The conventional solar harvesting replies on natural spectrum of sunlight from UV to IR which is not efficient for energy applications including photovoltaic due to incompatible photon energies with the bandgaps of semiconductors. Spectral selective solar harvest can address this critical issue by structurally tailoring the materials to absorb photon energies in the specified and desired regions. We have designed and synthesized transparent porphyrin-based hybrid thin films that characteristically exhibit absorption peaks near 400 nm (blue-violet) and 700 nm (NIR) with a high average visible transmittance (AVT). To be able to tune the absorptions, a unique porphyrin-based hybrid is developed with systematic additions of phthalocyanine and Fe_3O_4@$Cu_{2-x}S$ with much stronger NIR absorptions. Phthalocyanine has more pronounced UV and NIR absorptions, but a narrower “optical window” than that of chlorophyllin. Fe_3O_4@$Cu_{2-x}S$ is known for broad and strong IR absorptions around 1200 nm. UV-Vis and Raman spectroscopy experiments have been carried out to characterize the porphyrin-based hybrids. We have found congruent mixtures between chlorophyllin and Fe_3O_4@$Cu_{2-x}S$ resulting in even broader NIR absorptions while maintaining the optical window between 400 and 650 nm for high AVTs. This will provide an ideal spectrum for a transparent but strongly UV/NIR absorbing characteristic for photothermal energy generation. Also discussed are the operating mechanisms underlying the thermal-photonic behaviors associated with the hybrid structures.

On the Formation of Halogen Bonds to Boost the Charge Carrier Mobility in NDI Semiconductors Tero-Petri Ruoko[1], Marc-Antoine Stoeckel[2], Rakesh Puttreddy[1], Chi-Yuan Yang[2], Ziang Wu[3], Nuno Candeias[4], Han Y. Woo[3], Simone Fabiano[2] and Arri Priimägi[1]; [1]Tampere University, Finland; [2]Linköping University, Sweden; [3]Korea University, Korea (the Republic of); [4]University of Aveiro, Portugal

Organic semiconductors with a high charge carrier mobility are essential to ensure efficient electronic devices, such as field-effect transistors (FETs), solar cells, and light-emitting diodes. The charge carrier mobility in these organic materials is the consequence of the interplay between a complex set of physical parameters related to morphology, energetic and structural disorder, and defects, which ultimately are related to the molecular chemical structure. Therefore, one strategy to improve the performances of semiconducting small molecule is to promote a defect-free packing. This can be achieved through processes that lead to different qualities of materials, via the formation of molecular single crystals. Another approach consists of attaching certain functionalities to the semiconducting backbone that will improve the packing through specific interactions. This approach, however, can result in a deterioration of the initial performances of the semiconductor, as it can strongly affect its properties (different packing, energy levels and orbitals, …).
An under-explored strategy to enhance the performances of molecular semiconductors in OFETs is to enhance the crystallinity of the thin film by using a blend of a semiconductor and an ad hoc molecule that will selectively bind to it and impose a molecular packing with superior performances.
To this end, we employed here an NDI molecule bearing a pyridine group in the 2, 6 positions. Upon the addition of an aromatic halogenated molecules, the nitrogen of the pyridine is able to form a bond with this aromatic molecule through the formation of a halogen bond. Upon the formation of this bond, the as-casted film not only present a higher crystallinity, but also larger crystalline domains. This is therefore reflected in the electron mobility that increases by almost two orders of magnitude for the blend compared to the pristine molecule. Through a systematic study of the electrical performances of these materials, and supported by AFM, GIWAXS, Raman spectroscopy and simulations, we were able to rationalize the underlying mechanism to interpret the higher performances observed with OFETs.

SB06.14.26
Twisting Organic Semiconductors Crystals for Orientation Control to Improve the Charge Injection and Photoconductivity Sehee Jeong, Alexander Shtukenberg, Bart Kahr and Stephanie Lee; New York University, United States

Orientation control in organic semiconductors has been at the forefront of organic electronics research over the past few decades, with up to orders of magnitude variations in charge mobilities, absorption coefficients, photoluminescence intensities along different crystallographic directions. In this work, we demonstrate a generalizable strategy to introduce periodic variations in the out-of-plane orientations of small molecule 5,11-bis(triisopropylsilylethynyl)anthradithiophene (TIPS ADT) crystals via twisting. TIPS ADT crystallized from the melt in the presence of 16 wt % polyethylene (PE) forms banded spherulites of crystalline fibrils that twist in concert with one another about the radial growth direction. One full rotation in crystal orientation occurs over a distance of 40 – 400 mm depending on the crystallization temperature, introducing periodic variations to the absorption, photoluminescence and Raman spectra on a commensurate length scale. Although TIPS ADT molecules and straight crystals are not optically active, Mueller Matrix imaging revealed strong circular dichroism (CD) of twisted crystals, with TIPS ADT banded spherulites exhibiting domains of positive or negative CD signal depending on the crystal twisting sense. The introduction to continuously varying out-of-plane orientations from spontaneous crystal twisting further resulted in significant improvements in both the conductivity and photoconductivity in twisted TIPS ADT crystals compared to straight TIPS ADT crystals. Local conductive atomic force microscopy mapping revealed enhanced charge injection and extraction in films of twisted TIPS ADT crystals compared to those comprising straight TIPS ADT crystals. The photocurrent and external quantum efficiency of twisted TIPS ADT photodetectors were measured to be 3.2 and 11.6 times larger, respectively, than those measured for photodetectors comprising straight TIPS ADT crystals. These

improvements are a direct consequence of twisted TIPS ADT crystals possessing out-of-plane orientations that present smaller barriers to charge transport compared to straight TIPS ADT crystals.

SB06.14.27
All-time Operation Hybrid Energy Harvesting System through Non-fullerene-based Organic Photovoltaics and Triboelectric Nanogenerator
Hyojeong Choi[1], Yongju Lee[1], Selim Han[1,2], Swarup Biswas[1] and Hyeok Kim[1]; [1]University of Seoul, Korea (the Republic of); [2]Korea Institute of Industrial Technology(KITECH), Korea (the Republic of)

With the rapid development of the Internet of Things (IoTs), the number of sensors used in IoT is expected to exceed 200 billion by 2025. Therefore, research on creating a sustainable energy source with the stimuli that can be obtained is becoming crucially indispensable. Among various energy harvesters, Organic Photovoltaic (OPV), which produces energy through light absorption, is easy to be fabricated due to the solution process and can be manufactured in a large area. However, since OPV is greatly affected by the surrounding environment, it is difficult to harvest energy that can be always operated, and many studies are being conducted to solve this problem. Accordingly, by incorporating a Triboelectric Nanogenerator (TENG) to the system, we have developed an OPV-TENG hybrid energy harvesting system that harvests electrical energy from wasted mechanical energy in the surrounding environment, while simultaneously producing low-illuminance energy through bandgap matching. In addition, we developed TENG with newly synthesized Deco-flex® with good elasticity and output characteristics using an eco-friendly elastomer, which has a high resolution of 0.4 kPa and is sensitive enough to obtain a maximum output of 5 V and 1.03 μA. This was combined with OPV in series and measured at low illumination (LED 1000 lux: 0.32 mW/cm^2). As a result, the output voltage and current of about 10.5 V and 1.3 μA were come out, respectively. It was confirmed that it increased about 4.6 times compared to when measured with a single OPV and increased by 1.03 times compared to when measured with a single TENG. Through this, the OPV-TENG hybrid energy harvesting system can harvest energy not only under 1-Sun (AM 1.5: 100 mW/cm^2) and low light (LED 1000 lux: 0.32 mW/cm^2, Halogen 1000 lux: 4.98 mW/cm^2) light sources but also under various climatic environments. Moreover, it is expected to supply sustainable power by supplementing the low open circuit voltage (V_{OC}) of OPV through TENG, thus complement the limit of OPV in terms of 'climate-dependent energy harvesting' through TENG power generation.

SESSION SB06.15: Processing of Photovoltaic and Optoelectronic Devices

8:30 AM *SB06.15.01
Strategies to Improve the Efficiency of Organic Photovoltaics Thomas D. Anthopoulos; King Abdullah University of Science and Technology, Saudi Arabia

The power conversion efficiency (PCE) of organic photovoltaics (OPVs) has been increasing steadily over the past decade with reported PCE values now exceeding 19% and 20%, for single and tandem cell configurations, respectively. Despite the breath-taking progress, however, further improvements are anticipated via i) the use of new materials, and ii) by minimising performance losses associated with incumbent cell architectures and materials. In this talk, I will discuss recent work in my group in the field of OPVs with focus on practical strategies for boosting the cell performance. In particular, I will discuss the development and use of electronic additives, such as molecular dopants, and the implementation of self-assembling monolayers (SAMs) as charge extracting interlayer technologies for OPVs. I will show how addition of dopants can improve the PCE of state-of-the-art OPVs while the use of SAMs can dramatically increase the material utilization and circularity of the ensuing cells without compromising their performance.

9:00 AM SB06.15.02
Non-Halogenated and Low Synthetic Complexity Active Layer for Efficient Outdoor and Indoor Organic Photovoltaics Sergi Riera-Galindo[1], Xabier Rodríguez-Martínez[2], Marta Sanz[3], Laura López-Mir[3], Olle Inganäs[2] and Mariano Campoy-Quiles[1]; [1]Institut de Ciència de Materials de Barcelona, Spain; [2]Linköping University, Sweden; [3]Eurecat Technology Centre, Spain

Organic photovoltaics (OPV) requires the use of non-halogenated solvents and low synthetic complexity (SC) materials, without compromising power conversion efficiency (PCE), for large-scale processing as a low-cost and sustainable energy harvesting technology. First, we present a non-halogenated and low SC ink formulation for the active layer of organic solar cells, comprising PTQ10 and PCBM as donor and acceptor materials, respectively, showing a record PCE of 7.5% in blade coated devices under 1 sun, and 19.9% under indoor LED conditions. We have achieved these high performances analysing by combinatorial screening the compatibility of the active layer with of 5 different electron transport layers (ETLs) in inverted architecture.
On the other hand, we report the impact of the molecular weight of the donor polymer PTQ10 with benchmark non fullerene acceptors (Y6, Y12, IDIC) on the organic solar cell performance. In all cases, we have characterized the performance of the solar cells as a function of the thickness of the active layer. The PCE improves from values around 2% up to more than 10% with the optimized active layer thickness under 1 sun conditions. Further, we characterized the system by using a plethora of techniques such as recombination processes from light intensity–dependent measurements, field effect mobility, photoluminescence as well as grazing incidence wide angle X-ray scattering.
Regarding the stability, semi-transparent devices based on fullerene and manufactured entirely in air *via* lamination show indoor PCEs exceeding 10% while retaining more than 80% of the initial performance after 400 and 350 hours of thermal and light stress, respectively. In the case of NFAs based devices, we report the thermal stability dependence with the molecular weight of the donor polymer PTQ10.
As a result, we show promising materials to bridge the gap between research and industry, for indoor and outdoor low-cost OPV applications.

9:15 AM SB06.15.03
Performance and Long-Term Stability of Industrially Manufactured Non-Fullerene Based Organic Photovoltaics (OPV) Ngoc-Le Maria Lena Nguyen[1,2], Sebastian Meier[1], Morten Madsen[2] and Tamara Nunes Domschke[1]; [1]ASCA GmbH, Germany; [2]Mads Clausen Institute (MCI), Denmark

In the past years, organic photovoltaics (OPV) has experienced noticeable progress in material developments, device optimization, and industrial implementation towards commercialization. From lightweight, flexibility and the ability of solution-processing and large-area production at low-cost, organic solar cells have attracted increasing interests from academic and industrial entities. Initially, conjugated polymers were used as donor and fullerene as acceptor materials. However, the limitations in terms of synthetic flexibility, weak intrinsic absorption capability in the visible and near infrared region and poor coordination of energy levels restrained their further application. The evolution of non-fullerene electron acceptors (NFA) has mainly overcome these drawbacks. Hence, NFAs have been identified as promising materials for future OPV applications, and maximum power conversion efficiencies

(PCEs) of over 19% have been reported already. However, such high PCE numbers have so far only been achieved for small-area devices (few mm^2), usually fabricated using non-scalable materials (evaporated MoO_3), processing techniques (e. g. spin-coating) and conditions (inert environment), which together with the use of rigid substrates is far away from meeting industrial requirements.
This work focuses on large-scale solution-based manufacturing of NFA devices by means of roll-to-roll processing, taking into consideration industrial standards. Using a commercially available NFA-based material system and optimizing the device architecture, the active layer morphology and the coating process, PCEs of over 10% on cell level and close to 7% on module level were achieved so far, with potential for further improvements. In parallel, the stability of the fabricated devices was carefully investigated and optimized as well with a focus on thermally and photo-induced changes. The NFA-based devices feature very good photostability, with more than 80% of the initial PCE maintained after 2000 h of continuous illumination and under open-circuit conditions. Based on previous experience, even better results are expected at operating conditions, i.e. when holding the devices at the maximum power point. Thermal stability limiting factors, were studied by means of GIWAXS as well as UV-Vis-NIR, PL and impedance spectroscopy and steps were taken to stabilize the device performance under high continuous heat. The results presented in this work confirm the potential of NFAs for the next generation of high performing OPV solar cells and show promise for their commercialization.

9:30 AM SB06.15.04
Optimized Vertical Phase Separation via Systematic Y6 Inner Side-Chain Modulation for Non-Halogen Solvent Processed Inverted Organic Solar Cells Seung Un Ryu and Taiho Park; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Organic solar cells (OSCs) have entered a new phase of development with the advent of a high-performance non-fullerene acceptor known as Y6. Considering that the molecular curvature shape of Y6 allows for dense intermolecular packing with a grid-like packing structure, the modification of branched alkyl chains located on the pyrrole motif of Y6 is expected to have a significant impact on morphological properties, such as molecular packing/orientation behavior and vertical phase separation. In this work, we fine-tune the branched alkyl chain attached to nitrogen atoms of the Y6 main backbone and systematically investigate the relationship between the morphological features and photovoltaic performance of OSCs with a PM6 donor polymer. The systematic alkyl chain engineering effectively reduces the aggregation of Y6-analogs and substantially improves solubility, thereby providing solution processability in a non-halogenated solvent. Additional in-depth analyses reveal that the modification of branched alkyl chains allows the formation of an optimized bulk heterojunction morphology, which is advantageous for an inverted device architecture. In particular, the PM6:Y6-HU-based inverted OSC utilizing *o*-xylene as a processing solvent achieves a power conversion efficiency of 17.4% with a fill factor of 77.9% under the binary blend system and single non-halogen solvent processing.

9:45 AM SB06.15.05
High-Performance Organic Photodetectors Processed from Green Solvent Hoang Luong[1], Zhifang Du[1], Sina Sabury[2], Austin Jones[2], Ziyue Zhu[1], Patchareepond Panoy[1], Sangmin Chae[1], Ahra Yi[1], Hyo Jung Kim[3], Steven Xiao[4], Viktor Brus[5], Manjunatha Reddy[6], John Reynolds[2] and Thuc-Quyen Nguyen[1]; [1]University of California, Santa Barbara, United States; [2]Georgia Institute of Technology, United States; [3]Pusan National University, Korea (the Republic of); [4]1-Material Inc, Canada; [5]Nazarbayev University, Kazakhstan; [6]University of Lille, France

Organic photodetectors (OPDs) have emerged as a promising platform for a photosensing and optical communications in the last decades for their lightweight, flexibility, and great industry potential for high throughput solution processing. However, traditional solvents used for OPDs processing conditions are commonly highly toxic halogenated organic solvents like chlorobenzene (CB), o-dichlorobenzene, and chloroform, which are not only harmful to human health upon exposure but can also cause long-term effects on the ecosystem. Herein, we showcase a high-performance OPD based on a newly designed bulk heterojunction (BHJ) comprised of a PM7-D5 donor polymer and the Y12 non-fullerene acceptor processed from a green solvent, 2-methyltetrahydrofuran (2-MeTHF). The PM7-D5:Y12 OPDs simultaneously exhibits a remarkably high detectivity (with shot-noise-limited specific detectivity of above 10^{14} Jones) and surpasses the performances of OPDs processed from traditional chlorinated solvents. The relationship between processing solvents, active layer morphology, and photo-sensing performance of PM7-D5:Y12 devices were elucidated by combining several thin-film solid-state characterizations (atomic force microscopy (AFM), grazing-incidence wide-angle X-ray scattering (GIWAXS), transmission electron microscopy (TEM), and solid-state nuclear magnetic resonance (ssNMR) spectroscopy). The results suggest that the donor-acceptor molecules are well phase-separated with minimal disruption to the PM7-D5 and Y12 backbone packing, while smaller domain sizes due to changes to the sidechain conformations of acceptor molecules are observed in 2-MeTHF cast film in comparison to films processing from CB or *o*-xylene, which facilities the charge generation and collection process in the device. In addition, the PM7-D5:Y12 OPDs are employed as wearable flexible devices to monitor heart rate and blood oxygen saturation, which suggests the potential for practical applications.

The Impact of Channel Hydration on the Performance of Electrolyte Gated Transistors Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

Organic mixed (ionic and electronic) charge conductors and electrochemical phenomena at the solid-liquid interface have garnered significant attention for applications in bioelectronics, electrochromics, energy storage/generation, neuromorphic computing, and thermoelectrics. These devices operate in electrolytes that render ions mobile in the film, making the coupling between electronic and ionic charges crucial. A prime example of such devices is the organic electrochemical transistor (OECT), a high gain transducer used commonly to monitor bioelectronic signals. In this talk, I will introduce the emerging class of conjugated polymers that have been synthesized for use in OECT channels. Having developed in operando techniques, we found that the ions enter the semiconducting polymer channel hydrated, and the excess swelling of the polymeric channel had a significant effect on OECT performance, which can be traced back to changes in the overall structural order. I will introduce two postprocessing approaches that limit the water uptake of the film during device operation These approaches enhance the mixed conductivity of polymers while preventing degradation and lead to OECTs with longer shelf life and operational stability.

11:00 AM SB06.16.02

Elucidating Strength of Ionic Interactions in Conductive Polymers Spencer Yeager, Linze Du Hill, Jonthan K. Harris, Songyan Yu and Erin L. Ratcliff; The University of Arizona, United States

Pi-conjugated polymers (CP) have been utilized in a number of opto-electronic and (photo)electrochemical applications, including photovoltaics, organic electrochemical transistors (OECTs), organic field effect transistors (OFETs), electrochromic devices and biosensors. These soft materials can be easily and reversibly doped using electrochemistry, where the solvent and supporting electrolyte (anions and cations) can intercalate into the relaxed film to support long-lived carriers to do electrochemical work. The resulting enhancement of electronic properties such as conductivity are known. However, quantification of the strength of intermolecular interactions within the system, namely Coulombic attraction between anions and polarons, is less understood. Herein we postulate that the dielectric of the solvent system can impact the relative strength of interaction and depends strongly on the fraction of supporting counterion cation present. As a prototype system, we start from poly(3-hexylthiophene) (P3HT) and an ionic liquid 1-ethyl-3-methylimidazolium bis(trifluoromethylsulfonyl)imide ([EMIM][TFSI]). We consider different local environments including vacuum deposited ionic liquid on the polymer, interfacing the polymer with ion gels, and a moderate dielectric acetonitrile with complementary supporting electrolyte. Electrochemical and spectroscopic techniques are combined to probe in situ doping fractions using a prototypical OECT. Chemical shifts in the core level S 2p, F 1s, N 1s, and C 1s electrons corresponding to the [TFSI] and P3HT were observed as a function of the percentage of doped P3HT and give direct insight into the extent of electron density exchange between the system components. Insights gained are then used to lower the operating voltages of OECTs, towards all-printable configurations. Collectively, these studies helps provide a better understanding of the effects that anions have on the polymer, allowing for improved design guidelines when implementing these systems for device-relevant applications.

11:15 AM SB06.16.03
Electrochemical Doping Mechanisms in the Ordered and Disordered Domains of P3HT Priscila Cavassin, Isabelle Holzer, Demetra Tsokkou, Olivier Bardagot, Julien Rehault and Natalie Banerji; University of Bern, Switzerland

Organic mixed ionic-electronic conductors (OMIECs) are a class of organic materials that efficiently support both ionic and electronic transport. Due to this remarkable property, a broad range of emerging technologies, from energy storage to bioelectronics, rely on OMIECs. [1] A key property of these materials is their ability to be electrochemically doped, which is an efficient and reversible method to increase the materials electric conductivity. This process relies on the injection of carriers into the organic film, while the counterions from an electrolyte infiltrate the film and maintain charge neutrality. The electrochemical doping relies on a complex interplay between multiple factors, from electrolyte choice to molecule design and film morphology, and due to the increasing number of applications that rely on this process, there has been great interest in further understanding its properties and fundamental mechanisms. [2]

In this work, we explore the impact of the polymer film morphology on the electrochemical doping. We use time-resolved visible-near infrared (Vis-NIR) and in-situ Raman spectroscopy combined with electrochemical measurements to show that the ordered and disordered domains of poly(3-hexylthiophene) (P3HT) are doped through different mechanisms and kinetics. We demonstrate that for intermediate doping levels, polarons and bipolarons (singly and doubly charged species) coexist exclusively in the disordered domains. In the ordered domains, only polarons are observed until there are no more ordered undoped chains, and only at this point bipolarons start to be formed at these domains. We propose a kinetic model that described the reactions that take place and show that the ordered phase is doped faster than the disordered for all doping levels.

To confirm our propositions, we used in-situ electrochemical Raman spectroscopy, a technique very sensitive to local conformation. We obtained good agreement with the trends observed with Vis-NIR spectroscopy. Additionally, we compared the doping of P3HT films with different degrees of morphology. We use regiorandom P3HT to investigate the doping in purely disordered films, and the results strongly correlate with our proposed kinetic model. Finally, by measuring the Thz conductivity of our films, we investigate how the polarons and bipolarons impact electronic conductivity.

11:30 AM SB06.16.04
Hierarchical Self-Assembly of PEDOT:PSS to Enable Intrinsically Water Stable Conductors Laine Taussig[1], Masoud Ghasemi[2], Tatiana Proksch[1], Albert Kwansa[1], Sanggil Han[3], Ruipeng Li[4], George G. Malliaras[3], Yaroslava G. Yingling[1] and Aram Amassian[1]; [1]North Carolina State University, United States; [2]The Pennsylvania State University, United States; [3]University of Cambridge, United Kingdom; [4]Brookhaven National Laboratory, United States

Owing to the vastly tunable material properties, PEDOT:PSS has been regarded as one of the most promising material platforms for organic bioelectronics, neuromorphic computing, and transparent conducting electrodes in a wide array of optoelectronic and photovoltaic applications. As PEDOT:PSS is an electrostatically stabilized colloidal suspension, it is no surprise that the addition of ionic additives of late have shown some of the most remarkable control over the properties of PEDOT:PSS, including formation of conducting gels. Here, we report in-depth multi-modal experimental (in situ/ex situ GIWAXS, TEM, conductivity, rheology) and computational (MD) investigations of the effects of ionic additives on PEDOT:PSS from solution to solid state. Findings reveal new insights into solution-phase self-assembly of this material that explain its solid-state thin film properties such as high electronic conductivity, remarkable water insolubility, and crystalline structure. We demonstrate water-stable printing of PEDOT:PSS interconnects and devices, including OECT devices, without the need of crosslinking agents. This work offers new insights into the mechanisms responsible for the highly attractive properties of PEDOT:PSS for applications including wearable and implantable bioelectronic devices and neuromorphic computing.

SESSION SB06.17: Structure, Degradation in Organic and Hybrid Photovoltaics

Excited State Photodegradation of Organic Photovoltaic Materials Mihirsinh Chauhan, Ambika Pathak, Jacob Mauthe, Samuel Shepard, Somayeh Kashani, Xingao Zhang, Benjamin Hines, Felix Castellano, Harald Ade and Aram Amassian; North Carolina State University, United States

Stability or lack thereof is currently the Achilles heel of organic photovoltaics, which is otherwise close to reaching a power conversion efficiency of 20% and can already be processed using scalable manufacturing approaches using green and sustainable materials. Photodegradation is only empirically studied,

is not well understood, and there continue to be widely held misconceptions about the effectiveness of encapsulation whereby it is thought that effective blocking of O_2, H_2O and UV can address photodegradation. Unfortunately, modern donor and acceptor materials photodegrade in inert atmosphere under visible light illumination simply by being in the excited state, pointing to inherent photostability issues associated to the excitonic nature of conjugated materials that must be understood at a fundamental level and then mitigated either through material design or through engineering of the photophysics and photochemistry within the BHJ layer. In this talk, we will present our understanding of excited state photodegradation of conjugated materials in inert atmosphere and how this is directly associated to excited state lifetime in materials. We will demonstrate how photodegradation is dependent on the chemical resilience of various molecular classes and ways to mitigate photodegradation in inert atmosphere through judicious design of quenching approaches, including in bulk heterojunction films.

2:30 PM SB06.17.02
Visualizing Degradation at the Nanoscale from Morphological and Energetic Perspectives in Organic Photovoltaics Gaurab J. Thapa, Mihirsinh Chauhan, Daniel Dougherty and Aram Amassian; North Carolina State University, United States

Organic photovoltaics (OPVs) have received tremendous interest in recent decades due to their flexibility, ease of processing and cost effectiveness [1-3]. With the advent of non-fullerene acceptors (NFA), the efficiency of these solar cells has broken previous records and has currently achieved power conversion efficiency (PCE) > 18% [4]. OPVs is now confronting the next bottleneck which is its instability. Multiple pathways for degradation of organic solar cells have been reported [5], the most common route for the active layer being photodegradation and morphological degradation. The stability of NFA-based OPVs is contingent on the morphology and its evolution throughout the lifetime of the device. Since interfacial/mixed phase energetics are crucial for charge generation [6], it is imperative to maintain the energetics of Donor (D), Acceptor (A) rich region and mixed region in the blends during device aging and operation. Moreover, changes in the energetics caused by the morphological evolution due to de-mixing of D and A materials in the mixed region can have a vital role on degradation of device performance. A definitive morphological picture of the BHJ during degradation studies, down to a length scale of a few molecules, is therefore urgently needed, as this can shed light on the energetic landscape and its evolution within the BHJ. In this work, we take a deeper dive into the morphological aspect of degradation utilizing scanning tunneling microscopy/spectroscopy (STM/S), a unique and quite effective tool for characterizing morphology and associated energetics. We study the morphology of stable and unstable systems and the evolution of their domain and mixed phase energetics. We focus on PM6-based blends with ITIC-4F, Y6 and $PC_{71}BM$. Along with investigating the properties of the neat materials, we visualize and identify D and A-rich phases within the various BHJs and compare energetics within BHJ to neat D and A materials to correlate with its miscibility properties. In addition, we compare the histogram of Local Densities of States (LDOS) of the PM6 and A-rich phases in their neat and blend forms to gain insight into the energetic disorder as these materials are mixed in the blends. Finally, we visualize morphological degradation of PM6:Y6 and evaluate changes of LDOS within PM6, Y6 and mixed domains within the BHJ due to thermal annealing which is in correlation with changes observed in device performance parameters.

Mechanically Flexible Organic and Hybrid Semiconductor Devices—Role of Composition and Film Morphology Antonio Facchetti; Northwestern University/Flexterra Inc, United States

In this presentation we report the realization of new semiconductor films and devices with considerable mechanical flexibility and stretchability. Thus, organic films with great mechanical stress tolerance were realized for NDI and DPP-based polymers by creating porous honeycomb morphologies via a breath figure method. These films can be stretched by a strain larger than 100% and can retain excellent semiconducting properties. Furthermore, we were able to fabricate metal oxide films with considerable flexibility by incorporating organic polymers, or using organic polymers, to achieve desirable compositions or fibrotic film morphologies. The resulting devices, eg, TFTs, circuits and sensors, exhibit excellent response and good performance also upon considerable mechanical deformations.

3:45 PM SB06.18.02
Climbing "Up" the Near-Infrared Window of Dye-Sensitized Upconversion for Photovoltaics Kristin Becker[1], Maxim S. Pshenichnikov[1], Andries Meijerink[2] and J. C. Kees Hummelen[1]; [1]University of Groningen, Netherlands; [2]Utrecht University, Netherlands

One of the most promising and frequently talked about solutions to the current energy crisis and environmental pollution are *solar cells*. Classical silicon solar cells have a fundamental limit of power conversion of 32% and are nowadays very close to reaching that limit. This limit can be exceeded either by better adapting the solar cell to the solar spectrum or by changing the solar spectrum to one that a classical, cheap solar cell can use. The latter can be done by the process of photon upconversion, a non-linear process where two (or more) photons of longer wavelength (lower energy) are sequentially absorbed, followed by the emission of light at shorter wavelength (higher energy) than the excitation one. All the photons with energy lower than the bandgap of silicon (1.12 eV) go through the silicon layer without being absorbed. By incorporating an upconversion layer below the silicon layer in the device, such low energy photons can be absorbed in the upconverter layer, upconverted to higher energy photons, which can be reflected back and initiate exciton formation in the silicon layer. These two layers can be electrically isolated, which gives us the opportunity to optimize them separately in order to gain

optimum efficiency of the solar cell. In theory, the use of an ideal upconverter (2 bandgaps) with a photovoltaic active layer (with a bandgap of 2 eV) can increase the power conversion efficiency up to 50.7%.[1]

This research aims to study the process of dye-sensitized upconversion in the (so far) unexplored near-infrared (NIR-II) window (λ = 1000 - 1700 nm) for use in hybrid silicon/organic photovoltaics. Sensitization in the proposed window is challenging but using energy transfer from a luminescent species on a surface layer to lanthanide ions in the core of nanoparticle (NP) provides opportunities that cannot be realized in bulk materials.[2]

To achieve the upconversion in this range, we propose a hybrid organic/inorganic system consisting of an organic dye serving as an "antenna" and a lanthanide-based NP that will act as an upconverter. A newly synthesized cyanine dye that absorbs and emits in the NIR (λ_{max} = 1380 nm) will be attached (via a carboxylate linker group) to the NP, enhancing the upconverted luminescence due to a high molar absorption coefficient of the dye. The excitation energy transfers to the upconverting NP consisting of lanthanide ions, erbium and ytterbium (Er^{3+} & Yb^{3+}). The upconverted emission that follows, achieved by the Er^{3+} ions in the carefully designed NP, is 980 nm. The wavelength of the upconverted photons falls into the absorption window of silicon, opening avenues to modify existing silicon solar cells with new hybrid materials that could go beyond the Schokley-Queisser limit.

Effects of Molecular Encapsulation on the Photophysical and Charge Transport Properties of a Naphthalene Diimide Bithiophene Copolymer.
Stefano Pecorario[1,2], Jeroen Royakkers[3], Hugo Bronstein[4] and Mario Caironi[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Maastricht University, Netherlands; [4]University of Cambridge, United Kingdom

Molecular encapsulation is a powerful synthetic concept that can be used to study polymer chains (or molecules) in isolation by shielding the conjugated backbone with protective macrocycles, and preventing electronic cross communication between the π-systems. Here, we present a molecularly encapsulated form of the naphthalene diimide bithiophene copolymer PNDIT2, one of the most widely used semiconducting polymers with high charge mobility for n-type field-effect transistors and non-fullerene acceptors in organic photovoltaic blends. We introduced enclosing macrocycles covalently bonded to the bithiophene units, while the naphthalene diimide moieties are left open for intermolecular interactions. We found that the encapsulated equivalent shows more backbone planarity when compared to PNDIT2. Furthermore, molecular encapsulation prevents the polymer chains from pre-aggregating in common organic solvents, while allowing π-stacking in the solid state and fostering thin film crystallinity through an intermolecular-lock mechanism. As a result, field-effect transistors still exhibit n-type semiconducting behavior, despite charge mobility being lower than in PNDIT2 as a result of the lack of the fibrillar microstructure that results from pre-aggregation in solution. Thus, molecular encapsulation appears as an effective method to adjust the nanomorphology of cast films while preserving the electrical structure of the core polymer and the thin film charge transport properties.

Unraveling the Correlation Between Structure and Performance by Optical Techniques on Organic Solar Cells Carmen M. Ruiz Herrero[1], Yatzil Avalos[2], Anil K. Bharwal[1], David Duché[1], Jean-Jacques Simon[1], Christine Videlot-Ackermann[2] and Jörg Ackermann[2]; [1]Aix Marseille Univ.,Univ. de Toulon, UMR CNRS 7334, IM2NP,, France; [2]Centre Interdisciplinaire de Nanoscience de Marseille (CINaM, UMR CNRS 7325), France

Organic based photovoltaics present nowadays a bright future, due to its suitability for the integration on systems related with the IoT, its compatibility with lightweight and flexible substrate and the possibility of being deposited by easily scale-up techniques such as ink-jet printing. Furthermore, the development of Non-Fullerene Acceptors (NFA) has led to a jump on performances, approaching the 20% milestone. Nevertheless, there is still a lack of knowledge on fundamental properties of the devices that can compromise the successful transition of this technology into the industrial step.
In particular, there is still not a clear understanding of how the materials arrange themselves in the active layer and which impact it has on its optical and electrical transport properties and thud on the final performance of the functioning devices. In order to investigate the structural arrangement long time-consuming techniques such as synchrotron X-ray diffraction or Transmission Electron Microscopy (TEM) must be used. This, compound with the fact that samples have to be prepared on special conditions suitable for the measurement set-up limits the amount of information we can actually extract that will apply to the functioning device. In this work, we propose to use optical nondestructive techniques to explore the structural properties of the active layer on an actual device and compare with the electrical transport properties and performances.
For this, we analyze solar cells made by liquid deposition techniques with active layers composed by different NFA/polymers at different post-annealing temperatures. These devices have been studied with raman spectroscopy to determine the structural organization of the active layer, revealing the importance of NFA and polymer compatibility for enhancing a better microstructural arrangement of both materials. Photoluminescence measurements have also been carried both on separate materials and on solar cells to quantify the effective charge separation and its correlation with the active layer structure. Finally, Photovoltage Decay measurements allow us to have an estimation of the recombination states on these devices.

Radiative and Non-Radiative Recombination in Organic Photovoltaics Koen Vandewal; Hasselt University, Belgium

The currently best organic solar cells suffer from relatively large voltage losses due to non-radiative recombination as compared to inorganic or perovskite solar cells. Further enhancement of the power conversion efficiency to values over 20% will require a reduction of these losses, inevitably corresponding to an increase in the electroluminescence quantum efficiency of the devices.[1] For a large number of donor-acceptor combinations, we have observed that non-radiative voltage losses decrease with increasing charge-transfer-state energies, consistent with non-radiative decay being facilitated by a common high frequency molecular vibrational mode.[2] We further identify small molecule donor-acceptor blends with an optical gap in the visible spectral range, with strongly reduced non-radiative losses as compared to systems with a gap in the near infrared (NIR).[3] This highlights the possibility of a simultaneous occurrence of a high photovoltaic quantum efficiency as well as a high electroluminescence quantum efficiency, occurring in a single organic donor-acceptor blend. For photovoltaic blends with strong absorption in the NIR, we show that the lowest non-radiative decay rates correspond to systems with the narrowest emission linewidths and steepest absorption tails.[4]

The Role of Dipole Interactions on Intermolecular Charge Transfer in Y6 Non-Fullerene Acceptor Studied by Electroabsorption Spectroscopy
Sudhi Mahadevan[1], Taili Liu[2] and Sai Wing Tsang[1]; [1]City University of Hong Kong, China; [2]Yunnan Normal University, China

Organic photovoltaic cells (OPVs) with Y6 as electron acceptor have recently been reported with record high efficiency and negligible photovoltage loss. It is generally believed that intermolecular electrostatic interactions between Y6 molecules lead to strong charge transfer (CT) characteristics which results in efficient exciton dissociation and reduced non-radiative recombination. However, it is still unclear about the contribution of intermolecular dipoles and its effect on different dimer formations and enhanced CT characteristics. Here, we investigate the contribution of anisotropic dipoles to excimer formation and its impact on CT properties using electroabsorption (EA) spectroscopy. The EA spectra of Y6 are strongly dependent on the molecular packing as we observe strong second derivative characteristics around the S0 to S1 excitation while increasing the loading ratio of Y6 in the polymer matrix. We also observe dipole orientation in packed Y6 film while increasing the molecular concentration by quantitative analysis of the first harmonic EA spectra of pristine Y6. These preferred oriented dipoles are found responsible for the distinctive molecular packing of Y6 which leads to strong intermolecular charge transfer. Quantitatively, fitting the EA spectrum highlights the significance of polarizability (p) between ground and excited states in electron delocalization and intermolecular charge transfer property of Y6. The extracted Δu values of monomer and dimer configurations show excellent consistency with theoretical values from quantum calculation results. Our work mainly highlights the application of electroabsorption spectroscopy as an powerful technique to probe charge transfer characteristics, intermolecular interactions, binding energy, and delocalization of excitons etc. in pristine Y6. This research work provides insight into better molecular design of novel photovoltaic materials by tuning the intermolecular electrostatic interactions and delocalization of electron wavefunctions.

Exciton Transport in Nonfullerene Acceptors and Semiconducting Polymers Boosted by Transient Quantum Delocalization Samuele Giannini[1], Jochen Blumberger[2] and David Beljonne[1]; [1]University of Mons, Belgium; [2]University College London, United Kingdom

The transport of excitons in molecular systems is essential to the function of flexible optoelectronic devices (including organic solar cells) and biological light-harvestings. It is remarkable, however, that the nature of excitons and related transport mechanism in these soft materials have puzzled the community for so many years. Even for apparently simple systems such as organic single crystals: some experiments would better fit a localized particle picture, while others a coherent wave-like interpretation.
Our non-adiabatic molecular dynamics simulations show that energy carriers in OSs are neither waves nor particles, as previously assumed. By solving the coupled nuclear-electronic motion, we observe that in molecular OSs and non-fullerene acceptors (NFAs), including Y6, exhibiting some of the highest measured (singlet) exciton diffusion length to date [1], excitons undergo a transient quantum delocalization/localization mechanism that underpins the larger spatial displacements and diffusivity of the excitonic wavefunction in these materials [1] (in agreement with what found experimentally). This mechanistic scenario, by which the excitons can thermally access delocalized states within the excitonic band giving rise to long-range exciton transport, is similar to what we found for charge carrier transport in high charge carrier mobility OSs [3,4]. Similarities and differences will be discussed.
Remarkably, we also found that an analog transient delocalization mechanism takes place when simulating (singlet) exciton diffusion in highly ordered conjugated polymer nanofiber of P3HT [5,6]. Importantly, in the latter case, the mechanism is highly sensitive to the interplay between delocalization along the polymer chains and long-range interactions along the stacks [6]. Surprisingly, the diffusion coefficient is predicted to rocket by 3 orders of magnitude when going beyond nearest-neighbour intermolecular interactions in fibers of extended (30-mer) polymer chains (in line with transient absorption microscopy measurements [5]) and to be resilient to interchain energetic and positional disorders.
On the basis of our simulations we discuss a path for improving the exciton diffusion constant in organic semiconductors.

8:00 AM *SB06.21.01
Investigating Dopant Intercalation into Semiconducting Polymer Crystals by TEM, Rutherford Backscattering and Polarized UV-vis-NIR Spectroscopy Martin Brinkmann[1], Yuhan Zhong[1,2], Shubhradip Guchait[1], Dominique Müller[2], Viktoriia Untilova[1], Laurent Herrmann[1] and Thomas Heiser[2]; [1]Institut Charles Sadron CNRS, France; [2]ICUBE, France

Doping of polymer semiconductors is a central topic in plastic electronics and especially in the design of new better performing thermoelectric materials. Sequential doping of highly ordered polymer semiconductors is widely used to tune the charge carrier density that determines the thermoelectric properties. Various studies have demonstrated that dopant molecules intercalate into the layers of side chains in the crystals of polymer semiconductors.(1-3) It is therefore essential to clarify the way dopants are incorporated into the crystal lattice of the pristine polymer and how this is related to the dopant size and electron affinity. A combination of electron diffraction and polarized UV-vis-NIR spectroscopy on highly oriented P3HT and PBTTT thin films allows to quantify the amount of intercalated dopant molecules as well as the molecular orientation of dopants such as F4TCNQ, F6TCNNQ with respect to the polymer chains. A mapping of the orientational distribution of dopant molecules in the polymer crystal can thus be obtained. In the case of P3HT/F6TCNNQ, modeling of the diffraction patterns of doped crystals identifies the stoichiometry of the doped polymer phase and confirms the dopant orientation obtained from spectroscopy measurements as well as the lattice parameter variation induced by intercalation. In the case of Magic blue, Rutherford Backscattering is used to quantify the dopant amount in the films, Polarized UV-vis-NIR helps determine the diffusion coefficients of the dopant into the P3HT matrix whereas TEM demonstrates preferential location of MB in the amorphous phase of P3HT. It is demonstrated that the highest charge conductivities (up to 3000 S/cm) are observed in oriented P3HT films when the amorphous phase of P3HT is selectively doped with MB.

Organic Light-Emitting Devices Using Common Uneven Aluminum-Foil as the Electrode Satoru Ohisa, Taku Oono, Masashi Miyakawa, Takahisa Shimizu and Toshimitsu Tsuzuki; Japan Broadcasting Corporation (NHK), Japan

Here, we report the fabrication of organic light-emitting devices (OLEDs) using common uneven aluminum-foil as the electrode substrates, which show surface roughness of several hundred nanometers. In general, the use of such uneven electrodes causes serious electric leakage due to the application of ununiform electric field, resulting in improper operation of OLEDs. In this work, extraordinary thick phosphotungstic acid ($H_3PW_{12}O_{40}$) (PWA) buffer layer of several hundred nanometers was used for the mitigation of the ununiform electric field. PWA showed the property of negative differential resistance (NDR), and the property contributed to the realization of both of the low driving voltage and the suppression of the leakage currents. The origin of the NDR was also investigated by various analytical methods. We applied PWA to the OLEDs using aluminum-foil electrode substrates, and obtained leak-free OLEDs with uniform luminance images. Large area OLEDs with a light-emitting area of 64 cm^2 were fabricated. Even in crumpled and torn states, they emitted steady luminescence.

8:35 AM SB06.21.03
Laser Oscillation of Organic Distributed-Feedback Lasers at the Edge of a Mini Stopband Hidekazu Shimotani[1], Taiki Miura[1], Thangavel Kanagasekaran[2] and Katsumi Tanigaki[3]; [1]Tohoku University, Japan; [2]Indian Institute of Science Education and Research Tirupati, India; [3]Beijing Academy of Quantum Information Sciences, China

Organic semiconductor lasers have continued to attract attention because of their broad spectrum and diversity of materials, covering all wavelengths from UV to near IR.[1] In recent years, laser oscillation by current pumping, which does not require an external pumping source, has been actively studied. As a resonator structure for this purpose, DFB (Distributed Feedback) resonators with a single longitudinal mode and low threshold are often used.[2, 3] Although most of the laser oscillation wavelengths can be explained by the Bragg condition, several experimental results have been reported for polymer DFB lasers doped with organic semiconductors that do not match the Bragg condition in any mode.[4]
Here, we report the conditions that determine the oscillation wavelength of organic DFB lasers using 5,5″-bis(biphenyl-4-yl)-2,2′:5′,2″-terthiophene (BP3T) single crystals, a promising material for injection lasers,[5-9] with various thicknesses as an active layer. Analysis using experimentally obtained refractive indexes revealed that the oscillation wavelengths of some BP3T DFB lasers are at the edge of a stopband, while the others are at an edge of the mini stopband,[10] which satisfies the phase-matching condition between different transverse modes and has not been considered in DFB lasers so far. Finite-element optical-waveguide simulations of the BP3T DFB laser verified the coupling of different transverse modes.

Sticky Thermoelectric Materials to Fabricate Flexible Peltier Sheets Norifusa Satoh, Masaji Otsuka and Jin Kawakita; National Institute for Materials Science, Japan

Flexible Peltier sheets benefit to fit complex objects like human bodies and deliver cold energy efficiently because the amount of heat transfer increases with the contact area. To make a solid Peltier plate into a flexible sheet, however, we need a new material with a high Seebeck coefficient like inorganic materials and a low thermal conductivity like organic materials to generate and maintain the temperature difference between the top and bottom sides of the sheet. Herein, we employ Bi_2Te_3-based sticky thermoelectric (TE) materials due to the following two features: First, sticky TE materials have been inversely designed to mass-produce flexible TE generation sheets through lamination or roll-to-roll processes without using electric conductive adhesives. Second, sticky TE materials have been demonstrated as an inorganic/organic hybrid material of TE particles and low-volatilizable organic solvents to show Seebeck coefficients based on the TE particles and low thermal conductivities based on the organic solvents. In this presentation, we discuss the relation between Peltier performance and electric resistance.

8:45 AM SB06.21.07
Organic-Photoconductive-Film-Stacked Image Sensor with Thin-Film-Transistor-Based Active Pixel Sensor Readout Circuits Koki Imamura[1], Toshikatsu Sakai[1], Hidenori Yakushiji[2], Yuta Hashimoto[2], Tatsuya Aotake[2], Yuichi Sadamitsu[2], Hiroto Sato[1] and Satoshi Aihara[1]; [1]Japan Broadcasting Corporation, Japan; [2]Nippon Kayaku Co., Ltd., Japan

Organic photoconductive films (OPFs) are attractive optoelectronic materials because they possess high absorption coefficients surpassing those of conventional silicon photodiodes and are thus promising candidates for use in photoconductive parts of flexible, large-area imaging devices. In such applications, thin-film transistor (TFT)-based signal readout circuits with amorphous oxide semiconductors (AOSs) such as indium–gallium–zinc-oxide (IGZO) are useful owing to the high field-effect mobilities of AOSs (>10 cm^2/Vs), because image sensor applications require high response speeds and high-pixel-density integration. For example, IGZO-TFT-based flat-panel imagers have been proposed for the detection of X-rays [1]. On the other hand, our group has developed a three-layer-stacked image sensor for realizing compact cameras with high light utilization efficiency using two indium–tin–zinc-oxide (ITZO)-TFT-based readout circuits with blue/green-selective OPFs stacked on a complementary metal oxide semiconductor image sensor (for detecting transmitted red light) with a quarter video graphics array (QVGA) resolution (320 × 240) [2]. Most studies to date, however, have used the passive pixel sensor architecture, which contains one TFT in each pixel for readout of accumulated signals as a small current; thus, images reproduced from the TFT-based sensor were susceptible to external noise. To overcome this obstacle, introducing an active pixel sensor (APS) architecture is necessary, which has three TFTs in each pixel and can perform in-pixel signal amplification [3]. In this study, we describe an excellent performance of our blue-light-sensitive OPF including a dark current low enough to be used as a photoconversion unit of an APS [4], and we demonstrate imaging operation of the OPF-stacked TFT-based APS with a pixel number of 128 × 96 and a pixel pitch of 50 μm.
The TFTs used in this study had a bottom-gate staggered structure, and their channel width and length were 10 μm and 2 μm, respectively. The TFT-based readout circuit was fabricated on a glass substrate by sequentially forming gate electrodes (molybdenum (Mo) alloy, 50 nm), a gate insulator (silicon oxide, 200 nm), pixel electrodes (indium-tin-oxide, 50 nm), an active semiconductive layer (ITZO, 30 nm), via holes in the gate insulator, source/drain electrodes (Mo alloy, 70 nm), signal lines (Mo alloy/aluminum (Al)/Mo alloy, 75 nm), and a passivation layer (organic insulator, 600 nm). After fabrication of the TFT circuits, the OPF was formed on the pixel area by thermally evaporating in the order of an electron-blocking layer (2,7-bis(carbazol-9-yl)-9,9-spirobifluorene, 30 nm), a blue-light-sensitive active layer (2,9-diphenyl-dinaphtho-[2,3-*b*:2′,3′-*f*]thieno[3,2-*b*]thiophene, 200 nm), a hole-blocking layer (4,6-bis(3,5-di(pyridin-4-yl)phenyl)-2-methylpyrimidine, 50 nm), and a counter electrode (Al, 30 nm).
TFT and OPF performances were then measured. The on-off ratio and the extracted field-effect mobility of the TFTs were >10^8 and 24 cm^2/Vs, respectively. The OPF exhibited the blue-light sensitivity with a peak external quantum efficiency of ~59%, and the dark current density of the OPF was 88 pA/cm^2. Finally, an imaging experiment was conducted with an image sensor test system. Images from test charts with a blue light-emitting diode backlight were projected onto a camera lens and focused on the sensor. By applying operation voltages of a QVGA array at 60 frames per second, we successfully obtained an image output from the fabricated sensor with 128 × 96 pixels. The results obtained here are potentially applicable to not only three-layer-stacked image sensors with enhanced image quality, but also flexible, large-area TFT-based APSs.

8:50 AM SB06.21.11
Data Science Guided Experiments Identify Conjugated Polymer Solution Concentration as a Key Parameter in Organic Field-Effect Transistor Device Performance Rahul Venkatesh[1], Yulong Zheng[1], Campbell Viersen[1], Aaron Liu[1], Carlos Silva[1], Martha Grover[1] and Elsa Reichmanis[2]; [1]Georgia Institute of Technology, United States; [2]Lehigh University, United States

Organic semiconducting polymers have demonstrated potential in the production of large-area, low-cost, flexible electronic devices. Recently discovered push−pull copolymers (donor−acceptor (D−A) polymers), with a polymer backbone consisting of alternating electron-deficient (acceptor) and electron-rich (donor) units, have exhibited significant improvement in electronic performance compared to semicrystalline homopolymers. The high charge carrier mobility observed in D−A polymers has been attributed to the rigid, planar backbone conformation with minimal steric hindrance between the donor and acceptor units. However, the vast and complex device processing space combined with a lack of standardized reporting makes reproducibility within the field difficult and impedes the development of these materials. Curating and analyzing centralized datasets is a promising approach to resolve the issue of reproducibility, gain new insights, and guide future experiments. Here, a data set was constructed containing processing and performance information of 115 published organic field-effect transistor (OFET) devices, fabricated using the commercially available D-A polymer, DPP-DTT. A customized classification algorithm was applied to the data set, which interestingly identified polymer solution concentration as a key processing parameter in OFET device performance. The algorithm recommended a reduced experimental design range for polymer solution concentration that would potentially result in higher OFET hole mobilities as compared to devices fabricated outside this design range. Experiments performed to confirm the insights from the data curation and analysis exercise revealed a strong influence of solution concentration on the polymer chain interactions and electronic performance. Based on the recommendations by the classification algorithm and insights from supporting experiments, it was identified that OFET devices fabricated at the critical polymer chain overlap concentration, resulted in enhanced hole mobility. It is hypothesized that the polymer chain overlap in the solution state contributes to improved charge transport in the solid-state. The results highlight the advantage of integrating materials informatics approaches into the existing polymer electronics methodologies.

