a biphasic mechanism similar to NTO associated with the transition of $Na_2Ti_3O_7$ to $Na_{3-y}Ti_3O_7$ and then to $Na_4Ti_3O_7$. Thus, our study concludes that doping high valence transition metal ions like vanadium provides enhanced electrochemical performance attributed to the increased conductivity and formation of oxygen vacancies.

A Computational Study of the Intrinsic Defect Chemistry of Promising Sodium-Ion Cathode Material Na2FePO4F Daniel N. Sykes[1,2], Yong-Seok Choi[1,2] and David O. Scanlon[1,2,3]; [1]University College London, United Kingdom; [2]Faraday Institution, United Kingdom; [3]Diamond Light Source, United Kingdom

Long-term viability of Li-ion battery energy storage may be limited by global lithium reserves. Recently, Na-ion batteries (NIBs) have garnered a great deal of attention, particularly because of sodium's natural abundance, its more even distribution across the earth and its lower cost compared to lithium. NIBs are especially attractive for large-scale energy storage systems where cost and life cycle are essential.

To this end, Na_2FePO_4F has been a material of interest as a viable cathode material for sodium-ion storage due to the high discharge voltage and favourable theoretical capacity.[1] Recent work has shown the potential for doping in Na_2FePO_4F cathodes to increase average voltage, reduce band gap and Na-ion diffusion barrier.[2] Despite its promising performance after doping, the defect chemistry that governs the charge transfer of doped Na_2FePO_4F is yet to be understood, which inhibits the selection of optimum dopants for Na_2FePO_4F.

Density Functional Theory (DFT) has been proven to be a powerful tool for investigating the defect chemistry of solid-state materials. In this work, we will present work completed on computationally investigating Na_2FePO_4F using DFT implemented in VASP (Vienna Ab Initio Simulation Package). All calculations have been performed with the hybrid HSE06 (Heyd-Scuseria-Ernzerhof) functional to accurately depict the electronic structures of the defected crystalline structures.[3]
Based on the above techniques, we investigate the electronic/atomic structures of pristine Na_2FePO_4F and its response to intrinsic defects, which are essential to understanding the doping effect in the future.

Here we elucidated the bulk geometric structure of the material through structural relaxation as well as the most stable magnetic configuration. The electronic structure of the material has also been examined with a Density of States (DOS) and a band structure was obtained. Furthermore, to examine the defect landscape of the material, the different stable phases of Na_2FePO_4F have been investigated. The phase stability region for Na_2FePO_4F has been calculated along with its stable chemical potential regions which is important for understanding of synthesis conditions and defect formations. Lastly, by comparing the formation energies of vacancy defects at different chemical potential conditions, we plotted the transition level diagrams which show the likelihood of different defect formations. The present work provides an insight in improving the key performance indicators (KPIs) of Na_2FePO_4F as a cathode material for NIBs.

A Low-Cost Al-Graphite Battery with Urea and Acetamide-Based Electrolytes Franziska Jach[1], Maximilian Wassner[1], Erica Brendler[2], Max Bamberg[1,2], Gero Frisch[2] and Ulrike Wunderwald[1]; [1]Fraunhofer IISB, Germany; [2]Technische Universität Bergakademie Freiberg, Germany

A key challenge facing future battery technologies is finding alternatives for currently used raw materials, which are often expensive and are becoming increasingly scarce. In recent years, Al-graphite batteries have been proposed as a valid alternative to Li-ion systems due to their low-cost and sustainability.[1]
In contrast to commonly used expensive ionic liquid based electrolytes e.g. [EMIm]Cl/$AlCl_3$, our reported batteries use urea/$AlCl_3$ and acetamide/$AlCl_3$ deep eutectic solvents (DES) as low-cost alternative.[2]
By carefully selecting amide composition, Al speciation in the DESs can be modified, as confirmed by Raman and NMR spectroscopy. $Al_2Cl_7^-$ and $AlCl_4^-$ are actively involved in Al dissolution and deposition on the Al electrode, whereas $AlCl_4^-$ is intercalated between layers of graphite on the cathode.[3] Hence, battery performance such as specific capacity, long-term stability and self-discharge is greatly influenced by electrolyte composition as well as structure and morphology of the graphite cathode. We correlate the electrolyte speciation changes with resulting battery performance by systematic electrochemical investigations employing urea and acetamide eutectics of different compositions. The reversible graphite intercalation is examined for minimally processed natural graphite flakes of different particle sizes employing electrochemical methods and Raman spectroscopy.
In addition to this optimization of abundant raw materials, specific capacities can be enhanced by electrochemical treatment of the assembled batteries. Cycling experiments employing urea electrolyte with >8000 cycles, exhibiting a specific capacity of around 50 mAh/g at 2.5 A/g (50C) demonstrate the long-term stability. The development of a corrosion stable pouch cell design allows practical application of these batteries. Thanks to its high rate capability and stable long-term cycle life Al-graphite batteries are a promising candidate for high power applications.