PRESENTED ON-DEMAND ONLY: Multipurpose Organic–Inorganic Hybrid Dielectrics with Photothermal Crosslinking of Zirconium-Oxo Clusters Gahye Kim and Myung-Gil Kim; Sungkyunkwan University, Korea (the Republic of)

A hybrid structure of organic and inorganic building blocks enables us to design and tailor new materials with desired features and functions. Metal-oxo cluster molecules is one of the organic-inorganic hybrid materials. Metal-oxo cluster molecules having functional capping ligands offer remarkable promise in terms of thin film applications. Although there are a lot of metal-oxo cluster molecules reported so far, harnessing their potential is largely limited by lack of material processing strategy. We adopt a photothermally activated, cross-linked, and stable metal-oxo cluster molecular assembly based on hexanuclear zirconium-oxo cluster ($Zr_6O_4OH_4(OMc)_{12}$) (OMc: methacrylate) which can be a suitable for a new dielectric material in terms of electronic device applications since the zirconium-oxo core enhances the dielectric functionality and together the organic ligand (methacrylate) imparts a polymerizable functionality. Overall study not only proves that zirconium-oxo cluster activated by soft photothermal processing can be a new dielectric material candidate, but also other metal-oxo cluster thin film system may be further investigated by similar approach.
The hexanuclear zirconium-oxo cluster is synthesized, and its thin film is prepared by a solution process and then photothermally treated with various conditions. The effect of DUV irradiation on zirconium-oxo cluster thin film is characterized by a leakage current profile and dielectric constant measurements. Very interestingly, the photothermal activation strategy used in this work enables a direct patterning of the thin film like photolithography. We find that both a cluster spacing and degree of polymerization in the zirconium-oxo cluster molecular assembly can be well modulated by photothermal processing conditions. We demonstrate that the photothermally activated zirconium-oxo cluster thin film can be successfully applied to a gate dielectric material for thin-film field-effect transistors with different active layers. We believe that the photothermal activation strategy in this work allows a variety of metal-oxo cluster materials to be a promising dielectric material system for soft electronic applications, which could be generalized to other material systems.

9:10 AM SB06.21.13
PRESENTED ON-DEMAND ONLY: Orientation of Exciton-Polarons and Strain-Enhenced Photoluminescence in Soluble Phthalocyanine Thin Films Libin Liang[1,2], KimNgan Burrill[3,1] and Madalina Furis[4,1]; [1]University of Vermont, United States; [2]Intel Corporation (CA), United States; [3]Intel Corporation (NM), United States; [4]The University of Oklahoma, United States

Organic molecules, such as pentacene, rubrene and phthalocyanine are at the forefront of materials research, due to their desired electric and mechanical properties. They represent the feasible alternative to traditional silicon-based semiconductor applications when flexible electronics platforms are required, where materials will experience complex strain environment. Octabutoxy phthalocyanine (H_2-OBPc) is a soluble derivative of the Phthalocyanine (Pc). They have π-conjugated systems and large directional intermolecular interactions, which allow the formation of molecular crystal with well-defined structure of J-aggregate, where molecules are in a head-to-tail fashion. In the expanded theory of molecular exciton, the Frenkel exciton can couple between lattice and intramolecular vibration to form exciton-polaron state, and consequently exciton-polarons can delocalize along the coherent J-aggregates. In this case, the short-ranged excitonic exchange depends on the relative orientation of the HOMO (Highest Occupied Molecular Orbital) and LUMO (Lowest Unoccupied Molecular Orbital) from NN molecules in the crystal, while the long-ranged excitonic exchange depends on lattice vibration. The formation of these one-dimensional delocalized exciton states grants H_2-OBPc the potential for efficient excitation energy transport in the coherent exciton regime.

In this work, H_2-OBPc polycrystalline thin films were prepared using a solution-based deposition technique. These ordered thin films with macroscopic grain size (millimeter scale) uniquely offer the opportunity to spatially explore optical and excitonic properties within a single crystalline grain, free from the influence of grain boundaries or static disorder. Temperature-dependent absorption and photoluminescence (PL) experiment show when temperature T < 175 K, additional bulk bandgap transition state presents at 900 nm and 930 nm, respectively. Incident light **k**-vector dependent absorption experiment indicates this bandgap transition is linearly polarized within substrate plane that obeys the Davydov selection rules. [1] The PL studies further reveal the temperature-dependent polarization of these excitons, implying the formation of exciton-polaron due to the coupling between exciton and lattice vibrations in the J-aggregates. Strain-dependent absorption and PL studies imply that external tensile strain can soften the lattice vibration mode and tune the above exciton-phonon coupling. Remarkably, an 80% enhancement in PL intensity is observed with a tensile strain of 4.9%, which is equivalent to a temperature reduction approximately by 100 K below room temperature. [2] Our study demonstrates strain-engineering of coherent delocalized exciton states in flexible organic electronics.

PRESENTED ON-DEMAND ONLY: Solution-Processable POSS-Fluorene-Core Based Blue Lumophores with Lower Synthesis Costs and Process Complexity Parvez Akhtar, Rina Mahato, Anzalna Hamrah, Chinmoy K. Hazra and Madhusudan Singh; IIT Delhi, India

Polyhedral oligomeric silsesquioxanes (POSS) have previously been proposed as versatile chemical platforms for potential applications in displays and solid-state lighting [1,2], based on favorable charge transport, light absorption, and emission, resulting in high-efficiency OLEDs[3], including pyrene-based organic-inorganic hybrid materials[4,5]. However, synthetic processes for this class of lumophores require multiple stages and expensive process chemicals for purification. It is thus technologically relevant to synthesize cost-effective and efficient methods for synthesizing highly hindered novel chromophore compounds. We report on synthesis of a novel fluorene-based core emitter and its incorporation with the POSS platform or application in solution-processable OLEDs. A fluorene core was first methylated and alkylated using 1-chlorohexane. A Suzuki-Miyura cross-coupling reaction was used to link the pyrene moiety to the fluorene core. The Si-H terminal bond of the POSS cage was functionalized using hydrosilylation (Karsted's catalyst) with this MFPy blue emitter to produce the final compound (MFPy-POSS). The synthesized materials were confirmed by proton NMR 400MHZ (JEOLJNM-ECA Series (Delta V4.3)-400 MHz-FT-NMR). UV-Vis spectrometry (Perkin-Elmer) was used to infer a band gap of 2.94±0.04 eV. Photoluminescence spectra(Ocean optics HR4000, 405 nm source) exhibit a prominent peak at 437nm (FWHM ~86 nm). For organic LED fabrication, indium tin oxide (ITO) coated glass substrates were cleaned in a standard cleaning process prior to spin-coating poly(3,4-ethylene dioxythiophene) polystyrene sulfonate (PEDOT:PSS, Sigma-Aldrich), dehydration bake in the air (120°C), followed by spin-coating of the active material consisting of the lumophore and standard electron and hole conducting materials, under nitrogen, and a dehydration anneal at 110°C. Samples were transferred under nitrogen for thermal evaporation at a base pressure of ~$6.5x10^{-6}$ Torr (Angstrom Engineering) of bathocuproine (BCP,300 Å), LiF (8 Å), and Al (1000 Å) to complete the devices with a shadow-masked top contact of area 0.3 x 0.3 cm^2. Current-voltage (J-V) and light-intensity-voltage (L-V) characteristics were acquired using a Keithley 2450 SMU and a Newport 918-UV photodiode. Initial device data: a turn-on voltage (6V) with a deep blue EL emission color at 437.4 nm (FWHM ~83 nm) and CIE coordinates of (0.163, 0.134). The luminance of the device is 1761 cdm^{-2}, at a current efficiency is 0.33 cd/A. Work is ongoing on the device design, active material ink composition, and material chemistry to improve these figures of merit.

FET Mobility Versus Iodine Doping of P3HT Latonya Waller, Makhes Behera, Sam Sun and Messaoud Bahoura; Norfolk State University, United States

Polymers as the active layer for organic field effect transistors (OFETs) are inherently flexible, lightweight, cost-effective, biocompatible, and processing can be very versatile. Doping can drastically change and modulate the electronic properties of semiconductors and enable tunable FET devices. In this work, the charge mobility in a p-type conjugated polymer Poly-3-hexyl-thiophene (P3HT) doped by iodine are being evaluated. Preliminary results shows that the FET charge mobility initially increases at low doping concentrations but decreases at high doping concentrations. Mechanisms of such trend are being evaluated.

9:25 AM SB06.21.16
Design and Synthesis of New Two-Dimensional Non-Fullerene Acceptors for Indoor Light Harvesting Jianping Lu, Yinghui He, Salima Alem, Stephen Lang and Ye Tao; National Research Council of Canada, Canada

In recent years, organic photovoltaic (OPV) cells have attracted much interest for applications in indoor light harvesting to efficiently convert indoor light into electricity. As a matter of fact, OPV cells already outperform polycrystalline silicon photovoltaic devices in term of power conversion efficiency (PCE) under various indoor light sources largely due to the development of high-performance non-fullerene acceptors to replace previous widely used fullerene derivatives, such as $PC_{61}BM$ and $PC_{71}BM$. On the other hand, modern inorganic semiconductors based miniaturized electronic devices and sensors are highly efficient and some of them only require a few tens of microwatts of energy to operate. This makes it quite appealing to power them with OPV cells because of the unique features associated with OPVs, such as low cost, light weight, mechanical flexibility, customized shapes and form factors, high throughput production using solution processes, and facile integration with sensors. Recently, our group has designed and synthesized a new series of two-dimensional non-fullerene acceptors based on a rigid electron-deficient benzo[4,5]imidazo[2,1-a]isoindole central core. When blended with a p-type polymer (PM6), one of our non-fullerene acceptors demonstrated a promising PCE of 19.4% and a high V_{oc} of 0.75 V under an indoor LED illumination of 1300 lux in the PV cells with an active area of 1 cm^2. For comparison, the well-studied PM6:Y6 bulk heterojunction blend fabricated in our lab gave a V_{oc} of 0.66 V and a PCE of 17.5% under the same illumination condition. With rational design of side chains and substituents to finely tune the solubility, intermolecular packing, and energy levels of our new non-fullerene acceptors, we believe that their PV performance under indoor light can be further improved, which makes them promising materials for indoor light harvesting to power miniaturized electronic devices and sensors for applications in internet of things (IoT) and smart homes.

Multifunctional Magnetic Origami Robots Ruike Renee Zhao; Stanford University, United States

Millimeter/centimeter-scale origami robots have recently been explored for biomedical applications due to their inherent shape-morphing capability.

However, they mainly rely on passive or/and irreversible deformation that significantly hinders the clinic functions in an on-demand manner. Here, we report magnetically actuated crawling and swimming origami robots for effective locomotion and targeted drug delivery in severely confined spaces and aqueous environments. We design our robots based on the Kresling origami, whose thin shell structure 1) provides an internal cavity for drug storage, 2) permits torsion-induced contraction as the mechanism for crawling and controllable drug release, 3) serves as propellers that spin for propulsion to swim, 4) offers anisotropic stiffness to overcome the large resistance from the severely confined spaces in biomedical environments. These magnetic origami robots can potentially serve as minimally invasive devices for biomedical diagnoses and treatments.

Biomimetic soft robotic crawlers have attracted extensive attention in various engineering fields, owing to their inherent adaptivity to different terrains. Earthworm-like crawlers realize locomotion through in-plane contraction, while inchworm-like crawlers exhibit out-of-plane bending-based motions. The in-plane contractive crawling mechanism surpasses the bending-based one in confined spaces where out-of-plane motion is either constrained or unfeasible. Although in-plane contraction crawlers are more effective in confined spaces, miniaturization is challenging due to the limitations of actuation methods and complex structures. To address those challenges, we report a magnetically actuated small-scale origami crawler with in-plane contraction. The contraction mechanism is achieved through a four-unit Kresling origami assembly consisting of two Kresling dipoles with two-level symmetry designed for purely translational crawling motion. Magnetic actuation is utilized to provide appropriate torque distribution on the crawler, enabling a small-scale and untethered robot with both crawling and steering capabilities. Because the Kresling crawler exhibits anisotropic and magnetically tunable structure stiffness, it can overcome the large resistance from severely confined spaces during crawling. Finally, the multifunctionality of the crawler is explored by utilizing the internal cavity in the Kresling origami for drug storage and release. The magnetic origami crawler has the potential to serve as a minimally invasive device for biomedical diagnoses and treatments.

8:30 AM SB07.01.02
Magnetically Tunable Bistable Structures Aniket Pal[1] and Metin Sitti[1,2,3]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]ETH Zürich, Switzerland; [3]Koç University, Turkey

Bistable structures have become a common strategy in compliant mechanisms and soft robotics to overcome the intrinsic limitations of soft materials (e.g., high dissipation, low speeds and forces) as well as to create new functionalities (e.g., energy absorption, motion, deployable structures). The responses of bistable structures are determined by their geometric design and the mechanical properties of their constituent material. Here we introduce a strategy to dynamically program the responses of bistable structures by tuning their elastic energy landscape with external magnetic fields. We demonstrate that the stable states of a slender beam, fabricated with a magnetoactive elastomer, can be dynamically controlled to switch between a monostable and bistable response and the more energetically favorable state of a bistable element can be specified. We then harness the tunable responses of such bistable beams to control the propagation of solitary transition waves in an array of such beams, connected by linear spring elements. Specifically, we demonstrate the external magnetic-field-based control of the direction, speed, shape, and length of propagation of transition waves; without the need to change any of the physical components (beams and linear springs) of the array. We also show reconfigurable functional devices, such as logical gates, where a single physical system can be controlled to act as different gates with an external magnetic field.

8:45 AM SB07.01.03
Tailoring the Multistability of Origami-Inspired, Buckled Magnetic Structures via Compression and Creasing Yi Li; University of Connecticut, United States

Origami-inspired multistable structures are gaining increasing interest because of their potential applications in fields ranging from deployable structures to reconfigurable microelectronics. The multistability of such structures is critical for their applications but is challenging to manipulate due to the highly nonlinear deformations and complex configurations of the structures. In this talk, I will present a comprehensive experimental and computational study to tailor the multistable states of origami-inspired, buckled ferromagnetic structures and their reconfiguration paths. Using ribbon structures as an example, a design phase diagram is constructed as a function of the crease number and compressive strain. As the crease number increases from 0 to 7, the number of distinct stable states first increases and then decreases. The multistability is also shown to be actively tuned by varying the strain from 0% to 40%. Furthermore, analyzing energy barriers for reconfiguration among the stable states reveals dynamic changes in reconfiguration paths with increasing strain. Guided by studies above, diverse examples are designed and demonstrated, from programmable structure arrays to a soft robot. These studies lay out the foundation for the rational design of functional, multistable structures.

9:00 AM *SB07.01.04
Magneto-active Metamaterials for Controlling Sound and Vibrations Abigail Juhl[1], Vincent Chen[1,2], Carson Willey[1,2], Phil Buskohl[1], Kathryn H. Matlack[3], Connor D. Pierce[3], Stephan Rudykh[4], Nitesh Arora[4] and Artemii Goshkoderia[5]; [1]AFRL, United States; [2]UES, Inc., United States; [3]UIUC, United States; [4]University of Wisconsin–Madison, United States; [5]Technion–Israel Institute of Technology, Israel

Phononic metamaterials are subwavelength materials designed to control the propagation of elastic or acoustic waves for use in applications such as sound and vibration mitigation. The geometry, periodicity, and material properties that makeup the metamaterial define the scattering behavior and resulting dispersion from the structure. The metamaterial's dispersion properties are typically set at the time of manufacture, making it difficult to alter the frequencies that are permitted/prohibited to propagate without fabricating a new sample. However, if external stimuli can be used to dynamically vary the mechanical properties or the shape of the metamaterial, the dispersion properties can be tuned without remanufacture. In this work, magnetorheological elastomers (MREs) will be investigated as a means to adaptively tune the band gap properties of phononic metamaterials. The MREs in this work are composed of isotropically dispersed 3-10 micron iron particles within a PDMS matrix. Three demonstrations of magnetic field induced tuning will be presented for different metamaterial architectures. In the first demonstration, remote application of a magnetic field was applied to a 3D printed MRE elastic metamaterial to induce a stiffening of the MRE modulus to shift the frequency of vibration control to a higher frequency band. In the second demonstration, neodymium magnets are placed on a MRE-based acoustic plate by magnetic attraction and it is shown that that the absorption, transmission loss, and effective density of the acoustic metamaterial can be tailored through their reconfigurable spatial placement. And in the final example, we take advantage of the magneto-mechanical coupling within the MRE to promote an instability induced pattern change in a MRE/neat elastomer composite architecture. By understanding the magnetomechanical behavior, it may be possible to program the instability pattern formation for use in dynamic band gap control.

9:30 AM BREAK

10:00 AM SB07.01.05
Protein-Based Magnetic Composites for Self-Healing and Reconfigurable Actuators Zenghao Zhang and Abdon Pena-Francesch; University of Michigan–Ann Arbor, United States

Soft microrobots can achieve controlled motion and shape changing upon actuation, and thus are capable of performing non-invasive surgery in the human

body. Among soft actuation systems, magnetic actuation is advantageous for healthcare applications since magnetic fields can penetrate tissue, and can generate both pulling forces and torques remotely. One current challenge is that magnetic microrobots typically have limited actuation modes, which are determined mainly by the internal magnetization profile of the robot. In this study, we developed a magnetic soft composite based on squid-derived proteins and rare-earth magnetic particles with discrete magnetization profiles, and used self-healing to reconfigure their magnetization and actuation modes. The self-healing properties of the squid-derived protein matrix enable the rearrangement of modular components with different magnetic properties. By tailoring the composition, the anisotropy of the thermo-mechanical properties, the geometrical robot design, and the actuation magnetic field, we demonstrate control over complex robot deformations, and reversible reconfiguration of actuation modes. This work opens up the design space of magnetic soft robots and their reconfigurable actuation modes via the discrete programming of the magnetization directions and intensities throughout the microrobot body. This freedom in design can provide key advantages in soft and small-scale actuation to perform specific tasks in confined environments, with application in healthcare and industrial micromanipulation.

10:15 AM SB07.01.06
Design of Organic Soft Magnets for Applications in Small-Scale Robotics Abdon Pena-Francesch; University of Michigan, United States

Traditional magnetic materials consist of heavy metals and rare-earth elements that typically entail corrosion, toxicity, and sustainability concerns. On the other hand, organic magnetic materials present a metal-free opportunity to develop lightweight non-toxic magnets. Although magnetic molecules based on stable free radicals have been used as monolayers and dopants in spintronics and as imaging contrast agents, shortcomings in stability, limited processing, and loss of properties have hindered their expansion into other fields such as small-scale soft robotics. To address this issues, we have developed intrinsically magnetic polymer gels with stable nitroxide radicals in their backbone structure. Using TEMPO precursors, we can design the polymer network to tailor the bulk mechanical and magnetic properties. Although weaker than purely metallic magnets, these organic magnets exhibit lightweight, non-toxic, compliant, and bulk paramagnetic properties suitable for small-scale robotics applications, such as remote manipulation and navigation through confined spaces.

10:30 AM *SB07.01.07
Magnetic Programming of Soft-Bodied Wireless Minaiture Medical Robots Metin Sitti; Max Planck Institute for Intelligent Systems, Germany

Wireless miniature medical robots have the unique capability of navigating, operating and staying inside risky and currently hard- or impossible-to-reach small spaces inside the human body. On the other hand, soft-bodied robots have the unique capabilities of shape programming, physical adaptation, safe physical interaction, and multifunctional diverse behaviors. Combining the strengths of both systems, this presentation reports on our recent soft-bodied wireless miniature medical robots with magneto-elastic active materials, actuated and controlled by external magnetic fields and gradients. Magnetizing hard magnetic microparticles, embedded inside the elastomeric body of soft robots, in programmed orientations and magnitudes enable diverse, dynamic and programmable shape deformations on these soft robots. We can even reprogram such magnetization properties to drastically change the shape modes of the robots. Using various magnetic (re)programming methodologies, first, we propose a magneto-elastic sheet-shaped soft robot, called Wormmate. Wormmate is inspired by soft-bodied organisms, such as spermatozoids, caterpillars, jellyfishes, and bacteria. It has over nine locomotion modalities at the same time to be able to navigate in diverse confined environments inside the human body. Next, a baby jellyfish-inspired magneto-elastic milliswimmer is shown to realize multiple functionalities by producing diverse controlled fluidic flows around its body. Then, an array of cilia-inspired magneto-elastic cilia is developed to generate metachronal waves for efficient biological fluid pumping and fluidic object manipulation. Moreover, we propose a jig-assisted 3D assembly method to create the most advanced soft miniature robots with heterogenous diverse materials and complex magnetic programming for medical device and other applications. Finally, it is possible to scale down such soft-bodied magnetic robots down to micronscale by merging two-photon 3D microprinting and magnetic assembly techniques. As example wireless soft medical devices, a soft peristaltic pump, a tubular surface-anchoring metamaterial-based shape-programmable soft device, a stent-like soft robot, and an on-demand drug-releasing soft capsule are demonstrated. Such soft devices are guided under ultrasound and x-ray imaging to achieve various local active medical functions, such as drug delivery, liquid biopsy, stem-cell treatment, embolization, clot opening, and hyperthermia.

11:00 AM SB07.01.08
3D-printed Magnetic Elastomers: Identifying Key Structure & Processing Parameters for Enhanced Magnetoactive Performance Brittany Nelson-Cheeseman, James M. Ennis, Jimmy Lu, Sarah Ziemann, Nathan A. Fischer, Thomas M. Calascione and Thomas Höft; University of St. Thomas, United States

Magnetic elastomers are of interest for soft robotic applications where remote contactless activation is desired. These composite smart materials are made of magnetic particulate embedded in an elastomeric matrix and respond to applied magnetic fields with mechanical deformation, termed magnetoaction. It's been shown that anisotropic structures and properties within these materials leads to increased magnetoactive performance. Magnetic annealing is the main processing technique that has been used to increase magnetoactive performance through the introduction of local anisotropy. For further enhancements to magnetoaction, the 3D-printing technique, Fused Deposition Modeling (FDM), can be used to create additional anisotropy in the structures and properties of magnetic elastomers. FDM creates anisotropic sub-structures within a part by extruding 1D lines of the molten material (termed "infill") in 2D patterns that build up to a 3D part. This infill pattern is entirely customizable with respect to orientation and percentage filling allowing for one to readily tune the properties of the resulting part. While it's been clearly shown that these parameters significantly influence the resulting mechanical and magnetic properties of FDM-printed parts, their influence on magnetoaction (the confluence of mechanical and magnetic responses) has yet to be reported. Here, we investigate how a variety of parameters on multiple length-scales influence magnetoaction in FDM-printed magnetic elastomers. In particular, we study how FDM *infill percentage* and *infill orientation* relative to applied magnetic field influences magnetoaction of the printed part. We also report on additional filament and extrudate studies, where filament is the stock material used for FDM printing and extrudate is what exits the FDM nozzle before it builds up to larger printed structures. These studies involve *magnetic annealing* and a variety of *soft vs. hard magnetic particulates* in order to understand how these parameters (before the 3D printed structure has been introduced) can additionally influence magnetoaction of these materials. These parameters are then explored in the 3D printed structures to understand how they interact with the 3D printed structural features. A custom setup is used to measure magnetoaction, whereby the sample is suspended vertically from a fixed point and a transverse DC magnetic field is applied up to 0.4 T along the horizonal axis. The degree of magnetoaction is quantified as the angle of deflection of the sample relative to vertical for a given applied field. The data is captured visually in digital images that are then digitally processed in order to determine the quantitative deflection angle for a given applied field. Supporting magnetic, mechanical and structure (SEM) studies are utilized to investigate the origins of the differences in magnetoaction. We find that for the FDM architectures studied that the greatest magnetoaction is found for a combination of low infill percentages and infill oriented perpendicular to the applied magnetic field. These effects arise from both maximizing anisotropy and limiting infill crosslinking within the structure. We also find that magnetic annealing of the stock filament increases magnetoaction in the filament, and that this increase is maintained in the extrudate after extrusion through the FDM nozzle. This surprisingly and exciting result allows for more accessibility to FDM-printing of high performance magnetic elastomers. Finally, we find that the soft magnetic particulates (Fe and Fe_3O_4) give both the greatest magnetoaction and magnetoaction at lower fields when magnetically annealed, while the hard magnetic particulate (SrFerrite) gives the greatest difference in magnetoaction when magnetic annealing is applied. All of these results together highlight a number of key structure and processing parameters that lead to enhanced magnetoactive performance in 3D-printed magnetic

elastomers.

11:15 AM SB07.01.09
Magnetoactive Properties of 3D Printed Magnetic Elastomer Structures—Effects of Infill Orientation and Infill Percentage James M. Ennis[1], Hannah G. Thatcher[1], Thomas M. Calascione[2,1], Jimmy Lu[1], Nathan A. Fischer[1], Sarah Ziemann[1], Thomas Höft[1] and Brittany Nelson-Cheeseman[1]; [1]The University of St. Thomas, United States; [2]University of Colorado Boulder, United States

Magnetic elastomers are flexible smart materials that can be manipulated by magnetic fields to achieve reversible mechanical deformation. These highly configurable materials are instrumental in transforming biomedical applications in soft robotics enabling the manipulation of artificial muscles and other bio-actuators. Magnetic elastomer structures must be customizable to satisfy these complex applications leading to the use of fused filament fabrication (FFF) in creating them. FFF is a 3D printing process where material is extruded in 1D lines (infill) to build 2D planes layer-by-layer, resulting in a 3D structure. Structures can be created with different levels of anisotropy and complicated interior geometries enabling control of both the magnetic and mechanical properties. The meso structure or infill of a 3D printed part is critical in fine-tuning its properties since it defines the internal structure. Both infill percentage and infill orientation affect mechanical and magnetic properties of 3D printed magnetic elastomer parts. This research used magnetoactive testing to investigate how varying the internal meso structure affected the mechanical response of the structures within an applied magnetic field. Different infill percentages (40%, 60%, and 100%) were tested to account for different mechanical stiffnesses, and different linear infill orientations (0, 45, and 90 degrees) were tested to account for different internal geometries. The macro structure was a rectangular beam with dimensions of 60x5x5 mm^3. The elastomers were made with a microstructure of 40wt% magnetite (Fe_3O_4) with a thermoplastic polyurethane (TPU) matrix. To account for any magnetoactive effects due to the print layering or infill orientation, each sample was magnetoactively tested with three different transverse magnetic field orientations (Front, Back and Top) by rotating the sample around the longitudinal axis by 90-degree increments. The samples were placed between two electromagnets emitting up to a 0.4 Tesla field, and the angle of deflection was recorded as a function of applied field by using MATLAB to overlay pictures taken at each field strength with the sample at 0 Tesla. The samples that showed magnetoaction provided clear infill design goals for increased magnetoactive performance. These design goals enabled some samples to reach the maximum angle of deflection for the testing setup. *Infill Percentage*: Lower infill percentages translated to less material in the cross-section of the sample and thus lower bending stiffness, allowing for more magnetoaction. *Infill Orientation*: 0-degree (along long axis of sample) created much less crosslinking between infill lines which led to more flexibility within the sample, and more magnetoaction. *Print Layering Orientation*: Transverse fields applied parallel to the print plane (Front/Back sample orientations) demonstrated the most magnetoaction due to less crosslinking from adjacent layers. This layer crosslinking heavily constrained the bending stiffness in certain sample orientations (Top) similar to the infill orientation effects. The anisotropy of the meso structure likely also contributed to the large response from the 0-degree 40% and 60% samples. The long, isolated lines of the 0-degree meso structure had the greatest magnetic shape anisotropy causing the greatest rearrangement of the structure to align with the applied magnetic field. The sample would thus deflect to be as parallel as possible with the transverse field. It was concluded that for this fixed base material, it is more important to 3D print structures with lower stiffnesses (40% infill) than more net magnetic particulate (100% infill) in achieving the most magnetoaction. According to this data, meticulously designed 3D printed magnetite-TPU structures seem to be well suited for creating components easily stimulated by a magnetic field unlocking many possibilities for the creation of useful technologies in the biomedical field.

11:30 AM *SB07.01.10
Analytical Approaches to Modeling Thin-Film Magnetic Actuators Benjamin A. Evans[1], Jessica A. Liu[2], Minjeong Ha[3], Eduardo Sergio Oliveros Mata[3], Gilbert S. Cañón Bermúdez[3], Denys Makarov[3] and Joseph B. Tracy[2]; [1]Elon University, United States; [2]North Carolina State University, United States; [3]Helmholtz-Zentrum Dresden-Rossendorf, Germany

Flexible thin-film magnetic actuators are canonical constructs that underpin many magnetic soft-robotic devices. Understanding their behavior is therefore essential to the successful design and implementation of a broad range of magnetic actuators. In most cases, thin-film magnetic actuators may be effectively modeled with closed-form analytical expressions employing simple fundamental physical principles. Such closed-form solutions capture essential behavior of the devices across an expansive multidimensional parameter space, providing a powerful analytical platform for rapid design and optimization. This framework is easily accessible to outside users and translates readily to a wide variety of specific applications. In addition, analytical modeling provides ready insight into the physical mechanisms of device behavior, aiding in conceptual understanding and design.

In this work we explore simple analytical models that describe the performance of flexible magnetic films under the influence of actuating fields. We distinguish the effects of magnetic torques induced by uniform fields from magnetic forces mediated by applied field gradients and provide a framework for evaluating their relative impact. Considering films with both hard- and soft-magnetic fillers, we develop predictive expressions for range of motion, available actuating force, and work done by the device on its environment [1]. These models are then applied to special cases of thermoplastic shape-memory polymers and ‘snapping’ devices with stored elastic energy, and figures of merit are developed to characterize performance [2].

Throughout, predictions are shown to be in good agreement with experimental results derived from both soft- and hard-magnetic thin-film actuators comprised of both elastic [3] and thermoplastic matrices [2], thus validating a powerfully predictive modeling framework. This framework provides opportunities for rapid design and optimization of devices for specific tasks and aids in the identification and realization of unexpected behaviors.

Magnetic Composites—From Printed Magnetoelectronics to Smart Magnetic Soft Robots Denys Makarov; Helmholtz-Zentrum Dresden-Rossendorf

e.V., Germany

Composites consisting of magnetic fillers in polymers and elastomers enable new types of applications in soft robotics, reconfigurable actuation and sensorics. In particular, soft-bodied robots emerge as the closest synthetic system analogous to living organisms mimicking their mechanical behavior and going beyond in performance. We will introduce lightweight, durable, untethered and ultrafast soft-bodied robots performing large amplitude of deformations at high frequencies of up to 100 Hz and exhibit high specific energy density of 10.8 kJ/m3/mT [1]. Our soft-bodied robots can walk, swim, levitate, and transport cargo being driven using external magnetic fields. This inspires new classes of soft robots that impact biosensorics [2], biological tissue engineering, confined and high-speed mechanical (tissue) manipulation, and serve as working models to study fast biomechanical processes like hydro- and aero- dynamics of fast-moving organisms.
These mechanically active structures are typically designed to work in a specific prior defined parameter range and can malfunction when the conditions are changed. Specifically for magnetic soft robots, the change of the intrinsic magnetic properties due to temperature activations or time relaxation can lead to modifications in the actuation pattern. We present ultrathin and reconfigurable magnetic origami actuators based on a composite consisting of shape memory polymers and magnetic microparticles [3]. Self-sensing is achieved by laminating ultrathin magnetosensitive e-skins [4] on soft origami actuators. The sensor assesses the magnetic state of the actuator (magnetized vs. non-magnetized) and decides on its actuation pattern even before the actual actuation is done experimentally. Furthermore, the sensor enables communication of the actuator with external devices (rotation stage, electromagnets) for self-guided assembly of an initially flat layout and provides the possibility to control the sequentiality and quality of the folding process.
Magnetic composites can be readily used to realise not only actuators but also magnetic field sensors. We demonstrate that printed magnetoelectronics can be stretchable, skin-conformal, capable of detection in low magnetic fields and withstand extreme mechanical deformations [5,6]. We feature the potential of our skin-conformal printable sensors in augmented reality settings, where a sensor-functionalized finger conducts remote and touchless control of virtual objects manageable for scrolling electronic documents and zooming maps under tiny permanent magnet.
Furthermore, we will present high performance dispenser printed magnetic field sensors based on non-magnetic half-metallic bismuth powder [7]. Printed Bi sensors reveal non-saturating large magnetoresistance (LMR) effect, reaching up to 146% resistance change at room temperature at 5 T (>3900% at 20 K at 7 T). The LMR is a fingerprint of topological properties of the band structure of Bi. In this respect, this work constitutes the very first use of topological material properties in printing technologies. Due to their thermal and mechanical stability, the sensors printed on thermoplastic foils can be reformed in a stable three-dimensionally shaped object enabling applications of our technology for in-mold electronics. We demonstrate magnetically controlled interactive devices based on a printed array of sensors, to be used for interactive advertisement, smart wallpapers, and security input panels.

On Fracture Toughness of Isotopic and Anisotropic Magnetoactive Elastomer Under an External Magnetic Field Nusrat Jahan Salim, Ignacio Arretche, Connor D. Pierce and Kathryn H. Matlack; University of Illinois at Urbana Champaign, United States

The emerging studies in the field of soft robotics include design, modeling, and manufacturing of soft active materials that can control soft bodies. Magneto-mechanical coupling has been recently explored as a mechanism for soft robotic control, for example in elastomeric materials that incorporate magnetic particles, typically known as magnetoactive elastomers (MAEs). Magneto-mechanical properties of MAEs such as tunable damping, vibration control, and soft structure deformation under magnetic fields have been extensively studied. Further, the magneto-mechanical coupling can be amplified by curing the MAEs in a magnetic field, producing a highly anisotropic chain-like microstructure. However, fracture toughness mechanisms in MAEs, and their dependence on anisotropy and an applied magnetic field, have not yet been explored. Cracks or any kind of damage can lead to impaired function and control of soft robotic materials. While the dependence of volume fraction and orientation of reinforcing particles on the damage response of soft materials has been studied, the fracture behavior of MAEs, which contain micron-sized reinforcing particles, is currently unknown. In this work, we experimentally study the fracture toughness and toughening mechanisms of MAEs and their dependence on particle volume fraction and chain anisotropy. To fabricate the MAEs, micron-sized carbonyl iron particles (CIPs) were suspended, and then cured, in a polydimethylsiloxane (PDMS - Sylgard 184) matrix. Magnetic fields were applied in different directions while curing to introduce anisotropy in the particle chains. We quantified the effect of particle volume fraction and chain orientation on fracture toughness through a unified experimental method with and without magnetic fields. Various volume fractions and chain orientations of CIPs were used to explore the dependence of the damage mechanisms on CIP volume fraction and chain orientation without a magnetic field. The results show that increasing particle volume fraction increases the fracture toughness. Further, fracture toughness is enhanced when particles are aligned with the direction of loading. To elucidate the dependence of fracture toughness on the magneto-mechanical coupling, similar experiments were repeated under an applied magnetic field. Finally, SEM micrographs were used to explain the micromechanics behind the variations in fracture toughness. This revealed that the mechanism is driven by inducing and controlling crack pinning, crack deflection, and interface debonding of particles. These experiments can provide a basis to understand fracture of MAEs that could enable improved damage mechanisms in soft robots controlled by magneto-mechanical coupling.

2:15 PM SB07.02.03
Digitally Controlled Self-Assembly of Magnetic Materials by Micro Atmospheric Pressure Plasma Jet Luke J. Tinsley, Prakash Karipoth and Russell A. Harris; University of Leeds, United Kingdom

Introducing a magnetic response to soft materials is of growing interest to a number of fields, with the ability to fabricate soft structures featuring spatially varied anisotropic magnetic properties being key to enabling many applications. Magnetically actuated soft robots are an example of this, demonstrating remarkable feats throughout healthcare and micro-robotic applications owing to their untethered operation and inherent dimensional scalability. In particular for medical applications, it is desirable to be able to tune the design of the soft robot to the specificities of the patient. Digitally driven fabrication approaches, such as 3D printing, provide the flexibility to do this, but come with limitations linked to processing speed, resolution, and compatible materials. Here we present a novel approach to the patterning of magnetic materials whereby they self-assemble into a programmable shape, overcoming these limitations. This is accomplished by exposing a silicone elastomer film to a highly localised source of plasma, produced by a bespoke computer-controlled micro atmospheric pressure plasma jet(μAPPJ), to selectively create patterns of plasma treatment across its surface. The plasma induces a chemical change on the surface of the film, which corresponds to a large increase in the polar component of free surface energy. Consequently, polar fluid dispersions containing customised magnetic nanoparticles, which have undergone chemical functionalisation to enable stable suspension in the fluid, align with the treated regions autonomously. Subsequent evaporation of the polar fluid then leaves solely the magnetic material. We show that through variation of the voltage and frequency used to generate plasma in the μAPPJ the resolution of the treatment can be varied between 50μm and 1200μm. Furthermore,

a maximum processing rate of $3.6mm^2s^{-1}$ is orders of magnitude quicker than comparable 3D printing techniques and due to the dynamically controllable resolution, large patterns with fine details can be processed efficiently. We demonstrate the process through the fabrication of stretchable, soft and magnetically responsive thin films.

2:30 PM SB07.02.04
Reprogrammable Hard-Magnetic Cilia Matthew R. Clary[1], Joseph B. Tracy[1], Saraah N. Cantu[1], Benjamin A. Evans[2] and Jessica A. Liu[1]; [1]North Carolina State University, United States; [2]Elon University, United States

Artificial magnetic cilia are hair-like structures that are actuated with magnetic fields. Most prior research on magnetic cilia has involved soft magnetic materials, in which the absence of magnetic hysteresis limits the ability to program their magnetization state. In contrast, use of hard magnetic materials in magnetic cilia makes possible programming and reprogramming of the magnetization state and corresponding actuation behaviors. In this work, hard-magnetic cilia are fabricated through self-assembly by solvent casting of a slurry of NdFeB microparticles dispersed in a solution of a thermoplastic polyurethane elastomer. These hard-magnetic cilia are capable of attractive and repulsive responses to magnetic fields, which are determined by the remanent magnetization of the NdFeB microparticles. An array of cilia can be magnetically reprogrammed by immobilizing the cilia in ice, applying a damped alternating magnetic field first to reduce the remanent magnetization, and then remagnetizing the cilia with a large external field. Through this approach, different responses to magnetic fields can be programmed, including spatially non-uniform behaviors. Reprogrammed hard-magnetic cilia exhibit unique behaviors in a rotating magnetic field. When the magnetization direction is reprogrammed along the width of the cilia, rotation and torsion cause the cilia to slowly coil and then quickly uncoil in a snapping behavior. A theoretical model explains the observed effects and provides a comparison between hard-magnetic and soft-magnetic cilia.

Magnetic 3D Micro-Machines and Functional Soft Composites Meng Li; MPI for Intelligent Systems, Stuttgart, Germany

Summary: 3D mechanical structures integrated with functional magnetic components enable complex motions at the sub-millimeter scale. Magnetic composites that respond synergistically to optical and magnetic stimuli enable self-sustained motions by forming physical negative feedback loops.

3:45 PM SB07.03.02
Capacitor Integrated Magnetic Actuator Hajun Lee[1], Yeonwoo Jang[1], Junghyo Kim[1], Heejae Won[1], Kwon-Hyung Lee[1], Sang-Young Lee[2] and Jiyun Kim[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

In robotics, especially in soft robotics with electronic devices such as motors, light emitting diodes (LEDs) and sensors, a stable power supply is one of the major concerns to operate their components properly. For the remote control and simple body structure without tethering to outer signal/power line, integration of the power source such as battery or capacitor is an unavoidable option. Although there are several types of substitutes such as thermal-, optical-, and hygro-energy based systems, it is obvious that electric energy is still used as major power source.
Most of electronic systems rely on batteries for their power supply and many of electronic energy harvesting systems require batteries for stable energy storage and supply. Accordingly, researches on materials and manufacturing methods related to power sources have been actively conducted, and they led remarkable improvement of the energy efficiency and electrochemical properties related to safety and stability. Conventional-shaped power sources, however, is limitation in design of electronic devices because they have to secure specific space and geometry for the deployment of power sources. For the reason, developing advanced power sources with various form factor has been encouraged for scalability, design diversity, shape compatibility, and so on. There were several approaches to promise form factor-free power sources in printable power sources or smart materials combined power sources. Although they showed high flexibility and responsibility to external stimuli compared to previous rigid counterparts, it was still a challenge to integrate them into complex surface or 3D structure, and an additional actuator was required to be fabricated and attached for actuation. To address this limitation, we fabricated a capacitor-integrated magnetic actuator having monolithic structure by combining flexible capacitor as a power source and soft magnetic actuator as driving parts. We used neodymium-based magnetic particle to compose an active material of capacitor to assign magnetically responsibility. Mask-based printing technique makes it possible to fabricate several capacitors having seamless pattern on a single substrate at once. The pattern of the capacitors is created from linear shape to origami pattern for 3D structure, and it is designed for series connection, parallel connection, or hybrid connection between each capacitor. Furthermore, not only by pre-patterning of capacitor, but also by magnetic actuation on the designed electronic circuit, we can control the state of connection of the capacitors to certain circuit as a switch, for example, on and off control and changing connection state from series to parallel.
Finally, we built a firefly-shaped robot to demonstrate a LED lighting control using magnetic actuation. We installed a LED for lighting in the tail of the 3D printed firefly-shaped body and, on the shoulder, origami patterned capacitor-integrated magnetic actuator which was designed as a pair of wings. Wings were connected parallelly and each of them composed of serially connected 3 capacitors. According to on and off of the external magnetic field, origami patterned wings were folded and stretched. When the wing was folded by applied magnetic field, the tab from the electrode of the capacitor connected to the electric circuit, and then a LED is turned on. Conversely, the LED is turned off when the wing is stretched.
Here, we suggest a new approach to fabricate power suppliable actuator having monolithic structure. We demonstrated several capacitor-integrated magnetic actuators by leveraging power source with magnetic functionality. Our fabrication methods provide the way to design power source having different energy level related to series/parallel connection as well as shape-morphing properties.

4:00 PM *SB07.03.03
MOFBOTS—Metal–Organic Framework-Based Biomedical Magnetic Microrobots Josep Puigmartí-Luis; Universitat de Barcelona, Spain

In the field of small-scale robotics there is a growing interest on providing locomotion to soft materials, as these materials mimic more closely the physicochemical properties of biological tissues. Hydrogels, for example, can efficiently lead to biocompatible and biodegradable advanced small-scale robots that can find application in the biomedical field, e.g. in diagnostics and/or targeted drug delivery. However, even though hydrogels are an excellent

platform to accomplish a new generation of functional small-scale robots, other materials that could allow highly integrated robotic platforms are yet highly demanded. In this context, metal-organic frameworks (MOFs), a class of soft material with high porosity and tunable physicochemical properties, could be a key component for developing future highly integrated small-scale robotic platforms. While some initial efforts have been made to produce mobile MOF-based small-scale machines, the locomotion features of most of these systems are not at the level of sophistication of current state-of-the-art micro- and nanoswimmers.

In this presentation, I will present our recent contributions to the field where three-dimensional MOF-based soft micromachines have been designed, fabricated and characterized. I will show how these structures can swim and follow complex trajectories by means of weak rotating magnetic fields. The proposed systems can achieve, for example, single cell targeting in a cell culture media and/or a controlled delivery of cargo payloads inside a complex microfluidic channel network. We believe that this new approach towards the fabrication of highly integrated multifunctional systems will undoubtedly open new avenues in soft robotics beyond current applications.

4:30 PM SB07.03.04
Magnetic Alignment for Plasmonic Control of Gold Nanorods Coated with Iron Oxide Nanoparticles Mehedi Hasan Rizvi[1], Ruosong Wang[2], Jonas Schubert[2], William D. Crumpler[1], Christian Rossner[2,3], Amy L. Oldenburg[4], Andreas Fery[2,5] and Joseph B. Tracy[1]; [1]North Carolina State University, United States; [2]Leibniz-Institut für Polymerforschung Dresden e.V, Germany; [3]Dresden Center for Intelligent Materials (DCIM), Germany; [4]University of North Carolina at Chapel Hill, United States; [5]Technische Universität Dresden, Germany

Plasmonic nanoparticles that can be manipulated with magnetic fields are of interest for advanced optical applications, diagnostics, imaging, and therapy. Alignment of gold nanorods yields strong polarization-dependent extinction, and use of magnetic fields is appealing because they act through space and can be quickly switched. In this work, cationic polyethyleneimine-functionalized superparamagnetic Fe_3O_4 nanoparticles (NPs) are deposited on the surface of anionic gold nanorods coated with bovine serum albumin. The magnetic gold nanorods (MagGNRs) obtained through mixing maintain the distinct optical properties of plasmonic gold nanorods that are minimally perturbed by the magnetic overcoating. Magnetic alignment of MagGNRs arising from magnetic dipolar interactions on the anisotropic gold nanorod core is comprehensively characterized, including structural characterization and enhancement (suppression) of the longitudinal surface plasmon resonance and suppression (enhancement) of the transverse surface plasmon resonance for light polarized parallel (orthogonal) to the magnetic field. MagGNRs can also be driven in rotating magnetic fields to rotate at frequencies of at least 17 Hz. For suitably large gold nanorods (148 nm long) and Fe_3O_4 NPs (13.4 nm diameter), significant alignment is possible even in modest (<500 Oe) magnetic fields. An analytical model provides a unified understanding of the magnetic alignment of MagGNRs.

4:45 PM SB07.03.05
Magnetic Actuation of Magneto-Photonic Particles for Targeted Light Delivery Seung Yeol Lee and Ognjen Ilic; University of Minnesota Twin Cities, United States

The capability to deliver light of desired properties (wavelength, intensity, polarization, etc.) to any target spot in a medium has broad relevance for applications across biology and biomedicine to nano-chemistry and radiation therapy. Key challenges for such delivery are that (i) it exhibits high directionality and significant selectivity for desired light properties, that (ii) it be adaptively controlled with a non-invasive mechanism, and that (iii) it does not require direct line-of-sight access to the target spot. However, existing platforms for light delivery, such as nanoscale scatterers or photonic surfaces with subwavelength patterns, have their limitations on actively orienting the direction of light scattering.
Here, we discuss a concept of a magneto-photonic particle with an optically active surface for targeted light delivery where the particle can be remotely actuated with a magnetic field. The photonic surface that provides sophisticated control of direction of scattering properties is patterned onto the particle using nanoimprint lithography, which enables the production of complex features at nanoscale resolution, while being highly scalable. Once the orientation of the pattern of a photonic surface and direction of magnetization are synchronized, the position of the target spot of light delivery can be controlled with an external magnetic field. We believe our approach can be used to realize a platform that enables targeted delivery of light within relevant biological windows, with possible applications in opto-genetics, neural stimulation, and localized heating.

SB07.04.01
Impact of 3D Printing Extrusion on Magnetically Annealed High Performance Hard/Soft Magnetic Elastomers Jimmy Lu, Nathan A. Fischer, Sarah Ziemann, James M. Ennis, Thomas Höft and Brittany Nelson-Cheeseman; University of St. Thomas, United States

Magnetic elastomers are flexible materials that can mechanically deform under the application of a magnetic field. This magnetoactive motion is highly desirable for developing biocompatible soft robots. The magnetic particulate within the polymer matrix gives magnetic elastomers unique magnetoactive properties depending on whether it is magnetically hard or soft. Hard magnetic elastomers can perform more complex movements, but soft magnetic elastomers have a greater magnetoactive response to the field. The unique properties of both hard and soft magnets can be transferred into magnetic elastomers by combining hard and soft magnetic particulate into one elastomer. 3D printing, such as Fused Deposition Modeling (FDM), can also enhance the magnetoactive properties of magnetic elastomers by creating anisotropy within the part. It allows users to create complex-shaped components easily and makes magnetic elastomers more accessible. Since 3D printing allows for accurate and rapid prototyping of flexible designs, the printability of magnetic elastomers allows for exciting applications in soft robotics. Typically, 3D printing filaments are the stock material for FDM. Recent work has shown that magnetic annealing of magnetic elastomer filaments during extrusion creates greater magnetoaction in the filaments; however, it is unclear whether this enhanced performance is maintained once they are subsequently extruded through the FDM printing nozzle. This research investigates whether the enhanced performance of magnetically annealed magnetic elastomer filaments remains after they are extruded through a 3D printer nozzle. The following three types of composite samples were made from a thermoplastic polyurethane matrix and varying amounts of soft and hard magnetic particulate (carbonyl iron (Fe) and strontium ferrite (SrF)): 5vol%Fe + 10vol%SrF, 10vol%Fe + 5vol%SrF, and 0vol%Fe + 15vol%SrF. The composites were extruded into 1.75 mm diameter filaments. Magnetically annealed filaments traveled through a uniform axial magnetic field. Final samples were then extruded through a 0.8 mm FDM printer nozzle into 220 mm long extrudate samples. The magnetoactive properties were measured by a custom setup, whereby short extrudate samples were hung freely and vertically between two electromagnets. Images of samples' behaviors were captured at incremental

transverse magnetic field strengths from 0-0.4T. Then, an image processing program was developed to overlay images so that the angle of deflection at a given applied field could be analyzed. The mechanical properties were obtained by tensile testing. The magnetic properties were captured via hysteresis loops. The enhanced magnetoactive performance seen from magnetic annealing of the filaments was still present in the final extrudate samples, indicating that the magnetic annealing effects were preserved after printer nozzle extrusion. These higher performance magnetic annealing effects were (1) magnetoaction at lower
applied fields for the Fe-containing samples and (2) non-zero magnetoaction in the highest SrF samples (control samples showed no magnetoaction). Quantitatively, the least magnetoactive deflection was seen in the highest SrF samples. The mechanical data showed that as the percentage of SrF increased, the mechanical stiffness of the composite variant increased simultaneously. Therefore, the high stiffness could be a contributing factor to the low magnetoaction of the high SrF samples. Magnetically, the samples with more SrF content had lower saturation magnetization (Ms) and higher coercive field (Hc), which would also contribute to the limited magnetoactive response. Since the enhanced magnetoactive properties of the filaments from magnetic annealing hold after the FDM extrusion process, this unconventional approach to magnetic annealing of magnetic elastomers shows promising potential 3D print the accurate and complex components that high-performance soft robotic applications require.

SB07.04.02
Reproducible and Long-Ranged Magnetic Organization of Micropillar Arrays Jeong Eun Park[1], Sei Jin Park[2], Augustine Urbas[3], Zahyun Ku[3] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Lawrence Livermore National Laboratory, United States; [3]Air Force Research Laboratory, United States

The magnetically responsive organization has been explored mostly in the form of spherical magnetic particles coated with a polymer. This process is beneficial for remotely triggering chain-like organization of magnetic composites by highly penetrable magnetic fields. However, magnetic interactions often prevent the uniform and reversible organization of multiple magnetic objects. Instead, for reproducible magnetic organization, periodically arranged micropillar arrays are adopted as a geometric form of magnetic polymer composites. While the pillar base consists of magnetically inert and soft neat polydimethylsiloxane (PDMS), the pillar top is made of PDMS and highly concentrated magnetic particles. Here, the pillar base acts as the soft hinge for the reversible organization of micropillars, and the pillar top serves as a highly magnetized micro-magnet under an external magnetic field. As the magnetic field increases, adjacent two dipolar micropillars are paired by quadrupolar attractive forces. By further increasing the magnetic field, two paired micropillars are quad-assembled, and finally connectively assembled. In this presentation, we would discuss the critical magnetic field threshold for the stepwise organizations as well as parameters affecting the magnetic organization including the cross-sectional geometry of micropillars and angles of the magnetic field with respect to the micropillars.

SB07.04.03
Magneto-Responsive Shape Fixable Vitrimer Micropillar Arrays Jae Gyeong Lee, Hojun Moon, Woongbi Cho, Jisoo Jeon, Jeong Eun Park and Jeong Jae Wie; Inha University, Korea (the Republic of)

Magneto-responsive materials have been emerged owing to the contactless actuation with untethered system at the room temperature. However, temporary magneto-induced structure disappears after removing external magnetic fields and recovers its original configuration. In this study, we manufactured micropillar arrays with vitrimer matrix embedding magnetic particles to retain magneto-induced temporary shape. We introduced epoxy vitrimer to facilitate dynamic covalent bond via transesterification. We also discuss trade-off relationships between mechanical stiffness and magnetization depending on the concentration of magnetic particles through the investigation of structure-property relationship. The maximum magneto-mechanical bending is obtained with an optimum magnetic particle concentration. Furthermore, we will discuss shape fixation of vitrimer micropillar arrays by magnetically driven thermomechanical stimuli.

SB07.04.04
Nanowire Motion Control by Magnetic Field Roman Kolisnyk, Allison Harpel, Pang-Hsiao Liu, Yicong Chen and Bethanie J. Stadler; University of Minnesota, United States

The development of next generation nanomachines—such as drug delivery vehicles, on-board nano-agitation devices, self-assembled structures and nanocomposites—requires efficient manipulation of nanoparticle motion. Magnetic field manipulation provides a contactless, sensitive, easy and cost-effective solution to the problem. Moreover, this method could be a good indicator of viscoelastic properties of fluids.
Here, magnetic nanowires (MNWs) of various lengths and radii were fabricated via electrochemical deposition into nanoporous templates, using a Cu film sputtered on one side of the template as a working electrode. To create suspensions, the nanowires were removed from the template by first etching away the Cu film and then dissolving the template in NaOH. The nanowires were then collected with a permanent magnet placed against the wall of the flask containing them, rinsed several times with water, and then redispersed using ultrasonic agitation and placed into the liquid to be studied. The small dimensions of nanoscale entities result in an extremely low Reynolds number, which means the fluid is viscous and the drag force dominates the inertia force. A rotating external magnetic field can apply a magnetic torque to balance the drag torque and rotate the MNWs in sync with the field. Magnetic torque arises when the magnetic field is not parallel to the nanowires. As the viscosity of the fluid increases, the time required to align the nanowire in the direction of the field increases. In addition, nanowire size has a large effect on their rotation speed - a longer MNW will experience slower acceleration and larger drag, while a MNW with larger diameter rotates faster because the drag force is a weak function of r but the magnetic driving force and rotational inertia are proportional to r^2. If the density of MNWs is high, a local field effect may occur where the field experienced by each particle is the sum of the applied external field and the local field induced by neighboring particles. The consequence of the local field is that the dipoles may not align in the direction of the applied field. At low-frequency rotations of the magnetic field, the nanowires rotate synchronously with the applied field. The nanowires phase lag increases with rising of the rotating field frequency and when the critical frequency is reached that is proportional to the square of the field strength asynchronous regime of the nanowires motion arises. In addition, when the frictional torque exceeds the magnetic torque, the MNW no longer synchronizes with the rotating external field. In the asynchronous regime, the phase lag angle of a rotating MNW increases periodically with time as the MNW rotates more slowly than the external magnetic field. When increasing the viscosity of fluid the frequency of synchronous and asynchronous regimes decreases. When the driving field frequency is very high the nanowire will keep oscillating around its position. By exploring MNW diameters from 20-200nm and lengths from 1-5µm and rotation frequencies from 60-200rpm in liquids from aqueous to viscous (including cryopreservation agents for the new field of nanowarming organs and tissues), a phase diagram of MNW control has been created.

SB07.04.05
Understanding Magnetocapillary Particle Dynamics Through Bayesian Parameter Estimation, Model Selection and Experiment Design Dimitri Livitz, Kiran Dhatt-Gauthier and Kyle J. Bishop; Columbia University, United States

The field-induced motion of magnetic microparticles at curved liquid interfaces can be used to drive mixing and transport of emulsion droplets. Accurate models of these magnetocapillary motions are useful in designing time-varying fields to achieve targeted functions (e.g., droplet propulsion). Existing models reproduce many of the qualitative behaviors observed in experiments but fail to accurately predict particle trajectories along the interface of a

spherical droplet. Here, we apply methods of Baysian data analysis to investigate and compare a series of improved models incorporating additional physics that aim to improve model accuracy and enable predictive design. We develop strategies for batching data from multiple experiments that helps to accelerate parameter estimation and model selection. We show how experimental design can be used to accelerate these processes further to enable accurate predictions using data from few carefully selected experiments. The improved model identified by this procedure highlights the significance of gravitational forces and particle orientation in predicting magnetocapillary dynamics. More generally, the analysis methods developed herein should prove useful in other contexts involving large datasets and ODE-based models.

SB07.04.06
Vortex-Induced Cargo Transportation by Programmable Collective Behavior of Polymer Nanocomposite Robots Sukyoung Won[1], Hee Eun Lee[1], Young Shik Cho[2], Kijun Yang[1], Jeong Eun Park[1], Seung Jae Yang[1] and Jeong Jae Wie[1]; [1]Inha University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Cooperation of multiple robots is essential to enhance actuation efficiency for time-consuming missions and complete complicated tasks that are unable from a single robot. Herein, we present agile (~180 body lengths per second) and collective above-water swimming of multiple polymer nanocomposite robots, which can transport thousands of microplastics via the water vortex control. To achieve agile above-water swimmability and resultant vortex generation, a musculoskeletal system-mimetic design is adopted to prepare stiff yet lightweight hierarchical nanocomposite robots. By simply varying magnetic frequencies of a pulsed electromagnetic field, swimming modes of the nanocomposite robots are selectively programmed on-demand between rectilinear translational swimming and rotational swimming, allowing the robots to block, deliver, confine, or release thousands of floating microbeads in a divided space rapidly and simultaneously. Moreover, through the collective behavior, the multiple nanocomposite robots generate vortex and demonstrate a collection of > 4,000 floating microplastics in an open space. We further discuss the vortex-induced transportation capability of semi-submerged and underwater millimeter-scale cargos with rolling resistance or sliding resistance.

SB07.04.07
Magnetically Controlled Micro-Deformation of 3D Cell Culture Environments for Long-Term Mechanobiological Studies *In Situ* Daphne Asgeirsson[1], Avni Mehta[1], Nicolas Hesse[1], Michael G. Christiansen[1], Anna Scheeder[2], Andrea De Micheli[3] and Simone Schuerle[1]; [1]ETH Zürich, Switzerland; [2]University of Cambridge, United Kingdom; [3]University Children's Hospital of Zürich, Switzerland

In living tissues, mechanical forces are key regulators of cell fate and behavior. In addition to chemical signals, physical parameters such as material stiffness or shear stress provide cues that are pivotal during developmental processes and the maintenance of physiological function.[1] At the same time, alterations in tissue mechanical properties have been shown to both indicate and drive the progression of pathological states such as tumor growth and malignant transformation.[2,3] These physical forces are increasingly considered and integrated in the design of biomimetic *in vitro* systems for basic research, drug development and personalized medicine. Approaches targeting stiffness of cell environments, perfusion of *in vitro* systems or (cyclic) stretch and compression of tissue constructs have been implemented to measure and control forces within a model of interest.[4]
To study the mechanics of 3D tissue models *in vitro* from the perspective of individual tissue-residing cells, we used rod-shaped magnetic microparticles (µRods) to probe and manipulate sample volumes on the microscale. The combination of an eight-coil electromagnetic field generator and high-resolution optical microscopy enabled us to study the heterogenous mechanical landscape within Collagen I (Col I) hydrogel networks in 3D. Further, analysis of fluorescently labelled Col I network deformation during magnetically controlled deflection of embedded µRods indicated that displacement of the Col I fibers propagated across a distance that exceeded multiple times the length of a single µRod.[5]
Using a motor-driven Halbach-cylinder to create a uniform rotating magnetic field, we performed long-term magnetic actuation of µRod-enriched 3D tissue samples within a cell culture incubator. With this tool, we sought to examine how cyclic microscale deformation of 3D ECM models influences the invasive behavior of metastatic cancer models as a function of the applied actuation pattern. High-resolution fluorescence imaging of cell-free ECM samples monitored the collagen integrity during actuation. Supplemented with cells, our studies provided insight about the progress of cell invasion to the surrounding matrix over several days of culture. The presented method aims to complement current approaches to analyze patterns of mechano-sensitivity within biomimetic *in vitro* models that could, for instance, accelerate the development of drugs targeting mechanical signaling pathways.

Local Stiffness Tailoring of Magneto-Active Composites Produced by Laser Powder Bed Fusion Kilian Schäfer[1], Matthias Lutzi[1], Darius Laniewski[1], Sebastian Bruns[2] and Oliver Gutfleisch[1]; [1]Functional Materials, Germany; [2]Physical Metallurgy, Germany

Mechanically soft sensors and actuators are beneficial when compliant and safe interaction with the human body is needed [1]. Magnetic actuation mechanisms allow fast response, wireless operation and the possibility to operate in enclosed confined spaces. With additive manufacturing, the production of magneto-active composites in complex and bioinspired shapes is possible. However, to completely transfer the functional properties of biologic systems to technology, the fabrication of composites with locally different mechanical properties is needed, since natural materials often have gradients in their mechanical properties [2]. In addition, in a soft robotics system like a locomotion assistance system the mechanical soft functional materials are often connected to rigid components, which results in the stiffness mismatch at the interface, which can lead to mechanical failure [3].

In this work, we present a method to locally tailor the stiffness of a magneto-active compound, consisting of hard magnetic $Nd_2Fe_{14}B$ particles in a thermoplastic polyurethane (TPU) matrix with laser powder bed fusion. In this process, a laser beam selectively fuses powder layer by layer. By utilizing different laser parameters at different locations during the process, the mechanical properties of the composite are modified locally. For the process, the digital file of the parts must be divided into regions which should have different properties in the end. Hereby, the minimum layer height of these regions must be an integer multiplier of the layer height if the laser parameters are changed in the z-direction. If a gradient in x-y direction is needed, these regions should be the same size as the hatch distance.
The range in which the mechanical properties can be tailored is investigated with compression and tensile tests of the composite produced with different laser parameters. The stiffness can be increased tenfold when the laser power is increased from low to high values. The stiffness gradient within one sample is verified by line scans of Vickers indentations with a nanoindentation system.

After magnetisation of the composites, the actuation performance is tested within an electromagnet. We present a shape that contracts when a magnetic field is applied. The shape consists of two platforms with beams in between the platforms to provide flexibility. The two platforms can then connect to other parts of a soft robotics system. With the presented method, the platforms can be produced with high stiffness and gradually reduced stiffness towards the centre of the shape, where more flexibility is needed for the actuation. A larger deformation can be reached when a magnetic field is applied to the gradient composite in comparison to a non-gradient counterpart. We show that the production of shapes with locally tailored stiffnesses with a single process is possible with laser powder bed fusion, which can be applied in bioinspired magneto active composites and help to integrate the soft functional components into robotic systems.

8:15 AM *SB07.05.01
Ultraflexible, Reconfigurable and Self-Propelling Particle Structures Assembled and Driven by Magnetic Fields Orlin D. Velev; North Carolina State University, United States

We will present strategies for the magnetic field driven assembly, manipulation, and propulsion of a rich variety of colloidal particle structures. We will first present responsive structures made of filaments from lipid-coated magnetic nanoparticles suspended in water. The nanocapillary liquid binding results in ultra-high filament flexibility and responsivity. Alternatively, the nanoparticle chains can be embedded inside silicone microbeads, resulting in a few types of soft macromagents and microvoxels. These soft magnets can be incorporated into homocomposite thixotropic silicone pastes and can be directly shaped on a 3D printer to enable multiple classes of active magnetically reconfigurable structures. In the second part of the talk, we will discuss the principles of using magnetic assembly and actuation of dynamically reconfigurable active particle structures. We will show how assemblies of Janus polymer-metal microcubes can store energy through magnetic polarization of the metallic facets and release it on-demand by microscale reconfiguration. The reconfiguration pattern of folding and shape changes of the assemblies is encoded in the sequence of the cube orientation. Such structures can be directionally moved, steered, and maneuvered by external magnetic fields, acting as prototypes of microbots, micromixers and other active microstructures. These reconfigurable clusters can also be designed to be self-motile in media with non-Newtonian rheology. Such active assembles can serve as microtools for interfacial studies in liquid crystal and biological systems.

8:45 AM SB07.05.02
Nature-Inspired Soft Robotics—On Magnetically-Actuated Artificial Cilia and Magnetic Micro-Swimmers Patrick Onck; Univ of Groningen, Netherlands

Nature has developed astonishing concepts to manipulate fluids at small length scales and to enable micro-organisms to efficiently navigate through fluids at low Reynolds numbers. Motile biological cilia for instance can produce net fluid flows at low Reynolds numbers because of their asymmetric motion and emerging metachrony of collective beating. Mimicking this with magnetic artificial cilia can find application in microfluidic devices for fluid transport, mixing and directional particle transport. In addition to magnetic artificial cilia, also soft robotic magnetic micro-swimmers can be applied for future wireless medical robots for operation inside the human body. In this presentation I will discuss recent work we carried out [1-4] on the computational modelling of magnetically-actuated artificial cilia and soft-robotic magnetic micro-swimmers performed in close collaboration with experimental groups.

To generate fluid transport we studied the metachronal beating of magnetically-actuated artificial cilia whose individual non-reciprocal motion and collective metachronal beating patterns can be independently controlled [1,2]. We have developed a computational framework that is able to account for the magnetic actuation forces, the ciliary deformation, the coupled interaction with the surrounding fluid and the resulting fluid flow. We study arrays of magnetic cilia subject to a full range of metachronal driving patterns, including antiplectic, symplectic, laeoplectic and diaplectic waves. We analyse the induced primary flow, secondary flow and mixing rate as a function of the phase lag between the cilia and explore the underlying physical mechanism.

In addition, we developed a versatile particle transportation platform consisting of arrays of magnetic artificial cilia actuated by a rotating magnet [3]. By performing a tilted conical motion, the artificial cilia are capable of transporting particles on their tips, along designated directions that can be fully controlled by the externally applied magnetic field, at high resolution (particle precision), with varying speeds and for a range of particle sizes. The results show that the adhesion and friction between the particle and the cilia are essential ingredients of the mechanism underlying the multi-directional transportation. This work offers an advanced solution to controllable transport particles along designated paths in any direction over a surface, which has potential applications in diverse fields including lab-on-a-chip devices, in-vitro biomedical sciences, self-cleaning and antifouling.

In addition to magnetic artificial cilia, we also studied soft robotic magnetic micro-swimmers for future wireless medical robots operating inside channels, vessels, tubes and cavities of the human body, filled with flowing or stagnant biological fluids [4]. Driven by different external magnetic fields, the swimmer's motion can be changed between undulation crawling, undulation swimming, and helical crawling. By using computational modelling, we analyze the transport mechanisms of the soft robots and study the effect of different parameters to provide guidelines for the design of the robots in specific applications. Our design method provide unprecedented opportunities for studying ciliary biomechanics and creating cilia-inspired object manipulation, lab- and organ-on-a-chip devices, mobile microrobots wireless microfluidic pumping and bioengineering systems.

Magnetic Nanorobotics—Fabrication, Materials and Forces Peer Fischer[1,2]; [1]Max Planck Institute for Medical Research, Germany; [2]Heidelberg University, Germany

Micro-/nano-robotics holds great potential for biomedical applications. Structures that are smaller than the macromolecular mesh size in gel-like media and tissues may be propelled relatively more easily compared to larger structures, even though the strength of the magnetic moment reduces with size. We have shown that magnetic nanopropellers can penetrate real biological tissues. If functionalized with enzymes they can soften mucine so that they can be propelled with weak magnetic fields. If coated with an anti-adhesion layer, they can propel over cm distances through the vitreous of the eye and steered to a small region at the optic disc of the retina. Our work indicates that transport into and inside tissues requires careful design, but is possible such that micro and nanopropellers can overcome biological barriers. This is an important first step to realize targeted delivery in dense tissues. An important aspect is the choice of magnetic material that is used to penetrate tissues and/or for the delivery of genetic material into cells. Magnetic nanopropellers and nanorobotic systems benefit from hard magnets. Fully biocompatible magnetic nanocarriers, that are not cytotoxic and that ideally also degradable over time, are promising tools for biomedical applications, but call for careful material choices. In this talk, we discuss the material selection, fabrication, and the resultant forces that are necessary for magnetic actuation and penetration of tissues.

Elucidating Mechanotransduction in Magnetomechanical Neuromodulation Amanda Gomez, Rohini Guntnur and Gabriela Romero; The University of Texas at San Antonio, United States

Neuromodulation techniques have shown great potential for the treatment of neurological disorders. Specifically, the use of novel magnetic nanotechnologies have allowed for non-invasive and targeted approaches that can stimulate deep structures. Magnetic nanodiscs (MNDs) are suitable for evoking neural activity because they are transducers of low-frequency and low-amplitude alternating magnetic fields (AMFs). When targeted to the cell membrane MNDs AMFs-triggered mechanoactuation enhances or inhibits cell membrane receptors for the modulation of biological signaling. However, there remains largely unknown information about the underlying cellular and molecular mechanisms of magnetomechanical neuromodulaiton. It is known that cortical neurons express different mechanosensitive ion channels such as TRPV1, TRPV2, TRPV4, Piezo1, TRPC1 and indirectly actuated G-protein coupled receptors. This project aims to investigate magnetomechanical neuromodulation using 685 nm MNDs targeted to the cell membrane of primary rat cortical neurons and unveil the key ion channels involved during mechanotransduction.

10:15 AM SB07.05.05
Micro-Scale Aerosol Jet Printing of Magnetic Materials for Soft Robotics Silvia Taccola[1], Samuel C. Moorcroft[1,1], James Mcdonald[1], Hadi Bakhshi[2], Wolfdietrich Meyer[2] and Russell A. Harris[1]; [1]University of Leeds, United Kingdom; [2]Fraunhofer Institute for Applied Polymer Research, Germany

Small-scale magnetic soft structures that respond to an externally applied magnetic field have attracted wide research interest because of their unique capabilities and promising potential in a variety of fields, especially for applications in soft robotics. Current attempts for their micro-fabrication are largely based on adapted conventional template-driven fabrication processes, *e.g.* photolithography, template-based electro-deposition, and soft lithography, which require multiple processing steps and complex instrumentation, making them expensive and time-consuming, and do not effectively support mass customisation. Alternatively, digital fabrication technologies such as 3D printing facilitate the manufacturing of soft robots but are often limited by material selection and offer limited printing resolution. Within this framework, aerosol jet printing (AJP) is an emerging digitally driven, non-contact and mask-less printing process that has distinguished advantages over other technologies as it offers direct-write, high-resolution, versatile deposition of a wide range of materials onto a variety of substrates. Although AJP has primarily been used for surface patterning, researchers are beginning to explore its potential for producing 3D microstructures with complex architectures. Moreover, dual-material aerosol jet printing has been successfully demonstrated for the printing of composite structures with variable composition. Such capabilities illustrate the possible value of AJP in this field as an enabling manufacturing process which could introduce new possibilities of producing unique soft magnetic structures at the micro- and meso-scale by harnessing the unique capabilities of the process.
In this work, two different approaches are presented: 1) single material aerosol jet deposition of magnetic nanoparticles (MNPs) on soft/flexible substrates; 2) dual-material aerosol jet deposition of polymer/MNPs free-standing nanocomposite structures. Using the first approach, micro-patterns of MNPs in the region of 20 μm wide were successfully printed onto soft and flexible materials commonly used in soft robotics and biomedical engineering applications, such as polydimethylsiloxane (PDMS) films and poly-L-lactic acid (PLLA) nanofilms. The second approach allows the fabrication of magnetic nanocomposite with tailorable and controllable composition. An MNPs ink and a polymer ink are separately atomized in different atomizers and the resulting aerosols are mixed uniformly and *in situ* during the AJP process prior to deposition. The mix ratio of the two aerosols determines the MNPs loading in the nanocomposite, which can be used to locally control the magnetic properties of the printed structures, a significant feature that can't be achieved in traditional multi-materials printing using liquid/liquid or liquid/solid phases. The entire manufacturing process is digitally driven, thereby providing the capability to rapidly alternate and produce different designs, and to do so within time and cost boundaries that would be unachievable by template-based manufacturing approaches.
We believe that the use of this scalable, accurate, and versatile digitally-driven processing technology could enable a route for the development of novel magnetic microstructures.

SESSION SB07.06: Applications of Magnetic Micro- and Nanorobots I
Session Chairs: David Cappelleri and Salvador Pane i Vidal
Wednesday Morning, November 30, 2022
Hynes, Level 3, Room 308

11:00 AM *SB07.06.01
Engineering Magnetic Micro-and Nanorobots for Biomedicine Simone Schuerle; ETH Zürich, Switzerland

Engineering robots at the cellular scale could allow us to gain new insights into disease development and provide more targeted means for diagnostic and

therapeutic interventions. Magnetic fields have proven to serve as safe strategy to wirelessly power magnetic microrobots for remote control in physiological environments. In this talk I will give an overview of three distinct examples of magnetic micro-and nanorobots for biomedical applications and describe their respective design and control schemes.

First, I will present a method for 3D spatiotemporal probing of tissue models from a single cell perspective using microrobots. We fabricated rod-shaped magnetic microrods and leveraged 3D magnetic field generation, physical modeling, and image analysis to reveal local shear moduli and remotely apply mechanical stimuli [1]. The heterogenous mechanical landscape of a tumor's extracellular matrix (ECM) is in part a result of increased local release of enzymes, in particular certain proteases, which degrades the ECM and is associated with tumor invasion. In a next example, I will describe nanorobots that are either activated or detected via magnetic fields and designed to report a tumor's proteolytic activity as novel diagnostic [2].

Last, I will show how an individual, synthetic and swarms of living magnetic microbots can help to locally enhance transport of nanoparticles (NPs) mimicking drug carriers in a tissue model [3]. We employed two distinct micropropeller designs powered by rotating magnetic fields to increase diffusion-limited transport of NPs by enhancing local fluid convection. In the first approach, we use a single synthetic magnetic microrobot called an artificial bacterial flagellum, and in the second approach, we control swarms of magnetotactic bacteria to create a directable "living ferrofluid" by exploiting ferrohydrodynamics. With both strategies, we demonstrated the ability to locally and wirelessly drive convective transport in tissue models. The latter strategy has also shown to outperform synthetic ferrofluids in terms of ferrohydrodynamic coupling to drive NP transport (Fig.1) [4]. Lastly, I will share insights into how these living magnetic microrobots can be further engineered to function as therapeutic vectors themselves that can be magnetically controlled [5].

Targeted Magnetic Vortex Disc Delivery Enables Magneto-Mechanical Control of Mouse Behavior Florian Koehler[1], Katherine Lei[1], Belinda Hetzler[2], Ye Ji Kim[1], Rebecca Gillette[1], Dirk Trauner[2] and Polina Anikeeva[1]; [1]Massachusetts Institute of Technology, United States; [2]New York University, United States

Low frequency magnetic fields pass through the body without attenuation, enabling the delivery of magnetic stimuli to deep tissue structures. We and others have previously demonstrated that magnetic nanodiscs (MNDs) composed of iron oxide can exert force on mechanoreceptors and control Ca^{2+} influx into sensory neurons in dorsal root ganglia and human embryonic kidney cells (HEK293) engineered to express the putative mechanoreceptor TRPV4[1]. These prior studies have, however, relied on electrostatic targeting of the MNDs to cell membranes, and consequently magnetomechanical modulation lacked specificity to a particular cell type.

Here, we demonstrate the functionalization of MNDs with Benzylguanine (BG), a moiety that specifically binds to the genetically expressed SNAP tag to enable targeted delivery of MNDs to mechanosensitized cells. We employ a slowly varying alternating magnetic field to deliver the stimuli to the MNDs. Using Ca^{2+}-imaging, we confirm the targeted stimulation of HEK293 cells and primary hippocampal neurons engineered to express mechanoreceptors. We further investigate the effects of the magnetomechanical stimulation on the cell membrane potential using the patch clamp electrophysiology.

Finally, we explore the possibility of magnetomechanical stimulation as a means to control neuronal activity and behavior in untethered freely-moving rodents. We anticipate that magnetomechanical stimulation will complement an existing array of tools aimed at connecting molecular and circuit function in the context of behavior.

Magnetically Actuatable 3D Liquid Multi-Electrode Arrays for Electrophysiological Monitoring of Brain Organoids Enji Kim[1,2], Young-Geun Park[1], Inhea Jeong[1], Junghoon Kim[1,2], Eunseon Jeong[1,2], Seung-Woo Cho[1,2] and Jang-ung Park[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Institute for Basic Science (IBS), Korea (the Republic of)

Brain organoids have emerged as a miniaturized substitute for the human brain to investigate the electrophysiological developments and mechanisms in three-dimensional (3D) neural network circuits. To fully apprehend the volumetric neural connectivity, monitoring of signals arising inside the organoid, intra-organoid signal, is imperative. However, existing devices require either the section of organoids or the insertion of rigid electrodes to grasp intra-organoid signals, which destruct the 3D cellular organization of the organoids and cause inflammatory responses. Also, a restricted number of electrodes in fixed positions is inadequate for the examination of complex neural activity throughout the organoid. These limitations have disturbed the chronic electrophysiological analysis in the 3D spatial scope of the organoids.
Herein, we present a magnetically actuatable 3D liquid multi-electrode array (MEA) by high-resolution 3D printing of biocompatible metals for electrophysiological monitoring of brain organoids. Adaptable spatial distribution and soft mechanical properties of 3D liquidous microelectrodes enable long-term recording of intra-organoid signals from entire spatial points throughout the organoid. Furthermore, the flexibility of these 3D liquidous electrodes facilitates magnetic control in the tip position of the electrodes. Targeted recording from desired locations guided by magnetic actuation multiples the density of recording sites inside the organoid with the identical number of electrodes. High-resolution 3D mapping of recorded signals through a multi-spot detectable electrode array is a promising method to clarify the origins of neurodevelopmental diseases by understanding the electrophysiological volumetric network of brain organoids.

1:30 PM *SB07.07.01
MANiACs to Micro-Force Sensing Microrobots—Magnetic Soft Microrobots for Biomedical Applications David Cappelleri; Purdue University, United States

Small soft robotic systems are being explored for myriad applications in medicine. Specifically, magnetically actuated microrobots capable of remote manipulation hold significant potential for in vivo applications such as targeted delivery of therapeutics and biologicals as well as for in vitro applications such as micromanipulation and biological material characterization. In this talk I will present families of wireless soft mobile microrobots driven by external magnetic fields that we have developed over the years for biomedical applications. These include the micro-scale tumbling microrobots (μTUM), magnetically aligned nanorods in alginate capsules microrobots (MANiACs), and the micro-force sensing mobile microrobots (μFSMM), and recent work in the area of adaptive soft microrobotics for advanced functionality.

2:00 PM SB07.07.02
Scalable Magnetic Torque Based Actuation Enhances Tumor Infiltration of Bacterial Drug Delivery Vehicles Tinotenda Gwisai[1], Nima Mirkhani[1], Michael G. Christiansen[1], Thuy Trinh Nguyen[1], Vincent Ling[2] and Simone Schuerle[1]; [1]ETH Zurich, Switzerland; [2]Takeda Pharmaceuticals, United States

Bacterial microrobots combining self-propulsion and preferential tumor accumulation have been recognized as promising drug delivery vehicles for targeted cancer therapy. Tumor-targeting bacteria are appealing because of their capacity to autonomously navigate through the body, transport a wide range of payloads, and modulate intratumoral inflammatory responses. Nevertheless, translation of this approach has been hindered by incomplete clinical responses, in part due to insufficient tumor colonization. Developing control strategies to enhance accumulation of bacteria within tumors is essential for facilitating robust colonization while concurrently lowering the required dose of bacteria, thus increasing therapeutic efficacy and safety.

Recently, innately magnetic strains of bacteria acting as steerable therapeutic agents have been manipulated with external magnetic fields. *In vivo*, strains of magnetotactic bacteria (MTB) carrying payloads have been shown to preferentially proliferate in deoxygenated regions of tumors following magnetic guidance. Magnetic control strategies for these living bacterial microrobots have thus far utilized directing magnetic fields, limited by propulsive forces of the bacterial flagella motor, or poorly scalable magnetic field gradients.

We established a hybrid control strategy that harnesses magnetic torque-driven motion followed by autonomous taxis-based locomotion to enhance the infiltration of *Magnetospirillum magneticum* AMB-1 as a carrier for covalently-coupled liposomes (MTB-LP). Unlike some forms of magnetic stimulus, uniform rotating magnetic fields (RMF) can be generated at clinically relevant scales for deep sites within the body. We demonstrated the suitability of RMF for simultaneous actuation and inductive detection, which could be exploited for closed-loop operation and real-time monitoring. We also assessed extravasation with computational models and *in vitro,* and found that the main mechanism driving the enhancement of translocation is increased surface exploration resulting from torque-driven translational motion at the cell interface. In a 3D tumor model, fluorescently labeled MTB-LP achieved stable colonization of the core regions of spheroids, with up to 21-fold higher signal in samples exposed to RMF. Finally, we demonstrated, for the first time to our knowledge, enhanced MTB tumor accumulation under RMF *in vivo*. Our findings illustrate that the MTB-LP platform combined with an RMF actuation scheme is a versatile biohybrid system that could improve targeting and colonization of therapeutic bacteria in tumors.

2:15 PM SB07.07.03
Scalable Scheme for Spatially Selective Actuation of Living Microrobots, Demonstrated by Colonization of Tumor Spheroids Nima Mirkhani, Tinotenda Gwisai, Michael G. Christiansen and Simone Schuerle; ETH Zürich, Switzerland

The ability to minimize off-target effects is a desirable feature for drug delivery platforms. This is often realized by either localizing the accumulation of active compounds to the target site or by selectively activating the portion that arrives in the targeted tissue. In the context of bacterial therapeutics, it is rational to ensure localized delivery since any off-target accumulation may result in complications associated with their toxicity. Simultaneously, due to their tumor tropism, local amplification at the tumor site can act as a form of selective activation. However, targeted accumulation of bacteria equipped with onboard sensing is contingent on the ability of their innate propulsive forces to overcome biological barriers. As a result, strategies for targeted introduction of external energy can potentially offer a much-needed element for enhanced selectivity of these living therapeutics. Magnetotactic bacteria (MTB) that biomineralize iron-rich nanocrystals provides this opportunity owing to their intrinsic responsiveness to magnetic fields.
We report on a spatially selective actuation scheme for the remote manipulation of MTB as a model system for magnetically responsive delivery vehicles. This actuation strategy is realized by superimposing a magnetostatic selection field onto a rotating magnetic field (RMF). The spatially controlled bacterial accumulation in tumor spheroids as a physiologically relevant model of cancer is studied. Human breast cancer cells, MCF-7, are used to form spheroids of roughly 400 in diameter. Spheroids are then placed inside separate wells containing MTB suspension within a 1.5cm × 1.5cm workspace. Since spheroid colonization relies on penetration of bacteria into these 3D cancer models, we first verify spatial selectivity of the actuation of MTB in response to the selection field by measuring their translational velocity inside the wells. Results under 12 mT RMF at 14 Hz superimposed by the gating field from small magnets demonstrate the suppression of torque-driven motion of MTB. The same experiment with the stronger magnetostatic field improves the level of off target suppression but also reduces the extent of actuation within the target well.
While the main resistance force and torque arise primarily from viscous drags for actuation in suspension, the spheroid presents an additional barrier for successful penetration. To account for the added resistance, prepared samples with spheroids are exposed to RMF of 20 mT and 14 Hz for 1 hour. Small NdFeB block magnets are responsible for the gating field in all the spatially selective actuations. Following magnetic actuation, the tumor spheroids are washed thoroughly in culture media and then incubated for 24 hours. Staining bacteria with a proliferative day allows tracking of daughter cells within the course of the experiment.
Quantification of the stained bacteria demonstrates significantly higher accumulation (2.3 fold) when exposed to the RMF compared to control. Most importantly, MTB colonization of the target spheroids is shown to not experience any drop under application of the selection field, resulting in an approximately 3-fold increase compared to the control. However, at off-target sites, a significantly lower accumulation is observed in the presence of a superimposed gating field. The trade-off between the overall suppression and selectivity is caused by the field gradients present in the miniaturized system. While stronger static fields lead to complete suppression of the off-target transport, the associated field gradients cause forces that act against the transport to the target. However, scaled-up setups with larger targeting areas feature lower field gradients which makes this undesired effect less physiologically relevant. Owing to the scalability and selectivity of the proposed control strategy, the progress towards the clinical translation of magnetically based delivery strategies can be facilitated.

Selective Artificial Neural Network and Stimulation by Targeted Delivery of Neuronal Cells Using Magnetically Controlled Cell-Based Cellbots

Hongsoo Choi; Daegu-Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Several *in vitro* neural network models have been developed to mimic neural networks' reconstruction and interconnection to study brain function and related diseases. Traditional manufacturing methods, including two-photon polymerization, have been chosen to build sophisticated microrobots for neuronal cell delivery, but the manufacturing time to make a single microrobot has limited its practical use. Here we report various magnetically actuated cell-based microrobots (cellbots) for selective neurite alignment, neuronal connections, and/or selective stimulation. A biodegradable spherical gelatin methacrylate (GelMA) microrobot was fabricated in a flow-focusing droplet generator by shearing a mixture of GelMA, photoinitiator, and superparamagnetic iron oxide nanoparticles (SPIONs) with a mixture of oil and surfactant. Human turbinate stem cells (hNTSCs) were loaded onto the GelMA microrobot, and the hNTSC-loaded microrobot exhibited a precise rolling motion in response to an external rotating magnetic field. The microrobot was enzymatically degraded by collagenase and released hNTSCs proliferated and differentiated into neuronal cells. A stamping magnetoelectric microrobot (SMM) composed of neuron-like cell spheroids loaded with magnetoelectric nanoparticles will be also presented. The SMM allows for effective targeted delivery of cells to multiple target areas (via minimally invasive stamping with magnetic actuation) to facilitate selective neuronal differentiation through magnetoelectric (ME) stimulation. The SMMs were made using SH-SY5Y cells, and magnetoelectric nanoparticles for ME stimulation reacted to an alternating magnetic field, ensuring targeted cell differentiation. The proposed cellbots show the potential for *in vitro* cell delivery and neural experiments to understand how neurons communicate in the neural network by actively connecting neural clusters.

4:00 PM SB07.07.06
Inductively Detectable Nanorobots for Detecting Protease Activity Michael G. Christiansen, Ines Oberhuber, Matej Vizovišek, Lucien Stöcklin, Manuel Strahm and Simone Schuerle; ETH Zürich, Switzerland

Proteases, a class of enzymes that cleave peptide bonds, are centrally involved in healthy processes throughout the human body. Many chronic ailments, including cancer, arthritis, and nonhealing wounds exhibit altered patterns of extracellular protease activity, making proteases a powerful diagnostic target for stratifying patients, monitoring treatment, or informing therapeutic decision making. For measurement of proteolytic activity to become commonplace in the clinic, new technologies are needed to lower the barrier to detection at the point-of-care.

Here, we explore a concept for the inductive detection of protease activity based on magnetic nanorobots. These nanorobots consist of a self-assembled monolayer of iron oxide magnetic nanoparticles (25 nm) on a larger silica core (600 nm), covalently bound via selectively cleavable peptide linkers. Cleavage of these linkers then triggers the magnetic nanoparticles to dissociate from the core particle, altering their magnetization response to applied magnetic fields. To detect their disassembly, a prototype pulsed field magnetometer has been designed, which makes use of capacitive discharge to produce a driving field with a variable timescale of 100s of µs and adjustable magnitude of 10s of mT. Compared to inductive detection based on alternating magnetic fields, the pulsed field approach offers the possibility for a smaller form factor and full integration into mass producible printed circuit boards, considerations that suggest greater suitability for point-of-care detection devices.

4:15 PM SB07.07.07
Magnetic Soft Robotic Platform Enables the Decoupling and Reprogramming Complex Gaits Generated by Invertebrates Neng Xia[1], Bowen Jin[2], Dongdong Jin[1], Zhengxin Yang[1], Chengfeng Pan[1], Qianqian Wang[1], Fengtong Ji[1], Veronica Iacovacci[1,3], Carmel Majidi[4], Yang Ding[2] and Li Zhang[1,1,1]; [1]The Chinese University of Hong Kong, China; [2]Beijing Computational Science Research Center, China; [3]Scuola Superiore Sant'Anna, Italy; [4]Carnegie Mellon University, United States

The complex and highly multimodal locomotion behavior of natural organisms allows them to dynamically adapt to complex environments and achieve energy-efficient or fast propulsion. These biological behaviors at different scales generally involve the coupling of basic motion primitives. Emulating and investigating their coupling locomotion are of great significance for understanding their fundamental mechanisms and developing high-performance robots. Despite advances in developing new simulation models and bio-mimetic testbeds, it generally remains challenging to analyse the complex coupling effect of locomotion gaits adopted by invertebrates. Herein, we develop a magnetic-responsive robotic platform to understand and analyse the coupling effect of swimming gaits adopted by midge larva. Studies are performed with a magnetic soft robot – named LarvaBot – that is operated using magnetic field inputs to decouple and reconstruct the complex wiggling motion of midge larvae. Diverse new coupled gaits can be generated and tuned with a phase shift by the LarvaBot, including the key swimming gaits adopted by natural larvae, which consist of side-to-side flexures and body rotation. Our studies reveal that the optimal rotation amplitude and the synchronization of curling and rotation can significantly enhance the propulsion performance. The magnetic LarvaBot exhibits multimodal locomotion and upstream capability at the moderate Reynolds number (Re) regime. The robotic platform offers new insight into the design and operation of new soft-bodied swimmers with coupled swimming gaits that may outperform their natural counterparts.

Magnetically Enhanced Marangoni Convection for Efficient Mass and Heat Transfer Like a Self-Driving Liquid Conveyor Belt Feng Lin[1], Hang Zhang[2], Tian Tong[3], Runjia Li[3], Jiming Bao[3] and Zhiming Wang[2]; [1]Yunnan University, China; [2]University of Electronic Science and Technology of China, China; [3]University of Houston, United States

Temperature gradient-induced Marangoni convection has attracted much attention for basic research and applications since it provides an effective means for mass and heat transfer through a liquid surface flow. Here we first propose a general principle to enhance such surface flow by hindering its transition to recirculation flow using an external field. We subsequently identify ferrofluid and use it validate the principle since its reduced magnetic susceptibility at higher temperatures will make the heated surface liquid stay on the surface by a thermomagnetic body force. Using a laser beam to create a heated local

surface and a magnet beneath the ferrofluid to provide a vertical field, a high speed and long-range Marangoni flow is confirmed experimentally and further supported by computational fluid dynamics simulations. To demonstrate possible applications, we show a self-driving pipeless liquid conveyor belt that can efficiently transfer heat from a source to sink without external power. The demonstration of enhanced Marangoni convection opens new avenue to explore interfacial fluid dynamics and its wide applications.

Self-Assembled Nanoscale Ciliary Actuators Hoon E. Jeong, Minsu Kang, Minho Seong and Donghyuk Lee; Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of)

Self-assembly of nanoparticles (NPs) is a powerful route to constructing higher-order structures. However, the programmed self-assembly of NPs into non-close-packed, 3D, shape-morphing nanocilia arrays remains elusive, whereas dynamically actuated nanometer cilia are universal in living systems. Here, a programmable self-assembly strategy is presented that can direct magnetic NPs into a highly ordered responsive artificial nanocilia actuator with exquisite nanometer 3D structural arrangements. The self-assembled artificial NP cilia can maintain their structural integrity through the interplay of interparticle interactions. Interestingly, the nanocilia can exhibit a field-responsive actuation motion through “rolling and sliding” between assembled NPs rather than bending the entire ciliary beam. It is demonstrated that oleic acid coated over the NPs acts as a lubricating bearing and enables the rolling/sliding-based actuation of the cilia.

Magnetic Origami for Soft Robotics and Microrobotics Oliver G. Schmidt; Research Center MAIN, Germany

On-chip micro-origami is used to generate highly integrated 3D magnetic microsensor arrays driven by active matrix electronics for soft magnetic e-skin applications [1]. The 3D magnetic sensors respond to the displacement of magnetically rooted hair creating directional perception in the vicinity of the artificial skin surface. Similar technology is used to manufacture highly integrated microelectronic catheters with drug delivery and magnetic sensing capabilities [2] as well as autonomously and remotely controlled microelectronic microbots [3].

11:00 AM *SB07.09.02
Flexible Magnetic Sensorics Jürgen Kosel; Silicon Austria Labs, Austria

Current trends for digitalization and green tech require materials that can enable sensor systems with new features and functionalities, while considering the availability of resources and sustainability in general. In these regards, magnetic materials are particularly attractive, as they offer unique capabilities like remote interaction, and they can be environmentally benign. One such material are iron-based magnetic nanowires, which feature both a large remanent magnetization and biocompatibility. Their fabrication via electrochemical deposition is efficient and provides a high control over the structural and magnetic properties. By using them as fillers in polymer composite materials, a flexible magnetic sensor skin is created, which can be remotely interrogation, is biocompatible and conformable. It combines mechanical flexibility with magnetic functionality. Through the concentration of the filler particles, the magnetic and mechanical properties of the composite materials can be widely modulated and tailored for the specific needs of an application. Examples will be shown, in which the magnetic composites are employed for the localization of subcutaneous medical devices or as tactile skins, for flow measurements or braille reading. As ultra-flexible magnetic skins, they can be worn like tattoos or camouflaged with the color of the skin tone and enable gesture-controlled wireless operations. This is demonstrated by controlling a wheelchair with facial gestures.
Modern fabrication processes combined with the advantages of magnetic sensor systems are a strong combination, which can lead to new sensor solutions. Examples are flexible magnetic tunnel junction sensors, which offer a high magnetic field sensitivity. They are employed for 3-axes orientation monitoring on biomedical instruments. On the other end of the spectrum are laser-induced graphene Hall effect sensors with less sensitivity but high temperature and corrosion resistance. Coated with a magnetic composite material, a robust tactile sensing platform is realized.

11:30 AM *SB07.09.03
Moving with Magnets—Taking a Look at Microswimmers with Random Shapes Damien Faivre; CEA Cadarache, France

Microswimmers are smart devices with potential applications in biotechnology and in particular medicine. Helicoidal magnetic micropropellers with their remote control via rotating magnetic fields have emerged as the standard devices with a linear velocity-frequency dependence propulsion mechanism. My group has gone an alternative path, synthesizing and studying magnetic micro- and nanoswimmers with random shapes.
Besides devices exhibiting the standard velocity-frequency dependence propulsion, we found more complex, non-linear velocity-frequency dependences, which offered new possibilities for the actuation control. We particularly emphasized a behavior we called frequency-induced reversal of swimming direction (FIRSD) where the propeller swims in two opposing directions for two different field frequencies of the external actuating magnetic field, while no other parameter is changed. We tested if recent 3D-printing techniques enabled the reproduction of these devices in large quantities. However, the identically shaped swimmers do not only displayed the FIRSD but also exhibited a variety of additional behaviors that arose from differences in their magnetic moment orientations. This underlined not only the role of shape in microswimmer behavior but also the importance of determining magnetic properties of future micropropellers that act as intelligent devices, as single-shape templates with different magnetic moments can be utilized for different

operation modes.

1:00 PM *SB07.10.02
Plasmonic and Magnetic Hybrid Nanostructures for Smart Materials Yadong Yin; University of California, Riverside, United States

Smart materials hold great promises for many intriguing applications in soft robotics as they exhibit chemical and physical responses to the applied external stimuli. This presentation will focus on the synthesis and assembly of plasmonic and magnetic hybrid nanostructures for enabling optical and mechanical responses for robotic applications. In particular, we will discuss a novel space-confined synthesis method for the production of magnetic/plasmonic hybrid nanostructures. The shape-dependent plasmonic and magnetic properties can be integrated into anisotropic hybrid nanostructures such as nanorods and nanodisks to not only control their nanoscale connectivity but also enable collective orientational alignment, allowing the design of smart materials with colorimetric and mechanical responses.

1:30 PM SB07.10.03
Soft Driving Coils for Conformal Electromagnetic Actuators Cindy K. Harnett; University of Louisville, United States

New developments in magnetically driven soft actuators typically focus on the magnetic materials' orientation, microstructure and reconfigurability. Meanwhile the driving apparatus is usually a rigid circuit at some distance from the magnet. These setups enable researchers to control the magnetic field strength and direction in free space, controlling untethered magnetic materials. However, in soft robotic skins, soft active surfaces, and in wearable applications such as haptics for augmented reality, the driving circuit and magnetically actuated material are usually integrated into the same surface. In these systems, there are fewer requirements for magnetic actuation at a distance, and more requirements for the system to be be conformal, thin, and lightweight. This presentation describes a textile-based method for designing thin electromagnetic driving coils with surface actuation in mind. It covers methods for modeling the magnetic forces specifically from thin wire coils, describes coil fabrication methods, and evaluates the produced coils' blocking forces, thermal performance, and bandwidth.
For haptic systems that generate pressure sensations, devices are usually designed to produce vertical forces by inflation or by solenoid-type actuation. While the thin driving coils discussed in this work can produce vertical forces, their lateral force production is stronger over longer distances because lateral operation keeps the magnetic material close to the coils where the field and its gradient are strongest. These lateral motions produce lesser-explored haptic brushing sensations in the 5-mN "pleasant touch" range.
Toward actuators that produce such lateral forces, a new rotary actuator is demonstrated on a 250-micron thick driving surface consisting of embroidered magnet wire in a nonwoven porous textile. Its thermal characteristics are measured in the 0- to 1 Ampere driving current range. A flexible and breathable 3D woven spacer fabric provides both thermal and mechanical isolation for the actuator coils and a moving magnet. Methods will be discussed for using stationary magnetic materials to provide restoring torque and latching forces for position holding. In addition, textile and thin sheet cutting methods can translate rotary magnetic motion into vertical motion of curved thin-film or thin-fabric beams by twisting the attachment points. This alternative to direct vertical magnetic motion is able to lift thin beams >5 centimeters above the surface for light-touch haptic actuators, soft robotic skins that can change their surface texture, and other applications requiring soft active surfaces. High-speed automated assembly methods will also be discussed for placing magnetic materials on top of coils using textile machinery.

Molecular Design and Biosynthesis of Polypeptides Inspired by Spider Silk Spinning Keiji Numata[1,2]; [1]RIKEN Inst, Japan; [2]Kyoto University, Japan

Structural protein is one of the key factors to realize the unique properties and functions of natural tissues and organisms. However, use of structural proteins as structural materials in human life is still challenging. One of the major drawbacks of protein/polypeptide-based materials is their limited synthesis/process method. My research group has successfully synthesized various polypeptides, such as spider silk protein-like and elastin-like multiblock polypeptides, even with unnatural amino acids or nylon units, via chemoenzymatic polymerization. Those artificial polypeptides containing unnatural units achieve several properties that cannot be done by natural polypeptides. These synthetic polypeptides with nylon units are highly biodegradable and less environmentally toxic. Thus, this enzyme-mediated polymerization of amino acid monomers provides a new insight for material design of polypeptide. My research group also reported the new finding in spider silk spinning, which is essential to clear the hierarchical structure of spider silk. The scalable and sustainable synthesis method along the clarified structure-function relationship of natural proteins provides a new insight for structural and functional material design of amino acids-based polymers.