Insights into the Effect of Ti/Zn Dual-Doping on the P3-Type Mn-Ni Based Cathodes for Na-Ion Batteries—Combined First-Principles and Experimental Study Yong-Seok Choi[1,2,1], Stephanie Linnell[3,2], A. Robert Armstrong[3,2] and David O. Scanlon[1,2,1]; [1]University College London, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]University of St Andrews, United Kingdom

Having dominated the market for over the past three decades, Li-ion batteries (LIBs) are now faced with a challenge for the use in grid-scale energy storages because of the rarity of Li resources. To meet the growing demands of power sources, Na-ion batteries (NIBs) have emerged as a promising alternative for LIBs owing to the high abundance of sodium. Despite the considerable attention to NIBs, their overall electrochemical performance remains inferior to LIBs because of the less negative redox potential and larger ionic radius of Na [1,2]. Thus, the development of Na-ion cathodes with high energy densities and long cycle lives are critical for NIBs to be widely applied as an alternative to LIBs.
Among various crystalline phases reported to date, P3-type cathodes can be synthesized at lower temperatures [3] and have a higher Na content [4] than P2-type oxides. Moreover, thanks to the prismatic Na sites, P3-type cathodes have larger interlayer space than O3-type counterpart [3], endowing improved rate capability. To maximize the performance of P3-type cathodes, extensive studies have been conducted on doping other elements on the transition metal (*TM*) sites. [5] In the journey of research on heteroatom doping, various relationships between dopant property and cathode performance have been suggested: 1) dopant possessing higher electronegativity than *TM* elements increases thermodynamic redox potentials, according to the inductive effect [6]. 2) Dopants with lower oxidations states and smaller ionic radii (e.g., Mg^{2+}, Al^{3+}) widens the interlayer distances while causing TMO_6 octahedra shrinkage, enhancing the rate performance [7,8]. 3) The redox inactivity of dopants stabilizes the *TM* layer upon battery cycling, which mitigates the capacity fading [9]. However, the selection of a single dopant satisfying all above criteria is nearly impossible, as electronegativity is positively correlated with oxidation states and ionic radii. From this perspective, dual or multiple doping is inevitable to design future cathodes with high performance.
In this study, using combined technique of experiments and first-principles calculations, we investigated the effect of two dopants (Ti and Zn) with contrasting properties (electronegativity, oxidation state, and ionic radii) on P3-type $Na_{0.7}Mn_{0.75}Ni_{0.25}O_2$, aiming for the synergetic effect of dual doping. Galvanostatic cycling test showed that each dopant has different effect on cyclability; Zn and Ti dopants improved the cyclic stability at the early and later stage of cycling, respectively. Furthermore, the redox voltages of $Na_{0.7}Mn_{0.75}Ni_{0.25}O_2$ decrease after doping, where the degree of decrement is greater for Zn dopant. When both elements are doped, the resulting cathode exhibits greater performance than Zn- or Ti-doped samples in both cyclability and rate performance. Considering the recent interpretations on dopant-property relationships, we interpret the observed behaviours employing first-principles calculations. Finally, based on the conclusions obtained from each dopant effect, we discuss how the combination of dopants with contrasting properties can lead to the improved Na-ion cathodes.