11:00 AM SB08.01.02
Reverse Engineering Spider Silk by Disassembly and Assembly Dinidu Perera, Linxuan Li and Hannes C. Schniepp; College of William & Mary, United States

Spider silk combines outstanding strength and toughness with biocompatibility and light weight, thus outperforming some of the best synthetic materials. Despite extensive research, fully comprehensive experimental evidence of the formation and morphology of the internal structure of spider silk is still limited and controversially discussed. We used mechanical exfoliation to completely exfoliate spider silk, which showed that the silk of the golden orb-weaver is entirely composed of parallel, 10 nm-diameter nanofibrils featuring a particular morphology. This process allowed us to mass-produce spider silk nanofibrils for the first time. Furthermore, we show that the silk protein possesses an intrinsic mechanism to form nanofibrils of the same morphology via shear-induced molecular self-assembly, which can be easily triggered *in vitro*. By altering the physical and chemical environment of this process, we were able to study the conditions of formation of spider silk and to reveal both physical and chemical triggers for assembly at molecular scales. This knowledge will help understand the fundamentals of this exceptional material, paving the way for the realization of silk-inspired high-performance materials.

11:15 AM SB08.01.03
Protein Secondary Structure in Spider Silk Nanofibrils Qijue Wang and Hannes C. Schniepp; College of William & Mary, United States

Nanofibrils play a pivotal role in spider silk and are responsible for many of the impressive properties of this outstanding natural material. However, little is known about the internal structure of these protein fibrils. We carried out polarized Raman and polarized Fourier-transform infrared spectroscopies on native spider silk nanofibrils for the first time and determined the concentrations of six distinct protein secondary structures, including β-sheets, and two types of helical structures, for which we also determined orientation distributions. Our advancements in peak assignments are in full agreement with the published silk vibrational spectroscopy literature. We further corroborated our findings with X-ray diffraction and magic-angle spinning nuclear magnetic resonance experiments. Based on the latter and on polypeptide Raman spectra, we assessed the role of key amino acids in different secondary structures. For the recluse spider we developed a structural model with unprecedented detail, featuring seven levels of structural hierarchy. The approaches we developed are directly applicable to other proteinaceous materials.

11:30 AM SB08.01.04
BioMIPs Biocompatible Biomimetics—Molecular Imprinting Ties the Know with Natural Polymers. Synthesis, Properties and Future Perspectives of Silk Molecularly Imprinted Nanoparticles. Alessandra Maria Bossi[1] and Devid Maniglio[2]; [1]University of Verona, Italy; [2]University of Trento, Italy

The process of molecular imprinting allows to produce biomimetics of nanometric dimensions (nanoMIPs) by means of a template assisted synthesis [1]. NanoMIPs are gaining momentum for their outstanding recognition properties *in vitro* and *in vivo*, proving effective in cell imaging, tumor-cell targeting, drug delivery [2-5]. The expectations for nanoMIPs in medicine stake high. Yet, nanoMIPs are currently prepared starting from synthetic monomers (e.g. acrylamides), while focal point for their translation into clinical applications should be biocompatibility.
In this framework, we imagined a possible breakthrough development, based on the original idea to synthesize fully biocompatible nanoMIPs starting from the natural polymer silk fibroin, that is characterized by non-toxicity and high biocompatibility. Given the natural origin, we named the silk imprinted nanoparticles bioMIPs.
We investigated and optimized the synthesis of the bioMIPs by a three parameters (quantity of silk fibroin, pH, photoinitiator) response surface method (RSM) that enabled to model the landscape of the possible synthetic conditions. In set conditions, uniform (polydispersity index < 0.25) nanometer sized populations of bioMIPs, with $Z_{average}$ ~50 nm or $Z_{average}$ ~100 nm, were obtained.
The possibility to imprint recognition cavities on the bioMIP and the ability of these bioMIPs to trap a defined target molecule was also studied. Target molecules of different sizes (i.e. a peptide and a protein) were chosen as templates, so to consider the effects of the template size on the imprinting process [6,7]. Both isothermal titration nanocalorimetry and fluorescence spectroscopy proved the molecular recognition abilities of the formed bioMIPs. The estimated dissociation constants of the bioMIPs for the targets were in the nanomolar range, moreover the bioMIPs had selectivity and specificity for the target and a quasi-single binding site per nanoparticle. Additionally, the bioMIPs proved to be nontoxic for cultured mouse embryonic fibroblasts even at significantly high concentrations (2 mg/mL). Finally, we produced functional biomaterials with tailored recognition by coupling the bioMIPs to silk micro- and nano-fibers. Such bioMIP-silk specialized functional fibers proved to selectively trap the targeted molecule [6].
Hence, the unprecedented combination of silk fibroin building blocks to molecular imprinting appears as a compelling strategy to entail recognitive-functions to bio-nanoparticles. BioMIPs open for a new class of biomimetics that conjugate natural polymers to the custom design of molecular recognition

abilities, with foreseen impact in precision medicine and instructive biomaterials.

Artificial Enzymes and Electrochemically Molecularly Imprinted Polymers Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Molecular complexes that are inspired from biological enzyme-substrate interactions can be mimicked with the lock-and-key templating process. The use of functional monomers that can be electrochemically polymerized enables the formation of cross-linked polymer films with cavities that enable high binding assays of analytes: chemical and biological. There are a number of methods to improve sensitivity and selectivity in sensors but usually, this requires more elaborate instrumentation methods In this talk, we will show the effective and bio-inspired artificial enzymes for the detection of chemical and biological analytes. We will focus on the
demonstration of electropolymerized molecularly imprinted polymer (E-MIP) sensor elements and their ability to utilize transduction methods such as surface plasmon resonance (SPR) spectroscopy or quartz crystal microbalance (QCM) to enable high sensitivity and selectivity. The monomer and molecular design for optimized analyte interaction enable effective templating protocols in a conducting polymer matrix with tunable oxidative states to enable a high volume of analyte-cavity sites. Optimized electropolymerization methods are important for film deposition and surface characterization.

SESSION SB08.02: Designing and Understanding Biomaterials
Session Chairs: Fiorenzo Omenetto and Massimo Trotta
Monday Afternoon, November 28, 2022
Hynes, Level 3, Room 313

1:30 PM *SB08.02.01
Biomaterial Innovation Through Deep Time—How Spiders Have Evolved Spectacular Silks and Inspire Biomimetics Jessica E. Garb; University of Massachusetts Lowell, United States

Spiders are unrivalled in the diversity of high-performance silk types they produce. Biomaterial studies of spider silk primarily focus on orb-weavers, renowned for their seven functionally distinct silk types, including the well-studied dragline due its ease of collection and high tensile strength. However, orb-weavers are just one of many spider lineages that have further diversified silk into materials with unusual structures and properties, modified for wide-ranging mechanical demands. In this talk I provide an overview of the rich diversity of spider silks and highlight how recent advances in genomics are revealing the greater complexity of these materials, as well as recipes to mimic or re-imagine them. In addition to reviewing the silk types investigated to date and their underlying genetics, I will highlight unexplored species and silk types that could yield roadmaps to novel biomaterials and describe the challenges to closing our knowledge gaps.

2:00 PM SB08.02.02
Phase Front Assembly for Mesostructured Design of Biopolymer Microneedles Doyoon Kim, Yunteng Cao, Zheng Li, Federica Rigoldi, Hui Sun, Rajeev Ram and Benedetto Marelli; Massachusetts Institute of Technology, United States

Many biological processes, including biomineralization, are modulated via condensation phenomena at the interface between biopolymer matrices and inorganic ions modulate. Despite their enormous inspiration for high-performing materials design, little is known about simultaneous behaviors of inorganic io crystallization and biopolymers assembly. In this study, we present the control of co-occurring silk fibroin assembly and inorganic nucleation at their phase front to drive the formation of microneedles with designed nano-porous and hollow microstructures. This phase front assembly approach, for the first time, enabled the one-pot manufacturing of mesostructured microneedles with hollow and nanoporous tips: different internal microneedle structures develop in one type of mold via the interaction of silk fibroins and ionic salts. These mesostructured microneedles will serve as new connecting tools between biotic-abiotic worlds. For the agricultural application, we demonstrate the transport of biomolecules and detection of early-stage bioaccumulation of environmental contaminants (e.g., cadmium and arsenic) in tomato plants.

2:15 PM SB08.02.03
Efficient Deployment of Gibberellic Acid in Plants with Minimal Wounding Using Silk-Based Microneedles Yunteng Cao[1], Sally Koh[2,3], Yangyang Han[4], Javier Tan[2], Doyoon Kim[1], Nam-Hai Chua[4,2], Daisuke Urano[2,3,4] and Benedetto Marelli[1,4]; [1]Massachusetts Institute of Technology, United States; [2]Temasek Life Sciences Laboratory, Singapore; [3]National University of Singapore, Singapore; [4]Singapore-MIT Alliance for Research and Technology, Singapore

New systems capable of precise and efficient agrochemical delivery in plants will foster precise agricultural practices and provide new tools to study plants and design crop traits, as conventional delivery practices such as standard spray suffer from a significant loss, severe environmental side effects, and limited access to remote plant tissues. We previously demonstrated that silk-based microneedles could circumvent these limitations, capable of delivering a variety of payloads ranging from small molecules to large proteins into specific loci of various plant tissues. However, the plant responses to microneedle injection and microneedles' efficacy in deploying physiologically relevant biomolecules are unknown. Here, we show that gene expression associated with *Arabidopsis thaliana* wounding responses decreases within 24-hours post microneedles' application. Microneedles-mediated gibberellic acid (GA_3) injection in *A. thaliana* mutant *ft-10* is more effective and efficient than spray in activating GA_3 pathways and accelerating bolting. Microneedles' efficacy in delivering GA_3 is also observed in several crop species, i.e., tomato (*Solanum lycopersicum*), romaine lettuce (*Lactuca sativa*), and carmel spinach (*Spinacia oleracea*), underpinning the use of this new tool in plant science and agriculture.

2:30 PM SB08.02.04
An Engineered Standard Amino Acid for Unconventional Silk Fibroin with Unique Water-Responsivity Woojin Choi, Milae Lee, Kyungtae Park, Moonhyun Choi, Sungwon Jung and Jinkee Hong; Yonsei University, Korea (the Republic of)

In nature, water diffusion is the principal driving force of all organisms for performing the homeostatic motions, so-called hydration-adaptive actuation. For instance, animals reshape their feather through the hydration-adaptive buckling, and plant seeds exhibit a twisted opening response to osmotic stimulation. The structural biopolymer, such as silk fibroin, and keratin, spontaneously demonstrate the hydration-adaptive crystallization, *i.e.,* phase transition into β-sheet crystals. This crystallization enhances structural stability. Meanwhile, the crystallized biopolymers become inert and hardly interact with the surroundings. Hence, the inevitable biopolymeric crystallization exerts significant leverages in biomedical fields, for instance, pros in human-robot interfaces or cons in tissue adhesives. However, the underpinning chemical and physical aspects of hydration-adaptive crystallization have rarely been investigated up to date.
We have developed an unconventional silk fibroin by regulating hydration-adaptive crystallization, the mechanism of water responsivity in nature. Technically, the crystallization rate is modulated by activating a standard amino acid (Serine; Ser). Inspired by the natural activation of polar amino acid of an insect and shellfish *via* chelation of Ca^{2+}, the silk fibroins with different activities of Ser (7.90-10.8%) are prepared through divalent cation-mediated protein modification. In detail, Ser morphs into the exposed activated status according to the interaction between the divalent cation and the hydroxyl group of Ser.
A rheological model of case II diffusion through silk fibroin is demonstrated to deeply understand the hydration-adaptive crystallization. Case II diffusion is relevant to the hydration-adaptive crystallization as it regards the water-biopolymer interaction as a decisive parameter in entire diffusion kinetics. According to the proposed model, activated Ser enables downregulating the rate of silk fibroin crystallization. Moreover, the crystallization of protein secondary structures is monitored *in situ* by Raman spectroscopy. Both model and empirical results exhibit the inverse relationship between Ser activity and the crystallization rate, proving the active Ser-dependent crystallization kinetics. Particularly, a 30% increased activity of Ser results in an approximately 55% decreased rate of hydration-adaptive crystallization from 0.206 to 0.0936.
The mechanism of amino acid-based regulation of hydration-adaptive crystallization is figured out based on the thermodynamic water stability. In the hydrated biopolymer, the less-stable water molecules bridge the frame amino acids and cause crystallization. The hydroxyl group of Ser is more favorable in water stabilization than the carboxyl group of Gly and Ala. Hence, the crystallization-triggering water molecules spontaneously construct the stable lattice network in the silk fibroin with highly-activated Ser. The measured results (*i.e.,* number of hydrogen bonding of water molecule and exothermic enthalpy) indicate that the water stability is enhanced by approximately 2.5 folds by a 20% increased activity of Ser. In summary, the active Ser stabilizes the water molecules and delays the hydration-adaptive crystallization.
Finally, the active Ser-dependent crystallization regulation realizes the unconventional silk fibroin, irrelevant to the crystallization-induced inevitable loss of adhesive force. The silk fibroin with less-activated Ser losses 82% of initial adhesive force after 120 s hydration, suggesting the limited biomedical potential. Meanwhile, the silk fibroin with highly-activated Ser maintains a strong adhesiveness of 160 kJ m^{-3}, enabling stable adhesion on *ex vivo* porcine mandible tissue. In conclusion, the amino acid-based regulation technology imparts the unique mechanochemical response to the silk fibroin itself.

3:15 PM *SB08.02.05
Building Biomaterials with Bioinstructive Elastic Molecules Anthony Weiss; University of Sydney, Australia

There is an unmet demand for ways to restore functional tissues following damage. Elastic tissues do not typically regenerate in adults because they rely on an exogenous supply of elastin's primary building block, tropoelastin. We have developed ways to make and use tropoelastin to build a range of elastic repair materials. To our surprise, tropoelastin also promotes broader tissue repair. Powerfully, the use of tropoelastin promotes healing following surgery, including the recovery of full thickness wounds.

An emerging model for tropoelastin is that it delivers this potency by emulating extracellular matrix interactions including those needed in development and repair. This paradigm for enhanced tissue repair encompasses a novel, pure, synthetic material that promotes the repair and fixation of soft tissues. These biomimetic and bioinspired materials leverage an innate ability to promote new blood vessel formation and cell recruiting properties to accelerate healing. Utilizing our accumulated knowledge of their assembly and interactions has led to the realization of a diverse range of powerful biomaterials with tunable mechanical and self-assembly properties.

4:00 PM SB08.02.07
***In Situ* Mineralization for the Mechanical Reinforcement of Metal-Coordinate Polymer Hydrogels** Jake Song, Sungjin Kim, Crystal Owens, Gareth H. McKinley and Niels Holten-Andersen; Massachusetts Institute of Technology, United States

Metal-coordination interactions are promising chemical motifs for the design of bioinspired polymeric materials that mimic the mechanical performance of biogenic materials such as the arthropod fangs and mussel byssal threads. Building upon the use of such motifs for the design of associative polymer gels, we demonstrate a bioinspired strategy to introduce additional mechanical reinforcement and novel functionalities into metal-coordinate hydrogels, by using the strongly metal-coordinating ligands as templates for the mineralization of metallic nanoparticles in the hydrogels *in situ.* We demonstrate ability to induce significant mineralization of iron oxide nanoparticles in a catechol-based polymer network, which results in significant stiffening (surpassing that arising from metal-ion coordination alone) as well as magneto-responsivity in the hydrogel. These findings further advance our utilization of metal-coordination interactions in bioinspired soft materials, and offer promise for their use in technological areas such as soft robotics, energy harvesting, and medicine.

4:15 PM DISCUSSION TIME

4:30 PM SB08.02.09
Studying the Effect of Dextran Conjugation on Thermosensitive Bottlebrush Polymer Conformations Through Coarse Grained Molecular Dynamics and Deep Learning Soumil Y. Joshi, Parisa Farzeen and Sanket A. Deshmukh; Virginia Tech, United States

Dextran, a neutral bacterial exopolysaccharide made up of repeating 1-6 linked glucose subunits, has been widely recognized for its water solubility, inherent inertness and biodegradable nature. Owing to these properties and its ability to conjugate with different polymers, dextran has shown promise in several biomedical applications. Copolymers between dextran and poly(N-isopropylacrylamide)(PNIPAM) - a thermosensitive polymer with a lower critical solution temperature (LCST) of 305 K - and their star-like architectures have shown potential for creating targeted drug delivery systems. This has led to significant research in studying other soft-material architectures consisting of dextran-PNIPAM copolymers, with bottlebrush polymers (BBPs),

being a particularly interesting example. BBPs, traditionally seen as worm-like cylindrical molecules, can be designed in various shapes by adjusting structural parameters such as the grafting density as well as side chain length and arrangement. Furthermore, temperature-sensitive BBPs (TS-BBPs) of PNIPAM, have shown that the shapes of these architectures significantly impact their overall conformations, leading to different properties and applications. In the present work, we perform coarse-grained (CG) molecular dynamics (MD) simulations of BBPs of dextran-PNIPAM copolymers, broadly belonging to three shapes - (i) cake-like, (ii) dumbbell-like and (iii) plus-like. We study in comparison to non-dextran conjugated BBPs, the effect of BBP shape and temperature (below and above LCST of PNIPAM) on the conformations of overall BBPs, their backbones and side chains as well as the structure of solvent around these architectures. We also investigate the effect of dextran chain length and conjugation density on these architectures by grafting dextran 10-mers and 30-mers onto the TS-BBP in different arrangements. Through conventional analyses like free volume, contact maps, asphericity, etc., we show that the lengths of conjugated dextran chains around the backbone and their immediate environments influence the compactness of overall structures while also affecting PNIPAM conformations in the core of these architectures to varying degrees. Finally, we use a recently developed convolutional neural network (CNN)-based analysis protocol to quantify the similarities and differences between conjugated and non-conjugated TS-BBPs by capturing molecular-level features that may go unnoticed using conventional analysis. Through this analysis, we attempt to unravel the relationship between the degree of dextran conjugation and its effect on PNIPAM side chains in the TS-BBP, to further provide guidance in designing novel BBPs of dextran-PNIPAM conjugates.

Innovating and Characterizing Bioinspired Soft Materials with Multiscale Models and Machine-Learned Metamodels Jingjie Yeo; Cornell University, United States

Globally, rapidly aging human populations are significantly accelerating the occurrence of non-communicable diseases. Understanding the fundamental mechanisms of tissue damage due to aging can provide predictive capabilities that will inform medical treatments. Coupled with this understanding, nature-inspired dynamically responsive biomedical devices and implants can address this major health crisis due to their excellent environmental adaptability and biocompatibility. We apply multiscale molecular modelling and machine-learned metamodels to characterize aging-related diseases and engineer various candidate materials in two aspects: (1) dynamically-responsive silk and silk-elastin-like materials, and (2) customized molecular and material designs for ligands and polymers. Through this approach, we unveil the myriad material properties of chemically and physically processed silk-based materials, such as ionic conductivity. We also rapidly and efficiently determine the material parameters of constitutive models governing the time-dependent behavior of soft polymers. We further design customized ligands that potentially bind better to integrins than existing ligands for neural implants.

An Autopilot Single Polymer Jet Self-Constructing Organ-Scale-Mimicking 3D Electrospun Scaffolds for Tissue Engineering Applications
Balchandar Navaneethan[1,2,1] and Chia-Fu Chou[1,1]; [1]Academia Sinica, Taiwan; [2]National Tsing Hua University, Taiwan

Genetics and exogenous factors, such as aging, diseases and injury, affecting the human body highly demand clinical repairs to restore the functions and morphologies of the damaged tissues or organs. Tissue engineering is an emerging multidisciplinary field involving biology, medicine, and engineering to modernize the ways which can improve the health and quality of life of affected people by restoring, maintaining or enhancing tissue and organ functions. A successful scaffold construction requires mimicing the native tissue both physiologically and anatomically.
Electro(static) spinning is one of the most established techniques for constructing ECM mimicking fibrous scaffolds from various biodegradable polymers/biomaterials with diverse morphologies. However, smaller pores from the inter-fiber gaps than the human cells and poor jet path controllability due to complex jet-field interactions produce cell-impermeable sheet-like 2D scaffolds. We report here a “novel autopilot polymer single jet (AJ) electrospinning” capable of self-switching between cantilever-like armed jet motion (M1) and whipping motion (M2) due to charge-retention and dissipation of pre-deposited fibers. This new operation mechanism empowers successful fabrication of cell permeable porous scaffolds with buckled fibers that exhibited gradient porosity and mechanical strength thus satisfying physiological requirements from simple, homemade electrospinning setup in one shot. In this study, we also show the AJ-electrospinning is reproducible, robust and tunable which brings consistency to electrospinning produced scaffolds for the first time.
Further, we also demonstrated the self-searched writing of AJ on various 3D templates in the attempt of fabricating 3D scaffolds mimicking human organs anatomically, in which the AJ took various 3D bending paths which follows dynamically the self-modulated optimal field lines to deposit fibers on different sides of a 3D collector. Novel writing strategies were adopted thus avoided the competitive field lines to templates having complex 3D geometries. The AJ displayed high target recognition/specificity and resolution with pattern features as small as 100 μm to 10’s cm and capable of direct writing challenging 2D and 3D scaffolds, including human-organ-scale 3D face, female breast & nipple and vascular graft, by achieving conformal fiber deposition thus produced exact 3D replicas. The physical and biological characteristics revealed as-spun scaffolds were spongy and showed exceptional shape memory through M1/M2 switching of AJ-electrospinning with multi-directional 3T3 cells attachment and proliferation. To our knowledge, this is the first study to introduce reproducibility and direct-writing 3D scaffolds with excellent shape memory to the century-old electrospinning thus pave the path of adding this technique as a new 3D scaffold fabrication method.

SB08.03.03
Tyrosinase-Mediated Redox System for Tissue Engineering Su-Hwan Kim; Dong-A University, Korea (the Republic of)

Hydrogel system based on enzyme-mediated mild crosslinking reaction has been a promising approach in tissue engineering. Inspired by skin melanin synthesis and marine mussel adhesion, tyrosinase-mediated hydrogel crosslinking has been exploited as cell-friendly reactions and explicit reaction mechanisms. Hydrogel prepared by tyrosinase exhibits appealing properties as a dynamic scaffold for cell delivery and as a bioink for 3D bioprinting. Recapitulating the structure of the native extracellular matrix (ECM), innovative tyrosinase-mediated hydrogel crosslinking has now shifted to the field of translational medicine. Biomimetic hydrogel with in situ tyrosinase crosslinking can be efficiently and easily applicable to the disease model for therapeutic

purposes. We demonstrate that the novel enzyme-based crosslinking hydrogel has a robust potential in tissue engineering and regenerative medicine.

SB08.03.05
Exploring the Diverse Morphology of Porous Poly(lactic Acid) Fibers for Developing Long-Term Controlled Antibiotic Delivery Systems JR Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

E. coli and *S. aureus,* along with many other bacteria can cause pathogenic effects. One of the most common bacteria species commonly presenting on human skin is *S. epidermidis*: about two-thirds of human infections and a serious threat to human life. *E. coli*, the gram-negative strain, is commonly found in the large intestine of humans and other warm-blooded animals that can cause various types of extraintestinal infections. Nanofibers have recently been used in fibrous materials for a wide range of applications in medicine and hygiene, including health care and coatings, medical devices, water purification systems, and air filters. Consequently, the use of antimicrobial fibers has become an attractive idea because microorganism activity in textiles are detrimental to both the user and textile itself.
Polylactic acid (PLA) is a natural biodegradable thermoplastic aliphatic polyester that can be replaced synthetic polymers in terms of environmental aspects as well as their biodegradable nature, high safety, mechanical strength, fabricability, and biocompatibility properties. Electrospinning is one of the most widely used techniques to fabricate PLA nanofiber mats in hygiene, medical, and industrial filter applications. In particular, functional PLA fibers such as core–sheath, or porous morphology have been studied to carry and control the release of antimicrobial agents. In this study, porous functional PLA fibers obtained through electrospinning techniques with the different ratios of solvents in a high-humidity environment. In this study, a variety of porous surfaces were developed using polymer-solvent systems to enhance surface physical properties with the average size and the depth of pores of PLA fibers from various electrospinning conditions and solvents formulations. These porous PLA fibers have high surface to volume ratio, small fiber average diameter, and high nanoscale porosity. These high surface to volume ratio and nanoscale porosity result in controlled release of antimicrobial agents.
The aim of this study was to fabricate various morphology of porous PLA fibers and control the release of antibacterial agents, such as chitosan, trimethyl *chitosan (TMC)*, gentamicin, kanamycin, and amikacin. Antimicrobial agents-loaded to porous PLA fibers were evaluated antibacterial activities using three types of antibacterial assays (inhibition zone tests, live/dead bacterial cell assays and antibacterial kinetic growth assays) against *E. coli* and *S. epidermidis*. Among the samples, gentamicin-loaded PLA fibers had the most bactericidal activity, with the widest inhibition zone and the highest visible dead bacteria on the fiber. In order to analyze quantitatively antibacterial activities, chitosan and chitosan derivatives-loaded PLA fibers, growth kinetic curves were analyzed using OD_{600} against *E. coli* and *S. epidermidis*. For the results, we found that antibacterial performance was as follows gentamicin > amikacin > kanamycin > TMC > chitosan and more efficient on *S. epidermidis* than *E. coli.* This is mainly attributed to the different peptidoglycan layer structures in the cell wall of *E. coli* and *S. epidermidis*. *S. epidermidis* has a thicker peptidoglycan layer with a higher cross-linking degree in the cell wall compared with that of *E.coli*. It has been found that nonporous PLA fibers exhibits the initial-burst release profile whereas porous PLA fibers with highly porosity or deep-depth pores indicate a steady release. This study offers how to develop various morphology of PLA fibers to carry antibacterial agents efficiently and how long to control the release of antimicrobial agents depending on the type of PLA fibers to protect humans from biohazards in many applications. This investigation will provide a better and comprehensive understanding of porous microfiber formation during electrospinning and the fiber morphology-antibacterial property relationship.

SB08.03.06
Radiopacified and Hyaluronan Enhanced Polyethylene for Use as Artificial Heart Valve Leaflets Justin Gangwish, Cara Leone, Julianne Kindsfater, Harvinder Singh Virk and Susan P. James; Colorado State University, United States

Over 80,000 heart valve replacements were performed in the United States in 2014 and the global need is expected to exceed 850,000 by 2050. Currently available replacements fall into two categories, mechanical valves and bioprosthetic valves. While both types of valves improve patient's lives, they also pose significant risks to patient health. Mechanical valves are durable but require patients to take vitamin K antagonists for life-long anticoagulation therapy. Vitamin K antagonists have significant risks including but not limited to risk of death from minor trauma, significant fetal loss for pregnant women, and major dietary restrictions. Bioprosthetic valves have significant reoperation rates ranging up to 20% within 10 years of implantation when they are implanted via open heart surgery. However, when implanted via catheter, failure rates for bioprosthetic valves are even higher. 50% of these valves have structural deterioration within 7 years of implantation. A paradigm shift is needed to address the growing need for artificial heart valves. An ideal valve would operate in a non-thrombogenic manner preventing the need for anticoagulants, provide longevity seen from mechanical valves, could be placed via catheter preventing the surgical risks associated with open heart procedures, and would be made from low-cost materials. Furthermore, designing a radiopacified valve that could be monitored in-vivo using computed tomography could help prevent irregular deployment, monitor for leaflet deterioration, and prevent poor placement leading to coronary artery overlap. Finally current valves are evaluated using echocardiograms which identifies issues only once valve function has been reduced. Direct imaging with CT scans has the potential to shift the paradigm from waiting on a reduction in function to active monitoring of valve behavior.
In this work we describe a method to incorporate radiopaque materials (tungsten and bismuth trioxide) into linear low-density polyethylene (LLDPE) so that the material can be imaged via x-ray. The radiopacified LLDPE is then treated with hyaluronic acid to form an interpenetrating polymer network that has been previously shown to increase blood compatibility. This final material is structurally complex consisting of radiopaque filler embedded in LLDPE with an interpenetrating polymer network between the LLDPE and hyaluronic acid. The material is demonstrated to be radiopaque when imaged using an EPX-F2800 x ray source and a Universal Imaging MyRad digital radiography machine. Next the material was evaluated for the presence of hyaluronic acid using captive bubble contact angle goniometry and toluidine blue O staining. The captive bubble contact angle goniometry shows a significant increase in hydrophilicity (a hallmark of hyaluronic acid), while the toluidine blue O strains carboxyl groups found in HA. Control samples were not hydrophilic, nor did they stain with toluidine blue O. Uniaxial tensile testing demonstrated the radiopaque materials had no significant reduction in yield strength or yield strain compared to control materials and only slight reductions in toughness, elongation at break, and ultimate tensile strength. Finally, the material was demonstrated to be non-cytotoxic when cultured with red blood cells. This work demonstrates significant progress toward developing a structurally complex heart valve leaflet material that addresses the major shortcomings of currently available replacements while providing an additional diagnostic tool for physicians and patients to evaluate the health of the replacement valve.

SB08.03.08
Functions of Prolyl Hydroxylation in Elastin Chengeng Yang and Anna Tarakanova; University of Connecticut, United States

Connective tissues and organs of high tensile strength, like lung, heart and skin, extensively express elastin. Elastin is a key extracellular matrix protein responsible for elasticity, resilience, and mechanical strength in these tissues; on this basis, elastin-based materials have been widely applied in various fields such as tissue regeneration and drug delivery. During elastogenesis, the hierarchical elastic fiber assembly process, elastin is subject to a less-studied post-translational modification, prolyl hydroxylation, where, mediated by prolyl-4-hydroxylase, a hydroxyl group replaces one of the hydrogen atoms at the C-gamma position in proline residues. The structural stability of other connective tissue proteins, such as collagen, is thought to be mediated in part through hydroxylation of proline residues. This calls into question the role of prolyl hydroxylation in elastin. According to recent experimental studies, elastin-like peptides with hydroxyproline modifications are more resistant to enzymatic digestion, and subject to an abnormal behavior in elastogenesis. We hypothesize that hydroxylation alters elastin's biological behavior via protein-solvent interactions. To substantiate our hypothesis, we used existing mass

spectrometry data of elastin samples obtained from humans to build representative molecular models and perform extensive molecular dynamics simulations. As a starting point, we employ our recently developed fully atomistic model of elastin's precursor, tropoelastin. Our findings suggest that in comparison to prolines, hydroxyprolines exhibit an increase in hydrogen bonding with water and a rise in surrounding hydrophilic hydration. Such enhanced protein-solvent interactions rearrange the residue's local configurations, reducing elastin's global dynamics required for essential biological process, thereby preventing it from targeted degradation and hierarchical assembly. Overall, our investigation provides insights into functions of prolyl hydroxylation in elastin at a nanoscopic scale. We propose that strategically-placed hydroxyproline residues may be useful for tuning the sustainability of engineered elastin-based materials.

SB08.03.09
Crocodile Skin-Inspired Stretchable Piezoresistive Pressure Sensor Seung Goo Lee[1], Giwon Lee[2] and Kilwon Cho[2]; [1]University of Ulsan, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Stretchable pressure sensors are important components of multimodal electronic skin needed for potentializing numerous Internet of Things applications. In particular, to use pressure sensors in various wearable/skin-attachable electronics, both high deformability and strain-independent sensitivity must be realized. However, previously reported stretchable pressure sensors cannot meet these standards because they exhibit limited stretchability and nonuniform sensitivity under deformation. Herein, inspired by the unique sensory organ of a crocodile, we developed an omnidirectionally stretchable piezoresistive pressure sensor made of polydimethylsiloxane (PDMS)/silver nanowires (AgNWs) composites with microdomes and wrinkled surfaces. Our stretchable pressure sensor exhibits high sensitivity that changes negligibly even under uniaxial and biaxial tensile strains of 100% and 50%, respectively. This behavior is attributed to the microdomes responsible for detecting applied pressures being weakly affected by tensile strains while the isotropic wrinkles between the microdomes deform to effectively reduce the external stress. In addition, because our device comprises all-PDMS-based structures, it exhibits outstanding robustness under repeated mechanical stimuli. Our device shows strong potential as a wearable pressure sensor and an artificial crocodile sensing organ, successfully detecting applied pressures in various scenarios. Therefore, our pressure sensor is expected to find applications in electronic skin for prosthetics and human–machine interface systems.

SB08.03.10
Machine Learning Enabled Biofabrication Ruishan Liu, Sebastian Timmler, Yang Cao, Yifei Pan and Yan Yan Shery Huang; University of Cambridge, United Kingdom

The versatility and consistency of tissue engineering scaffolds could be vastly enhanced by converging different 3D printing, biofabrication, and data-driven techniques into a single process flow. Here, we report additive manufacturing of three-dimensional fibrous devices via integrating fused filament deposition and low-voltage electrospinning patterning. Polylactic acid scaffolds and gelatin fibres (with 3-5 um diameter and 150 um inter-fibre pitch) were printed automatically without manual stacking. Fibroblast cell line and brain cancer cell line were seeded onto the three-dimensional fibres. Cell attachment and proliferation experiments demonstrated good biocompatibility of the culture devices manufactured. We subsequently applied a machine learning model to find the correlations between operating parameters and fibre device quality. Future work involving multi-functional fibres deposition is proposed to accelerate the application of fibrous devices in tissue engineering and drug discovery applications.

SB08.03.11
Universal Coating for Spheroid Culturing on Arbitrary Materials Jingxian Wu and Haeshin Lee; Korea Adanced Institute of Science and Technology, Korea (the Republic of)

Three-dimensional culture of cells, allowing cells to interact with their surroundings in all dimensions, provides a more *in vivo* like microenvironment than traditional two dimensional cell culture. Organoids and artificial tissues or organs made by three dimensional cell culture are promising in both *in vivo* transplantation and *in vitro* experiments such as disease modeling and drug screening. However, existing three dimensional culture methods are always dependent on specific substrates or equipment, such as round-bottom culture plate, cell spinner and cell rotator. In addition, cell spheroids with uniform and controlled size are still difficult to make while are highly required in various applications to ensure the reliable and reproducible results.
In this study, we developed a universal coating for three dimensional cell culture. The coating was made with chitosan-gallol (CHI-G), and both somatic cells and stem cells automatically self-assemble into spheroids on it. CHI-G coating could be universally coated onto any materials in any shapes simply by immersing and shaking in the CHI-G solution for 48 hours. As a result, any materials coated with CHI-G coating could be substrates for spheroid culturing. We coated CHI-G onto the surface of regular two-dimensional cell culture platform (eg. cell culture plate with flat bottom and glassware for confocal) and inner-surface of three dimensional materials (eg. porous scaffolds and silicon tubes), and cell spheroids were cultured inside. Interestingly, cell spheroids cultured on substrates with different shapes could be applied in different scenarios. Porous scaffolds with spheroids cultured and imbedded inside is promising to be used as tissue engineering scaffolds. Silicon tubes with CHI-G coated on the inner-surface could be used as the device for continuous generation of spheroids. With the continuous injection of cell suspension solution and cell culture medium into the CHI-G coated silicon tube, spheroids could be generated and collected at the another end of the long silicon tube. The size of cell spheroids generated in silicon tubes is much more uniform than those generated on the two dimensional culture plate, which is mainly because of the restriction of round shape in tube. Furthermore, by changing the cell density of the cell suspension solution injected, spheroids with controlled size ranging from 60 um - 300 um could be generated, thus realizing fabricating spheroids with controlled size in a continuous and high-throughput way.

SB08.03.12
Tuning the Elastic Modulus of Ionically Crosslinked Alginate Hydrogels Elaine Nagahara, Yi Zuo and Luo Gu; Johns Hopkins University, United States

Introduction: Alginate hydrogels have unique mechanical properties that can be used to control biological responses in tissue engineering applications. Stiffness, for instance, has been shown to influence cell adhesion, differentiation, morphology, etc. in both 2D and 3D culture. The advancement of designing tissue-specific biomaterials therefore depends on our ability to chemically or physically tune these mechanical properties. In this study, we characterized how changes in calcium concentration influence the initial elastic modulus of ionically crosslinked alginate hydrogels independent of their varying stress relaxation rates. In addition, we observed that overmixing resulted in a reduced elastic modulus.
Materials and Methods: Alginate hydrogels (15 mm diameter, 2 mm thick) were formed by ionically crosslinking LF20/40 alginate with CaSO4. Alginate polymers of four different molecular weights were used to make hydrogels with four different rates of stress relaxation; lower molecular weight results in faster stress relaxation. The crosslinker concentration was adjusted (13.4 mM-54.9 mM) to tune the elastic moduli of the hydrogels to achieve the same modulus (7 kPa) independent of the various stress relaxation rates. After incubating the gels in medium for 2-3 days, compression testing was used to measure their elastic moduli.
The effect the amount of mixing has on the elastic modulus was evaluated on the fastest stress relaxing hydrogels. They were mixed five, seven, and eleven times before their moduli were characterized.
Results and Discussion: From the slowest to the fastest stress relaxing hydrogels, crosslinker concentrations of 13.4 mM, 26.8 mM, 37.8 mM, and 47.6

mM, respectively, were initially used. The two fastest relaxing hydrogels were much softer than 7 kPa; the fastest relaxing gels had an average elastic modulus of 2.1 kPa, and the second fastest relaxing gels had an average elastic modulus of 4.4 kPa, so the calcium concentration was increased for those two conditions. From slowest to fastest stress relaxation rates, the hydrogels had final average elastic moduli of 8.5 kPa, 7.2 kPa, 7.8 kPa, and 6.2 kPa with crosslinker concentrations of 13.4 mM, 26.8 mM, 42.7 mM, and 54.9 mM, respectively. While all four conditions had average moduli near 7 kPa, the target value, the second slowest relaxing hydrogels had the closest average elastic modulus to 7 kPa. The second fastest relaxing hydrogel had the lowest variability followed by the second slowest relaxing condition. This result may be explained by the fact that these two conditions had alginate solutions with intermediate viscosity (due to their intermediate molecular weights) and intermediate calcium concentrations compared to the slowest and fastest relaxing conditions. The slowest relaxing gels are made with alginate solution that is highly viscous, so it is difficult to combine the alginate solution with the crosslinking solution quickly enough to evenly mix the two, resulting in considerable variability. The fastest relaxing hydrogels are made with a high crosslinker concentration, which causes the alginate solution to crosslink quickly, again making it difficult to achieve more homogeneous mixing.
The effects of the amount of mixing of the alginate and crosslinker solutions were studied using the fastest stress relaxing hydrogels. They had average elastic moduli of 10.3 kPa, 6.2 kPa, and 5.8 kPa when mixed five, seven, and eleven times, respectively. There was a significant difference between the hydrogels that were mixed five times and seven times as well as the hydrogels that were mixed five times and eleven times. These preliminary results suggest that increased mixing results in lower elastic moduli. While enough mixing is desired to evenly distribute the crosslinks, overmixing can result in damaging the gel after crosslinks have formed, causing some to rearrange. Such rearrangement can give rise to an inhomogeneous gel with reduced elastic modulus.

SB08.03.13
Fabricating Stretchable Paper-Based Substrates with a Core-Sheath Structure for Papertronics Joab Dorsainvil; Binghamton University, The State University of New York, United States

Introduction: Paper-based bioelectronics, papertronics is an emerging technology for next-generation sensing and energy storage due to its significant material properties; including high surface-to-volume ratio, porous structure, biocompatibility, biodegradability, low-cost availability, foldability, and lightweight composition [1]. However, due to the intrinsic mechanical properties of cellulose, these stiff mechanics create undesirable substrates for stretchable bioelectronics. As a result, papertronics demonstrate limited conformability to the complex microarchitecture of skin and fail to exhibit deformation mechanics required to address the mechanical mismatch between rigid electronics and skin. To bridge the gap between papertronics and electronics skin (e-skin), herein we studied engineering strategies to exploit the material, chemical, and physical properties of paper (cellulose acetate or cellulose) amalgamated with the soft mechanics of a silicone elastomer (e.g., Dupont Liveo Soft Skin Adhesives) through coaxial electrospinning. The core-sheath silicone elastomer-cellulose acetate fibers mimic the extracellular matrix of human skin while maintaining the chemical surface properties of paper, enabling the integration of electronic components with existing manufacturing and printing techniques.
Materials and Methods: Cellulose acetate (CA) (MW = 30,000) and organic solvents (e.g., THF, DMF, Acetone) were purchased from Sigma Aldrich. The 7-9700 soft skin silicone adhesive (SSA) was gifted from DuPont. We used a coaxial needle with an electrospinning unit (MSK-NFES-3; MTI Corporation, CA) to create the fibrous mats while systematically testing operational parameters (e.g., feed rate, applied voltage, polymer concentration, etc.). Scanning electron microscopy (SEM) and confocal microscopy was used to analyze fiber alignment and core-sheath structure. Fiber diameter was measured with the utilization of ImageJ. Mechanical properties of the engineered fiber mat were evaluated by tensile testing with a 5 N load cell at a 5.10 mm sec^{-1} strain rate. Fourier transform infrared (FTIR) spectroscopy and Electron Dispersive Spectroscopy (EDS) determined the chemical and elemental characteristics of the fabricated stretchable papers.
Results and Discussion: SEM confirmed a fibrous structure of the fiber mat with an average fiber diameter of 1.38 ± 0.37 µm (n=250). Confocal microscopy revealed the core-sheath structure of the SSA core (blue) and CA sheath (red) via coaxial electrospinning. Energy dispersive spectroscopy (EDS) identified elemental peaks that reflect a core-sheath structure of an individual SSA-CA fiber. Using this stretchable paper, we were able to develop a microbial fuel cell by stacking three stretchable papers as an anode, membrane, and cathode material, which generated a max power output of 10.5 µW in PBS.
Conclusions: The coaxial structure of cellulose acetate and soft skin adhesive improves the stretchability of paper substrates up to 45% strain which is greater than the stretchability of conventional paper substrates (< 2%). Fabricating an MFC device using our stretchable paper demonstrates fabrication processing compatibility of these materials and thus shows the potential for future application in various ranges of papertronics while also sharing characteristics from soft bioelectronics.
Acknowledgments: This research is supported by the National Science Foundation (NSF; ECCS#2020486). We thank DuPont for donating the SSA elastomer.

SB08.03.14
A Technology for Rare Earth Elements Recovery by Genetically Engineered Elastin-Like Polypeptide Zohaib Hussain and Inchan Kwon; Gwangju Institute of Science and Technology (GIST), Korea (the Republic of)

Rare earth elements (REEs) are described as the vitamins of modern industry owing to their use in high-tech and clean-energy industries. Growing concerns of the unpredictable supply, possible health risks, and unsustainable extraction practices demand the development of green technologies for the selective extraction and recovery of REEs. Protein based polymers called elastin-like polypeptides (ELP) were genetically engineered for the selective and repeated recovery of REEs. ELP exhibits a fully reversible thermal coacervation behavior over multiple cycles of cooling and heating and was exploited to enable easy recovery of the bound REEs for repeated use. A lanmodulin protein which exhibits an unusually high affinity and selectivity for REEs was fused to the ELP to provide the highly selective nature to the biopolymers in the presence of higher concentrations of competing non-REEs. Selective binding of REEs was demonstrated at an expected ratio of 2 REE/biopolymer, and minimal binding of competing heavy metals (magnesium and zinc), even at a 300-fold excess, was observed. The REEs were extracted and recovered easily, enabling continuous reuse of the biopolymers. Utility of the biopolymers for REEs recovery from real world samples such as steel slag leachate (≈0.13 mol% REEs) was demonstrated with no decrease in recovery efficiency, the recovery efficiencies of non-REEs were minimal. Results establish the potential of engineered thermoresponsive protein-based polymeric materials as biotechnological tools for environmentally friendly extraction and recovery of REEs with a minimum carbon footprint, which is essential for the sustainability of metal life cycles, from mining to end-of-life to recycling.

SB08.03.15
Bio-Inspired Surface for Real-Time Coronavirus Detection Andrea Barbaglia, Andrea Valsesia and Pascal Colpo; European Commission Joint Research Centre, Italy

The COVID-19 global crisis shows that preparedness plans need to be developed, including methodologies enabling the early stage detection and identification of potential health threats, in order to contrast effectively future pandemics [1]. In particular, new technologies enabling the identification of the “latency period”, in which the virus is circulating among small communities but it is not yet recognized, are sought. Despite many efforts, current technologies for virus detection based on PCR or immuno-recognition show significant limitations. In particular, PCR cannot resolve the latency period, as

it requires typically 24 to 48 hours to analyse the samples. On the other hand, immune assays show much lower sensitivity, giving rise to a significant amount of false negatives.
In this project, we developed a new bio-inspired surface allowing highly sensitive, real-time virus detection in air samples. This system is a label-free virus detection platform, with single viral particle sensitivity. Its concept, inspired by biology, could give rise to a new generation of lab-on-chip devices for studying many different viral infections, not only related to the respiratory system.

SB08.03.16
The Molecular Structure and Mechanics of Beta Keratin (corneous Beta Protein) and Beta Fibril Chiang H. Lin, He Y. Kang, Chien Y. Pan and Chia-Ching Chou; National Taiwan University, Taiwan

In reptiles and birds, the claws, scales, feathers, and beaks are composed of beta keratin with exceptional material properties and outstanding performance. The beta keratin protein is a hierarchical structure, and a four-antiparallel-beta-sheet of 34 amino acids forms a monomer, the basic unit of materials. We focus on a bottom-up atomistic model of the beta keratin to study the molecular structure and the mechanics of the different hierarchical assemblies, including monomer, dimer, and fibril. For the monomer and dimer systems, the unfolding force in the dimer is larger than the monomer. Moreover, beta strands unfold at the monomer's pulling end for the dimer when the dimeric-sandwich structure remains intact in the peak force regime. For the fibril model, the unfolding peak force in shear loading is larger than in tensile loading. In shear and tensile loading, the initial unfolding of the fibril occurs in the interface of the interdimer, and the dimer structure remains when the fibril fails, suggesting that the dimer serves as a more stable building block of the beta keratin. We further compare our results with the mechanical properties of other proteins with similar beta-sheet structures and discuss how the hydrogen bond formation affects the mechanics between the materials. Our study provides insight into the quantitative comparison to the hierarchical structure of beta keratin at the atomistic level. The results could be further applied to designing bioinspired materials for the specific functions from a bottom-up perspective.

SB08.03.17
One Pot Synthesis of Reinforced Hydrogels with Bioinspired Complex Microstructures Using Magnetic Assisted Slip Casting Slocha Sapasakulvanit, Xin Ying Chan and Hortense Le Ferrand; Nanyang Technological University, Singapore

Composite materials with bioinspired microstructures are of high interest in numerous engineering applications. Indeed, thanks to their unique microstructure where inorganic particles are distributed in hierarchical patterns, unusual combinations of properties can be achieved, such as strength and toughness in nacre-like composites. However, contrary to many synthetic composites, nature produces its materials in a 'one pot' fashion where inorganic and organic components are assembled simultaneously. Also, water plays a great role in natural composites and is often absent in synthetic materials. Although examples of nacre-like hydrogels exist, they often contain a low concentration of reinforcing inorganic particles and more complex microstructures have not been realized. To address this issue, we developed a one pot synthesis approach where complex microstructures are built while the concentration of inorganic particles is getting concentrated. We study the capabilities and limits of the method and carry out mechanical testing to illustrate how the microstructure and presence of water can be leveraged to increase strength and toughness. To do so, we used an established method called magnetically assisted slip-casting (MASC) and adapted it to interpenetrated hydrogel matrices. MASC uses an external magnetic field that controls the orientation of magnetically responsive anisotropic particles in a water-based suspension, which is being removed through a porous mold. MASC therefore offers the capability of building complex bioinspired microstructures. Here, we used MASC to assemble Al_2O_3 microplatelets while polymerizing an interpenetrating network hydrogel made of poly-acrylamide (PAM) and poly(N-isopropylacrylamide) (PNIPAM). The resulting composites, containing around 40 vol% of Al_2O_3, show tunable alignment of microplatelets with polymer strands in-between when observed under SEM. From compression tests, aligned samples containing the hydrogel show higher strength and toughness than aligned samples without the hydrogel and randomly aligned samples, which were 6.5 MPa and 1000 kJ/m^3, respectively. Interestingly, thanks to the presence of hydrogel inside, the dried samples absorb moisture from air and show small recovery under compression. These results highlight the potential of MASC as a processing method to create reinforced hydrogels for development of novel materials.

SB08.03.18
***Euglena gracilis*–Derived Extracellular Vesicles as Skin-Regenerative Wound Healing Agents** Hwira Baek[1], Yuri Go[1], Seungpyo Hong[2] and Jin Woong Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]University of Wisconsin–Madison, United States

Extracellular vesicles are known as an important mediator for signaling in cell-cell communication and cellular processes including immune response and antigen presentation. Since extracellular vesicles contain therapeutic proteins, a variety of cell therapeutic strategies are developing while avoiding side effects such as low survival rate and immune rejection response associated with direct use of cells as a therapeutic agent. Most of the exosome studies conducted so far are based on animal-originated cells. Recently, there are challenging attempts to extract extracellular vesicles from other types of raw materials such as plant cells and microalgae. The approach to obtain extracellular vesicles from microalgae is of special interest because they have abundant biomolecules such as proteins, vitamins, minerals, and amino acids. This study proposes using microalgae containing carbohydrate bioactives, an Euglena gracilis–derived extracellular microvesicle (EMV_{EG}) system, for enhanced skin regeneration. The critical deformation ratio, 1.67, during cell extrusion enables us to tune the particle size of the EMV_{EG} at approximately 1 μm, thus satisfying the encapsulation yield of b-1,3-glucan and the cellular delivery performance. In vitro 5-bromo-2'-deoxyuridine and cell scratch assays revealed that the EMV_{EG} promoted the proliferation and migration of skin cells, thereby increasing both collagen synthesis and the expressions of proliferation-associated proteins. An ex vivo wound healing test using both artificial and porcine skin revealed that similar to that seen using b-1,3-glucan, the EMV_{EG} could substantially increase the cell population, expressing the proliferation-related protein, termed proliferating cell nuclear antigen. These results demonstrate that our EMV_{EG} system shows considerable potential in the field of skin regeneration. This technique is expected to design new types of extracellular vesicles that are applicable for skin regeneration in the pharmaceutical and cosmetic industries.

SB08.03.19
Investigation of the Self-Assembly and Nanomechanical Properties of Synthetic Amyloid Peptides Hannah G. Abernathy[1], Jhinuk Saha[2], Vijay Rangachari[2], Tristan D. Clemons[1] and Sarah E. Morgan[1]; [1]University of Southern Mississippi, United States; [2]The University of Southern Mississippi, United States

Amyloids are highly ordered, self-assembled protein aggregates most commonly associated with neurological diseases such as Alzheimer's and Parkinson's. However, their structural self-assembly into highly stable aggregates or fibrils has been shown to enhance cellular functions such as cell growth, bio-adhesion, and mechanical strength in various organisms. Synthetic biomaterial films or gels (inspired by natural amyloids) with tunable properties can be designed through peptide sequence changes that promote specific intermolecular interactions to form fibrils and strongly adhere to a

variety of surfaces. Although synthetic amyloid-based materials have shown promise, there is still a lack of understanding of the influence peptide structure has on adhesive and mechanical properties. For this work, a library of amyloid peptides was synthesized and their self-assembly was investigated under varying environmental conditions. The structural and nano-mechanical properties were characterized using circular dichroism (CD) spectroscopy and atomic force microscopy (AFM) in quantitative nanomechanical mapping (QNM) mode.

SB08.03.20
Development Biomimetic Functionally Graded Materials That Mimic Insect Self-Cleaning Organs Masanori Yoshida[1], Rikima Kuwada[1], Ito Shuto[2], Mikihiro Hayashi[1] and Daisuke Ishii[1]; [1]Nagoya Institute of Technology, Japan; [2]Nikkou Kasei Co. LTD., Japan

Functionally graded materials (FGMs) are the materials with varying composition and structure gradually over volume, resulting in corresponding changes in the properties of the materials. Unlike traditional composites of homogeneous materials, FGMs can compromise between the desirable properties of the component materials in the desirable places in the materials. The exoskeleton of insects is a notable example of FGMs in nature. Cuticle, the constituent material of insect exoskeleton, is characterized by a wide range of elastic moduli, which can be as high as metals and as low as rubbers, are integrated without boundaries to achieve high strength, lightweight, and multifunctions.
The purpose of this study is to analyze the correlation between the composition and functionality of exoskeletons developed through evolution and to apply the insights to the engineering of novel biomimetic FGMs.
Honeybee (*Apis mellifera*) was selected as a model organism in this study. The antennae of honeybees have many sensors like the five human senses, and when the antennae become contaminated, dirt accumulates on the surface sensors and interferes with the sensing function. Therefore, in order to maintain their sensing function, honeybees clean their antennae using antenna cleaners on their forelegs. We focused on antennae and its specific body parts, antenna cleaners, to investigate the correlation of its material composition and functionality.
A confocal laser scanning microscope (CLSM) was used to analyze the morphology and composition of antennae and antenna cleaners. The CLSM images showed that both antennae and antenna cleaners were not homogeneous in composition, but had a combination of soft and hard parts. The antenna cleaner was also found to have a sandwich structure with soft parts sandwiched between hard parts by observation at high magnification.
We analyzed the correlation between composition and functionality by quantitatively analyzing the efficiency of the antenna cleaners in removing contaminants from the antennae. The results showed that most of the contaminants were removed in a single cleaning and that contaminants were more easily removed closer to the tip than at the base of the antennae. Based on these results, we thought that the high removal rate of antenna cleaners can be attributed to the sandwich structure, and will try to fabricate biomimetic FGMs based on these structures. In this study, we attempted to develop the FGMs with a sandwich structure having a soft and a hard layer by using vitrimers which are a special type of cross-linked material with associative dynamic covalent bonded cross-links. Vitrimers can enhance interfacial adhesion and help fabricate FGMs because the bond exchanges are occurred by heat treatment. At last, we evaluated the interfacial adhesion of the fabricated materials by atomic force microscope (AFM) and the cleaning efficiency of the fabricated materials by independent test.

SB08.03.21
Evaluation of Fluid Resistance Reduction and Antifouling Function of Scale-Mimicking Surfaces Honoka Sugiyama and Daisuke Ishii; Nagoya Institute of Technology, Japan

In recent years, many studies have been conducted to improve the antifouling properties of surfaces in water and to reduce the fluid resistance, and it needs to elucidate the essence of the structural shape and surface composition that provide optimal properties. For example, fish scales are hydrophilic surfaces with riblet structures, and it is known that these structures produce a water layer in water flows to prevent adhesion of dirt and exhibit excellent self-cleaning ability. It is also believed that the microstructures of the scale surface are responsible for further improvement of antifouling properties and reduction of fluid resistance.
The purpose of this study is to evaluate the properties of shark mimetic surfaces that could lead to the elucidation of the unexplained mechanism of shark fluid resistance reduction. Measurement method of dynamic wetting in a liquid atmosphere that established in our laboratory was used to evaluate the antifouling properties and reduction of fluid resistance ability of microstructured surfaces in a water atmosphere.
In the past, surface properties under a water atmosphere were mostly evaluated only from static contact angles. However, surface properties under an air atmosphere are evaluated by combining static and dynamic wettabilities. The reason is dynamic wettability shows functional behavior that cannot be predicted from static wettability. Therefore, we have created a new experimental method to measure the dynamic wettability under a water atmosphere. The dynamic contact angles of air bubbles and oil droplets on the surface with tilting were measured in a water atmosphere.
Experimental substrates were a commodity polymer resin with a riblet structure mimicking shark scales. Hydrophilicity and hydrophobicity of the polymer surfaces were changed by fabricating a self-assembled monolayer after gold-ion sputtering. 10mL of ethanol solutions including hydrophilic and hydrophobic molecules with thiol groups were prepared and the gold-coated polymer substrates were immersed in each ethanol solutions for 3 hours. After immersion, the substrate was washed thoroughly with ethanol and dried naturally. 5 kinds of surface-modified substrates having various ratio of hydrophilic and hydrophobic molecules in outermost surfaces were fabricated and measured by the dynamic wettability analyze system in air or water atmospheres. In an air atmosphere, 15μL of water or 6μL of n-hexadecane was attached and the substrate was tilted. In a water atmosphere, 11μL of an air bubble or 20μL of n-hexadecane was attached and tilted.
As a result, the value of the contact angle when air bubbles were attached in a water atmosphere was larger than that expected from the contact angle when water was attached in an air atmosphere. In addition, the tilt angle required for the bubbles to leave the substrate was smaller. This is thought to be because of product of a water layer on the substrate surface by the shark's microstructure. This result suggests that the shark's scale surface prevents bubbles from attaching to the substrate and reduces fluid resistance by not creating surface irregularities.
Next, the contact angle value when n-hexadecane was attached in a water atmosphere was significantly larger than the value expected from the contact angle when hexadecane was attached in an air atmosphere. However, the tilt angle required for the n-hexadecane to leave the substrate was also large. This is thought to be because of the difference in the height of the microstructure on the shark-mimetic surface. This is thought to this difference in height cause a petal effect, which prevents the oil droplets from leaving the substrate surface even when the substrate is tilted up to 90°. These results strongly emphasize the necessity of measuring dynamic wetting behavior in water atmosphere and indicate the possibility of creating new functional surfaces through further clarification of the functions of organisms existing in water.

SB08.03.22
Evaluation of Metal Surfaces with Microscopic Mimetic Structures and New Forming Methods for Metal Substrates Sumire Isachi and Daisuke Ishii; Nagoya Institute of Technology, Japan

Despite being gill-breathing organisms, Ligia exotica are unable to swim. They breathe to use transported water without external energy caused by using capillary action of microscopic protrusion structures on the surface of their legs. Energy-less liquid-control surfaces not to require the external energy will be possible to create in mimicking of the structure of legs. In previous studies, it has been found that fabrication of microscopic protrusion structures on the polymer surface enables spontaneous liquid transport. However, while polymers are easy to form, there is a fear of deformation and softening above the glass transition temperature. Therefore, the goal of this research is to replace the material of the mimic substrate from polymer to metal. For this purpose,

we fabricated a metal film on the surface of a polymer substrate with a mimic structure and checked shapes of droplets on the surface to verify whether the substrate material could be replaced from polymer to metal. Next, a new metallization method was examined, in which a metal substrate is formed by thick plating on a porous polymer mold.
Polymer substrates with mimic structures were fabricated by pouring polydimethylsiloxane (PDMS) into polyethylene (PE) molds. Conical and triangular pyramidal protrusions were fabricated and arranged evenly spaced grid. We also examined whether the behavior of the droplets differed depending on the kinds of metal, such as gold and nickel, and the method of the metal coatings, such as gold vapor deposition and electroless plating. A 1.5 μL drop of water was dropped onto each prepared substrate and spreading of the droplet was observed. As a result, the spaces between the protrusions functioned as flow paths, and the droplets spread vertically and horizontally. Further, the droplet shape on the metal surface was like that on the polymer surface, with the droplet shape being nearly square on each substrate with conical structures, and nearly rectangular on each substrate with triangular pyramids. The aspect ratio was calculated from the wetting shapes of droplet at the point when wetting stopped. The aspect ratio was about 1.0 for cones and about 1.5 for triangular cones. The difference in wetting shape is closely related to the capillary pressure caused by the structure shape. In the case of conical protrusions, the distance between adjacent protrusions is equal from vertical to horizontal, and the strength of capillary pressure does not vary from vertical to horizontal. On the other hand, in the case of triangular pyramidal protrusions, the distance between adjacent protrusions is not constant, which causes a difference in the strength of capillary pressure. Even if the surface is coated with metal, the projection shape without any change, so the capillary pressure gradient is the same as on the polymer surface and the droplets have the same shape.
From the above, it was confirmed that the structure inspired by the legs of ligia exotica can be applied to metal surfaces. As the next step, we tried to fabricate a metal substrate with the mimic structure by the thick plating method. A thin metal film was fabricated on the surface of the mold, and electrolytic plating was utilized to obtain the metal substrate. To facilitate detachment of the mold after molding the metal substrate, the mold was made of flexible PDMS, but PDMS substrates have a very weak durability of the metal thin film fabricated on their surface. Therefore, the PDMS molds were immersed in a polydopamine solution to form a hydrophilic dopamine film on the surface of the molds, and metal films were fabricated on the dopamine film. As a result, the durability of the metal film against peeling increased and electrolytic plating became possible for thicker plating.

SB08.03.23
A Systematic Study of Polydopamine (PDA) Building Blocks Jiwon Lim, Shuo Zhang and Jinsang Kim; University of Michigan–Ann Arbor, United States

Since mussel-inspired polydopamine (PDA) was introduced in 2007, dopamine chemistry has attracted huge attention due to the surface-independent coating capability in mild alkaline conditions. Based on the unique binding property, PDA and its related analogues (i.e. phenolic polymers) have been adopted in various fields such as cell culture, composites, microfluidics, drug delivery membrane, and others. However, a comprehensive understanding of PDA is still limited owing to the abundant reactive sites of dopamine monomer. Due to the polymerization in multiple regions, PDA has various building blocks, which are composed of 5,6-dihydroxyindole (DHI) and dopamine units in various oxidation states. This complex structure restricts the systematic analysis of PDA.
Here, we rationally designed the series of PDA derivatives (DA1, DA2, DA3, DA4, DA5, DA6, and DA7) and synthesized its corresponding polymers to investigate the role of each building block as well as bonding mechanisms on different substrates. The chemical structures of each polymer are logically controlled by blocking or removing reactive sites that enable the successful isolation of building blocks of PDA. Therefore, a series of polymers is characterized to disclose a secret of PDA. First, molecular structures are confirmed by Nuclear Magnetic Resonance (NMR), Mass spectrometry, Fourier-transform infrared spectroscopy (FTIR), and X-ray Photoelectron Spectroscopy (XPS). Then we focused on the adhesion and cohesion mechanism of PDA derivatives that determine various coating modes on metal, silicon, polymers, etc. Based on the comparison among DA1, DA2, and DA4, we found both catechol and amine play a pivotal role in surface-independent adhesion regardless of the presence of DHI unit. In contrast, DA5, a catechol-only polymer, exhibits limited adhesion. Meanwhile, film and particle morphologies were examined by Scanning Electron Microscopy (SEM) and Atomic Force Microscopy (AFM) to reveal the aggregation mechanism that determines the surface roughness and the coating thickness. Finally, the optical properties of PDA are analyzed by UV-vis spectroscopy. We successfully figured out the origin of the dark brown color of PDA that is attributed to the combination of various oxidized modes of catechol quinone and DHI units.

SB08.03.25
NIR-Sensitive Polymer for Living Cell Photostimulation Vito Vurro[1], Ilaria Venturino[1,2] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

Optical methods represent a powerful and non-invasive tool to stimulate and probe biological matter. In particular, conjugated molecules and macromolecules have been demonstrated a great platform to interface with cells and living organisms.[1,2] This interaction has been promoted by materials high optical absorption/emission cross sections, versatility in chemical synthesis and low toxicity. Even though the efficiency of this approach has been demonstrated in neurosciences and cardiology,[3–5] the visible light absorption and the relative low penetration inside human body is still a critical point.

In this work, we evaluate the use of a novel NIR-absorbing organic bulk heterojunction (composed by a conjugated polymer and a small molecule) for living cells photostimulation. We initially developed a fabrication method to produce a diffuse interface shaping the material in the form of nanoparticles. Furthermore, we evaluate biocompatibility and photostimulation ability of the proposed blend.

Ideal Diffuse Reflector with Layered Structure Inspired by Animal Eyes Junyong Ahn, Seohan Yun, Taehyun Ryu and Junyong Park; Kumoh National Institute of Technology, Korea (the Republic of)

Many wild animals that are active at night have evolved to have layered eye structures that include thin reflectors to improve night vision. Light incident on the eyes of these wild animals is primarily absorbed by the retina, but some transmission loss is unavoidable. A naturally occurring biological reflector located behind the retina provides an opportunity for the retina to absorb residual light. In this presentation, we introduce a new type of diffuse reflector

with excellent scattering properties by applying the optical amplification mechanism resulting from the layered structure to the scattering behavior. The newly developed diffuse reflector has a biologically inspired layered structure of an ordered nanoporous medium serving as a scattering layer and a metallic thin film serving as a reflective layer. The secondary scattering caused by the reflector enables an exceptionally homogeneous diffuse reflection close to the Lambertian distribution, which is predicted through optical simulations (FDTD or FEM) and verified experimentally. Finally, we present several advanced optics, including smart contact lenses, by utilizing miniaturized diffuse reflectors through photopatterning.

SB08.03.27
A Highly Conductive, Dry Adhesive Patch with a Layered Structure for Independent Control of Adhesion and Conductivity Seohan Yun, Junyong Ahn and Junyong Park; Kumoh National Institute of Technology, Korea (the Republic of)

Since the 2000s, various types of dry adhesives have been proposed that mimic the hierarchical ciliary structure of gecko lizard's paws. Recently, deviating from the research paradigm of simply mimicking the adhesive function, conductive dry adhesives made of nanocomposites in which conductive nanomaterials (e.g., CNTs and AgNWs) are dispersed in an elastomeric matrix have been developed. Attempts have been made to acquire various bio-signals by using them as skin-mountable dry electrodes, but their sensitivity is still limited due to the inherent trade-off relationship between electrical conductivity and adhesion in typical nanocomposites. Here, we propose a functionally layered, highly conductive, dry adhesive patch through rational design of spray coating and molding processes. Lateral collapse of the high aspect ratio ciliary structures, which frequently occur during spray coating of conductive dispersions, can be avoided through optimization of the process sequence. The dry adhesion and electrical conductivity of the patch are independently controlled by the aspect ratio of the ciliary structure and the amount of spray-coated AgNWs. We have finally succeeded in realizing a large-area (4 in^2), defect-free dry adhesive patch that exhibits high electrical conductivity (< 100 ohms) and favorable normal adhesion (> 1.3 N/cm^2) to human skin. Several proof-of-concepts utilizing the developed highly conductive dry adhesive patch will be presented.

SB08.03.28
Self-Assembly of Glucose Containing "Janus-Type" Linear Dendritic Block Copolymers for Biomedical Applications Kevin Green[1], Mahesh L. Yaddehige[2], Davita L. Watkins[3,2], Lisa K. Kemp[1] and Sarah E. Morgan[1]; [1]The University of Southern Mississippi, United States; [2]The University of Mississippi, United States; [3]The Ohio State University, United States

The self-assembly of highly branched Janus dendrimers (JD) into Janus dendrimersomes (JDS) comprised of a hydrophilic/hydrophobic bilayer has shown promise for drug encapsulation and delivery. However, at higher concentrations and degrees of generation, the hydrophilic portions of traditional JDs have proved to be cytotoxic. To improve biocompatibility, JDs have been decorated with saccharide groups which assisted in the self-assembly of non-toxic Janus glyco-dendrimersomes (JGDS). It has been seen that, due to distinct peptide/polymer hydrogen bonding interactions, saccharide stereochemistry plays an important role in carbohydrate functions such as biological recognition, protein binding, and peptide aggregation pathways. This work explores using synthetic glycopolymers as the hydrophilic layer to amplify the structures' hydrogen bonding ability, potentially enhancing the self-assembly of JGDS. The stereospecific arrangements of the pendant saccharide groups may be used for cell targeting, lectin specific binding in the body, and to mimic the biological glyco-clustering effect. Linear glycopolymers were synthesized through reversible addition fragmentation chain transfer (RAFT) at different target molecular weights and coupled to polylactic acid (PLA) branched dendrons. While maintaining a constant molecular weight of the hydrophobic dendron and altering the hydrophilic segment, a multitude of nanostructures may be seen. Coupled conjugates and nanostructures were characterized through nuclear magnetic resonance (NMR), gel permeation chromatography (GPC), dynamic light scattering (DLS), transmission electron microscopy (TEM), and atomic force microscopy (AFM).

SB08.03.29
Chloroplast Encapsulation in Pectin Hydrogel via Thiol-ene Photo-Click Reaction Jaeho Choi, Jonghyun Shin, Youngwoo Han, Changhee Woo, Woojin Jeong, Jinho Hyun, Seon-Yeong Kwak and Chang Seok Ki; Seoul National University, Korea (the Republic of)

Bioengineered chloroplast has great potentials in carbon sequestration as well as production of biological molecules. Although plants are preferred in chloroplast engineering, isolated chloroplasts provide benefits in terms of environmental friendliness, abundant resource in nature, and cost effectiveness. For example, the isolated chloroplasts are more efficient than plant in carbon dioxide absorption, because they did not discharge carbon dioxide unlike plants. However, isolated chloroplasts lose their photosynthetic activity quickly. It requires a novel platform for chloroplast incubation as maintaining intactness of chloroplast. Chloroplast encapsulation in biopolymers or synthetic materials has been proposed to prolong the photosynthetic activity. Nevertheless, sufficient photosynthetic activity of encapsulated was not achieved in these attempts. In this study, we fabricated pectin hydrogels as a novel matrix, which mimicked plant cytosol for preservation chloroplast photosynthetic activity. Chloroplast-laden pectin hydrogels were formed via thiol-ene photo-crosslinking with pectin-norbornene and dithiothreitol. As a result of modulus measurement, the network integrity was maintained in incubation medium for 14 days. In pectin hydrogel, the encapsulated chloroplasts showed photosynthetic activity for 7 days, while the depletion of the photosynthetic activity of the chloroplasts suspended in the medium was relatively quick. The use of antioxidant even improved the photosynthetic activity in pectin hydrogel. Importantly, caffeic acid was most effective in preventing chloroplast damage by reactive oxygen species during photosynthesis. In conclusion, photo-crosslinked pectin hydrogel provided a suitable microenvironment for encapsulated chloroplasts, resulting in extended photosynthetic activity.

SB08.03.30
Vertically Aligned Peptide Nanotube Arrays as a Substrate for Neural Cell Differentiation Jordan Pagliuca, Alecsander Da Silva, Prathyushakrishna Macha and Milana C. Vasudev; University of Massachusetts Dartmouth, United States

There is an increasing need for biocompatible neuronal cell proliferation and regeneration scaffolds as regeneration of the neurite structures is slow and complex, which results in permanent nerve cell damage. Non-invasive electrical stimulation could potentially enhance neural cell proliferation and differentiation. Interfacing cells with biocompatible materials with electrical properties could be harnessed to introduce potential gradients across the cell membrane for neurological activation and repairs. The ability to stimulate individual neurons can impact the development of neural networks, and enhanced motor rehabilitation. The influence of voltage stimulation on human neural progenitor cells will be studied in-vitro using a high-density array of peptide-based nanotubes deposited via plasma-enhanced chemical vapor deposition (PECVD). Peptide-based building blocks containing aromatic amino acids that can self-assemble to form highly organized nanoscale structures with key functional properties such as biocompatibility, high aspect ratios, semi-conductivity, and stiffness will be used as the scaffold in this study. Tryptophan and tyrosine are aromatic amino acids known for their redox properties and roles in neurotransmitter synthesis. These structures have the ability to "carry" cells, which should result in functional modifications and an altercation in protein behavior, which can lead to highly polarized cells. Following the analysis of physicochemical properties of these peptide nanostructures, we studied the biological interactions and influence these scaffolds on human bone marrow neuroblasts and neural progenitor cells and subjected to an electrical stimulation. Prior studies have used carbon nanotubes scaffolds for subsequent electrical stimulation protocols, but their cytotoxicity makes their use in many biological systems undesirable. Electrical stimulation can induce the depolarization of the plasma membrane, as well as affect the function of membrane proteins, including enzyme activity and ion-transporting channels. These processes are most likely generated via the increased presence of reactive oxygen species (ROS), which are highly reactive molecules that have also been found to potentially act as an intermediate signal transducer

between neural cells for the purpose of cell differentiation. To test the same, MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) cytotoxicity studies, morphological cellular interaction imaging through SEM and confocal imaging, dopamine-enzyme linked immunosorbent assay, immunostaining for neuronal markers, and real-time polymerase chain reaction (q-PCR) for gene expression were carried out on the neuronal cells cultured on the synthesized peptide bioscaffolds.

Molecular Dynamics Simulations for RNA—Benchmark and Folding-Stretching Experiments Arpenik K. Kroyan and Sondre K. Schnell; Norwegian University of Science and Technology, Norway

The ability to accurately model RNA in computer simulations is important as potential applications are increasing with the mRNA vaccine platform. Various length and shape of RNA chains as well as their interactions with the environment, play an important role in medicine, origin of life and homochirality studies. The extensive experimental research on short RNA strings provide an excellent opportunity to utilize those structures as benchmarks for nucleic acids force-fields[1], and increase our understanding of structural and dynamic properties RNA strings. In recent years, *all-atom* molecular dynamics was used to show accurate RNA folding[2], dynamic protein-RNA binding[3] and plasticity of dsRNA duplexes[4] among others.
We have studied a series of RNA dinucleotides, tetranucleotides and hairpin loops, GAGA (IZIG) and UUCG (2KOC), with respect to structural stability in vacuum, and in presence of implicit- and explicit water, for AMBER-OL3, OPLS-AA/M, and CHARM-36. The results of J3 coefficients from dihedral angles were compared with experimental NMR data. For these models, AMBER recreated the structures with best agreement with experimental data, compared to OPLS and CHARMM. Based on results stretching-folding experiments were conducted on selected nucleotides in AMBER-OL3/bsc0 force field with explicit water and vacuum. The dynamic and mechanical properties of RNA chains were shown as a function of chain length and investigated further for size effects.

Glycopolyelectrolyte Nucleic Acid Transfection Agents to Address Tick-Borne Diseases Sarah E. Morgan, Kelli Stockmal, Latoyia P. Downs, Lisa K. Kemp and Shahid Karim; University of Southern Mississippi, United States

Black-legged ticks (*I. scapularis)* are vectors for a number of pathogenic bacteria, parasites, and viruses that affect both humans and livestock. Reducing the expression of key tick proteins, such as Selenoprotein K (SelK), through RNA interference is a promising approach to reduce pathogen transmission, but efficient delivery of nucleic acids to arthropods has proven challenging. Cationic glycopolymers have shown great promise with human cells as non-viral gene delivery vehicles to protect RNA and enhance delivery while also mitigating polymer cytotoxicity. Previous work established that glucose- and galactose-based glycopolymers exhibited variations in hydrogen bonding patterns in solution and resulted in different polymer-protein aggregation behavior. In this study, statistical acrylamide-based cationic glycopolymers with glucose or galactose pendent groups were synthesized by RAFT polymerization and the effects of saccharide pendent group and cationic monomer loading on polymer cytotoxicity, RNA complexation, and SelK gene knockdown in ISE6 cells were evaluated. All polymers exhibited low cytotoxicity, yet RNA/copolymer complex cell uptake and gene knockdown were highly dependent on saccharide structure and N:P (amino to phosphate groups) ratio.

SB08.03.34
The Role of Water Hydration States in a Bacteria Derived Biopolymer (EPS) /Nanoclay Hydrogel Ziyi R. Qian[1], Yi Yang[2], Yiwei Fang[3], Miriam Rafailovich[3], Kuan-Che Feng[3], Allen Bethancourt[3] and Steven Larson[4]; [1]Wayzata High School/Garcia Institute, United States; [2]Amador Valley High School/Garcia Institute, United States; [3]Stony Brook University, The State University of New York, United States; [4]U.S. Army Corps of Engineers, United States

With the onset of climate change, there is increasing concern about its effects on soil erosion. Microorganisms produce extracellular polymeric substances (EPS) that have shown potential in lessening the impact of environmental stressors. Specifically, a Rhizobium tropici (R. tropici) derived biopolymer has been reported to effectively strengthen the soil and mitigate soil erosion. Another study suggests that this biopolymer enhances the plant growth, proliferates leaf production and develops a compact root structure. To probe the mechanism behind EPS and its role in compacting soil and stimulating plant growth, we studied water retention and water-biopolymer, soil-biopolymer interactions.
EPS produced from Rhizobium tropici bacteria were ethanol precipitated into EPM(ethanol precipitated materials). 5%, 10%, 20% EPM biopolymers rehydrated with different kaolinite (EPK) concentrations were prepared. For each concentration of biopolymer and water mixture, four samples were made, containing clay that are 0%, 5%, 10%, and 20% by mass. The hydrated water molecules in polymer can be divided into three classes: free water, intermediate water (weakly bonded), and non-freezing water (tightly bonded). Differential Scanning Calorimetry (DSC) was carried out on EPS/EPK hydrated samples by a cooling scan from 25°C to -50°C followed by a heating scan to 25°C at 10 °C/min rate. The proportion of the freezable water (free water), non-freezable water was calculated based on the enthalpy of the melting peaks. The calculated non-freezable water in rehydrated EPS increased from 5% to 21% with higher EPS concentrations. This indicates a possible formation of a more compact structure when EPS is at high concentration. In the EPS/EPK system, the presence of a secondary melting peak at -8°C which is not observed in EPK/water mixture indicates that kaolinite in EPS induces a weakly bounded water layer. On the other hand, the percentage of non-freezable decreases as more EPK is introduced in EPS. A possible explanation of this is that the surface of kaolinite contact water diminishes the surface where water is enclosed by entangled biopolymer EPS. A model of nacre-like structure of EPS-EPK-EPS is supported by cryo-SEM images, and postulated to be the mechanism of EPS stabilizing the soil.
Next, the water retention behavior of EPS was investigated by two means. A low concentration of 1% rehydrated EPS water solution droplet ~ 5 µL was dropped on untreated silicon wafer. Subsequently, the droplet width and height versus time were measured at 3-minute intervals using the goniometer. Using water contact angle analysis, the rate of evaporation was determined for each sample at pH 5, 6, 7, 8, and 9 to simulate performance in real environmental soil conditions. Lastly, the water retention ability of biopolymer EPS was also assessed by taking one droplet~10 mg on a mass balance to record the rate of evaporation by mass over time.
Calorimetry data indicated that higher concentrations of biopolymer and percent of non-freezable water were positively correlated. Also, the addition of kaolinite changes the surface chemistry of EPS biopolymer. Droplet analysis of all three solutions revealed that the biopolymer evaporated height-wise, while water evaporated equally in height and width. Biopolymer solutions from varying pH all evaporated height-wise, with greater height change in solutions further from the original 7 pH solution. The formation of a complex from the EPS/EPK may explain its soil strengthening ability. These suggest

possible applications such as maintaining crop-soil moisture and aiding soil compaction during freeze-thaw cycles. Future goals are to solidify our understanding of the interaction between EPS and nanoclay with field tests, and properties that promote soil health, paving the way to an environmentally friendly future.

The Role Played by the Extra-Fibrillar Volume in the Structural and Mechanical Properties of Bones Amadeus Alcantara[1,1,2], Levi C. Felix[1,1], Douglas S. Galvao[1,1], Paulo Sollero[1,1] and Munir Skaf[1,1]; [1]University of Campinas, Brazil; [2]Massachusetts Institute of Technology, United States

Due to their complex network of distinct physical structures at different length scales, bones are responsible for body support, structure, motion, and several other functions for many different life forms. At the nanoscale scale, bones can be characterized as a fiber composite, i.e., a bundle of mineralized collagen fibrils surrounded by a matrix of water and calcium minerals. Different fractions of these constituents lead to different bone mechanical properties, making each bone unique, thus patient-specific.
It is well established in the literature that a higher concentration of mineral content leads to superior mechanical properties, i.e., stiffer bones. Moreover, most of the mineral content in bones, about 80%, is found in the matrix surrounding the fibrils, also labeled the extra-fibrillar volume (EFV). However, the literature presents models that include minerals in the intra-fibrillar volume (IFV) only, models that resemble mineralized collagen fibrils.
In this study, we investigate the structural and mechanical properties of all-atom bone molecular models constituted of type-I collagen, hydroxyapatite, and water through molecular dynamics (MD) simulations. Our models resemble fibers in bones, they encompass an EFV, explore different degrees of mineralization, and consider mineral content in both the EFV and the IFV, consistent with experimental observations presented in the literature. An analysis of the radial distribution function reveals that the local tetrahedral order of water is lost in similar ways in the EFV and IFV regions for all mineralized models, as calcium and phosphate ions are strongly coordinated with water molecules. By performing MD simulations using LAMMPS, we subject our models to uniaxial tensile loads and analyze their mechanical response. An analysis of the spatial stress distribution shows that the EFV plays a crucial role in the mechanical response of bone fibers. Both mineral and water content concentrate higher stresses when located in the EFV. Our results also corroborate the well-established finding that high mineral content makes bone stiffer. Our study reveals the EFV, which has been only recently contemplated in all-atom models, as an essential region to be considered when studying the mechanical properties of bones at the nanoscale. The mechanical properties of bones at such small scales can directly affect the properties at higher length scales, making bone more or less prone to fracture. Further development and studies on such elaborate all-atom models can give us additional insight into deformation and failure processes in bone, leading to a better understanding of bone diseases like osteoporosis.

SB08.03.36
Deposition of DNA onto Polymethacrylate (PMMA) Thin Film Gratings in Preparation for the Tagmentation of DNA with Tn5 Transposase
Rachel Y. Na[1,2], Deryn O'Leary[3,2], Hannah Saks[4,2] and Jonathan Sokolov[2]; [1]Friends Academy, United States; [2]Stony Brook University, The State University of New York, United States; [3]Our Lady of Mercy Academy, United States; [4]Walt Whitman High School, United States

In recent years, next-generation sequencing (NGS) has significantly advanced high-throughput sequencing. However, the NGS library preparation process can result in the loss of information regarding spatial organization, making reassembly difficult [1]. This study examines the application of depositing DNA onto flat polydimethylsiloxane (PDMS) samples that are then contact-printed onto PMMA-coated thin film gratings to suspend the DNA (bridging) and provide steric clearance for the Tn 5 transposase to simultaneously cut and label the DNA strands, a process termed tagmentation.

Samples of PDMS were dipped into solutions of λ DNA (NEB) in either DNase I reaction buffer (NEB) or Tris-EDTA (TE) buffer with sodium chloride to promote DNA adsorption to PDMS. Glycerol was also added to some solutions at a 1% (v/v) concentration to encourage the DNA to transfer from the PDMS to the Si grating. The samples were then imaged with a LEICA fluorescence microscope at 10x and 63x magnification. Samples with linearly stretched DNA were stamped onto a PMMA-coated Si wafer for various lengths of time up to 180 seconds using various weights up to 70 g. Results indicated that PDMS cured in a 60°C oven for 48 hours increased the adhesion of DNA onto the PDMS. However, this made it too difficult for the DNA to be stamped and transferred onto the Si wafer. PDMS that was cured for less time (4 hours) resulted in improved separation of adsorbed strands. Additionally, the NaCl made it difficult to transfer the DNA, causing the DNA to tear and not bridge. To address this problem, glycerol was added instead of salt to aid transfer. Furthermore, it was found that finer gratings were preferable because the DNA did not need to stretch as far to bridge. A solution with a concentration of 2.5 ng λ DNA per µL of DNase I reaction buffer with 1% (v/v) added glycerol deposited on PDMS and stamped across an 8.6 µm linear grating for 15 seconds and no weight yielded the best results thus far. Further development of this method will allow NGS to be analyzed with minimal risk of losing important genome information.

We acknowledge the Morin Charitable Trust for funding.

Lubricant Skin on Diverse Biomaterials with Complex Shapes via Polydopamine-Mediated Surface Functionalization for Biomedical Applications
Kijun Park and Jungmok Seo; Yonsei University, Korea (the Republic of)

Implantable biomedical devices require an anti-biofouling, mechanically robust, low friction surface for a prolonged lifespan and improved performance. However, there exist no methods that could provide uniform and effective coatings for medical devices with complex shapes and materials to prevent immune-related side effects and thrombosis when they encounter biological tissues. Herein, we developed a facile method to fabricate a robust lubricant-infused surface for biomedical devices which can be applied to any materials regardless of their size, shape, and composition. The application of the robust lubricant-infused surface to the materials was facilitated by a bio-inspired adhesive polymer, polydopamine (PDA) that activates the substrate surface to form stable covalent bonds with an engineered fluorinated polymer. The bio-inspired adhesive layer makes the application of the fluorinated polymer suitable for any type of surface with different material compositions and shapes. The resultant fluorinated polymer forms a very thin layer with a controllable thickness which exhibits swelling behavior in fluorinated lubricant forming lubricant-infused skin (L-skin). This allows the surface to maintain an adequate amount of lubricant even without the hierarchical structures of conventional liquid-infused surfaces. The smooth surface of L-skin provides superior anti-biofouling properties against viscoelastic fluids (blood, saliva, bacterial suspension) and solids (feces, biological tissues) which make L-skin suitable for biomedical applications. Unlike conventional self-assembled monolayer (SAM) based lubricant-infused surfaces, L-skin is both mechanically and chemically robust that maintains its functionality following swabbing, scratching, and sterilizations. To further investigate the wide adaptability of the

L-skin, various applications in which complex structure requires anti-biofouling properties were demonstrated in small diameter bioprinting needle (Inner diameter = 53 µm), microfluidic channels (Channel height 150 µm), and long narrow silicone tubing (2 meters long).

Biopolymers from a Bacterial Extracellular Matrix Affect the Morphology and Structure of Calcium Carbonate and Calcium Oxalate Crystals
David N. Azulay, Malachi Fraenkel, Ilanit Ben Simhon, Razan Abbasi, Sergei Remennik, Amarendar Reddy and Liraz Chai; The Hebrew University of Jerusalem, Israel

Biomineralization is a mineral precipitation process occurring in the presence of organic molecules and used by various organisms to serve a structural and/or a functional role. Many biomineralization processes occur in the presence of extracellular matrices that are composed of proteins and polysaccharides.
There is growing evidence that bacterial biofilms induce calcium carbonate mineralization, giving the system enhanced mechanical properties and that this process may be related with their extracellular matrix (ECM). In addition, recently, it has been suggested that bacteria and biofilms may play a role in calcium oxalate kidney stones genesis and development. Therefore, we explored, *in vitro,* the effect of the ECM components, the exopolysaccharide EPS, and the protein TasA on calcium carbonate and calcium oxalate crystallization. Moreover, the protein TapA was also tested on calcium carbonate.
By characterizing the crystals using SEM, micro-Raman spectroscopy, FTIR, XRD, FIB-SEM and SAED we showed that: In both the calcium carbonate and calcium oxalate, the biopolymers had an effect on the morphology of the crystals by the interaction of the polymers with specific planes. In the presence of the proteins the calcium carbonate crystals were composed of single crystalline domains that assemble together into spherulites (in the presence of TapA) or dumbbell-like shapes (in the presence of TasA). The TasA produced rounded microstructure crystals of calcium oxalate. The EPS, in addition, affected the structure of the crystals, producing less thermodynamically stable crystals, vaterite and calcium oxalate dihydrate.
Our results suggest the EPS affects the nucleation of calcium minerals unlike the proteins that seem to affect only the crystal growth. Biomineralization processes induced by bacterial ECM macromolecules make biofilms more robust and difficult to remove when they form, for example, on pipes and filters in water desalination systems or on ship hulls. Understanding the formation conditions and mechanism of formation of calcium carbonate and calcium oxalate in the presence of bacterial biopolymers may lead to the design of suitable mineralization inhibitors as well as better approaches for kidney stones treatments.

Photoinduced Polymerization of Small Molecules for the Formation of Organic Electronic Devices
Marios Savvakis[1], Xenofon Strakosas[1], Tobias Abrahamsson[1], Maciej Gryszel[1], Katriann Arja[1], Mathieu Linares[1], Ioannis Petsagkourakis[2], Eva Miglbauer[1], Marc-Antoine Stoeckel[1], Benjamin Granroth[1], Jennifer Gerasimov[1], Magnus Berggren[1] and Daniel Simon[1]; [1]Linköping University, Sweden; [2]RISE, Research Institute of Sweden, Sweden

The application of small self-organized molecular systems for the formation of soft and in situ electrodes with combined electrical and biochemical signals leads to new means of bridging the biology-technology gap. Such systems have seen increased attention over the past few years with their promise of entirely novel pathways for monitoring and augmenting biological function. In parallel, organic electrochemical transistors (OECTs) have become a standard tool in the field of organic bioelectronics as they can take full advantage of ion (biomolecule) injection from an electrolyte (or physiological system) to modulate the volumetric conductivity of an organic semiconductor channel. In addition, overall biocompatibility and synthetic tunability of the organic conductive polymers make OECTs ideal for interfacing with biological systems. In this work we have combined the burgeoning field of in situ formed organic electronic materials into an OECT platform by using light-assisted photocatalysis. Specifically, we used direct light excitation, as well as excitation of porphyrins, for the in situ photoinduced polymerization of conjugated oligomers. The conjugated oligomers, bis[3,4ethylenedioxythiophene]3thiophene sulfonic acid (ETE-S, *i.e.*, an EDOT-thiophene-EDOT trimer with a sulfonate ligand) and a variety of derivatives (ETE-CooNa and EEE-CooNa) were implemented, and the photoinduced polymer films were assessed by cyclic voltammetry as well as transistor output and transfer characteristics. The resulting OECTs exhibited excellent figures of merit (Transconductance, on/off ratio) with performance approaching PEDOT:PSS but with several advantages. We believe that these results pave the way for expanded in situ bioelectronics and even OECTs and similar component fully formed/fabricated in vivo.

SB08.03.40
Determining the Efficiency of Using Transposase (Tn5) to Cut DNA on PMMA Surfaces
Tanya Shukla[1], Yuhang Wu[2] and Jonathan Sokolov[3]; [1]Ardsley High School, United States; [2]Worcester Academy, United States; [3]Stony Brook University, The State University of New York, United States

DNA sequencing technology has been evolving throughout the past century, however, in the past 10 years, new approaches to sequencing technology, namely Next Generation Sequencing (NGS), have been emerging to make this process more streamlined. With current technology, sequencing reads are limited to the order of 10,000 base pairs or less. Therefore, cutting the DNA into sequenceable portions is vital [2]. After cutting, the spatial ordering of the DNA fragments is usually lost, requiring a complex computational method for reassembly. One novel solution to this problem is using soft lithography and hydrophobic surfaces instead of solution-based cutting [1]. This allows for preservation of DNA order.
In our experiment, Transposase (Tn5), an enzyme that cuts and moves DNA strands, was tested at its ability to fragment surface-immobilized DNA on a PMMA surface. Tn5 solution was made by mixing transposase solution, Tagmantase buffer, and water of varying concentrations. Silicon wafers were cut into 6 mm wide and 15 mm long samples to be spun cast with 70 nm thick films of PMMA. The wafers were dipped into DNA solution and later in Tn5 solution for the DNA-cutting reaction. Using a Leica Fluorescent microscope, images of the SyBr Gold labeled DNA strands were taken and then used for data analysis. To test the efficacy of using SDS and Proteinase K as a Tn5 removal agent, this experimental procedure was repeated with different concentrations of Tn5 solutions (0.0008 mg Tn5/mL, 0.0016 mg Tn5/mL, and 0.0032 mg Tn5/mL) for both SDS and Proteinase K reactions. Additionally, Proteinase K reactions were repeated at both room temperature as well as 55 degrees C.
The results indicate that after Proteinase K removed Tn5, DNA strands were cut into linear segments with ordering preserved; while with SDS, the DNA strands were curled up and in disorder. The trials with Proteinase K were analyzed using ImageJ. It was found that DNA strands were fragmented after the Tn5 reaction. At 0.0016 mg Tn5/mL, room temperature and heated, the strand length averaged 1.87 µm and 0.91 µm respectively after the Tn5 reaction. Before the Tn5 reaction, the strand lengths averaged 16.20 µm and 16.29 µm respectively. At 0.0032 mg Tn5/mL, room temperature and heated, the strand length averaged 0.71 µm and 1.05 µm respectively after the Tn5 reaction. Before the Tn5 reaction, the strand lengths averaged 17.91 µm and 12.28 µm respectively. This indicates that Tn5 can effectively fragment DNA on surfaces when the transposase is pre-loaded onto the DNA in solution before surface adsorption.

We would like to acknowledge the Morin Charitable Trust for funding.

Self-Polymerized Plant Polyphenols as Antibacterial Agents Zhen Tian and Young Jo Kim; University of New Hampshire, United States

Polyphenols are a class of biologically active compounds that are derived from plant-based natural products such as fruits, vegetables, coffee, and tea. Polydopamine, dopamelanin, gallic acid, pyrogallol, and tannic acid contain the representative chemical features of polyphenols which can form coordination bonding with protons, ions, or electrons via redox reaction. Due to their physical, chemical, and electrochemical properties, polyphenols have attracted significant interest in various research areas, including charge storage, heavy metal ions removal, or drug delivery. Recent studies have shown that phenol-based polymeric particles can inhibit bacterial growth and prevent biofilm formation by releasing the reactive oxygen species in aqueous environment. However, the surface disruption of polymers in complex surroundings and the poor efficiency due to the low surface area to volume ratio of the coating remain the potential challenges that shorten the long-term stability.
Herein we report the facile synthesis of a free-standing poly(pyrogallol) (1,2,3-trihydroxybenzene, PPG) polymer that can be used as an environmental friendly and efficient antibacterial agent. PPG consists of homogeneous nanofibrous microstructure containing the chemical moieties that allow the reversible redox reaction via catechol or gallol groups. Fourier transform infrared spectroscopy and X-ray photoelectron spectroscopy corroborated the formation of the ether functional groups that are induced by the polymerization between the hydroxyl group and the carbons of the benzene. The antibacterial activity of PPG was examined using the gram-negative *Escherichia coli*. The antibacterial activity was quantitatively evaluated by a colony count method after incubating the *E. coli* with the concentration of 1.5 X 10^5 CFU mL^{-1}. The survival rates were compared with the natural melanins extracted from *Sepia Officinalis* that contains the catechol groups. PPG achieved 63.1% and 99.9% *E. coli* inhibition within 30 min and 4 h of incubation, which is approximately 50% higher than the catechol-containing melanins. This is mainly due to the higher density of phenolic compounds available in PPG to produce ROS in the aqueous environment. The results herein suggest that PPG exhibits potential to be utilized as functional antibacterial agents for a variety of applications in biomedical and environmental engineering.

SB08.03.42
Determining the Extent to Which Sodium Dodecyl Sulfate Could Desorb DNA from Flat Surfaces Derek Days[1], Ohm P. Patel[2] and Jonathan Sokolov[3]; [1]Noble and Greenough School, United States; [2]Patchogue-Medford High School, United States; [3]Stony Brook University, The State University of New York, United States

The use of Tn5 transposases is essential to Next Generation Sequencing (NGS) as it is required to cut DNA into shorter and more manageable lengths while also labeling the shortened strands to be later rearranged into the original sequence[1]. However, Tn5 transposases have to wrap around DNA in order to cut, posing an issue for surface-adsorbed DNA samples[2]. In recent transposon experiments, evidence suggests that sodium dodecyl sulfate (SDS), which is already used to remove the Tn5 transposases from DNA molecules after cutting is complete, could desorb the DNA from a flat surface, specifically polymethyl methacrylate (PMMA) spun-cast on silicon. Finding a method of desorbing DNA from a flat surface remains important because it provides an opportunity to increase the efficiency and decrease the cost of NGS in fields such as medical diagnoses and forensic science. Although there are already existing methods of desorbing DNA, they are cumbersome and time-consuming. In this study, we aimed to investigate whether or not SDS could desorb surface-adsorbed DNA. To do this, 0.286% DNA in DNAse buffer dyed with SYBR Gold was prepared and machine-dipped onto PMMA spun-cast onto silicon. After doing so, the DNA sample was imaged under a fluorescence microscope under 63x magnification to determine the quality of the sample. Once the quality was confirmed, the sample was placed into a well containing 350 µL of varying concentrations of SDS in water. This way, half of the wafer would have been treated with SDS while the other side would serve as a control. The wafer, still in the well, was then placed into a column heater and heated at 55°C for 20 minutes. Once finished, the wafer was once again placed under the microscope for analysis. Initially, it was thought that the SDS did in fact desorb the DNA from the surface as no DNA could be seen on the SDS-treated side. Microscope images showed a distinct border between the SDS-treated side, where no DNA was visible, and the non-SDS side, where DNA was clearly visible. However, after re-dyeing the SDS-treated side in SYBR Gold, DNA was once again shown on the surface. This implied that SDS could not desorb surface-adsorbed DNA but could remove SYBR Gold dye from DNA. Although SDS likely cannot desorb surface-adsorbed DNA, future experiments will be done on Triton X-100 instead in an effort to find an easier method of desorbing DNA from flat surfaces.

Rheological and Toxicological Properties of the Extracellular Polymeric Material (EPM) Produced by Rhizobium Tropici ATCC 49672 Eliana Samuels[1], Maytal Chelst[1], Gabriel Rothman[2], Marcia Simon[3], Miriam Rafailovich[3], Kuan-Che Feng[3], Yiwei Fang[3], Stephen Walker[3] and Steven Larson[4]; [1]Yeshiva University High School for Girls, United States; [2]The Frisch School, United States; [3]Stony Brook University, The State University of New York, United States; [4]ERDC, United States

Soil erosion is a significant issue costing the U.S. economy forty-four billion dollars per year and increasing water pollution (Sulaeman & Westhoff, 2020). Typical erosion treatments use toxic, non-biodegradable petrochemicals that pose threats to surrounding ecosystems and agricultural efforts. An alternative may come from symbiotic Rhizobium tropici bacteria which secrete gel-like biopolymers known as EPS that can then be ethanol precipitated into EPM (non-dialyzed EPS) (Maróti & Kondorosi, 2014). EPS soil treatments have been tested by the ERDC and results indicate that the soil was strengthened substantially, reducing erosion. REF Analysis of the vegetation showed that plant root systems were larger, which was postulated to be a contributing factor to the soil stability increase. The role of bacterial infection and nitrogen sequestration in root development has been extensively studied, but less is known about the role of bacterial EPS in strengthening the soil via gelation or other interactions with the soil particles. In order to study the possible mechanisms through which the EPS can strengthen soil, we performed a series of experiments where the biopolymer was precipitated in alcohol and subsequently rehydrated. In this manner no bacteria was present and only the material properties of the EPS are probed.
The rehydrated EPM's rheology behavior with various concentrations was tested on DHR-2 rheometer oscillation-amplitude and oscillation-frequency mode. The results show that upon rehydration the polymer formed a gel at concentrations of 2% with a modulus G'=20Pa. The modulus increases approx. linearly with concentration to a value of G'=300Pa at a concentration of 20%. In each case a distinct yield point was observed, at 20-170Pa between the lowest and highest concentrations measured, where G' approached zero. The systems were rested for 30 min without an applied force and the amplitude scan was repeated. The gels completely recovered in each case after at least three cycles, indicating that in each case physical gels were formed and then reformed when the forces were removed. Measurement of the gels in the frequency mode indicated shear thinning behavior in all cases at room temperature. The chemical structure of the gels was investigated using Raman spectroscopy and TGA. RAMAN spectroscopy indicated that the EPM was

composed of polysaccharides with a high content of potassium dihydrogen phosphate. TGA showed that ~50% of the gel was removed at T<100C, and another 10% was removed at T<257C. This is consistent of a gel with large water content, while the additional 20% indicated strongly adsorbed water and a high degree of water retention. A surprisingly high fraction, ~30% of the gel was stable to temperatures of at least 800C. This temperature is higher than organic polymers, and was attributed to the dihydrogen phosphate salts. RAMAN spectroscopy of this residue confirmed this where one large and narrow peak was observed consistent with a crystalline compound formation. Auxiliary testing for the antibacterial, antiviral, and cytotoxic effects of the EPM were performed to determine the safety of EPM application into soil. Results indicated that EPM is neither antiviral nor antibacterial. Application of EPM into human fibroblast cultures indicated no adverse effects on the doubling time nor any other function of the tissue.