Anode Architecture Design for Enabling Deep Cycling Sodium Metal Anodes Yue Deng, Lynden A. Archer, Jingxu Zheng and Prayag Biswal; Cornell University, United States

Rechargeable sodium batteries are of increasing scientific and technological interest as they promise a pathway towards low cost and long-duration electrical energy storage. Versions of these batteries that incorporate metallic sodium as the anode can exhibit high theoretical specific capacity of 1166 mAh/g, low electrochemical potential of -2.71V (vs the standard hydrogen potential), and simplicity. However, sodium metal anodes (SMAs) are plagued with high reactivity and poor electrochemical reversibility that renders that impractical for commercial deployment. In this work we investigate the failure mechanisms of sodium anodes in liquid electrolytes and develop approaches that mitigate the failure modes to enable deep cycling of SMAs. We report that the fundamental cause of premature failure of SMAs is not the loss of morphological control of the plated metal but the inherently poor anchoring/root structure of electrodeposited sodium to the anode current collector. Poorly rooted sodium deposits are prone to break-away (orphaning) from the current collector producing massive levels of dead sodium and poor anode reversibility. Accordingly, we propose two approaches to improve the reversibility of SMAs: 1) utilizing non-planar electrode architectures that provide continuous and morphology agnostic access to the metal at all stages of electrochemical cycling; 2) developing thin metallic interphase coatings with sodium solubilities that undergo reversible alloying reactions with sodium enabling stable root-growth of deposited metal. We show that high reversibility of SMAs can be achieved with simple electrolyte design regardless of the detailed morphology via reinforced root structure originating from non-planar electrode architectures or thin metallic coatings on current collectors.

1:30 PM EN03.16.04
Lithium Insertion into Nearly Empty Type II Silicon Clathrate Yinan Liu, Joseph Briggs, Ahmad A. A. Majid, Thomas E. Furtak, Michael Walker, Carolyn A. Koh, P. Craig Taylor and Reuben T. Collins; Colorado School of Mines, United States

We explore thermal diffusion of Li into the guest sites of a nearly empty silicon clathrate framework to synthesize Si-Li clathrate (Li_xSi_{136}) for electrochemical applications. Silicon clathrates are novel silicon allotropes with a cage-like structure that have been recently investigated as potential anodes. Cubic and amorphous silicon, in fact, are both high density anode materials for the development of lithium-ion batteries. However, the main limitation is the significant volume change after the lithiation process, causing instability or even pulverization of the silicon anodes. In the silicon clathrate materials, initial insertion of Li is expected to occur into the cages, with Li acting as guest atoms and the open-framework structure making them less susceptible to volume expansion during lithiation. Moreover, since Li guests are expected to be donor atoms, lithiated clathrates should exhibit excellent electrical conductivity. These properties make Si-Li clathrates potentially promising for electrochemical applications. Exploring this potential requires the synthesis of Si clathrates with Li atoms in the cages and understanding of Li ionic diffusion in the clathrate lattice. The major barrier to the direct formation of Li-guest clathrates is that unlike Si-Na clathrates which have been formed through the thermal decomposition of a Zintl precursor NaSi phase, the Si-Li phase diagram is more complex and an equivalent LiSi phase, which can decompose into Li_xSi_{136} clathrate, has not been demonstrated.
In this work, Li insertion into the clathrate structure is made possible by our ability to synthesize extremely low Na type II Na_xSi_{136} ($x \sim 0.016$). Low-x Na_xSi_{136} is sealed into a quartz ampoule with Li metal under vacuum and annealed at temperatures between 250 to 400 ºC. X-ray diffraction (XRD) shows that the clathrate structure exhibits reduced structural stability in the presence of Li converting to polycrystalline or amorphous phases for anneals above 375 ºC (or at slightly lower temperatures with high Li content or longer annealing time), while the starting material in the absence of Li shows no change in structure for anneals as high as 400ºC for 72 hours. At temperatures < 350ºC, the Li diffused clathrate structure is maintained for anneals shorter than 3.5 hr. XRD also shows that the guest content in the material increases after diffusion. Raman shows a frequency reduction due to Li diffusion, especially for higher frequency modes based on a systematic study using Raman line scans. Li guests are expected to be donors and this frequency reduction is consistent with previous reports that donating electrons to the anti-bonding conduction band of Si clathrate causes a reduction in the vibrational frequency. Time of flight secondary ion mass spectrometry confirms the presence of Li, and was used to obtain the ion profiles through the film to extract effective diffusion constants at different temperatures. Electron Paramagnetic Resonance (EPR) was applied to detect low concentration guests and study the interaction of the Li guest with the clathrate cages. EPR results suggest that Li atoms tend to form pairs with other Li or Na atoms in the clathrate structure and diffusion of Li results in a large increase of the free carriers in the clathrate material.
Results of this work provide a new method for filling the clathrate cages, potentially allowing several alternative guest atoms to be explored. These findings also provide useful insights into the potential use of Si clathrate as an anode material in Li-ion batteries. This work was supported by National Science Foundation Award 1810463.