Extraction and Characterization of *Stichopus* cf. *horrens* Collagen with Potential Stimuli-Responsive Properties as Collagen-Based Films Kim Marie D. Sisican, Vicenzo Paolo M. Torreno, Eizadora T. Yu and Marlon T. Conato; University of the Philippines, Philippines

The mutable collagenous tissue (MCT) of echinoderms has been extensively studied because of its mechanism that allows rapid change in its stiffness and extensibility. Collagen is also the most abundant protein in the extracellular matrix and provides its main structural component. Thus, research on its physicochemical and mechanical properties will be useful for identifying its potential for cosmeceutical and biomedical applications. Moreover, the unique properties of MCTs can also be an inspiration for the design of new smart functional biomaterials. Sea cucumbers, like other echinoderms, also have MCTs that respond according to different environmental stress conditions. There are many sea cucumber species found in the Philippines, but only a few are studied well. Among the less studied ones is the *Stichopus* cf. *horrens*, which is also commonly found in other Southeast Asian countries. In this study, we have extracted the collagen from *S. horrens* and characterized its physicochemical properties. Pepsin-solubilized collagen (PSC) was prepared, and using SDS-PAGE we observed the presence of the ß, α1, α2, and α(1)3 chains at 75 to 250 kDa, typical for Type I collagen. Protein identification and sequence analysis were also performed. Protein blast search showed the presence of sequences commonly found in Type VII and XII collagen. This suggests that *S. horrens* collagen is heterotypic, consistent with related proteomic studies of collagen from other species. The maximum absorbance of PSC was also measured at 212 nm using UV-Visible spectrometry, attributed to the presence of multiple peptide chains of collagen. The susceptibility of collagen to heat is another way of determining its potential application. We identified a higher maximum transition temperature (T_m = 56 °C) for the PSC extracted from *S. horrens* using differential scanning calorimetry (DSC) as compared to other sea cucumber species. The T_m of collagen correlates to its stability and durability, suggesting that *S. horrens* PSC has higher thermal stability—uncharacteristic of marine-derived collagen. After the physicochemical characterization, the extracted collagen was used for the facile preparation of collagen-based films through the solvent casting method using phosphate-buffered saline at pH 7.4 as the solvent. The FTIR spectra of the films showed the characteristic peaks of collagen—Amide A (3341 cm^{-1}), I (1657 cm^{-1}), II (1553 cm^{-1}), and III (1241 cm^{-1}). AFM imaging also showed that the collagen fibers making up the films have a diameter of 145 ± 31 nm. Due to the high thermal stability of *S. horrens* PSC based on the DSC findings, the thermal response of the films was also analyzed using thermomechanical analysis (TMA) at a constant applied force of 0.1 N. Here, we observed that thermal degradation only starts at a temperature of >190 °C. Meanwhile, at lower temperatures of 100 and 150 °C, the films changed from translucent and soft into an opaque and brittle physical state due to the removal of moisture. Subsequent AFM images showed that the collagen fibers are still present and intact after TMA. Upon exposure to ambient temperature (25 °C) for 10 min, the collagen-based films returned to their original translucent and soft state due to the reabsorption of moisture. TMA analysis at lower temperatures was repeated at least three times before the films started degrading based on apparent discoloration. This study shows that *Stichopus* cf. *horrens* is a potential source of collagen that can be prepared into useful smart biomaterials, such as collagen-based films stable at higher temperatures, for food and biomedical applications.

Bio-Inspired Macromolecular Ordering in Elastomer Composites to Achieve Enhanced Contact Electrification Andris Šutka, Linards Lapčinskis, Osvalds Verners, Liva Germane and Juris Blums; Riga Technical University, Latvia

Polymer contact electrification (a.k.a. triboelectrification) is crucial for mechanical energy harvesting in triboelectric nanogenerators (TENG), droplet generators, and ferroelectrets [1]. Polymer triboelectrification can be enhanced in several ways, including surface functionalization, adjustment of the electronic and physicochemical properties or by increasing the specific contact area via nanostructuring.
Contact electrification can be observed also in nature. Spider ballooning is one of the most exciting natural phenomena. Using electrified strands of silk, spiders can travel in the airstream for distances of hundreds of kilometers [2]. Spider silk is electrified due to contact and friction with airborne particles or during the spinning process. A strong surface charge is required to ensure the electrostatic flight, holding the weight of a spider even in the absence of any air stream.
This work presents triboelectric polymer composites with structure inspired by the macromolecule ordering in spider-silk leading to strongly enhanced contact electrification. The ordering in polyether block amide (PEBA) is induced by the addition of inorganic goethite (α-FeOOH) nanowires that form hydrogen bonds with the elastomeric matrix. The addition of as little as 0.1 vol% of α-FeOOH into PEBA increases the surface charge by more than order of magnitude. Hydrogen bonds between α-FeOOH and PEBA promote the formation of inclusions with higher degree of macromolecular ordering, analogous to the structure of spider silk. The formation of these inclusions is proven *via* nanoindentation hardness measurements, and correlated with H-bond induced changes in structure shown by fourier transform infra-red spectroscopy, and direct scanning calorimetry. Theoretical studies reveal that the irregularity in hardness provides stress accumulation on the polymer surface during contact-separation. Subsequent molecular dynamic studies demonstrate that stress accumulation promotes the mass-transfer during contact electrification. The proposed macromolecular structure design provides a new paradigm for developing materials for applications in mechanical energy harvesting.

Investigating Virus-Induced Thrombogenicity at the Molecular Level Ekam Singh[1], LeAnn Tai[2], Keonhyoung Kim[3], Matthew Lu[4], Miriam Rafailovich[5], Kuan-Che Feng[5], Adam Hansen[5] and Kao Li[5]; [1]Washington High School, United States; [2]Arnold O. Beckman High School, United States; [3]Jefferson Forest High School, United States; [4]Chapel Hill High School, United States; [5]Stony Brook University, The State University of New York, United States

Fibrinogen is a plasma-soluble glycoprotein that is responsible for thrombogenesis, the formation of blood clots. While thrombogenesis is an important process, excessive blood coagulation can cause serious health conditions such as strokes, heart attacks, and embolisms. Viruses such as SARS-CoV-2 and H1N1 can cause thrombosis in host vascular systems, despite endothelial cells lacking the necessary receptors for SARS-CoV-2. Epithelial cells surrounding blood vessels are susceptible to viral infection, and once infected, produce lipids in and around cells. When blood vessels are damaged, infected cells and conditioned media enter the bloodstream, and provide ample hydrophobic surfaces for fibrinogen to polymerize onto and for thrombosis to occur. Here a model is proposed to explain the correlation between virus-induced lipid secretion and fibrinogen fiber formation.
To study the formation of fibrinogen fibers on hydrophobic surfaces, solutions of polybutadiene, polystyrene, and polylactic acid were spuncast onto silicon wafers for their thrombogenic and biocompatible nature. Fibrinogen was added to the films, imaged through AFM, and analyzed for morphological properties. To test lipid production, Madin-Darby canine kidney (MDCK-2) cells and human umbilical vein endothelial cells (HUVEC) were plated and infected with the H1N1 virus. Human gingival keratinocytes as models of epithelial cells were also infected with H1N1 through direct infection and conditioned media taken from previous MDCK-2 cultures. After fixing, cultures were stained for actin, lipids, and DNA, and imaged using EVOS microscopy. The images showed multiple lipid droplets concentrated within the MDCK-2 and the gingival keratinocyte cells following infection. Conditioned media and infection in MDCK-2 and HUVEC cultures yielded increases in lipid droplets of 35.13% and 15.02%, respectively. On the HUVEC cultures no brightly stained droplets were visible following direct infection. Only large diffuse regions of green stain were visible following exposure to the conditioned media. Some of these large domains were also found in the epithelial cell cultures following infection, and were likely formed when the lipid droplets were released into the media following the disintegration of infected cells. These diffuse lipid rich regions were then carried from the conditioned media onto the surface of the endothelial tissue after exposure to the conditioned media, demonstrating that the hydrophobic secretions of an infected culture spreads to nearby tissue at the systemic scale.
Polyvinylpyrrolidone (PVP), a hydrophilic surface, will be treated with conditioned media taken from control and H1N1-infected MDCK-2 cultures. According to the model, the non-infected sample should remain relatively hydrophilic, while the infected sample should become more hydrophobic, as measured through contact angle analysis. It is hypothesized that fibrinogen fibers will form on the infected hydrophobic polymer surface and not form on non-infected hydrophilic surfaces. This project reveals that fibrinogen fibers after viral infection are due to the lipid showers in epithelial tissue that make the environment suitable for blood coagulation, which provides insights into the treatment of COVID.

An On-Demand Bioresorbable, Ultrasound-Mediated Triboelectric Nanogenerator as an Energy Solution of Electronic Medicine System Dong-Min Lee and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

Over twenty million people in the United States have so far benefitted from implantable medical devices (IMDs) intended for different purposes; therapeutic, diagnostic and rehabilitation. Efforts to improve IMDs have seen the development and use of transient materials, which dissolve in the body after a programmed lifetime, therefore, eliminating the need for secondary surgery to remove the IMD. However, the conventional lithium-ion batteries are non-transient, therefore limiting the use of transient IMDs. Recent advances in energy harvesting technologies have provided transient materials based options with great potential to power transient IMDs. Photovoltaic and thermoelectric in vivo energy harvesters were introduced as sources of power for transient electronics, but their use is limited by lack of light sources, and constant body temperature, respectively. On the other hand, the biodegradability of piezoelectric catalysts is unverified limiting the use piezoelectric nanogenerators in transient electronics. Triboelectric nanogenerators (TENGs) are an emerging technology with great potential for powering transient IMDs, offering a number of advantages including wide material selection and minimizable system scale. Conventional transient TENGs exploit passive operation, referring the circumstances in which their transience starts when implanted and deployed inside the body. Due to the long timescale from the loss of energy generation to the complete transience, undesirable burdens and potential hazards can be induced to the patients.
Here, we demonstrate a new protocol by establishing a remotely stimulated transience mechanism using biologically certified ultrasound sources. To demonstrate the feasibility of ultrasound-triggered TENGs, we developed a fully biodegradable and implantable TENG (FBI-TENG) consisting of a magnesium (Mg) electrode layer, poly(3-hydroxybutyrate-co-3-hydroxyvalerate) (PHBV) membranes, and a poly(ethylene glycol)-based polymeric composite (PHBV/PEG) layer. We aimed to determine the efficiency of the FBI-TENG by solely altering the degree of ultrasound intensity. The ultrasound-triggered transient process which originated from high ultrasound intensity, was initiated by the microporous structure of the PHBV encapsulation layer developed using finite element method (FEM) simulation that facilitates the distribution of intensified acoustic pressure inside the micropores. When the FBI-TENG was inserted into a porcine tissue, we observed a significant reduction in electrical output 20 minutes after applying high ultrasound intensity. Our findings support that ultrasound, a verified non-invasive and reliable power source, can be used for powering IMDs and for provoking device dissolution after a programmed lifetime.

8:30 AM SB08.04.01
Self-Assembled Peptides Form a Highly Catalytic Interface on Graphite Wei Luo[1], Hironaga Noguchi[1], Chen Chen[1], Yoshiki Nakamura[1], Chishu Homma[1], Oleksii Zozulia[2], Ivan Korendovych[2] and Yuhei Hayamizu[1]; [1]Tokyo Institute of Technology, Japan; [2]Syracuse University, United States

De novo-designed peptides emerged to form nano-fibrils in solution and exhibited chemical reactions with activities comparable to natural enzymes.[1] These materials are often referred to as catalytic amyloids.[2] Their versatility in productive accommodation of various cofactors,[3] highly designable sequences, and simple molecular structures that can be produced in large amounts at low cost offers an exciting possibility for creating highly efficient hybrid materials for different electrochemical applications. Although all the currently reported applications of these catalytic peptide amyloids were demonstrated in solution, there are no attempts to incorporate these into complex assembled structures on solid surfaces for electrochemical applications. We hypothesized that assembling catalytic peptides on a graphitic surface would fully harness the catalytic potential of peptide assemblies in an electrochemical manner and create a highly functional interface capable of efficiently catalyzing practical chemical reactions. There have been multiple reports demonstrating peptide self-assembly on graphite surfaces.[4,5] These catalytic amyloids may have the ability to form self-assembled structures on the surface. In a proof-of-concept study, we focused on peroxidation reactions due to their potential applications in various processes ranging from cancer

therapy, and wastewater purification, to polymer production. Especially, the enhanced capability of accelerating the reduction of H_2O_2 is essential for constructing the electrocatalysts of various peroxidation applications due to its role as an electron acceptor in most peroxidase reactions. Furthermore, peroxidase activity in natural enzymatic and model systems has been extensively studied, providing important activity and stability benchmarks.
To test our hypothesis, we employed several peptides found to self-assemble in the presence of hemin into catalytic amyloids with high peroxidation activities in solution. Among them, we selected highly active (LMLHLFL, LILHLFL) and moderately active (LHLHLFL, VHVHVYV) peptides in this work.[6] First, we investigated their ability to form highly ordered nanostructures on graphite surfaces. Atomic force microscope images revealed that all peptides could form monomolecular-thick peptide self-assembled thin film on graphite surfaces. Hemin molecules were successfully immobilized on the peptide thin film on the graphite surfaces. The immobilized hemins on peptides exhibited their catalytic activities under electrochemical measurements over H_2O_2.
Additionally, we introduced 3,3',5,5'-tetramethylbenzidine (TMB) to demonstrate the model of peroxidase reactions for multiple substrates and analyze the efficiency during the electron transfer process. In both catalytic reactions, the highly ordered nanostructures of peptides with hemins promoted peroxidation with kinetic parameters approaching the natural enzymes in the same reaction at a fraction of the cost. The robust structure, ease of production, and high peroxidation activities of our hybrid system make them notable interfaces for electrocatalysis.

Squid-Inspired Polypeptides as Dynamic Self-Healing Materials Abdon Pena-Francesch; University of Michigan, United States

Squids have developed predatory teethed structures in their suction cups that are composed of structural proteins. Unlike other hard tissue in cephalopods, these biological materials are stabilized by β-sheet nanocrystalline structures that give rise to high-strength materials without mineralization. Here, we introduce cephalopod-inspired polypeptides with a repetitive diblock design (alanine-rich and glycine-rich blocks) that self-assemble into β-sheet nanocrystalline structures. These β-sheet nanocrystals act as physical and reversible hydrogen-bonded crosslinks in supramolecular protein networks, where β-sheet size and network topology regulate the physical properties. We demonstrate the dynamic properties of squid-inspired polypeptides in self-healing networks with healing strength and kinetics (~25 MPa strength after 1 second of healing) surpassing those typically found in other natural and synthetic soft polymers. This family of proteins and their biosynthetic derivatives open new opportunities in bioinspired design for adaptive functional materials, and we demonstrate their potential in actuator prototypes for applications in soft robotics and wearable technology.

9:00 AM SB08.04.03
Surfaces with Instant, Persistent and Broad-Spectrum Antimicrobial Efficacy Taylor Repetto, Abhishek Dhyani, Dylan Bartikofsky, Carmen Mirabelli, Zhihe Gao, Sarah Snyder, Geeta Mehta, Christiane E. Wobus, J. Scott VanEpps and Anish Tuteja; University of Michigan, United States

Surfaces contaminated with infectious bacteria and viruses contribute to transmission and pose a significant threat to global public health. Common liquid spray disinfectants kill microbes in seconds to minutes, yet they require reapplication often. Surfaces that rely on heavy metals or metallic nanoparticles for antimicrobial efficacy remain antimicrobial over a long period of time but take hours to kill pathogens leaving time for disease transmission. There is currently no surface that can provide instant and persistent antimicrobial efficacy against a broad spectrum of bacteria and viruses. Inspired by the naturally antimicrobial secondary metabolites secreted by plants, we created a new class of highly durable polyurethane surfaces capable of rapid disinfection (>4-log reduction in minutes) of various pathogens, including *Escherichia coli*, *Pseudomonas aeruginosa*, methicillin-resistant *Staphylococcus aureus*, and SARS-CoV-2. These surfaces maintain this efficacy over several months and under significant environmental duress due to the chemical stabilization of the natural antimicrobial components within the polyurethane. Additionally, we show that the surfaces can be applied to surfaces using various commercial techniques such as spray-, flow-, or brush-coating allowing for a wide range of potential applications.

Cephalopod-Inspired Material Design for Potential Food Applications Bianca C. Datta[1,2]; [1]Massachusetts Institute of Technology, United States; [2]New Harvest, United States

As the global population rises alongside a worsening climate outlook, alternative proteins such as plant and cell-based meat provide exciting avenues for meeting the increasing demand for meat sourced from animals and have implications for planetary and human health. While food science is a well-established field with a rich history, inclusion of methods and research paradigms from the materials community can accelerate the development of promising food technologies. In this work, we review the complex and interesting structure and functionality of cephalopods, the landscape of existing materials advances towards replicating these creatures, and extensions towards food and edible materials. In doing so, we bridge the rich culinary traditions around cuttlefish, octopus, and squid[1] with advancements in tissue engineering and bio-inspired design.

Few creatures generate as much wonder and curiosity as cephalopods. Renowned for their protective and communicative capabilities (camouflage, texture and shape change), they also demonstrate fascinating behavioral and cognitive abilities[2].Researchers have looked to cephalopods for inspiration in designing systems as varied as displays[3], programmable coloration[4], self-healing coatings[5], mechanochromic windows[6], and bioelectronics[7]. Here, we look to their unique structure and properties to inspire a new domain of compelling alternative food materials.

9:30 AM BREAK

10:00 AM SB08.04.05
Design of Lightweight and High-Strength Functionally Graded Materials Inspired by the Hard Shells of Plants Rikima Kuwada and Daisuke Ishii; Nagoya Institute of Technology, Japan

Functionally graded materials (FGMs) are novel composite materials with gradual variations in their structures and chemical compositions throughout their bodies, so that FGMs possess locally tailored properties. Since FGMs consist of continuous structures without borders of physical property changes, conflicting physical properties within a material can be maintain not to break in their bodies. In contrast to isotropic bulk materials, the structures and chemical compositions of FGMs can be accurately designed to create tailored multifunctional properties. Noted to the natural world, there are many kinds of FGMs such as bones, teeth, bamboos, shells, and crustacean shells. They continuously change their microstructures and chemical compositions, with corresponding smooth changes in mechanical properties such as hardness, stiffness, and toughness. These natural materials mentioned above are composed of elements lighter than iron, such as carbon, silicon, and calcium. They are both lightweight and strong with limited resources by placing these elements in the necessary quantities and in the necessary places. In recent years, much research has been conducted to mimic these natural materials to reduce the weight and increase the strength of materials. In this study, we focused on the grass species, Job's tears (Coix lacryma-jobi). The seeds of Job's tears are covered with the involucre, a thin, lightweight, hard shell containing a high amount of silica. This shell is only about 740 μm thick, but is strong enough to withstand a load of about 280 N. We analyzed the spatial distribution of porosity, chemical composition, and hardness of these shells to investigate the factors that contribute to their lightweight and high-strength. Then, FGMs mimicking the shells of Job's tears were fabricated based on the analysis results.
We used scanning electron microscopy (SEM) to observe the cross-sectional microstructures of the shell of Job's tears and energy dispersive X-ray spectroscopy (EDX) to analyze their chemical compositions. The inner layer of the shell was composed of tubular plant cells with a diameter of approximately 2 μm. The plant cells became smaller and more isotropic toward the outer layer and were densely distributed. The outermost layer of the shell was deposited with fine particles less than 100 nm in diameter. Therefore, the porosity of the shell decreased toward the outer layer. EDX analysis showed that the shells contained more silica toward the outer layers.
We measured the change in hardness from outer to inner layer in the cross-section of the shell by Vickers hardness test and nanoindentation test. The Vickers hardness test revealed that the outer layer of the shell was about four times harder than the inner layer, and the nanoindentation test showed a gradual decrease in elastic modulus from the outer to the inner layer of the shell. In addition, we analyzed the stiffness characteristics of the shells by performing three-point bending tests in different loading directions. The shells withstood three times more strain and twice as much load when bent from the outer layer of the shell compared to when bent from the inner layer.
These results indicate that the outer layer of the shell is harder and the inner layer softer due to spatial gradients in both shell porosity and chemical composition. This material property would allow the shell to withstand loads from outside the shell.
Based on our analyses, we fabricated FGMs mimicking the shells of Job's tears. We printed porous materials with a spatial gradient of porosity using fused deposition modeling 3D printer and polyurethane filaments whose extent of foaming and hardness changes with heating temperature. By impregnating the porous materials with glass or silicone resin, we expressed the spatial gradient in chemical compositions and hardness. This study may provide design guidelines for lightweight, high-strength organic/inorganic hybrid FGMs.

10:15 AM SB08.04.06
Peptidomimetic Wet-Adhesive PEGtides with Synergistic and Multimodal Hydrogen Bonding Minseong Kim and Byeong-Su Kim; Yonsei University, Korea (the Republic of)

The remarkable underwater adhesion of mussel foot proteins has long been an inspiration in the design of peptidomimetic materials. Although the synergistic wet adhesion of catechol and lysine has been recently highlighted, the critical role of the polymeric backbone has remained largely underexplored. Here, we present a peptidomimetic approach using poly(ethylene glycol) (PEG) as a platform to evaluate the synergistic compositional relation between the key amino acid residues (i.e., DOPA and lysine), as well as the role of the polyether backbone in interfacial adhesive interactions. A series of PEG-based peptides (PEGtides) were synthesized using functional epoxide monomers corresponding to catechol and lysine via anionic ringopening polymerization. Using a surface force apparatus, highly synergistic surface interactions among these PEGtides with respect to the relative compositional ratio were revealed. Furthermore, the critical role of the catechol−amine synergy and diverse hydrogen bonding within the PEGtides in the superior adhesive interactions was verified by molecular dynamics simulations. Our study sheds light on the design of peptidomimetic polymers with reduced complexity within the framework of a polyether backbone.

10:30 AM SB08.04.07
Sea-Mussel Inspired Bioadhesives for Surgical Applications Aishwarya V. Menon, Jonathan J. Wilker and Julie C. Liu; Purdue University, United States

Current methods of surgical joinery look as though they were devised in a medieval torture chamber. Sutures concentrate mechanical stresses, punch holes into healthy tissue, and create sites for infection. Patient outcomes will improve when we can devise alternate means of connecting tissues. Adhesives are appealing here. However, we do not yet have any materials that are simultaneously able to set in a wet environment, create strong bonds between tissues, and exhibit no toxicity. Further properties that are desirable include cure times compatible with surgeries, an ability to degrade, and having moduli (i.e., flexibility or stiffness) matched to the surrounding substrates. Our research team has developed sea-mussel inspired synthetic adhesives by taking cues from the way they attach themselves strongly onto surfaces in the ocean and synthesizing glues that mimic their chemistry. We have recently shifted our focus from synthetic to natural materials and developed inexpensive, bio-derived and non-toxic bioadhesives from corn protein (Zein)and Tannic acid (TA). Zein being a by-product of ethanol production from corn has been used as a wood adhesive. Tannic acid is a plant-based polyphenol and also one of the cheapest sources to impart sea-mussel inspired chemistry to any adhesive. We studied the *in vitro* burst pressures of these bioadhesives on several tissue substrates including sausage casings, porcine skin, heart, liver, lungs, aorta, dura and stomach. Our studies found these natural bioadhesives really promising with the ability to withstand pressures greater than the normal physiological pressures experienced in most of these organs. Moreover, we successfully conducted *ex vivo* studies on multiple tissue substrates to demonstrate the ability of our bioadhesives to plug body fluid leakages. We envision the potential application of our bioadhesives to seal surgical incisions and wounds under wet condictions.

10:45 AM SB08.04.10
Highly Nanoporous Multi-Functional Wood Aerogels Yuanyuan Li; KTH Royal Institute of Technology, Sweden

Aerogels, featuring low density (< 0.5 g/cm^3), high porosity (>90%), and high specific surface area (SSA) (> 100 m^2/g), show vital roles in various areas such as super thermal insulation, separation, catalyst, etc. Cellulose stands out ascribing to the abundant and fossil-free resources and the favorable

mechanical properties. The mainstream fabrications of cellulose aerogels are from a bottom-up approach, the energy consumption and hierarchical porous structure reconstruction are challenging for cost-effective and scalable production. A top-down approach directly from wood was reported recently through delignification and sometimes followed by hemicellulose extraction. However, the SSA is low and meso/micro pores are limited. Here, we propose an approach to fabricate hierarchical wood aerogel through cell wall partial dissolution and regeneration in the lumen space. The aerogel combines high SSA (up to 250 m^2/g) with good mechanical strength (1.2 MPa) and abundant of meso/micro pores. The aerogel could be further modified for advanced applications such as thermal insulation, energy harvesting, etc.

11:00 AM SB08.04.11
The Impact of Mycelium Inoculation on 3D Printed Structural Composites Sabrina Shen, Nicolas A. Lee and Markus J. Buehler; Massachusetts Institute of Technology, United States

The creation of living materials has received increased attention for its potential to provide sustainable, functional materials with novel properties. Mycelium-based materials have been of particular interest due to their relatively rapid growth rate and filamentous hyphae, which can act as fibrous reinforcement in packaging, structural, and other material applications. Characterization of mycelium composites in the materials science and architecture fields has typically been limited in scope, often focusing on bulk mechanical properties in sheets or molded bricks with single-material feedstocks. Here, we introduce a library of living-hybrid composites for additive manufacturing with resolution as high as 1 mm, and specifically characterize the impact of various inoculation methods, printing methods, and time-resolved growth on mechanical and chemical properties. We further explore interesting phenomena such as self-healing behavior and potential applications for these bio-hybrid composites.

11:15 AM SB08.04.12
All Bio-Phosphors for Highly Performing Low-Energy Biohybrid Light Emitting Diodes Sara Ferrara and Rubén D. Costa; Technical University of Munich, Germany

Bio-phosphors have emerged as an alternative to rare-earth color down-converting filters in light-emitting diodes (LEDs). They are mainly produced with biogenic emitters, like Fluorescent Proteins (FPs), embedded in polymer matrices.[1–3] The first biohybrid LED (Bio-HLED) with FP-phosphors featured a loss <10% of the emission intensity after 100 h.[1] This performance was recently enhanced using zero-thermal quenching PMMA-FP phosphors, reaching >150 days and 5 min of stability at low and high powers.[4] However, the ideal combination of highly efficient and stable fully biogenic phosphors is still in its infancy.[5] Here, we disclose the optimization of a bio-derived biodegradable polymer hosting and stabilizing a natural red FP – *mCherry,* as red-emitting phosphor in Bio-HLEDs. The photoluminescent properties of the bio-phosphors - PLQY> 20% with λ_{em} = 630 nm - led to Bio-HLEDs with excellent photostabilities > 2000 h operating, representing 2 orders of magnitude enhancement. We are strongly convinced that our work represents a crucial breakthrough in the development of red emitting bio-phosphors and in the stabilization of further natural FPs.

SESSION SB08.05: Functional Biomaterials II
Session Chairs: Paul Meredith and Giuseppe Paternò
Tuesday Afternoon, November 29, 2022
Hynes, Level 3, Room 313

1:30 PM *SB08.05.01
Biomaterials for Boosting Food Security Benedetto Marelli; Massachusetts Institute of Technology, United States

Applications of robotics and sensing technologies, big data analysis and biotechnology in farming, plant and food science are highly sought to guarantee global food security while mitigating the environmental impact of agriculture. In this scenario, the potential benefit of applying biomaterials science and drug delivery principles to enhance food security remains underexplored when compared to material- based research efforts in biomedicine, energy and optoelectronics. In this seminar, we highlight recent development in the nanomanufacturing of structural proteins to engineer a new generation of advanced materials that can be interfaced with food and plants. We will present newly developed techniques to direct the assembly of structural proteins into nanostructured, hierarchical materials that can serve as: edible coatings to prolong the shelf-life of perishable food, microenvironments to boost seed germination in marginal land and injectors to precisely deliver payloads in plant vasculature. These examples will provide an opportunity to discuss how the establishment of a successful interface between biomaterials and plants tissues requires the development of a basic scientific knowledge on: mechanics of disorder to order transitions in proteinaceous materials during condensation phenomena, fluid mechanics and transport phenomena in plants vasculature, and swelling of porous materials exposed to plant fluids.

2:00 PM SB08.05.02
Adaptive Recombinant Nanoworms from Genetically Encodable Star Amphiphiles Davoud Mozhdehi; Syracuse University, United States

Recombinant nanoworms are promising candidates for materials and biomedical applications ranging from templated synthesis of nanomaterials to multivalent display of bioactive peptides and targeted delivery of theranostic agents. However, the molecular design principles to synthesize these assemblies (which are thermodynamically favorable only in a narrow region of the phase diagram) remains unclear. To advance the identification of design principles for programmable assembly of proteins into well-defined nanoworms and to broaden their stability regimes, we were inspired by well-documented findings of topological engineering for accessing rare mesophases formed by synthetic macromolecules. To test this design principle in biomacromolecular assemblies, we used posttranslational modifications (PTMs) to generate lipidated proteins with precise topological and compositional asymmetry. Using an integrated experimental and computational approach, we show that the material properties (thermoresponse and nanoscale assembly) of these hybrid amphiphiles are modulated by their amphiphilic architecture. Importantly, we demonstrate that the judicious choice of amphiphilic architecture can be used to program the assembly of proteins into adaptive nanoworms, that undergo a morphological transition (sphere-to-nanoworms) in response to temperature stimuli. Due to their amphiphilicity, these nanoworms can easily solubilize hydrophobic chemotherapeutics without resorting to

complex, inefficient, and time-consuming conjugation/purification protocols. The recombinant nature of this system enables the fusion of genetically encoded bioactive or targeting peptides, which can be used to optimize the delivery and efficacy of these nanoplatforms. We anticipate that these methods will be generalizable to other classes of proteins and PTMs. Thus, this work advances the study and design other hybrid systems, such as proteins modified with other classes of lipids or charged PTMs such as phosphorylation.

2:15 PM BREAK

2:45 PM SB08.05.04
Robust Spines of Biopolymer Microspheres for Enhanced Adhesion Muchun Liu, Yunteng Cao, Zheng Li, Rajeev Ram and Benedetto Marelli; Massachusetts Institute of Technology, United States

Polymeric microparticles are widely used in agriculture, food processing, biomedical and electronic industries. Their structures and surface patterns are critical in specific applications. However, assembling intricate polymeric microstructures in a simple, repeatable, and at-scale manner is challenging compared with inorganic counterparts. To address this issue, we will describe a universal, template-free approach to fabricating spiny biopolymer microspheres. Silk fibroin – a natural protein with outstanding mechanical properties, biodegradability, and biocompatibility – is selected as an example here. Silk fibroin spiny microspheres are prepared with different sizes, spine numbers, and payloads. The mechanically robust spines are analyzed and tested. The enhanced adhesion performance in agriculture and micro-robotic applications will be demonstrated.

3:00 PM DISCUSSION TIME

3:15 PM SB08.05.06
Cellulose Nanocrystals Orientation Order Control via Tuning Nanocrystals Coulombic Interactions Daria Bukharina, Minkyu Kim, Moon Jong Han and Vladimir Tsukruk; Georgia Institute of Technology, United States

Here we present how the ionic strength and effective charge density affect the final structural organization of cellulose nanocrystals (CNCs) after drying suspensions with different ionic strengths in terms of quantitative characteristics of the orientation order. We demonstrated that electrolyte's introduction into CNCs dispersion results in dramatic changes in electrical double layer thickness and subsequently, the effective charge density, measured experimentally, as well as the interparticle interaction energy calculated from the DLVO theory. The question of whether electrostatic interactions by themselves can control the nanocrystals' chiral organization is frequently debatable. We showed with high-resolution AFM that the reduction of the Debye charge screening length below a critical value of 3 nm results in the loss of the long-range helicoidal order and the transition to a disordered morphology with random packing of nanocrystals within thin films' layers. Subsequently, very high local orientation ordering with the 2D orientation factor, S, obtained by applying image analysis software that was within 0.8–0.9, gradually decreased to a random order with the final value $S = 0.1–0.2$. The effect of Coulombic interaction on CNCs chiral assembly is clearly supported by the measured shrinking of the helical pitch length and shifting the photonic band gap from 400 to 250 nm, and increase in helical twisting power from 4 to 6 μm^{-1} and doubling of the twisting angle between neighboring monolayers from 5.5 to 9°. Thus, we conducted quantitative characterization of the CNCs molecular organization down to the level of individual nanocrystals and their orientational organization at nanoscale and microscale levels. Simultaneously with these comprehensive molecular characteristics, we measured optical appearance, chiral activity, and evaluated their charged state, offering unique comprehensive and quantitative characterization of the molecular orientational order of the CNCs.

3:30 PM SB08.05.07
Laser Processing of Aligned Polylactic Acid Nanofibers—Process, Structure and Function Matthew Flamini, Mohamad Keblawi and Vince Beachley; Rowan, United States

Problem:
Electrospun nanofibers should have higher strength then their larger scale counterparts, however, due to the difficulty in drawing the fibers, a critical processing step that creates high molecular alignment in the fiber, their promise of high strength remains unkept. Individual nanofibers have been drawn using a parallel based track collection and drawing system, but this has only been done at ambient temperatures. The proper application of heat will allow for the fibers to be drawn to much higher draw ratios, and allow for the release of chain entanglements and imperfect crystal structures so that the resultant fibers can have optimal chain alignment and straight chain crystals.
Solution:
We aim to apply the technique of laser zone drawing to track electrospun nanofibers. Laser zone drawing heats up just a small portion of the fiber at a time, allowing for precise thermal control over the fiber, both spatially and temporally. This technique has been applied to larger fibers with incredible results but has yet to be applied to nanofibers. We believe that by combining the techniques of track electrospinning and laser zone drawing, we can create nanofibers with near ideal macromolecular properties, which may result in polymer nanofibers with the highest tensile strength to date. Additionally, this method is scalable and flexible, and should be applicable to any thermoplastic polymer that can be spun into nanofibers.
Methods:
Track electrospinning and Laser Processing: Polylactic acid (PLA) nanofibers are electrospun onto a parallel track collection system, which allows to the collection of aligned nanofibers. The fibers are then transferred onto a robotic stage which passes the fibers through a 9.3 micron wavelength laser beam.
Raman Spectroscopy:
Single fiber Raman spectroscopy is used to measure changes in the molecular alignment and crystallinity of the fibers.
Scanning Electron Microscopy (SEM):
SEM is used to evaluate the diameters and morphology of the fibers.
Mechanical Properties:
Dynamic Mechanical Analysis is used to determine the modulus off fiber mats, because individual fibers do not produce a large enough load.
Results:
We have demonstrated that PLA fibers of different diameters can be predictably thinned to diameters of less than 20% of the original diameter with low variability simply by increasing the power density of the processing laser. This allows for the nanofibers' diameters to be precisely controlled after the spinning process. We have also established that this effect is not dependent on the duration of laser exposure, indicating that the fibers reach thermal equilibrium during the process, despite being exposed to very high laser power densities. This is explained by their enormous surface area to volume ratio, which only increases as they thin, which keeps them from melting even under extreme laser exposure. We have also demonstrated that the fibers can be thinned in a single step, as there was no difference in diameter compared to fibers that were treated multiple times at incrementally increasing powers. By comparing the power density of the laser to the diameter, using Newtons law of cooling, and assuming thermal equilibrium, we can calculate the convective heat transfer coefficient of the nanofibers. Knowing this will allow us to predictably raise the fibers' temperature using the laser, which will aid in the zone drawing process, by allowing us to heat just above Tg, which has been shown to be the optimal temperature for zone-drawing.

Modelling and Simulation of DNA-Based Nanomaterials Torsten John[1], Jeffrey Gorman[1], Hyungmin Jun[1,2], Xiao Wang[1] and Mark Bathe[1]; [1]Massachusetts Institute of Technology (MIT), United States; [2]Jeonbuk National University, Korea (the Republic of)

In nature, simple molecular building blocks self-assemble into complex structures to achieve outstanding functionality. For example, proteins are made up of amino acids and DNA (deoxyribonucleic acid) is made up of nucleotides. Proteins and DNA are involved in most processes in life, from genetic encoding of information to enzyme catalysis. The large sequence space and the variation of the physicochemical properties of biomolecules leads to their functional diversity. Inspired by the superior properties of such self-assembled systems, materials with unique properties can be designed. The base pair complementarity of DNA and the origami method laid the foundation for the field of DNA nanotechnology and synthesis of 2D and 3D nanostructures of desired geometry. Bioconjugate chemistry enables the modification of DNA strands with functional molecules that can be designed with optimized spacings and orientations within the DNA backbone, leading to applications in energy transfer, vaccine development, or enzyme catalysis.

In this work, we present the design of DNA origami for the development of functional nanostructures. Modeling and simulation have been used to better understand the molecular structure of functional DNA structures and to guide new designs. The 2D and 3D DNA structures were first generated using the ATHENA software package, followed by coarse-grained oxDNA simulations to investigate the structural integrity of the DNA nanostructures. As an example, hybrids of DNA wireframe structures decorated with fluorescent molecules have been tailored to achieve the desired spectroscopic properties. The goal was to mimic and engineer the outstanding efficiency of fluorophores in large protein complexes such as the light-harvesting antenna complex. Fully atomistic molecular dynamics (MD) simulations provided further insights. This approach enables the design of hybrid systems with functional properties for applications where molecules need to be arranged on the nanometer scale.

Computational Reverse-Engineering Analysis for Scattering Experiments (CREASE) on Biomacromolecular Assemblies Zijie Wu and Arthi Jayaraman; University of Delaware, United States

Many biomacromolecules are known to undergo thermoresponsive assembly into various morphologies, making them promising candidates for temperature-modulated applications such as drug delivery and tissue engineering. As two examples, methylcellulose (MC) chains self-assemble to form fibrillar structure in aqueous solutions at elevated temperature [Schmidt et al. Macromolecules, 2018, 51, 7767-7775]; elastin-like peptide-collagen-like pepetide (ELP-CLP) conjugates self-assemble to form vesicles at physiological temperatures [Luo and Kiick, J. Am. Chem. Soc. 2015, 137, 15362-15365]. Understanding the assembled macromolecular structure - domain shapes and dimensions - is key to precise control of the behaviors of such biomacromolecular materials in commercial applications. Small-angle scattering (SAS) is a useful experimental technique to characterize the structure of polymer assembly in solutions. However, interpretation of the SAS output - a scattering profile of averaged intensity (I(q)) at various wave factors (q) - often relies on analytical models only available for several conventional structures. Interpretation of I(q) vs. q plots for unconventional/non-equilibrium assembled structures with simple/complex polymer conformations remains challenging as relevant analytical models are not always available for such cases. In this talk, we present our recently developed computational method, CREASE, to analyze SAS results obtained from structures with high dispersity in dimensions formed upon assembly of complex polymer chemistries. Using genetic algorithm (GA) as the optimizer, CREASE takes as input I(q) vs. q plot and a general category of assembly morphology (e.g., “semiflexible fibril” or “bilayer vesicle”) and provides as output the relevant dimensions of the structure and dispersity in the dimensions whose computed scattering profile most closely matches input scattering profile. We test the performance of CREASE on both scattering profiles of methylcellulose fibrils and ELP-CLP vesicles and compare the predicted dimensions with those obtained from fitting analytical models. We also show how CREASE can be accelerated by incorporating neural network (NN) models. This talk will demonstrate CREASE’s potential to extract useful information about microscopic structure from SAS outputs without being limited by off-the-shelf scattering models and greatly improve the interpretability of small-angle scattering as a method to characterize polymer structures.

Enzyme-Free Biorecognition with Tailored PEDOT Derivatives Christina J. Kousseff[1], Achilleas Savva[2], Zixuan Lu[2], Shofarul Wustoni[3], Roisin Owens[2], Sahika Inal[3] and Christian Nielsen[1]; [1]Queen Mary University of London, United Kingdom; [2]University of Cambridge, United Kingdom; [3]King Abdullah University of Science and Technology, Saudi Arabia

The structure-based tuneability of the electronic and optical properties of conjugated polymers has enabled their application across a range of fields, including energy harvesting and optoelectronics. However, in the context of biological sensing, the use of conjugated polymers has thus far incorporated little specificity in terms of covalent modification.[1] Previously, we demonstrated a crown ether-functionalised PEDOT which displayed improved adhesion and electrochromic behaviors compared to unmodified PEDOT.[2] Now, we move towards an expanded landscape of materials investigating copolymers, deposition parameters, and alternative functional groups which enable the precise fine-tuning of material characteristics and functionalities.

Developing robust, highly selective, biologically compatible sensing platforms is of critical importance because the measurement of analyte concentrations in biological samples is crucial for the management or detection of many diseases.[3] Currently, many devices which function for this purpose are complex, multi-component systems. However, directed synthetic strategy with conjugated polymers enables the fine-tuning of analyte specificity, electroactive or optical functionality, and physical and morphological properties, within a single multi-purpose material. In addition, these entirely organic systems offer affordability, biocompatibility, and simple design and fabrication.

Here, we present a novel covalently modified EDOT monomer featuring pendant analyte-binding groups which, when electropolymerised in the presence of a glucose template, forms a porous molecularly imprinted matrix which is shown to be electrochemically responsive to glucose. Supported by in-depth topographical, electrochemical, QCM, and OECT analysis, we will discuss how this new design platform can be used to introduce sensing capability in an enzyme-free, single polymeric material, for next-generation device fabrication.

Multi-Valued Logic Structures for Optical Biocomputing—Photonically Triggered Bio-Organic Field-Effect Transistors Moon Jong Han, Minkyu Kim and Vladimir Tsukruk; Gerogia Institute of Technology, United States

Here, a photonic bio-organic multiphase structure is proposed for thin-film electronic nets integrated with multilevel logic elements for multilevel computing via reconfigurable photonic band gaps in chiral biomaterials. Inspired by an artificial intelligence system having efficient information integration and computing capabilities, the photon active dielectric layer of the chiral nematic cellulose nanocrystal is coupled to a printed p-type and n-type organic semiconductor as a bifunctional logic element. These adaptive logic elements can trigger customized quantized electrical output signals under light having different photon energies and with different photonic band gaps in active dielectric layers. A bifunctional structure enables complex memory operations due to repeated changes in photonic band gaps controlled by expansion and contraction of chiral nematic pitches and photon energy controlled by light absorption of complementary organic semiconductor layers. This conceptual demonstration of a multivalued logic structure facilitates an optical calculation system for low-power optical information processing integrated into an interface between a human and a machine.

Plant Based Biohybrid Systems for Energy Applications Eleni Stavrinidou; Linkoping University, Sweden

Plant processes such as photosynthesis, production of biomaterials and environmental sensing and adaptation, can be used in technology via integration of functional materials and devices. We demonstrated that plants can be functionalized with electronic materials by leveraging their biocatalytic machinery. Specifically, conjugated oligomers based on thiophene and EDOT polymerize in-vivo forming conductors within the plant structure. We showed that the polymerization is enzymatically catalyzed by endogenous peroxidases that are present in the plant cell walls, resulting in conducting polymers integrated within the plant cell wall structure. The plant is not only catalyzing the polymerization but also templates the polymer in a favorable manner. Recently we demonstrated intact plants with electronic roots that continue to grow and develop enabling plant-biohybrid systems that maintain fully their biological processes. The electronic roots were used to build supercapacitors that outperformed previous plant biohybrid charge storage demonstrations. Here I will also present our latest results on developing plant based biohybrid circuits for enhanced energy storage in plants and a demonstration in powering an electrochromic display. Furthermore, extending the concept to trees I will present our results on functionalizing wood in-vivo prior to harvest.

Polydopamine Polymerization in Anoxygenic Photosynthetic Organisms Rossella Labarile[1,2], Danilo Vona[2], Maria Varsalona[1,2], Matteo Grattieri[2,1], Paolo Stufano[1], Roberta Ragni[2], Stefania R. Cicco[1], Gianluca Maria Farinola[2] and Massimo Trotta[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Bari Aldo Moro, Italy

Photosynthetic microorganisms represent attractive tools for the harvesting and the conversion of solar light in bioelectronic devices [1, 2]. The optimization of the interfaces of poorly conductive bacteria with electronic components can be achieved *via* biocompatible polymers that encapsulate the bacterial cells and allow the intimate contact between the outer cell membrane and the electron acceptor surface, required for an efficient electron transfer in biohybrid systems.
The outer membrane of the metabolically active photosynthetic purple non sulfur bacterium *Rhodobacter (R.) sphaeroides* was coated with polydopamine (PDA), a bioinspired polymer produced by the self-polymerization of dopamine. Although the presence of oxygen is an essential requirement for dopamine polymerization [3], the PDA coting formation around the cell membrane occurred also in anaerobic condition.
Laccases, enzymes belonging to multi-copper oxidases family, have been reported to oxidize a wide range of phenolic compounds and aromatic amines, including dopamine. Using laccase, the polymerization rate of the dopamine monomer was greatly increased, and the polymer film resulted more uniform compared to traditional self-polymerization and uncontrolled mechanism [4].
Laccases have a wide taxonomic distribution in Nature but with few or little evidence of their presence in anaerobes, since these enzymes use oxygen as an electron acceptor [5]. Here we investigate the process of anaerobic polymerization of dopamine in the growth medium of *R. sphaeroides.*

Similarly, laccase from *T. versicolor* was also used to improve dopamine polymerization around the photosynthetic organisms belonging to diatom microalgae, with the goal of wastewater treatment and their bioremediation.

Algae-Based Biohybrid Microrobots for Biomedical and Environmental Applications Fangyu Zhang, Liangfang Zhang and Joseph Wang; University of California, San Diego, United States

Bioinspired microrobots capable of actively moving in versatile biological fluids and environmental surroundings have attracted considerable attention for biomedical and environmental applications because of their unique dynamic features that are otherwise difficult to achieve by their static counterparts. Herein, algae-based biohybrid microrobots are fabricated via click chemistry to functionalize algae with different agents from small molecules to nanoparticles (eg. angiotensin-converting enzyme 2 (ACE2) receptor and antibiotics-loaded cell membrane-coated nanoparticles). The resulting biohybrid microrobot displays fast (>100 μm/s) and long-lasting self-propulsion in diverse simulated biofluid and aquatic media, obviating the need for external fuels. In a mouse model of acute pneumonia, the resulting antibiotics-loaded biohybrid algae-based microrobots achieve significant therapeutic efficacy in reducing the bacterial burden and effective treatment of bacterial infection, while showing negligible *in vivo* toxicity. In another example, the ACE2-

modified algae microrobots display effective “on-the-fly” removal of SARS-CoV-2 pseudovirus in many contaminated water matrices.

Polyethylenimine Based Nanoparticles for Enhancing Photosynthesis in Plants Cyril Routier[1], Lorenzo Vallan[2], Yohann Daguerre[3], Marta Juvany[3], Emin Istif[2], Cyril Brochon[2], Georges Hadziioannou[2], Torgny Hasholm[3], Eric Cloutet[2], Eleni Pavlopoulou[2] and Eleni Stavrinidou[1]; [1]Laboratory of Organic Electronics, Department of Science and Technology, Linköping University, SE-60174, Norrköping, Sweden., Sweden; [2]Laboratoire de Chimie des Polymères Organiques (LCPO−UMR 5629), Université de Bordeaux, Bordeaux INP, CNRS, F-33607 Pessac, France, France; [3]Umeå Plant Science Centre, Department of Forest Genetics and Plant Physiology, Swedish University of Agricultural Sciences, SE-90183 Umeå, Sweden., Sweden

During photosynthesis, plants use light energy to transform carbon dioxide and water into carbohydrates for their own growth. The photosynthetic process comprises many steps that can in principle be optimized to have higher efficiency. RuBisCO (Ribulose 1,5-bisphosphate carboxylase/oxygenase) catalyzes the carboxylation reaction that is the initial reaction for carbon fixation and conversion of CO_2 to sugars. The reaction occurs in organelles called chloroplasts present in leaf cells. However, RuBisCO has naturally a poor affinity for CO_2 and the transfer of the atmospheric CO_2 to the RuBisCO enzyme is highly limited by the diffusion of CO_2 through the stomata and the intercellular space which ultimately considerably reduces the photosynthesis rate. Polyamines have been shown in-vitro to be able to transfer carbon dioxide to RuBisCO for the carboxylation reaction. In this work, we present biocompatible fluorescent polyethylenimine nanoparticles for enhancing the CO_2 transfer to the RuBisCO enzyme. With *in vitro* and *in vivo* studies, we evaluated the nanoparticles uptake of atmospheric CO_2 and transfer kinetics to RuBisCO for the carboxylation reaction. Then, we introduced the nanoparticles into the plant apoplast via localized infiltration. First, we studied the toxicity of the nanoparticles and results showed no evidence of a direct harmful impact. We then investigated their distribution within the plant leaf with confocal microscopy and showed that the nanoparticles not only are present in the intercellular space but also in the direct centers of photosynthetic activity: the chloroplasts, which indicate the possibility of a pathway to increase the diffusion of CO_2 in the plant tissue.

Pectin Hydrogel as Isolated Chloroplast Niche for *In Vitro* Photosynthesis Jonghyun Shin, Jaeho Choi, Youngwoo Han, Woojin Jeong, Chang Seok Ki and Seon-Yeong Kwak; Seoul national university, Korea (the Republic of)

Chloroplasts absorb atmospheric carbon dioxide in the plants, which play an important role in converting global carbon into a chemical energy source by light. Since isolated chloroplasts quickly lose their photosynthetic activities once isolated from plants, extending their viability is essential in engineering chloroplasts for sustainable carbon sequestration. Here, we suggest a plant cytosol-mimicking matrix to extend the photosynthetic activities of isolated chloroplasts. Encapsulation of chloroplasts within photo-clickable pectin hydrogels enabled uniform distribution of chloroplasts within the hydrogel and securely entrapped chloroplasts to maintain the mechanical properties. Antioxidants were introduced to protect chloroplasts from photooxidative damage. We evaluated the comprehensive *in vitro* photosynthetic activities by monitoring chlorophyll concentration, O_2 evolution, electron transfer rate, ATP synthesis, and glucose export. As a result, we found that antioxidants alone prolonged the isolated chloroplasts’ lifespan by 48 hours, and encapsulation within the pectin hydrogel extended their lifespan by 168 hours. In 96 hours of incubation, the chloroplast-laden pectin hydrogel with antioxidants showed a 3-fold O_2 concentration and 8-fold electron transfer rate compared to encapsulated chloroplasts without antioxidants. In addition, the ATP synthesis and glucose export were increased by 1.6-fold and 1.2-fold, respectively. These results will provide the potential perspective on the generation of carbon-fixing materials, the manipulation of biological functions, and the production of therapeutics using chloroplast culture in designing environmentally sustainable materials.

11:00 AM SB08.06.07
A Fruit Salad Recipe for Vision Restoration—Use of Natural Dyes for Photosensitive Organic Semiconductor Devices Toward Retinal Implants Aimee R. Sweeney, Leslie Askew, Cedric Vallée, Daniel Whelligan and Maxim Shkunov; University of Surrey, United Kingdom

Vision loss due to the degeneration of photoreceptor cells in the retina occurs in millions of people every year worldwide through diseases such as retinitis pigmentosa and age-related macular degeneration. The development of a photosensitive organic semiconductor device that can function in a way to replace lost or damaged photoreceptor cells may be a possible treatment for those suffering with these diseases. We demonstrate that natural dyes extracted from various berries and vegetables are excellent chromophore candidates for colour-specific organic devices with similar absorption spectra to those produced by human rod and cone cells. Using fabrication methods resembling those used in the development of dye-sensitised solar cells, bio-derived chromophores have been investigated and the production of active devices interfaced with electrolyte, phosphate buffered silane, have been demonstrated. Devices produce photo-current and photo-voltage spectra in the spectral regions corresponding to the activity of cones and rods. . Our results show the chromophores can respond to pulsed light in a similar way to photoreceptor cells and produce a rising photovoltage. In summary, we discuss if natural dyes can lead us to devices capable of stimulating neuronal circuitry in human eye.

11:15 AM SB08.06.08
Three-in-One Woody Zinc-Air Battery Engraved by Laser Hiroya Abe; Tohoku University, Japan

For the realization of sustainable development goals, regional ecosystems must develop and use universal sustainable technologies, and the widespread use of renewable energy is essential for this purpose. Thus, there is an urgent need to develop renewable energy production and storage devices. A wood-derived carbon is a promising electrode as an energy device because its high porosity improves the carbon's surface area Recently, we have reported a highly active wood-derived electrochemical catalyst for oxygen reduction reaction which occurs on the cathode of metal-air batteries and fuel cells (1). The pyrolyzed wood performed high porosity and high catalytic activity. Pyrolysis is required to control the atmosphere at high temperatures and under inert

gas, resulting in being expensive and cumbersome. Herein, we report the direct laser-pyrolysis of wood chips for an anode and cathode with a commercial blue laser and establish a three-in-one zinc-air battery.
Paulownia was used as a wood carbon source. Wood chips were pyrolyzed with the blue laser under the ambient atmosphere. The irradiated area became black and metallic. The obtained carbon had macro-scale pores confirmed by an optical microscope and showed the graphitic peaks confirmed by Raman spectra. The electric resistance was improved by increasing the intensity of the blue laser, and the obtained carbon performed highly active electrocatalytic activity by adding metal sources as catalysts.
We confirmed the electrocatalytic activity of the cathode for the oxygen reduction reaction. In this study, the Fe(NO3)3 was used as a metal source and added to the wood before the pyrolysis (wood-Fe). In addition, iron phthalocyanine was modified on the obtained carbon material using the organic solvent as a molecular catalyst (wood-FePc). The molecular catalysts are promising materials since they show superior oxygen reduction activity without any pyrolysis processes (2). The oxygen reduction properties were evaluated in 0.1 M KOH, and the catalytic activity was found to increase in the order of wood, wood-Fe, and wood-FePc. From these results, the wood-derived laser-induced graphene for the electrocatalysts of the oxygen reduction reaction was successfully obtained from wood using the blue laser under the ambient atmosphere.
Finally, we established the three-in-one zinc-air battery. The wood chips have porous structures, resulting in the solvent and electrolyte can be absorbed into their structure. We irradiated the laser at double sides on the wood chip to form the cathode and anode without a connection between each electrode. The FePc and zinc powder loaded onto the cathode and anode, respectively. The open-circuit potential was observed by adding the electrolyte (0.1 M KOH) into the wood chip. The woody battery showed over 10 mA/cm2 and 5 mW/cm2. The wood chip irradiated with the laser at double sides acted as the three-in-one zinc-air battery consisting of the cathode, anode, and separator without an assembly process.

Tunable Energy Absorption in Bioinspired Materials Designed for Additive Manufacturing Ludovico Musenich, Lorenzo Strozzi, Alessandro Stagni and Flavia Libonati; University of Genoa, Italy

Diatoms are the most widespread organisms in our planet's aquatic environments and among the most ecologically important. Indeed, the tens of thousands of existing species of these microalgae produce about half of the oxygen we breathe and are an extraordinary example of how Nature is capable of cyclically adapting biological systems to the natural environment by playing with the universality-diversity dualism. In diatoms, in particular, this binomial is determined by the multiscale architecture of their biosiliceous exoskeleton known as the "frustule". This biological material, in addition to being a marvelous and sophisticated physical barrier against predators, through its hierarchical porous structure allows diatoms to acquire nutrients through filtration, exploit buoyancy phenomena for photosynthesis processes, and thermally regulate the organism. Given the amazing multifunctionality of the frustule, diatoms are still widely studied for applications in filtration, drug delivery, biosensing, energy harvesting, and scaffolding. Yet, little is known regarding their mechanical properties. To extend the knowledge of the present relationship between the morphology of diatom frustules and their structural performance, in this work we focused on the mechanical analysis of the frustule of the diatom Coscinodiscus sp. Starting from the analysis of the multilayer structure that characterizes the microscale, we built biomimetic models on a macroscopic scale using CAD tools and studied their deformational behavior, both through numerical finite element simulations and through experimental tests performed on samples fabricated through additive manufacturing. In particular, we focused on the effect produced by variation in the morphological details that distinguish the natural sandwich-like structure of the frustule on its energy absorption properties. Through predictive techniques, we then researched the optimal topology and analyzed the potential benefits of using bioinspired design for the architected materials. Nature's design principles used to make biological materials and, in particular, the use of functional gradients and structural heterogeneity are a formidable source of ideas for increasing the efficiency and performance of man-made materials, and this research is evidence of that. To reinforce this, as a possible application, we propose in addition a new bioinspired prototype protective helmet designed for micromobility and outdoor activities that combines lightweight and the energy-absorbing capacity from impacts with breathability, waterproofing, and aesthetics.

1:45 PM SB08.07.01
Alginate Hydrogel Formation by Microdroplet Reactions on the Open-Channel Microfluidics Hiroyuki Kai; Tokyo University of Science, Japan

The alginate hydrogel is a natural polysaccharide that has high biocompatibility and is used for drug delivery, dressing for wound healing, scaffold for 3D bioprinting, etc. It can be readily prepared by mixing sodium alginate with divalent cations such as Ca2+ in solution to crosslink the alginate polymer chains. The most common method to facilitate the crosslinking of sodium alginate is to add a small amount of solution of sodium alginate into a bulk solution of CaCl2 slowly or in a dropwise manner. CaCl2 permeates into a blob of the alginate solution to immediately crosslink the alginate and form a hydrogel. Morphologies of the alginate solution being added (droplet or a stream of liquid, droplet size, etc.) affect the morphologies and properties of the resulting hydrogel, which are important for different applications. Since CaCl2 solution is normally of a bulk volume, if this reaction was conducted in a setting where both reactants are in microdroplets, it may lead to unique characteristics. However, it is difficult to facilitate efficient reactions between microdroplets by conventional techniques.

In this study, crosslinking reactions between sodium alginate and $CaCl_2$ were conducted by spraying them on the substrate surface with wettability patterning that collects and mixes microdroplets on the surface. We fabricated highly-branched "open microfluidic channels" [1,2,3] by patterning different wetting properties such as hydrophilic and hydrophobic ones. When aqueous microdroplets are sprayed on the open microfluidic channels, they are captured and transported along a hydrophilic channel surrounded by a hydrophobic surface, driven by capillary action. Superhydrophobic coating of TiO_2 and Capstone (R) ST-100 turns to be superhydrophilic upon irradiation with UV light, which makes complex patterning possible by simple photolithography. This photo-patternable surface was used to fabricate a highly branched tree-like microfluidic channels to collect microdroplets and facilitate mixing of solution at a large number of branching points that exists throughout the surface.

On the fabricated microfluidic surface, aqueous solution of 20 g/L sodium alginate (500-600 cP at 10g/L, 20 °C) and that of 20 g/L $CaCl_2$ were prepared. Droplets of different aqueous solutions were sprayed onto the unused channels using a spray nozzle with a controlled rate: (1) sodium alginate solution, (2) $CaCl_2$ solution, (3) both using two spray bottles containing each of them. The positions of liquid blobs after spraying were recorded by a digital camera.

When droplets of $CaCl_2$ solution, which has low viscosity, were sprayed on the channels, they were transported through the channels to form a large liquid blob at the focal point (the root of the tree structure) within 1 s. When droplets of sodium alginate solution were sprayed on the unused channels, they were also transported to the focal point despite their high viscosity (estimated viscosity is 1×10^3 cP). On the other hand, when the two kinds of droplets were simultaneously sprayed on the channels, the transport of droplets to the focal point was apparently hindered. This hindered transport can be attributed to crosslinking of alginate by Ca^{2+} upon merging of fine droplets of sodium alginate and those of $CaCl_2$ at the branching points, which turned the fluid droplet to a non-fluid hydrogel.

In conclusion, we demonstrated mixing and reactions of microdroplets of sodium alginate and $CaCl_2$ to form hydrogel on the microfluidic surface. More detailed investigation of the reaction dynamics between droplets as well as properties of the resulting alginate hydrogel is in progress.

Controlled Assembly of Sequence-Defined Peptoids into Hierarchical Materials Chun-Long Chen; Pacific Northwest National Laboratory, United States

Peptoid (N-substituted glycines), as one of the unique sequence-defined synthetic "foldamers that mimic proteins and peptides for functions, - have recently received increasing attention for the design and synthesis of biomimetic nanomaterials with hierarchical structures. [1] Due to the unique proteinase-resistance, chemical and thermal stabilities of peptoids, peptoid-based nanomaterials are promising candidates for applications in photonics, [2, 3] flexible electronics, [4] and biological systems. [2, 3, 5] Recently, by designing amphiphilic peptoids that contain aromatic hydrophobic domains, our group recently reported their self-assembly into highly crystalline membrane-mimetic 2D nanosheets[2, 6] and 1D nanotubes, [7] we demonstrated that these peptoid-based nanomaterials are highly stable and a wide range of functional groups can be precisely placed within these materials to achieve programmable functions. To gain a better understanding of their formation mechanisms of these biomimetic materials, herein, I will report my group's recent discovery of designing short peptoid oligomers, including tetramers, for controlled assembly into twisted nanoribbons, helices, along with nanosheets and nanotubes. Mechanistic studies using X-ray diffraction, AFM, TEM combined with computational simulations indicate the asymmetric packing of amphiphilic peptoids is the main driving force that leads to the formation of twisted nanoribbons and nanohelices. Tuning hydrophilic side chain chemistry and the number of hydrophobic side chains can significantly influence the peptoid assembly pathways and dynamics for the formation of hierarchical materials with designed morphologies.

Biodegradable, All-Organic Transistors Printed on a Bioderived Polymer Fabrizio A. Viola and Mario Caironi; Italian Institute of Technology, Italy

The growing demand of disposable electronics raises serious concerns for the corresponding increase in the amount of electronic waste (e-waste), with severe environmental impact. Organic electronics has been proposed long ago as a sustainable and energy efficient technological platform. Yet, such technology is inevitably leading to a drastic increase of plastic waste if common approaches for flexible substrates are followed. In this scenario, **biodegradable electronics** is an incipient need in order to mitigate the above mentioned issues. Flexibility, solution processability, low capital expenditure and energy-efficient processes, which are distinctive features of organic electronics, have to be complemented by a sustainable end-of-life of materials employed. This requirement calls for solutions where materials, especially substrates that represent the largest volume, can be biodegraded in the environment with no harm, yet assuring that no precious resources are dispersed. In this work, we succesfully employed a bioderived and biodegradable biopolymer as a substrate for an **all-organic field effect transistor** (OFET) based on an inkjet printed polymer semiconductor. The **OFETs showed good reproducibility**, a proper current modulation and **extremely low leakage**, which remained almost unaltered **also after intensive mechanical stresses as bending and rolling**. Such mechanical stability and flexibility, together with the biodegradability and bioderivation, make this approach an appealing candidate for the development of sustainable printed electronics, with widespread future applications in the biomedical and food packaging sector.

The Impact of Bacteria Exposure on the Plasmonic Response of Nanosilver and Hybrid Photonic Crystals Giuseppe M. Paternò[1,2], Francesco Scotognella[1,2] and Guglielmo Lanzani[2,1]; [1]Politecnico di Milano, Department of Physics, Italy; [2]Istituto Italiano di Tecnologia, Italy

Silver, in the form of nanostructures, is widely employed as an antimicrobial agent. Despite the large body of work addressing the effects of silver on the antibacterial mechanism and on the (bio)physical chemistry pathways that drive bacterial eradication, little effort has been devoted to the investigation of nanostructured silver plasmon response upon interaction with bacteria. We investigate the bacteria-induced changes of the plasmonic response of silver nanoplates after exposure to the bacterial model *Escherichia coli* (*E. coli*). Ultrafast pump-probe measurements indicate that the dramatic changes on particle size/shape and crystallinity, likely stemming from a bacteria-induced oxidative dissolution process, translate into a clear modification of the

plasmonic response.[1] Finally, we exploit such an effect to build up photonic crystals embedding silver nanostructures, which have the potential to reveal colorimetrically the presence of bacteria.[2–5] This study opens innovative avenues in the bio- physics of bio-responsive materials.

Nature's Strategy to Color "Blue"—Cases for Avian Feathers Jong-Souk Yeo, Deok-Jin Jeon, Jihun Kang and Seunghwan Moon; Yonsei University, Korea (the Republic of)

Colors of avian feathers can be produced by pigmentation and/or structural coloration. Interestingly, avian plumage colors, where optical nanostructures are present, only produce the color "blue". The reason why nature uses structural coloration instead of pigmentation to produce blue in the short wavelength regions of the visible spectrum is poorly understood, despite its fundamental significance to physiology and potential to spark advances in biomimetic applications. We may postulate that natural blue pigments are chemically less stable than red pigments due to their molecular complexity so that evolutionary process has led birds to use structural ways to produce diverse array of blue colors. Here, we discuss nature's strategy to produce color "blue" with structural ways by elucidating various cases of avian feathers using optical measurement, electron microscopy, numerical modeling, and biomimicry. We show that how birds produce and enhance appearance from photonic crystal or photonic glass nanostructures by addressing ingenious biological designs. To understand the various color-showing mechanisms in avian feathers, the correlations between the avian nanostructures and colorations were analyzed quantitatively, and the avian structural colors were mimicked with synthetic pathways to verify our understanding. For the case of common pheasant, we find that the photonic crystal nanostructures in their feathers can further modulate color in combination with the surrounding thin-film-like cortex layer to produce brilliant colors from blue to green. For Eurasian jay displaying periodic array of blue and white colors in their feathers, our analysis indicates that they vary colors by controlling only the thickness of color-producing optical nanostructures using multiple scattering effects. On the other hand, Kingfisher modulates plumage colors from blue to cyan by changing channel width of optical nanostructures. All these findings suggest that birds have various efficient way to produce blue colors with structural coloration. Inspired by nature's strategy to color "blue", we also demonstrate biomimetic "green" fabrication methods to display brilliant blue colors using synthetic nanoparticles and controlling the conditions similar to the cases in avian optical nanostructures.
This study was funded by the National Institute of Ecology through the grant number (NIE-C-2021-18) and Human Frontier Science Program through the grant number (RFP0047/2019).

4:15 PM SB08.08.03
Bio-Pigment Xanthommatin and Cephalopod Skin Photonics Richard M. Osgood[1], Akshay Nagar[1,2], Sean Dinneen[1], Valerie Adams[3], Jin Ho Kim[1], Leila Deravi[4] and Randy Hughes[5]; [1]DEVCOM SC, United States; [2]Brown University, United States; [3]Army Public Health Center, United States; [4]Northeastern University, United States; [5]U.S. Army Research Laboratory, United States

Biomaterials and biopolymer materials such as biopigments (melanin, xanthommatin, etc.) have fascinating optical properties, such as bright and structural color and advanced camouflage. These material properties are explored in basic research to learn about how the skin of cephalopods (e.g., squid, octopus) functions optically, based on pigment, texture, and photon-scattering granules (~50-500 nm in size). Natural pigment molecules and bio-polymers are attractive for photonics applications: displays, adaptive lenses, underwater optical communications, etc.
Small-molecule biopigments readily dissolve in polymer hosts, resist ultraviolet light, are toxicologically benign, and can be fabricated using large-scale chemical methods. Over 500 mg was synthesized and dried in our laboratory for toxicological analysis. Because of their small-molecule nature, their ability to combine with polymers such as polyvinyl alcohol (PVA), their manufacturability (biological and chemical synthesis), their high refractive index (RI), and their sustainability (they're eaten by animals), the bio-pigments and associated bio-polymers are useful for photonically functional thin films, anti-reflective coatings, photonic scattering for color, etc. Large-scale environmentally friendly synthesis may enable new designs of lightweight optical systems that can adapt and change shape, have a high numerical aperture, and aid in underwater detection or imaging.
The chromatophores in squid skin change from an expanded, pancake-like shape to a punctate, spherical shape and back again to influence photonic scattering and color; they are colored yellow, red, and brown, and are responsible for the bulk color changes. Underneath the chromatophore lie less-obvious iridocyte cells - multilayered Bragg reflectors that reflect color iridescently. The chromatophore cell, in its expanded state, contains multiple layer of sub-monolayers of photon-scattering granules.
Our group discovered that the cephalopod's Xa pigment has a high RI ($n > 1.55$), at 589 nm and at 532 nm. For the latter experiment, n may have been artificially low. Recently, we have carried out more comprehensive broadband (300 nm – 3200 nm) ellipsometric spectroscopy to determine the optical indices (n and absorption coefficient k) of Xa, extracting natural Xa pigment from the squid's chromatophores and forming smooth, high-quality films with concentrations of Xa as much as 90% in polyvinyl alcohol (PVA). Many samples containing natural Xa, and some with artificial Xa, show the same trends, providing a more complete description of Xa's optical properties (n, k) across the entire wavelength range of interest. We have observed an unreported infrared absorption peak and associated reduction in n, and explain possible origins.
Armed with ellipsometric data, we model optical properties (e.g., reflectivity) using a four-flux model (forward and backwards-propagating specular and diffuse light), to gain a more complete and quantitative understanding of squid skin optics, improving on an analytical model of light scattering and absorption developed in 2008 that made important breakthroughs, but lacked separate experimental data on fundamentals for the Xa, and did not comprehensively treat the full optical problem. Here, we update this model analytically, taking better account of the optical coupling between chromatophore and underlying iridocyte. Our 4-flux optical model of the chromatophore will not ignore the background reflectivity and scattering.
The to-be-reported physics modeling and theory, with experimental characterization, will enable new bio-pigment and bio-polymer materials and applications. By understanding how the color of the chromatophores changes, another important step can be taken to harnessing artificial and novel material platforms for more efficient control of light at the nanoscale. We discuss possible new functional nanophotonic systems, based on the bio-pigments, and possible applications.

4:30 PM SB08.08.04
Controlled Afterglow Luminescent Particles for Photochemical Tissue Bonding Seong-Jong Kim and Sei Kwang Hahn; Pohang University of Science and Technology, Korea (the Republic of)

Upconversion materials (UCMs) have been developed to convert tissue-penetrating near-infrared (NIR) light into visible light. However, the low energy

conversion efficiency of UCMs have limited their further biophotonic applications. Here, we developed controlled afterglow luminescent particles (ALPs) of ZnS:Ag,Co with strong and persistent green luminescence for photochemical tissue bonding (PTB). The co-doping of Ag^{+} and Co^{2+} ions into ZnS:Ag,Co particles with the proper vacancy formation of host ions resulted in high luminescence intensity and long-term afterglow. In addition, the ALPs of ZnS:Ag,Co could be recharged rapidly under short ultraviolet (UV) irradiation, which effectively activated rose bengal (RB) in hyaluronate – RB (HA-RB) conjugates for the crosslinking of dissected collagen layers without additional light irradiation. The remarkable PTB of ZnS:Ag,Co particles with HA-RB conjugates was confirmed by *in vitro* collagen fibrillogenesis assay, *in vivo* animal wound closure rate analysis, and *in vivo* tensile strength evaluation of incised skin tissues. Taken together, we could confirm the feasibility of controlled ALPs for various biophotonic applications.

Learning from Nature and a Century-Old Nobel Laureate to Make Mechanochromic Materials at Scale Mathias Kolle and Benjamin Miller; Massachusetts Institute of Technology, United States

Dynamic optical appearance plays a critical role for many animals that rely on adaptive camouflage or bright and varying color displays for their survival. The materials employed by these organisms have inspired scientific and engineering efforts to emulate their dynamic optical behavior in synthetic material analogues, such as mechanochromic photonic materials, which change their optical properties in response to mechanical forces. Mechanochromic materials provide a versatile platform for colorimetric force sensing in a variety of different research and technology fields, including healthcare, robotics, and human-computer interaction. We have developed a roll-to-roll manufacturing technique based on combining Lippmann photography with holographic recording materials, providing a fast, scalable, low-cost method of producing mechanochromic photonic sheets. The benefits of this technique include high-resolution spatial patterning across the entire RGB color space, printing in the near-infrared region to create hidden patterns that appear when stretched, control of the angular distribution of reflected light, and tuning of the mechanical properties of the material to map color variations to different force ranges.

10:15 AM SB08.09.05
Measuring Charge Transport Properties in Single and Double-Stranded RNA Oligonucleotides at the Nanoscale Subrata Chandra, Keshani G. Pattiya Arachchillage and Juan M. Artes Vivancos; University of Massachusetts Lowell, United States

RNA oligonucleotides and their biophysics are an essential part of therapeutics, sensing, and forensics applications. They have gained importance in the research focus in recent years for several reasons. Not only do several pathogens (e.g., SARS-CoV2) have RNA genomes, but many therapeutic[1], biotechnological[2], and modern molecular technologies (e.g., Gene editing[3], gene silencing[4]) use RNA oligonucleotides at their core.
Single-molecule electrical techniques have allowed studying the charge transfer process in biomolecules with unprecedented resolution in the last decade[5]. In the biomolecular electronics discipline, the electronic and charge-transport (CT) properties of short oligonucleotides (dsDNA &DNA: RNA hybrid) have been reported extensively[6]. But despite its biophysical and biological importance, the single-molecule electronic properties of double-stranded(ds)RNA and single-stranded (ss) RNA have not been studied to that extent.
Biomolecular electronics, the discipline studying the charge transfer process in biomolecules, has the potential to describe the interaction between electronic materials and biological systems (RNAs) at molecular interfaces. We use the Scanning tunneling microscope-assisted break junction method (STM-BJ)[7] to study charge transport in short oligonucleotides by reproducible conductance histograms related to their biomolecular structure and conformations. Each biomolecule will be confined within a nanometric gap at a well-defined molecular orientation to measure its electrical properties. Herein, we measured, for the first time, the conductance of individual dsRNA molecules and compared it with the conductance of DNA: RNA hybrids[8]. The average conductance values are similar for both biomolecules, but the distribution of conductance values shows an order of magnitude higher variability for dsRNA, indicating higher molecular flexibility of dsRNA. In our next study, we have demonstrated base-mediated charge transport in specific single-stranded 5 and 10 base pairs(bp) RNA oligonucleotide sequences. We found base stacking is the main factor for getting a probable conductance value for those spontaneously formed RNA oligonucleotide junctions. By comparing with their DNA counterpart, we have found that single-stranded DNA for both 5 and 10 bp sequences are less conductive than RNA due to a lack of base stacking in them.
These results pave the way for measuring various biomolecular interactions at a single-molecule level. In the future, we will measure the conductance of a protein (Argonaute)– RNA complex. This can give us a better understanding of the formation of the RISC(RNA-induced silencing complex) complex and allow the study of the thermodynamics and kinetics of gene expression at the individual complex level. Lastly, we can use these fundamental results for designing next-generation smart biomaterials and biosensors that may address improved biological performances and advanced health monitoring.

Towards Functionalized PEDOT:PSS for OECT-Based Sensing of Cytokine Bernhard Burtscher, Chiara Diacci and Daniel Simon; Linköping University, Sweden

Poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) is the most common organic semiconductor in OECTs. The comparably high transconductance compared to OFETs, combined with easy circuit integration, makes them good candidates for biosensors. While metabolites and neurotransmitters have been successfully sensed with OECTs, reports on other inflammatory proteins and especially cytokines are few.[1–3]

Here, we demonstrate a modification strategy using a small linker molecule to attach to the sulfonates on PSS, which then allows EDC/NHS coupling to bind a recognition element. In this study, we choose aptamers as the recognition elements to demonstrate the concept. Aptamers are synthetic oligonucleotides that exhibit high specificity, low production costs, good shelf-life, and can be modified for various immobilization strategies,[4] making this a versatile, cheap, up-scalable approach. While first investigations focus on cytokine sensing with aptamers, the approach is easily adaptable to bind other elements of interest (e.g., antibodies, enzymes, …).

10:45 AM SB08.09.07
Phenylalanine Assisted Conductivity Enhancement in PEDOT:PSS Films Divyansh Chamria and Ramesh Adhikari; Colgate University, United States

Biological materials such as amino acids are attractive due to their smaller environmental footprint, ease of functionalization, and potential for creating biocompatible surfaces for devices. Here, we report facile self-assembly and characterization of highly conductive films of composites of phenylalanine, an aromatic amino acid, and PEDOT:PSS, a commonly used conducting polymer, which has been shown to have increased conductivity when doped with polar organic compounds. However, the behavior observed with Phenylalanine is significant because it is non-polar in nature and is biologically derived. We have observed that the composite films formed by introducing aromatic amino acid phenylalanine in PEDOT:PSS can improve the conductivity of the film to about 594 S/cm, a 400% increment compared to the conductivity of a pristine PEDOT:PSS film of about 1.5 S/cm. In addition, the conductivity remains high even with a 10 vol% PEDOT:PSS solution. These conductive properties show a clear trend with changed proportions and the composites appear physically distinct. Using DC and AC measurement techniques, we have determined that the conduction in the highly conductive composites is purely due to efficient electron transport compared to pure PEDOT:PSS films. As observed from SEM and AFM, this is likely due to the phase separation of PSS chains from PEDOT:PSS globules which has previously been shown to increase conductivity since PSS regions impede charge transport. Fabricating composites of bioderived simple amino acids with conducting polymers using facile techniques such as the one we report here opens up opportunities for the development of low-cost biocompatible and biodegradable electronic materials with desired electronic properties.

11:00 AM SB08.09.08
Electrochemically Driven Polymerization of pH Sensitive Polymers on High Density Microelectrode Arrays for Neural Patterning *In Vitro* Jens Duru[1], Nako Nakatsuka[1], Josephine Löhle[1], Marcello Pozzi[1], Benedikt Maurer[1], Benjamin Simona[2], Csaba Forro[3] and János Vörös[1]; [1]ETH Zürich, Switzerland; [2]Ectica Technologies, Switzerland; [3]Stanford University, United States

In-vitro neuroscience makes use of dissociated neural networks of iPSC derived or animal origin, grown on the surface of microelectrode arrays (MEA) for electrical access. Upon exposure of neurons to a MEA surface, neurons adhere and connect to each other at random, creating highly complex systems. The complexity of neural networks can be reduced by various surface patterning methods, which render part of the surface cell adhesive and other parts cell repellant [1]. Alternatively, the use of biocompatible microstructures is a popular method to confine the neural adhesion and guide the growth of their axons. In the past, polydimethylsiloxane-based microstructures were used with great success to pattern precise neural networks *in vitro* on low-density glass MEAs with an electrode pitch of 500 µm [2,3] and more recently on high density complementary metal-oxide-semiconductor (CMOS) MEAs [4], that offer up to 26’400 electrodes at a pitch of 17.5 µm.
Here, we demonstrate an alternative patterning method that aims to establish neural guidance structures directly on the surface of the CMOS MEA with a spatial resolution only limited by the electrode pitch of the MEA. By inducing hydrolysis locally on user-defined electrode sets, the pH can be selectively altered in the vicinity of the selected electrodes. This mechanism allows for the local formation of polymers that show a pH-dependent formation, such as transglutaminase crosslinked hydrogel which assembles close to neutral pH [5] or the nature-inspired biopolymer polydopamine that forms in slightly basic (pH > 8) environments [6]. We demonstrate that we can alter the pH with single-electrode precision and can quantify the induced pH change optically using the pH reporter 5-(and-6)-carboxy SNARF-1. Using CMOS MEAs with platinum black coated microelectrodes, we are able to inject large enough currents to shift the local pH of the precursor solutions precisely from 6.6 to 8.4 for dopamine polymerization and 5.8 to 7.5 to form hydrogel. We observe constant pH elevations without precision loss for up to 35 min, which is enough time for local polymer formation. Finally, we provide preliminary results that show that the formed hydrogel guides the growth of primary rat cortical neurons and that the observed effects are dependent on the polymerization time of the hydrogel.

Sustainable Biopolymer Binders for Conformable Multifunctional Electrically Conductive Coatings Pietro Cataldi[1,2], Vicente Orts Mercadillo[2], Giovanni Perotto[1], Mark A. Bissett[2], Ian Kinloch[2], Mario Caironi[1] and Athanassia Athanassiou[1]; [1]Italian Institute of Technology, Italy; [2]The University of Manchester, United Kingdom

There is a growing demand for transitioning electronic circuitry and components from stiff and rigid substrates to compliant and flexible platforms, such as thin plastics, textiles, and foams. In parallel, the push for replacing expensive metals-based inks with cost-effective conductive inks has led to the development of formulations with novel nanomaterials and binders.[1,2] Among the nanomaterials, 2D materials, and in particular graphene-related materials (GRMs), have drawn attention due to their increasingly facile and scalable production, high electrical conductivity, and compatibility with industrial manufacturing methods.[3] The resulting conformable electronic materials are poised to unlock thrilling applications in the wearable, healthcare, and Internet of Things sectors. Nevertheless, the substrates, the binders, and the solvents employed are so far often selected without considering the outcome in terms of material sustainability.

We developed electrically conductive composite coatings based on GRMs and biobased and/or biodegradable binders.[2,4] The fabrication is simple and exploits green solvents such as alcohol and/or water. Sustainable binders, ranging from biopolymers and natural waxes such as polyvinyl alcohol and beeswax to proteins from the waste stream such as keratin extracted from wool/feather wastes, were preferred depending on the selected sustainable substrates (i.e., cellulose-/biopolymer-based). The as-obtained materials display a low sheet resistance of about 10 Ohm/sq and excellent stability to tens of folding events, hundreds of abrasions, and thousands of bending cycles. Thus, they can be applied as deformable conductors or strain sensors, depending on the material formulation (i.e., 2D-1D nanofiller hybridization and binder:nanofiller ratio) and the consequent electrical percolation preservation/disruption after mechanical stress. These materials are multifunctional since they exhibit enhanced thermal conductivities. As such, they can be applied simultaneously for thermal dissipation and electromagnetic interference shielding. Due to their flexibility, multifunctionality, and reduced footprint, such versatile electrically conductive coatings have the potential to enable applications in the wearables and conformable electronics field, reducing the environmental impact of the conductive materials for electronics simultaneously.

11:30 AM SB08.09.10
Hydrogel Protector for Stabilizing Water Splitting Photoelectrodes Byungjun Kang, Jeiwan Tan, Kyungmin Kim, Donyoung Kang, Hyungsoo Lee, Sunihl Ma, Gyumin Jang, Jooho Moon and Hyungsuk Lee; Yonsei University, Korea (the Republic of)

Human beings are facing severe problems related with the global climate change. There have been international efforts to replace carbon-based energy system with carbon-free/hydrogen-based energy one. Solar hydrogen conversion techniques gains attention as they can produce hydrogen using sunlight and water without emission of greenhouse gas. Photoelectrochemical (PEC) water splitting is considered as one of the promising solar hydrogel conversion techniques because it can be realized using low-cost thin-film materials. However, current low-cost thin-film based PEC devices have a relatively short lifespan due to its low structural stability. Light-absorbing semiconductor of the PEC device severely suffer from photocorrosion by electrolyte. Although amorphous TiO_2 is deposited via atomic layer deposition on the device to provide physical separation between the semiconductor and electrolyte, photoelectrons accumulated near the device surface induce the reduction and dissolution of the TiO_2 layer. In addition, platinum (Pt), which is the best hydrogen evolution reaction (HER) catalyst, can be easily agglomerated and detached from the PEC device.
Although various strategies including insertion of functional layer under the catalyst have been introduced, still there is a need to develop a versatile protection strategy which can prevent both co-catalyst detachment and photocorrosion for practical operation of PEC devices. We hypothesize that device-on-top protector made of nanoporous polymeric network may prevent the dissociation of components of the PEC device. A protector with a high transparency and water content can be preferred in order not to disturb light transmission and electrolyte transfer to the device. We are inspired by ocean plants where algae cells are covered by ‘hydrogel’ which has a transparent and nanoporous polymer network structure having high water content.
In this study, we demonstrate that the hydrogel protector on the PEC device enhances the structural stability of the PEC devices. As a hydrogel protector, we selected low cost polyacrylamide which has high chemical inertness in electrolyte solution. The hydrogel was coated on a reference $Pt/TiO_2/Sb_2Se_3$ photocathode via a mold casting method. Dynamics of hydrogen bubbles in the hydrogel and their escape can depend on the mechanical and structural properties of the hydrogel. We demonstrate that trapped bubbles cause the fracture of the protector in the case of high concentration of hydrogel. When the hydrogel protector is relatively thick, hydrogen bubbles are trapped inside the protector leading to reduction in photocurrent. With the protector having the optimal properties, bubbles can effectively escape from the protector through micro gas tunnels which are formed in the hydrogel at the initial stage of the PEC operation. The hydrogel protector coated on the PEC device can prevent detachment of Pt catalyst and dissolution of TiO_2 layer. Compared to without protector, the lifetime of the $Pt/TiO_2/Sb_2Se_3$ photocathode covered by the hydrogel protector was increased by 100 folds. Furthermore, we showed the hydrogel protection strategy can be applied to various types of PEC devices including SnS photocathode and $BiVO_4$ photoanode. We expect that further engineering of the hydrogel in terms of microstructure, poroelastic property, and chemical property can help to develop a semi-permanent hydrogen production system.

SESSION SB08.10: Biomedical Applications I
Session Chairs: Brendan Harley and Eleni Stavrinidou
Thursday Afternoon, December 1, 2022

1:30 PM *SB08.10.01
Biopolymeric Materials for Organoid Bioprinting Sarah C. Heilshorn; Stanford University, United States

Organoids are three-dimensional, multi-cellular constructs with emergent structural properties that mimic organizational features found in natural tissue. Individual organoids can fuse together to form tissue-like structures, termed “assembloids,” that can serve as *in vitro* models of human development and disease. A key requirement for assembloid fabrication is the spatial positioning of individual organoids, which is currently performed manually. To automate and scale-up this biofabrication process, we have developed a family of biopolymers that work together with a custom-built electromagnetic

bioprinter. Here, we demonstrate the capacity for an iron-oxide nanoparticle-laden hydrogel to mediate the spatial patterning and subsequent fusion of human induced pluripotent stem cell (iPSC) derived neural organoids within a support hydrogel. The support material is shear-thinning and self-healing to accommodate the motion of the electromagnetic printer, promote organoid hydration, and achieve stable placement within three-dimensional space while organoid fusion occurs. Unlike aspiration-mediated biofabrication approaches that can lead to irreversible plastic deformation of cellular aggregates, magnetic lifting was well tolerated by the organoids. We leveraged this system to create precisely arranged neural assembloids with excellent viability and maintenance of the internal cytoarchitecture of individual organoids. In summary, this platform represents a significant advance in the emulation of large, compositionally diverse neural tissues to enable high-throughput studies of neural development and disease.

2:00 PM SB08.10.02
DNA Aptamers and Self-Assembled DNA Materials as Bioinspired Modulators of Calcium Mineralization Aren E. Gerdon; Emmanuel College, United States

Synthetic DNA, as small functional molecules or in large self-assembled structures, provides exquisite addressability, functionality, and fidelity. As a poly-electrolyte with repeating negative charge DNA mimics poly-anionic proteins found in enamel, bone, and marine organisms. DNA aptamers have been selected to influence calcium phosphate mineral formation using a novel precipitation SELEX method. These aptamers have been demonstrated to slow mineralization kinetics while altering materials morphology depending on pH and the presence of G-quadruplex secondary structures. Current research efforts have been in applying DNA aptamers to calcium phosphate mineralization of collagen and to calcium carbonate mineralization. Using DNA aptamers in coordination with DNA self-assembled materials, such as DNA origami, is currently being explored as a means for building and mimicking hierarchical structures.

2:15 PM SB08.10.03
Dynamic Hydrogels as Models of Liver Fibrosis Progression Yueming Liu, Aidan Gilchrist, Yuan Guan, Gary Peltz and Sarah C. Heilshorn; Stanford University, United States

Hydrogels have emerged as a promising platform for three-dimensional (**3D**) *in vitro* models of disease progression. However, widely utilized animal-derived matrices (e.g. Matrigel/Cultrex) are highly variable and do not allow for tuning of biophysical and biochemical cues. Additionally, such matrices do not capture the dynamic features of the *in vivo* extracellular matrix (**ECM**), which is remodeled during disease progression and causes further dysregulation of cell behavior. Here, we present an engineered matrix crosslinked by dynamic covalent bonds that enable on-demand tuning of material mechanics to model the stiffening of the liver during fibrosis.

During disease progression of fibrosis, there is an associated increase in the deposition of elastin, fibronectin (**FN**), and hyaluronan (**HA**), resulting in an increase in stiffness. We have established a liver-mimetic environment by incorporating HA modified with benzaldehyde functional groups and a recombinant elastin-like protein (**ELP**) modified with hydrazine functional groups to create a HA-ELP (**HELP**) matrix. The engineered elastin-like protein (**ELP**) contains a cell-adhesion motif from fibronectin and a peptide sequence derived from elastin. When mixed, the benzaldehyde and hydrazine functional groups form dynamic hydrazone bonds, which can break and reform at physiological conditions, creating a dynamic microenvironment. By altering the wt% of HA and ELP, we have assembled a suite of HELP gels whose stiffnesses (0.5 – 6 kPa) reflect that of normal liver through those with advanced stages of fibrosis. To regulate HELP stiffness during culture, we have introduced a small molecule competitor that competes for crosslinking sites, which can decrease the crosslink density and stiffness of HELP. Over time these competitors diffuse out of the hydrogel, which leads to an increase in crosslink density that mimics the stiffening environment that occurs during the progression of fibrosis.

Using a library of competitors, we demonstrate that HELP stiffness can be reduced by an order of magnitude in a dose-dependent manner. By altering the chemical functionality of the competitor, we can tune the time-scale of modulus recovery, ranging from < 1 day to over three weeks. This enables us to examine the effect of acute stiffening and the effect of gradual stiffening occurring over a >2 week period. Using this chemically defined, adaptable hydrogel platform, we developed a model of liver fibrosis progression using human hepatic organoids (**HO**). We combine HELP with laminin-111 to promote the formation and culture of HO, and demonstrate long-term growth of HO across a variety of stiffnesses. Finally, we demonstrate that incorporation of competitors does not impact HO growth and morphology. Human HO grown in HELP matrices are viable, proliferative, and metabolically active, and they continue to express markers of differentiated hepatic tissue and accumulate lipids in a stiffness-dependent manner. We are currently evaluating the altered metabolic profile and lipid accumulation in these gradually stiffening materials.

Overall, we have developed of a dynamic HELP hydrogel with on-demand control of mechanical properties using crosslinking competitors. We demonstrated formation and growth of HO in dynamic HELP with liver-mimetic stiffnesses to model liver fibrosis progression.

2:30 PM BREAK

3D-Bioprinted Phantom with Human Skin Phototypes for Biomedical Optics Wonjun Yim, Jiajing Zhou, Lekshmi Sasi and Jesse V. Jokerst; University of California San Diego, United States

We report 3D-bioprinted skin-mimicking phantoms with skin colors ranging across the Fitzpatrick scale. These tools can help understand the impact of skin phototypes on biomedical optics. Synthetic melanin nanoparticles of different sizes (70–500 nm) and clusters were fabricated to mimic the optical behavior of melanosome. The absorption coefficient and reduced scattering coefficient of the phantoms are comparable to real human skin. We further validated the melanin content and distribution in the phantoms versus real human skins *via* photoacoustic (PA) imaging. The PA signal of the phantom could be improved by (i) increasing melanin size (>1,000-fold), (ii) increasing clustering (2–10.5-fold), and (iii) increasing concentration (1.3–8-fold). We then used multiple biomedical optics tools (*e.g.,* PA, fluorescence imaging and photothermal therapy) to understand the impact of skin tone on these modalities. These well-defined 3D-bioprinted phantoms may have value in translating biomedical optics and reducing racial bias.

3:15 PM SB08.10.05
Thermal Transport in Neuron-Inspired Polymer-Gold Nanoparticle Tree Networks Xingfei Wei and Rigoberto Hernandez; Johns Hopkins University, United States

Complex networks of polymer linked nanoparticles have potential applications in chemical separation, biomedicine and nanophononics. Inspired by Cajal's picture of a single neuron [Gomez-Marin, Science, 2022, vol 375, issue 6586, p 1237], the tree-like single neuron structure could be the key to developing new brain-like computing materials. In this work, we have designed computational models of binary tree networks using polymers and gold nanoparticles (AuNP) to mimic a neuron structure. The tree structure and thermal transport properties in polymer-AuNP networks are uncovered using all-atom molecular dynamics simulations. We vary the height of the binary tree structure from 1 to 5 levels corresponding to a total number of 2 to 32 leaves. The

heat flux in both directions, from leaves to the root and from the root to leaves, are reported. Two polymer types of similar branch chain length with different backbone stiffness are compared, *viz.* polyethylene (PE) and poly(*p*-phenylene) (PPP). We also compared tree networks with different branch chain length using 12 and 50 carbon length PE. The results from our simulations provide useful guidance for developing new bioinspired materials and devices.

3:30 PM SB08.10.06
Wireless Localized Electrical Stimulation of Neurons Using Biomimetic Synthesized EDOT-Pyrrole Nanoparticles Nicolas Muzzio[1], Manuel E. Martinez-Cartagena[2], Rohini Thevi Guntnur[1], Vanessa Fisher[1] and Gabriela Romero[1]; [1]University of Texas at San Antonio, United States; [2]Research Center in Applied Chemistry, Mexico

Non-invasive manipulation of cell signaling is critical in basic neuroscience research and in developing therapies for neurological disorders and new tissue engineering and regenerative medicine approaches. Current techniques for drug-free, selective, and deep stimulation of the nervous system present major drawbacks such as low spatial resolution, limited target depth or the requirement of highly invasive neurosurgical procedures. To overcome these limitations, nanotechnology approaches are being developed to allow for wireless and cell-type specific neuronal stimulation. Though it is known that electric fields modulate several biological processes and that neurons are electrogenic cells, electrical stimulation and conductive cues have been disregarded in tissue engineering and regenerative medicine approaches until recently. In this work, biomimetically synthesized conductive copolymer 3,4-ethylenedioxythiophene (EDOT)-Pyrrole nanoparticles (RB02 NPs) were used for enhancing neuronal differentiation and for wireless and localized neurostimulation.

Biomimetic synthesis of EDOT-Pyrrole copolymers doped with PSS was carried out using hematin as catalyst. The obtained RB02 NPs were characterized by means of Raman spectroscopy, Fourier transform infrared spectroscopy, electron microscopy and dynamic light scattering. The electrochemical properties were characterized by galvanostatic charge discharge, voltammetry, and electrochemical impedance spectroscopy. For electrical stimulation of neurons, NPs were charged by applying 3V using platinum electrodes, obtaining C-RB02 NPs. NPs effect on ND7/23 neuron hybrid cell line viability was assessed by live/dead staining using flow cytometry. ND7/23 differentiation was evaluated by cell cytoskeleton staining and quantification of morphological parameters such as dendrite number and length. Primary cortex neuronal stimulation was studied by calcium ion influx detectable through the dynamic fluorescence changes of Fluo-4.

The NPs presented a pseudocapacitive behavior and large specific capacitance, allowing their use as nanocapacitors by charging them through electrical current exposure, obtaining C-RB02 NPs. The live/dead assay showed that RB02 NPs presented no toxicity towards ND7/23 cells. Furthermore, charged NPs enhanced cell differentiation at short times after addition (<6 hours), evidenced in cells with more and longer dendrites. Charged RB02 NPs largely increased cortex neuronal activity assessed by intracellular calcium dynamics.

In conclusion, biomimetic synthesized conductive RB02 NPs were used for the localized stimulation of neurons. Biomimetic synthesis was utilized to avoid cytotoxicity of the nanomaterials associated with traditional wet chemistry protocols. RB02 NPs displayed similar charge-transfer velocity and larger specific capacitance than PEDOT:PSS, benchmark in electroconductive material for bioengineering. Electroconductive RB02 NPs were shown to enhance ND7/23 differentiation within 3 hours of co-culturing. The differentiation effect was more pronounced when charged nanoparticles were employed. Charged RB02 NPs largely increased neuronal activity in primary rat cortical networks assessed by calcium imaging. Overall, biocompatible RB02 NPs fabricated here have a great potential for the remote control of biological signaling, which is anticipated to contribute to the progress of basic neuroscience research and for developing neurological therapies.

3:45 PM SB08.10.07
Yield-Stress and Creep Control Depot Formation and Persistence of Injectable Hydrogels Following Subcutaneous Administration Carolyn K. Jons and Eric A. Appel; Stanford University, United States

Hydrogels that can be injected into the body using standard needles or catheters enable a minimally invasive strategy to prolong local delivery of therapeutic drug and cellular cargo. In particular, physically crosslinked hydrogels exhibit shear-thinning and self-healing behaviors enabling facile injectability and depot formation upon administration. While prior efforts to characterize these systems have focused on injectability and cargo release behaviors, prediction of cargo release in the body often assumes the materials form a depot rather than spreading out upon administration. Here, we evaluate how hydrogel rheology correlates with depot formation and persistence following subcutaneous administration in mice with two physiochemically-distinct, physically crosslinked hydrogel systems. We evaluate calcium-alginate and polymer-nanoparticle hydrogel systems exhibiting variable mechanical behaviors across several rheological properties (stiffness, viscoelasticity, yield stress, and creep). By relating measured rheological properties to depot formation and persistence time following subcutaneous administration, for these two gel systems we identify that yield stress is predictive of initial depot formation while creep is predictive of depot persistence. Indeed, only materials with yield stresses greater than 25 Pa form robust depots, and reduced creep correlates with longer depot persistence. These findings provide predictive insights into design considerations for hydrogel technologies capable of extended controlled release of therapeutic cargo.

4:00 PM SB08.10.08
Hyaluronic Acid Hydrogel with Gradient Mechanical Properties for Tissue Engineering Mina Kwon, Hye Eun Choi and Ki Su Kim; Pusan Natoinal University, Korea (the Republic of)

For cell physiology, the microenvironment can play an important role, and hydrogels can provide a three–dimensional microenvironment to allow native cell growth in vitro. Hydrogels, a crosslinked hydrophilic polymer that does not dissolve in water, have been widely studied as an artificial extracellular matrix (ECM) that can mimic the ECM of various tissues due to its high water retention capacity, permeability to cellular nutrients and metabolites, excellent mechanical properties and biocompatibility. The mechanical properties of the extracellular matrix (ECM) contribute to the regulation of various cellular behaviors, and controlling the mechanical properties of hydrogels is of key importance in enabling various cell-hydrogel interactions. However conventional hydrogels have a homogeneous environment with an isotropic distribution limiting complete mimicking of the complex architectures of native tissues and pathological gradients found in tumors, scars, and wounds. In this work, we report hydrogel with gradient mechanical properties using hyaluronic acid which is a natural polymer and an excellent candidate for use in tissue engineering due to its excellent biocompatibility and bio–functions. Hyaluronic acid was conjugated with methacrylate and ^{1}H NMR spectrum confirmed the successful synthesis of methacrylated hyaluronic acid. We successfully prepared the gradient hydrogel via photocrosslinking method, and the studies were performed with syringe pumps for gradient generation and a fluidic mixer for homogenous mixing of hydrogel precursors with different crosslinker concentrations. The gradient hydrogel was characterized and assessed the feasibility of tissue engineering application. The successful formation of the gradient in crosslinking density is confirmed by NMR spectrum and the viscoelastic properties of the hydrogels were tested on a rheometric fluid spectrometer. Scanning electron microscopy confirmed the different cross–sectional morphology and the pore size in our hydrogel system. For in vitro test, L929 fibroblasts were encapsulated in gradient hydrogel and stiffness–dependent cellular behaviors are monitored using a confocal microscope. In all samples, cells are highly active and spread well along the hydrogel

substrate, and enhanced cell spreading was confirmed as the degree of crosslinking decreases. We further investigated the hydrogels' cell differentiation ability by culturing human adipose tissue–derived mesenchymal stem cells (hAD–MSCs) and stiffness–dependent hAD–MSCs morphology, migration, and differentiation were studied. In vitro drug release analysis was conducted to evaluate the drug release profile of gradient hydrogel and a gradual release of the model drug was observed. Taken together, this gradient hydrogel will be exploited in a tissue engineering platform to mimic variable mechanical gradient tissues.

4:15 PM SB08.10.09
Functional Contact Lens for Colorimetric Visualization of Glucose Level Jeongin Seo[1], Jumi Kang[1] and Kyueui Lee[1,2]; [1]Kyungpook National University, Korea (the Republic of); [2]Kyungpook National University Hospital, Korea (the Republic of)

A non-invasive glucose monitoring system is ideal for measuring glucose levels. However, most diabetic patients still rely on the traditional invasive finger-prick measurements due to the cost issue. We developed a disposable contact lens-based colorimetric glucose sensing platform. A plant-derived polyphenolic polymer called poly(tannic acid) having substantial molecular adhesion was used as a functional coating layer for conjugating a nucleophilic molecule, 4-mercaptophenylboronic acid. The boronic acid-functionalized contact lenses showed a strong and reversible binding affinity for glucose depending on pH conditions. The bound glucose can be released by immersing the contact lens in an acidic enzymatic cocktail, resulting in an immediate color change. This allows a facile colorimetric determination of glucose levels. The glucose concentration dependent color change was quantified by UV-vis studies. The successive chemical modifications of the contact lens surface were characterized by XPS analysis and contact angle measurements. An in-vitro cytotoxicity test (i.e., CCK-8 assay) confirmed the biocompatibility of the system. Taken together, our glucose-sensing contact lens is expected to successfully replace the conventional glucose measurement methods; this will be especially beneficial for low-income people.

4:30 PM SB08.10.10
Mechanistic Study of Block Copolymer Interaction with Cell Membranes and Model Lipid Bilayers Mihee Kim[1], Timothy Lodge[2], Joseph Metzger[2], Benjamin Hackel[2] and Frank Bates[2]; [1]Los Alamos National Laboratory, United States; [2]University of Minnesota Twin Cities, United States

Disruption of cell plasma membranes, a crucial component of cells, is fatal for cellular functions. Poloxamer 188 (P188), a poly(ethylene oxide)-*b*-poly(propylene oxide)-*b*-poly(ethylene oxide) (PEO–PPO–PEO) triblock copolymer, is known to protect cell membranes against various external stresses and injuries, demonstrating its potential to treat diseases such as Duchenne muscular dystrophy or ischemia-reperfusion injury. However, the mechanism by which the polymer protects the cell membrane is poorly understood. Here, I present several systematic approaches to exploring how amphiphilic block copolymers interact with cell membranes and model lipid bilayers. First, we probed how block copolymer architecture affects cell membrane protection using a cellular membrane integrity assay and precisely synthesized PEO–PPO diblock copolymers. To gain a more quantitative assessment of the interactions at the molecular level, we employed supported lipid bilayers as model cell membranes. Binding kinetics and surface coverage of similar molecular weight P188 and a PEO homopolymer were examined using surface plasmon resonance spectroscopy. Distribution of P188 and PEO within the bilayer was studied using neutron reflectivity and atomic force microscopy. We discovered that P188 and PEO both adhere to the lipid bilayer with slow binding kinetics, and surprisingly, both penetrate into the inner lipid leaflet, suggesting that PEO plays a significant role in driving the block copolymer interactions with cell plasma membranes. Study with fluorescent dye-labeled polymers translates these finding to living tissue. Collectively, these results provide important clues regarding how block copolymers protect cell membranes.

4:45 PM SB08.10.11
Fabrication of Drug Loaded PLGA Microparticles Using a Microfluidic Flow-Focusing Device for Sustained Release Formulations Nelia D. Viza; Merck, United States

Long acting injectables aim to improve the current standard of care for various infectious diseases and neurological disorders, by eliminating the oral dose. As a result, decreasing dosing frequency with highly active, well-tolerated medications offers an avenue by which the challenges of pill/treatment fatigue, and desire for anonymity can be addressed, while also improving outcomes. To further simplify the dosing schedule and improve adherence, we aim to develop a pulsatile release formulation that enables long-acting delivery of API through either a subcutaneous or intramuscular administration.
A microfluidic approach is proposed to fabricate biodegradable, biocompatible PLGA drug loaded microparticles to enable high drug loading, sustained-release formulations. A glass focus-flow microfluidic design was used to form single oil-in-water emulsions and fabricate PLGA drug loaded microparticles. The dispersion, or oil phase, consists of the drug, organic solvents, and polymer. The continuous, or water phase, consists of a water miscible surfactant. The drug loaded (API_A), single emulsions formed droplets ranging from 150 um to 300 um. The size of the diameter has been shown to be tunable to a desired value based on the capillary number and the relative fluid velocities ratio.
A solvent evaporation step is incorporated to remove two organic solvents. As a result, a 73% reduction in drug loaded (API_A) microparticle size is observed after a timeframe of two days. Gas chromatography confirmed there to be no residual organic solvents detected in washing steps or in dissolved drug loaded (API_A) microparticles. SEM images showed a spherical shape maintained after mixing and washing steps. However, some large pores were captured on the microparticles based on the SEM images, perhaps due to one of the organic solvents, which is also miscible in water, leaving the PLGA polymer upon droplet formation.
A lyophilization step was incorporated after the washing step of the microparticles, to improve drug loading efficiency assessment using UV spectrometry. Furthermore, drug loading efficiency increased, from 3% to 10%, by increasing the polymer to API_A ratio. Due to one of the organic solvents forming a stream upon droplet formation on a chip, as the possible root cause to our low drug loading efficiency, a different API (API_B) was assessed. Furthermore, prodrugs of API_A, are also currently being investigated to improve its hydrophobicity and therefore increase its drug loading efficiency.
API_B, with its lower solubility in water, was also investigated and showed significant improvement to drug loading efficiency, in comparison to API_A, and eliminated the need of one of the organic solvents. The control release functionality of API_B, using a USP-4 apparatus is currently being investigated. An exploratory PK/PD study will also be conducted to test the microfluidic technology.

8:30 AM SB08.11.01
Motor Mobility Determines Actin-Myosin Network Contraction Characteristics Donyoung Kang and Hyungsuk Lee; Yonsei University, Korea (the Republic of)

Dynamic behaviours driven by intracellular cytoskeleton such as migration, division and endocytosis are mainly regulated by the contraction of cytoskeleton network consisting of cytoskeleton and motor proteins. Depending on the functional demand in each cell function, various structures and contraction characteristics of cytoskeleton networks are observed. For example, in the early phase of cytokinesis, chromosome segregation is progressed by the radial-directional contraction of the linear assembly of microtubules and motor protein dynein. During cleavage furrow ingression, the ring-shaped actin-myosin structure attached to the inner surface of cellular membrane shrinks at a constant speed by the circumferential-directional contraction of the ring.
Many have studied how the contractile behaviours of cytoskeleton-motor protein networks depend on protein concentrations, chemical environments and geometric boundaries. In vitro experiments found that concentrations of motor protein and network crosslinkers play a crucial role in modulating contraction speed of the cytoskeleton-motor network. KCl concentration is critical for the global and synchronized contraction of actin-myosin network. The speed and length scale of the network contraction were significantly affected by the network shape such as square and circle. Nonetheless, it remains unclear how the mechanical boundary condition of the motor protein determines the dynamics characteristics of cytoskeleton-motor protein network contraction.
Here, we analysed the contractile behaviours of actin-myosin network in two different mechanical boundary conditions of motor protein, myosin. We prepared “immobilized motor” (IMM) condition by firmly attaching myosin thick filaments to a glass surface. In “mobile motor” (MM) condition, actin network cross-linked with actin binding proteins (ABPs) were prepared on a glass surface coated with cellular lipid membrane allowing movement of motor proteins. Contraction of actin-myosin network in IMM and MM conditions were visualized using fluorescence-conjugated actin. We found that the relative concentration of actin and ABP which defines a network connectivity determines the contraction shape and speed. While contracting actin-myosin networks exhibited radial patterns in IMM condition, a global and isotropic contraction was observed in MM condition. Contraction speed increased with the network connectivity in MM but decreased with it in IMM condition.
To elucidate the mechanism of the actin contraction depending on the boundary condition of motor protein, we developed a computational model tracking each component of network such as actin, ABP and myosin during contraction. The radial contractile pattern of actin network was exhibited in IMM condition similar to the experimental results. The computational simulation found that local actin-myosin clusters gathered into a larger one leading to a global contraction in MM condition.
In summary, we showed how the characteristics of actin-myosin network contraction depend on the mechanical boundary condition of myosin motor protein. Changes of contraction behaviours in terms of contraction pattern and speed by the network connectivity depends on the mobility condition of motor protein. While the contraction speed increased proportional to network connectivity in MM, it decreased in IMM condition. Our study provides an intuition into not only the mechanism of cell dynamics but also the design of biomimetic systems. By modulating the mechanical boundary condition of motor protein, a dynamic molecular system transporting substances to a target destination can be designed.

8:45 AM SB08.11.02
Influence of Ca/P in Modified-Simulated Body Fluid Solution on Intrafibrillar Mineralization of Collagen with Polydopamine to Generate Collagen-PDA-HAp Scaffolds Urasawadee Amornkitbamrung, Yongjae In and Hyunjung Shin; Sunkyunkwan University, Korea (the Republic of)

Large bone defects have attracted attention as a remain major challenge in bone tissue engineering. In bone tissue, the mineralized collagen fibril is an important basic building block which collagen molecules are hierarchically assembled into fibrils and mineralized with the formation of hydroxyapatite (HAp) nanocrystals. Due to the uniformly distribution HAp in collagen fibrils and together built up hierarchically from nano to macrostructures in bone tissue, mineralized collagen fibril is regards as the important level for the mechanical properties. Collagen based scaffolds have been increasing used in tissue engineering due to its excellent biocompatibility. However, the insufficient mechanical strength and structural support limit it wider in bone regeneration application. Many attempts have been devoted to improve collagen-HAp based scaffolds’ properties by understanding the process of bone mineralization to fabricate bone mimicking scaffolds. The mineralization pathway of HAp has been suggested as non-classical crystallization as reported, but the physical and chemical mechanism is still poorly understood with a difficult challenge, especially in collagen fibril’s structure. In this work, with the presence of polydopamine (PDA) to promote the biomineralization process, the structure of intrafibrillar mineralized collagen-PDA fibrils in modified-simulated body fluid (m-SBF) solution was studied at the nano scale by STEM-EDS techniques to investigate a detail hydroxyapatite intrafibrillar mineralization pathway. Collagen-amorphous calcium phosphate (ACP) fibrils was obtained by assembling Collagen-PDA fibrils in SBF solution with the present of Mg^{2+} and polyaspartic acid as a precursor stabilizer. Then later the phase transformation of ACP to HAp was determined by tuning the phosphate concentrations in m-SBF. It was found, in this work, that the phase transformation of ACP to HAp in Collagen fibrils can be accelerated even in 12 hr-mineralization with the m-SBF solution of calcium and phosphate ratio of 1:10, higher phosphate ratio produces a monodentate Ca-P geometry and evolved directly to HAp, while the lower 1:5 would affect in slower phase transformation kinetic, and for 1:1 the crystallization of HAp cannot be initiated even up to 7 days of mineralization. The finding suggests that an elevated concentration of phosphate is crucial for initiate phase transformation of ACP to HAp. From these studies and strategy, we adopted to fabricate mechanically self-sustained Collagen-PDA-HAp hydrogels. By controlling the mineralization, it is beneficial for collagen-based scaffolds’ fabrication design. A synergistic effect was also investigated and observed in the Collagen-PDA-ACP and Collagen-PDA-HAp for both in vitro osteogenic differentiation of bone marrow mesenchymal stem cells (BMSCs). Thus, the results presented in this work could serve a better understanding the mechanism of the HAp mineralization in collagen fibrils, which may provide approaches to effective, and materials design for efficient osteogenesis bone tissue engineering.

9:00 AM SB08.11.05
Hyaluronate-Black Phosphorus-Upconversion Nanoparticles Complex for Non-Invasive Theranosis of Skin Cancer Gibum Lee, Jung Ho Lee and Sei Kwang Hahn; Pohang University of Science and Technology, Korea (the Republic of)

Black phosphorus (BP) has been widely investigated for various biomedical applications with the unique characteristics of 2D nanomaterials including its high photothermal conversion efficiency, biocompatibility, biodegradability and ultraviolet (UV)-meditated reactive oxygen species (ROS) generation. However, the finite depth of light penetration has limited further development of BP-based photomedicines. Here, we developed hyaluronate-BP-upconversion nanoparticle (HA-BP-UCNP) complex for near-infrared (NIR) light mediated multimodal theranosis of skin cancer with photoacoustic (PA) bioimaging, photodynamic therapy (PDT), and photothermal therapy (PTT). In contrast to the conventional BP-based skin cancer theranosis systems, HA-BP-UCNP complex could be non-invasively delivered into the tumor site to induce the cancer cell apoptosis upon NIR light irradiation. HA in the complex facilitated the transdermal delivery of BP into the tumor tissue under the skin. Upon 980 nm NIR light irradiation, UCNP converted the light to UV-blue light to generate ROS by sensitizing BP in the HA-BP-UCNP complex for PDT. Remarkably, 808 nm NIR triggered PTT for the apoptosis of tumor cells. The photoacoustic imaging of BP successfully visualized the non-invasive transdermal delivery of HA-BP-UCNP complex into the mice skin. The cell viability test revealed the low cytotoxicity of HA-BP-UCNP complex in fibroblast cells. On the other hand, the complex showed high cytotoxicity to tumor cells under NIR light irradiation by PDT and PTT. The combination therapy of PDT and PTT by 980 + 808 nm NIR light irradiation drastically reduced tumor growth compared to only single NIR light irradiation for up to 7 days in skin cancer model mice. The antitumor effect of HA-BP-UCNP complex with NIR light irradiation was also confirmed by immunohistochemical TUNEL assay. Taken together, we could demonstrate the feasibility of HA-BP-UCNP complex as a non-invasive theranostic nanoplatform for skin cancer.

Calcifications Can Trigger or Suppress Breast Precancer Malignancy Potential as a Function of Mineral Type in a 3D Tumor Model Netta Vidavsky; Ben-Gurion University of the Negev, Israel

The breast precancer stage will not necessarily develop into invasive breast cancer and theoretically does not always require treatment. However, it is impossible to predict whether precancers will become invasive cancer. More than 90% of breast precancer cases contain pathological minerals called microcalcifications. Most microcalcifications are calcium phosphate in the form of apatite, and their composition and crystal properties correlate with malignancy in clinical samples and may have a prognostic value. In clinical samples, apatite crystals with high and low carbonate content are associated with benign and malignant lesions, respectively, and calcium oxalate dihydrate (COD) is always found in benign lesions. Recent *in vitro* and *in vivo* studies show that specific changes in the properties of apatite crystals can trigger precancer progression.
Here, we developed a breast tumor *in vitro* model consisting of synthetic microcalcification analogs embedded in precancer multicellular spheroids that mimic the 3D microenvironment of mammary ducts. As microcalcification analogs, we use various synthetic mineral types that are physiologically relevant: apatite with high and low carbonate content and COD. Our methodology includes micro-CT for 3D imaging of mineral particles within soft tissues and scanning electron microscopy and vibrational spectroscopy for mineral characterization.
We show that cell proliferation and the expression of proteins associated with cancer change with the properties of the embedded mineral in our *in vitro* model. Low carbonate apatite promotes precancer malignancy compared to other types of minerals or conditions of no added mineral. Surprisingly, COD suppresses precancer malignancy compared to apatite or conditions of no added mineral. This finding suggests that microcalcifications can affect precancer cells by either triggering them to proliferate or inhibiting their proliferation, even compared to conditions of no minerals. Possibly, the presence of COD crystals only in benign clinical tissues is not random but is a result of its tumor-suppressing qualities. Insights from this study may suggest in the future ways of affecting disease progression by manipulating the crystal properties of breast microcalcifications *in situ*.

10:00 AM SB08.11.07
PhoCoil—An Injectable and Photodegradable Single-Component Recombinant Protein Hydrogel for Localized Therapeutic Delivery Nicole Gregorio and Cole A. DeForest; University of Washington, United States

Hydrogels have found widespread utility in many research areas including controlled therapeutic delivery and tissue engineering. Many gel systems have been developed that mimic properties of the extracellular matrix (ECM), providing biocompatibility and enabling 3D cell culture. Traditionally, hydrogels have been formed from polymeric precursors that are either naturally occurring or synthetic. Natural gels are derived from naturally occurring biomolecules, often extracted from tissues. As such, many of these hydrogels mimic the ECM at a chemical and/or structural level, making them a top choice for biomedical applications, but lack in their tunability, providing researchers with few options to control these systems in a defined manner. They also frequently suffer from batch-to-batch variation, creating technical challenges in their implementation. In contrast, hydrogels formed from synthetic polymers retain batch-to-batch similarity and provide significantly more tunability through incorporation of diverse chemistries during synthesis or crosslinking. However, many of these materials are dissimilar to the chemical and/or structural makeup of the ECM. On top of this, both synthetic and natural hydrogels are intrinsically polydisperse. This results in networks with an ill-defined inter-crosslink distance, impacting material elasticity and contributing to overall heterogeneity in these ideally homogenous systems. To unite the advantages of synthetic and natural hydrogels, there has been growing interest in engineering materials from recombinant proteins. These efforts remain nascent but promise perfectly monodisperse, customizable gel networks, with molecular tunability achieved through engineering at the amino acid and fusion protein levels, while also mimicking the proteinaceous nature of the ECM and conferring high biocompatibility. Our work is focused on further enabling external tunability of recombinant hydrogels by installing stimuli-responsivity, which has often been limited to synthetic polymers.

We have developed and characterized a novel, stimuli-responsive recombinant gel platform named PhoCoil. This material is injectable, photodegradable, and formed from a single protein. PhoCoil is crosslinked through homopentameric, physical coiled-coil interactions, resulting in a reversible gel-sol transition in response to applied shear force. Coil domain pairs are connected by an intrinsically disordered protein, originally engineered for high expression and low immunogenicity, providing intra-protein mobility and enabling intermolecular interactions without steric restriction. At the center of the protein is PhoCl, a photolabile green-fluorescent protein which undergoes irreversible cleavage of the polypeptide backbone in response to visible light. The resultant PhoCoil protein hydrogel is shear thinning and self-healing due to its physical crosslinking, enabling easy injection, as well as degradable on-demand in response to cytocompatible light. PhoCoil degradation can be spatiotemporally triggered through conventional mask-based and laser-scanning photolithography. Controlled hydrogel softening can also be achieved by modulating the light dosage, or through co-formulation with a non-light-responsive coiled-coil protein network. PhoCoil is the first fully recombinant protein hydrogel to utilize PhoCl as a cleavable linker and is differentiated from other previously developed photoresponsive recombinant hydrogels by its stability in ambient light and its simple single-component formulation, which does not require any small molecule or metal additives. PhoCoil hydrogels have applications in *in vitro* cell culture, as they show high cytocompatibility and enable bioorthogonal post-encapsulation release for single-cell analysis. Of particular interest is the use of PhoCoil for controlled, localized drug or cell delivery via post-injection photodegradation, which has been demonstrated in proof-of-concept *ex vivo* studies.

10:15 AM SB08.11.08
Development of a 3D *In Vitro* Model of the Neurovascular Unit (NVU) Using a Conducting Polymer Device for Real-Time Monitoring Chiara Barberio, Aimee Whiters, Chrysanthi-Maria Moysidou, Rachana Acharya, Shani Kirma Elias and Roisin Owens; University of Cambridge, United Kingdom

The neurovascular unit (NVU) is an essential component of the central nervous system with a vital role in maintaining brain homeostasis. The early onset of several neurological disorders has been associated with alterations in the blood-brain barrier (BBB), a component of the NVU that protects the brain microenvironment from potentially harmful substances circulating in the bloodstream (e.g., small molecule drugs, bacteria).[1] Despite recent advances in the study of neuro-pathologies, at present there are very limited effective treatments against neurological disorders and amongst others, the lack of appropriate research tools is a major limitation. *In vivo* animal models have high costs, are time-consuming, and carry uncertainties in the translation to human biology. Therefore, there is a compelling need to explore technologies capable of better resembling the human brain *milieu* in health and disease. *3D in vitro* models, such as 3D gels and scaffolds integrating human cells are excellent inert supports prompting *in vivo-like* tissue generation.[2]
Here, we used a composite electroactive scaffold integrating biomolecules of the human brain extracellular matrix (ECM) as a biomimetic substrate for hosting vascular endothelial and neural cells representative of the NVU. We reconstructed the neural tissue microenvironment using a tri-culture cell model, whose barrier formation, integrity, and neural-glia compartment were characterized via Confocal and Two-Photon Microscopy, showing the development of a multicellular neurovascular unit-like structure. Electrochemical Impedance Spectroscopy (EIS) was also used as a sensitive tool to provide a continuous and non-invasive readout of cell properties and tissue generation real-time. This NVU model has great potential as test bed for screening neurological drugs and disease modelling.

SB08-virtual

8:00 AM *SB08.12.01
The Avenue to "Green" in Organic Bioelectronics Mihai Irimia-Vladu; Johannes Kepler Universität Linz, Austria

Through its appealing avenues of processing the component devices at room temperature and from low-cost precursor materials, organic electronics has a tremendous potential for the development of products able to achieve the goals of production sustainability as well as environmental and human friendliness for electronics.

In an effort to stave off the e-waste growth, the presenter and his research group went further down the path opened by organic electronics research and investigated a large number of biomaterials as substrates, dielectrics, semiconductors and smoothening layers for the fabrication of organic field effect transistors, integrated circuits and organic solar cells. The presentation will focus on the highlights of our recent research, especially with respect to materials investigated, devices fabricated and the immense potential for follow up research:
-Flexible natural and biodegradable substrates
-Natural dielectrics
-Bioorigin, H-bonded semiconductors in the families of indigos, anthraquinones and acridones
-Biodegradation protocols for organic semiconductors

These highlights will be placed in the context of the mountain that one has to climb in order to reach the coveted "green" connotation for electronics, sensors and integrated circuits:
-Biocompatibility issue
-Biodegradability issue
-Compostability issue
-Cost of production / energy expanded in production issue
-Materials choice issue (carbon foot print)
-Toxicity and the environmental impact of the synthetic avenue for component materials

The potential of follow-up research in the green electronics field is immense, with large area electronics fabrication, biomedical implants, bio-sensing and smart labeling, representing only the tip of the iceberg of many more immediate possibilities of high interest for our group. Natural and nature-inspired materials have the unrivalled capability to create "safe-first" electronic markets for human and environment, with minimal or even neutral carbon footprint.

8:30 AM SB08.12.02
Bio-Inspired Skin Wearable Hydrophobic Voice Recognition Acoustic Sensor Based On *f*-MWCNTs-$BaTiO_3$@PDMS Composite Conductive Network Sasikumar Ragu and Byungki Kim; Korea University of Technology and Education, Korea (the Republic of)

Skin wearable piezoelectric nanogenerators (WPENGs) have recently drawn significant attention owing to their unique properties, like flexibility, sensitivity, and self-powered nature. Barium Titanate ($BaTiO_3$) is one of the eco-friendly piezoelectric ceramics. In recent days, $BaTiO_3$-based piezo-fillers use in WPENGs has attracted broad concern. Herein, bio-inspired microcracks, skin wearable, cost-effective, highly sensitive, and flexible PENGs were developed using functionalized multi-walled carbon nanotubes (*f*-MWCNTs) doped barium titanate ($BaTiO_3$)/poly(dimethylsiloxane) (PDMS) film. *f*-MWCNTs/$BaTiO_3$@PDMS was prepared by mixing of *f*-MWCNTs/$BaTiO_3$ and PDMS polymer solution by the overnight vacuum drying process. The sensor film was prepared by sandwiching *f*-MWCNTs/$BaTiO_3$@PDMS film between two PDMS films, followed by making electrical connections with two copper wires to form the WPENG. The as-prepared composite and PENG film were characterized by powder X-ray diffraction (PXRD), Fourier transform infrared spectroscopy (FT-IR), field emission scanning electron microscopy (FE-SEM), transmission electron microscopy (TEM), energy-dispersive X-ray analysis (EDX), Raman spectroscopy, and X-ray photoelectron spectroscopy (XPS). The composite PXRD data revealed the degree of crystallinity is 63%. FE-SEM and TEM results clearly showed that $BaTiO_3$ in-situ coupled with *f*-MWCNTs with the addition of $BaTiO_3$ with *f*-MWCNTs. The real-time application of the developed sensor was carried out by attaching the sensor to the throat to detect the minute oscillations produced during speaking. Monosyllabic, disyllabic, and polysyllabic words were spoken by the reader and their corresponding waveforms are recorded to show the ability of the sensor to clearly differentiate between these words. The sensor is also equally sensitive to male and female voices. A disyllabic word was spoken by a male and a female, and the recorded waveforms have a similar trend with different amplitudes. These results indicate the potential of the fabricated sensor to detect the human vocal cord vibrations efficiently, and paving a path to design a system for a wider range of applications in the next generation of noise detection and skin wearable sensors.

8:45 AM SB08.12.03
Designing Macroscopic Photonic Surfaces with Controlled Assembly of Polyhedral Emulsion Drops Jong Bin Kim, Seong Kyeong Nam, Sanghyuk Park and Shin-Hyun Kim; KAIST, Korea (the Republic of)

Colloidal arrays create structural colors originating from the constructive interference by the periodicity of the nanostructures. They are highly bright and angle-dependent when the colloids are periodically stacked. There have been several strategies to crystallize colloids in a film format; dip-coating, doctor-blading, infiltration, and roll-to-roll process. However, these methods cannot induce regioselective crystallization in the first place, but rather require additional processes for the patterning. Recently, many researchers exploit the secondary assembly of photonic spheres to construct a photonic surface. However, the spherical compartments have low reflectivity because of the lack of a planar region for backward reflection. Furthermore, several layers of spheres are needed because their monolayer inevitably leaves vacancy due to the interstices between roundish morphologies.
Here, we induce polyhedral deformation of photonic emulsions with built-in crystalline colloidal arrays to create planar surfaces with no voids even with a monolayer of emulsions. We use a microfluidic device to create monodisperse emulsions in fluorocarbon oil of which fast evaporation deforms emulsions

with the surfactant-stabilized interface even in the air. Inside the emulsions are silica particles dispersed in acrylate polymer and crystallized by interparticle repulsion, where the crystallization is enhanced by a shear force from the interface. The emulsions are extruded using a nozzle, assembled into a monolayer, and deformed to polyhedrons. As a result, the iridescent rainbow colors are developed on the particles, which are enhanced by thermal energy before curing. The surface is perfectly flat and it is UV-crosslinked to create fixed structural colors, leading to a more reflective photonic surface than a monolayer of photonic spheres.
The colloidal arrays are rearranged during the deformation of emulsions from spheres to polyhedrons and they follow the shear force that is larger on the polyhedron side than top or bottom because of larger curvature change and larger relocation of the fluid inside the emulsions. A large portion of colloids are crystallized from the side wall of the polyhedrons, but there are polycrystalline arrays inside the compartment because not all the regions are rearranged from a sideward shear force. (10-11) planes of hcp lattice are dominant at the center of the polyhedron, while (111) planes of fcc lattice are at the edge. (10-11) planes of hcp lattice stem from the combination of two shear forces from the top and side of polyhedrons, the latter of which is stronger so that they outnumber (111) planes of fcc lattice even at the center; the center part is close to top/bottom, but far from side. In contrast, the occurrence of (10-11) planes of hcp lattice is exceeded by that of (200) planes of fcc lattice which is slanted more compared to (111) planes of fcc lattice growing from the top. As the colloidal arrangement is polycrystalline with two dominant planes, the structural colors from the film assembled by emulsions are both iridescent and less angle-dependent. The accurate control of crystallization is not needed during the film formation because the colloidal arrays are crystallized in emulsions in advance; hand-assisted placement of emulsions in a mold rapidly forms a photonic surface. Most importantly, emulsions can be assembled and fixed on a three-dimensional surface which forms structurally-colored 3D objects such as a beetle and turtle. The advantage of this strategy is that the as-formed film can be diversely colored by deforming differently colored emulsions together or stacking the different groups layer by layer. It proposes a new way of regioselective manual formation of structural-color films and patterns both on 2D and 3D objects, of which the printed results have highly uniform color and height. Also, it unveils a new mechanism of colloidal crystal formation in polyhedral photonic compartments.

9:00 AM SB08.12.04
Bio-Inspired Porous Anodic Alumina/Aluminum Flake Powder for Multi-Band Compatible Low Detectability Siqi Fu; Shanghai Jiaotong University, China

Continuous development and advancement in modern detection technologies have increased demand for multi-band (e.g. visual, infrared) compatible camouflage. However, challenges exist in the requirements of incompatible structure resulting from the adaptation to different camouflage effects. This study is inspired by the light absorption structure of butterfly wing scales and demonstrates porous anodic alumina/ aluminum flake powder material, prepared by microscopic powder anodic oxidation technique for visual and infrared camouflage. The fabricated structures manipulate compromise condition for visual camouflage by low reflectance (R(400~800 nm)=0.32) and dual-band infrared camouflage by low emission (ε(3~5 μm)=0.081 and ε(8~14 μm)=0.085). Further, the characteristic of short-range disorder in these bio-inspired structure allows maintenance of the camouflage performance under omni-directional detection (0~60°). This study provides new insight and feasible method for coordinated manipulation of electromagnetic waves via bio-inspired structural design and improved fabrication.

9:15 AM SB08.12.05
Polysaccharide-Based Multi-Functionalization for Intravascular Catheters—Biocompatible Method to Enhance Antimicrobial and Antithrombotic Performances Se Kye Park[1,2], Jae Hak Shin[3], Jae Hee Jung[3], Dong Uk Lee[1], Dong Yun Lee[2], Seung Hwa Yoo[4] and Dong Yun Choi[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of); [3]Sejong University, Korea (the Republic of); [4]Jeonbuk National University, Korea (the Republic of)

Intravascular catheters (IC) are indispensable medical devices that allow diagnostics of heart conditions, dranage or injection of drug fluids and delivery of other surgical devices. However, IC has the potential to cause serious complications that put the patient at risk of death. The major critical issues with insertion of ICs are blood stream infections, thrombosis and damage of blood vessel[1, 2, 3].
Therefore, Antimicrobial, antithrombotic activity and low-friction functions are essential for the surface of intravascular catheters (ICs). One of the strategy for the multi-functionalization of ICs includes coating with hydrogel embedding antimicrobial and antithrombotic agents. Although catheters with hydrogel coating that contain antimicrobial agents contently prevent these issues, undesired side effects of cytotoxicity and tolerance can be caused. Moreover, hydrogel coated ICs showed unsatisfactory performance because of progressive loss of there functions owing to the leaching of functional agents from the coating layer[4].
O-carboxymethyl chitosan (CMC), could be a particularly promising material for functionalization of ICs owing to its outstanding functions including non-toxicity, biodegradability, biocompatibility, antimicrobial and antithrombosis properties. Although CMC has a sufficienct hemocompatibility, the antithrombotic activity is questionable due to its incomplete performance of thrombosis reduction and lack of clinical use cases[5]. Furthermore, there are only a few studies related to the multi-functionalization of IC by introducing chitosan derivatives such as CMC. Therefore, verification of such multi-functional performance, including antithrombotic activity, is still an unresolved challenge in the introduction of chitosan derivatives such as CMC to ICs. Here, we introduce a novel strategy for biocompatible and eco-friendly surface multi-functionalization of the ICs with CMC. In order to improve the intrinsic performance of CMC, we fabricated the surface of coating layer to be rough. Nanoscale porous CMC (pCMC) coating layer of pre-treated IC was simply fabricated through a selective leaching of the water-soluble polyethylene glycol (PEG) from heterogeneous CMC-PEG composite. The pCMC layer surface exhibited superhydrophilicity due to the increase in roughness. Especially, the antifouling effect by superhydrophilicity showed excellent anti-adhesion of Escherichia coli and platelets, and it gave a synergistic effect along with the intrinsic functions of CMC. Meanwhile, despite the rough surface of the pCMC layer, it showed adequate low frictions property under continuous wet friction conditions. Furthermore, we demonstrated that the practical pCMC coated IC tube provides superior trackability in a curved artificial blood vessel. The potential of the proposed coating strategy can be offered not only ICs, but also wide range of polymer-based vascular devices such as vascular filters, grafts, pacemakers and soft robots.

Deployable 3D Bioprinting for Modelling Cancer with Simulated Tumor Microenvironment Yaqi Sheng, Corrado Mazzaglia and Yan Yan Shery Huang; The University of Cambridge, United Kingdom

Three-dimensional (3D) bioprinting has emerged as a promising tool for constructing *in vitro* cancer models with tumor microenvironments (TME) in a rapid and reproducible manner. To realize the translational impacts of 3D bioprinting in a wider cancer research community, innovations in bioprinting workflows still required to integrate affordability, user-friendliness, and biological relevance. Here, we developed 'Bioarm', a simple, yet highly effective extrusion bioprinting platform, which can be folded into a carry-on pack, and rapidly deployed between facilities. Bioarm enabled TME reconstruction by printing 3D core-shell tumoroids with cancer-associated fibroblasts (CAFs) deposited as the shell. The population of CAFs showed heterogeneity in tumoroids and produced de novo synthesized extracellular matrices, demonstrating more *in vivo*-like characteristics compared to traditional 2D co-culture models. Embedding the 3D printed tumoroids in an immune cell laden collagen matrix permitted tracking of the cancer-immune interactions, and subsequent immune perturbation under immunotherapy treatments. Our deployable extrusion bioprinting workflow could significantly widen the accessibility of 3D bioprinting for replicating TME with complex multi-compartmental architectures, and for developing personalized cancer drug screening strategies.

Chemical Decoration of Living Microalgae for Bioremediation Danilo Vona[1], Cesar Vicente-Garcia[1], Pietro Cotugno[1], Emiliano Altamura[1], Stefania R. Cicco[2], Roberta Ragni[1] and Gianluca Maria Farinola[1]; [1]Università degli Studi di Bari Aldo Moro, Italy; [2]CNR-ICCOM, Italy

Many microorganisms produce specific protection structures, known as spores or cysts, exploited to increase their resistance to adverse environmental conditions. Scientists started to produce biomimetic materials inspired by these natural membranes, especially for industrial and biomedical applications.[1] Diatoms, for instance, are marine organisms able to uptake inorganic silicates from the ocean in order to build highly porous biosilica shells, called frustules, at mild environmental conditions. Diatoms shells, exploited for years for producing biohybrid materials for applications in photonics, optoelectronics and biomaterial science, can be chemically decorated via the common surface silanization reactions or the in vivo incorporation of functional organic molecules.[2] Our group has managed to obtain, via green processing, phosphorescent nanoparticles and fluorescent biosilica with specific optical features starting from simple feeding of diatoms with new synthesis fluorescent dyes [3-5]. We also produced 2D diatoms-based scaffolds for tissue engineering applications, after in vivo functionalization of living algae with pharmacological molecules like bisphosphonates, active towards osteogenic promotion and against osteo-resorption and bone degradation. [6-7] In this abstract we present biological data on the biocompatibility of a polydopamine-based artificial coating with diatom cells. Here living Thalassiosira weissflogii [8] cells were individually encapsulated with soft, artificial and easily functionalizable polydopamine layers with adhesive properties similar to feet proteins found in mussels. Polydopamine did not strongly interfere with diatom cells growth kinetics, and it can be exploited for entrapping detoxifying agents, like natural enzymes, and magnetic nanoparticles useful for living cells recovery after the decontamination process. These outcomes pave the way to the use of living diatom cells in the area of biomedicine, cell-based sensors and natural, and living devices for bioremediation. Polydopamine does not only confer certain sorption properties towards pollutants to surfaces [9], but it can encapsulate degrading functions, like catalytically active nanoparticles or enzymes, which bio-transform pollutants into small non toxic organic molecules.

CatchGel—A Molecular to Macroscale Investigation of Catch Bond-Crosslinked Polysaccharide Hydrogels Zarah Walsh-Korb[1,2] and Michael A. Nash[1,2]; [1]University of Basel, Switzerland; [2]ETH Zürich, Switzerland

Nature's exquisite designs are a constant source of inspiration for materials scientists, yet our ability to replicate biological interactions on the macroscale in engineered systems is often severely limited. Biological systems exist in perfectly balanced environmental conditions that regulate the functionality of

the processes within the system. Thus, a major obstacle in exploiting biological interactions in macroscale materials is a lack of understanding of how the changing chemical environment - from the molecular to the macroscale - affects the intrinsic molecular functionality of the biological unit, ultimately impacting macroscale behaviour.
From a material design standpoint bacterial adhesins are particularly interesting proteins. These proteins are expressed on bacterial cell surfaces to allow them to bind to, and colonise, a host. Many of these bacterial adhesins exhibit so-called 'catch bond' behaviour. Essentially, the adhesive force of these receptor-ligand complexes increases when subjected to high shear, in contrast to traditional 'slip' bonds, which decrease/rupture under high shear. On reaching a maximum applied force, the catch bond then reverts to slip bond behaviour resulting in a catch-and-roll type action that bacterial cells use to move in a targeted fashion along a surface. This behaviour also allows pathogens to continue to colonise host organisms despite aggressive actions from the host to remove colonies.
Transplanting catch bond-forming protein receptors and ligands onto polysaccharide chains opens up the possibility of creating bio-based hydrogel networks with unique tensile properties. Specifically, networks that display both shear-thinning and shear-thickening properties depending on the applied force, which also have the potential to self-heal as complexes rupture and reform. However, the complexity of intermolecular interactions in both catch-bond forming adhesin complexes and bio-based polymers mean the road to macroscale materials is less than straightforward.
Focusing on adhesins isolated from Staphylococcus epidermidis (serine-aspartate repeat protein G (sdrG)) and Staphylococcus aureus (serine-aspartate repeat protein E (sdrE), clumping factor A (clfA) and clumping factor B (clfB)), we use single molecule force spectroscopy to probe the fundamental interactions between these adhesins and their specific ligands to understand the impact of orientation, substrate, mutations and environmental composition on the stability of the catch bond behaviour. Expressing adhesins on yeast cells and probing substrate interactions with spinning disk microscopy, a deeper understanding of cooperative interactions as a function of environmental complexity is gained. Finally, functionalisation of polymer chains with adhesins and their corresponding ligands creates the building blocks for the catch bond cross-linked hydrogel networks, whose macroscale mechanical properties are probed using rheological measurements, completing the molecular to macroscale transition.
This multi-length scale approach to the design of catch bond cross-linked materials provides fundamental understanding of the impact of protein orientation, mutations and environment as we transition from the cell to a synthetically designed macroscale matrix. Examining how protein behaviour and macroscale materials properties change as a function of protein composition and environmental complexity allows more accurate development and manipulation of adhesin-derived responsive biomimetic materials. Thus, leading to a greater understanding of the nano-macroscale relationships in complex multiphase systems and enhanced strategies for the translation of biological interactions into macroscale materials.

11:15 AM SB08.13.03
Facile Preparation of Starch Biopolymer-Based Hydrogels for Flexible Electronics—Strain-Sensitive Batteries and Self-Powered Sensors David F. Xie[1], Cong Ma[2] and Peng Liu[2]; [1]Newcastle University, United Kingdom; [2]Guangzhou University, China

As a renewable biopolymer, high-amylose starch due to its higher content of linearly structured chains is more interesting to realise enhanced material properties and new functionality. However, the full dissolution of the compact granule structure of high-amylose starch is challenging under moderate conditions, which limits its applications. In this work, we have revealed that high-amylose maize starch (HAMS) granules can be easily destructed by certain concentrations of $ZnCl_2$, $MgCl_2$ and $CaCl_2$ solutions (43 wt%, 34 wt% and 31 wt%, respectively) at a moderate temperature (under 50 °C) without chemical derivatization. In particular, the $ZnCl_2$ and $CaCl_2$ solutions resulted in complete dissolution of HAS granules and the regenerated starch from the $CaCl_2$ solution was completely amorphous.
We found by simple mixing of the HAMS with a $CaCl_2$ solution followed by heating the mixture at 80 °C for 5 min, a flexible and ionically conductive starch-based hydrogel can be obtained. By varying the starch/$CaCl_2$ dry mass ratio, the materials exhibited tuneable mechanical strength (500–1300 kPa), elongation at break (15–32%), Young's modulus (4–9 MPa) and toughness (0.05–0.26 MJ/m^3), suitable electrical resistivity (3.7–9.2 Ω m), and strain-responsiveness. With plasticisation, a more flexible starch-based hydrogel was obtained, which can be easily reprocessed and has self-healing ability. The hydrogel was then developed into a galvanic cell-type battery, with an output voltage of 0.81 V, and a self-powered (SP) wearable sensor, which had high sensitivity (1.5371 kPa^{-1}) even under weak compression stress. This SP sensor can be used to detect human activities involving small strain such as wrist pulse and throat vibration. Considering the easy processability, cost-effectiveness, high strain-sensitivity, robustness, and greenness of the starch-based hydrogel and electronics, their brilliant application prospect is foreseen.

11:30 AM SB08.13.06
Spider's Pad Inspired Viscoelastic Hydrogel Damper for Nearly Dynamic Noise-Free Bioelectronics Byeonghak Park[1,2] and Tae-il Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Stanford University, United States

Bioelectronics needs to continuously monitor mechanical and electrophysiological signals for patients. However, the signals always include artifacts by patients' unexpected movement (e.g. walking and respiration under ~30 Hz). The current method to remove them is a signal process using a bandpass filter which may cause signal loss. We present an unconventional bandpass filter material, viscoelastic gelatin/chitosan hydrogel damper inspired by the viscoelastic cuticular pad in a spider to remove dynamic mechanical noise artifacts selectively [1]. The hydrogel exhibits frequency-dependent phase transition that results in a rubbery state that damps low-frequency noise and a glassy state that transmits the desired high-frequency signals. It serves as an adaptable passfilter that enables to the acquisition of high-quality signals from patients even with minimizing signal process for advanced bioelectronics.

Development of Adhesive, Non-Swelling, Electroconductive and Viscoelastic Hydrogels for Bioelectronics Younsoo Kim; Pohang University of Science and Technology, Korea (the Republic of)

As a new class of materials, implantable flexible electrical conductors have recently been developed and applied to bioelectronics. An ideal electrical conductor requires high conductivity, tissue-like mechanical properties, low toxicity, reliable adhesion to biological tissues, and the ability to maintain its shape in wet physiological environments. Despite significant advances, electrical conductors that satisfy all these requirements are insufficient. Herein, a facile method for manufacturing a new conductive hydrogel through the simultaneous exfoliation of graphite and polymerization of zwitterionic monomers triggered by microwave irradiation is introduced. The mechanical properties of the obtained conductive hydrogel are similar to those of living tissue, which is ideal as a bionic adhesive for minimizing contact damage due to mechanical mismatches between hard electronics and soft tissues. Furthermore, it exhibits excellent adhesion performance, electrical conductivity, non-swelling, and high conformability in water. Excellent biocompatibility of the hydrogel is confirmed through a cytotoxicity test using C2C12 cells, a biocompatibility test on rat tissues, and their histological analysis. The hydrogel is then implanted into the sciatic nerve of a rat, and neuromodulation is demonstrated through low-current electrical stimulation. This hydrogel has been shown tissue-like extraneuronal electrodes, which improve the tissue-electronic interfaces, promising next-generation bioelectronics applications.

Tissue-Interfacing Actuating Adhesive Prevents Muscle Atrophy Through Mechanical Stimulation Sungmin Nam, Bo Ri Seo, Alexander Najibi, Stephanie McNamara and David Mooney; Harvard University, United States

Introduction Hydrogel tissue adhesives serve as an attractive tool kit for surgical interventions, as they can provide mechanical support and hemostatic capacity while sealing the wound site and preventing leakage. While most existing strategies have focused on the biochemical properties of tissue adhesives, much less effort has been devoted to engineering their mechanical functions. One promising function of adhesives is the ability to provide mechanical stimulation to the tissue to promote tissue healing and rehabilitation. It is known that externally imposed mechanical stimuli and physical cues can regulate various biological processes, including cell proliferation, migration, and differentiation, through a process termed mechanotransduction, which converts mechanical signals into changes in cell function. Thus, hydrogel adhesives capable of generating active mechanical stimulation, in addition to the adhesive function, are expected to further promote wound closure, tissue healing and rehabilitation. The objective of this study is to develop a hydrogel adhesive system with a soft actuation mechanism to provide mechanical stimulation directly and locally on the target tissue in a precisely controlled manner. We hypothesized that the active hydrogel adhesive could activate disuse muscles and prevent the development of muscle atrophy.

Materials & Methods Active hydrogel adhesive was developed by combining a soft robotic actuator based on a shape memory alloy (SMA) spring and an elastomer that ensheathes the SMA, and a tough adhesive that efficiently transmits actuation to the underlying tissue. The actuation of SMA was achieved by applying a voltage (5V). The actuator and tough adhesive were assembled using benzophenone chemistry. The adhesive was then applied to tissue with chitosan and coupling reagents, 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and sulfated N-hydroxy-succinimide (NHS). To induce disuse muscle atrophy, hindlimb immobilization was performed for 2 weeks in female C57BL6/J mice with 14-18 weeks of age. One hindlimb was maintained in a knee joint extension and ankle plantar flexion position, and fixed by wrapping the hindlimb with a non-elastic surgical bandage to the foot. Mechanical stimulation was performed every day for 5 minutes at ~20 % of tissue strain and 0.1 Hz.

Results & Discussion The active hydrogel adhesive successfully achieved robust adhesion to muscle tissue (>500 J/m^2), maintained *in vivo* stability for 2 weeks, and was able to create tissue strain of up to 20%. Real-time high frequency ultrasound imaging revealed that the skeletal muscle underlying the adhesive was substantially deformed along the actuation axis during actuation, demonstrating mechanical stimulation *in vivo*. Next, the therapeutic effects on disuse muscle atrophy were evaluated. Mice treated with mechanical stimulation while undergoing disuse atrophy had muscle fibers with much larger cross-sectional area compared to untreated mice. The gross size and weight of muscles was also significantly greater in the stimulated mice. Muscle function analysis showed that the muscles of the treated mice generated substantially higher tetanic forces than those of untreated mice, with force levels similar to those of muscles in healthy, active mice. These results indicate that the active adhesive could prevent, or at least delay, the occurrence of disuse muscle atrophy due to immobilization.

Conclusions This work reports a hydrogel adhesive system with mechanically active elements, which not only forms robust tissue adhesion, but also generates stimulation on the target tissue for mechanotherapy. Mechanical stimulation was found to attenuate the onset of muscle atrophy, preventing the loss of muscle mass and maintaining muscle force generation. This work demonstrates the therapeutic potential of mechanical stimulation in the context of muscle atrophy and paves the way for the implementation of these stimulations in hydrogel adhesives.

11:15 AM SB09.01.04
A 3D Printable Tissue Adhesive Sarah Wu, Jingjing Wu, Hyunwoo Yuk, Heejung Roh and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Tissue adhesive materials are promising alternatives to sutures and staples for joining tissues, sealing defects, and immobilizing implantable devices. However, existing adhesive glues and patches typically offer little tunability over their shapes and physical properties, limiting their ability to be used for diverse applications. Here, we introduce a new strategy for fabricating customized adhesive patches and implantable devices using a 3D printable tissue adhesive ink based on a poly(acrylic acid)-grafted polyurethane brush-like polymer. The material confers high adhesion performance by integrating toughness, flexibility, and stretchability of the polyurethane backbone with tissue bond-forming moieties in the poly(acrylic acid) chains. As a result, the printed tissue adhesive patches exhibit fast, conformable, strong, and stable adhesion with defect specificity. Coupled with multi-material 3D printing, the tissue adhesive can also be used to manufacture various implantable devices, such as bioelectronic and drug delivery patches. Through in vivo rat and ex vivo pig models, we demonstrate the biocompatibility and potential versatility of the 3D printable tissue adhesive platform.

One-Pot Synthesis of Dual Functionalised Hyaluronic Acid for Tuneable and Adhesive Double Crosslinked Hydrogel Networks Cameron Milne, Wenxin Wang and Sigen A; University College Dublin, Ireland

Routine techniques to close wounds such as sutures and staples have significant drawbacks which can negatively impact wound recovery. Whilst sutures and staples have high tensile strength, they are time consuming to administer, require high surgical skill, create additional damage to the wound environment, can allow for bacterial infiltration and do not completely prevent fluid ingress and egress. Tissue adhesives have been studied for many decades as potential replacements of sutures but poor adhesion, mechanical properties, and biocompatibility precludes many system's translation to clinic. Although there are commercially available products e.g. Evicel, BioGlue, and ReSure, most have critical compromises that limits their efficacy. In this work, an aldehyde and methacrylate functionalised Hyaluronic acid (HA) biopolymer (HA-MA-CHO) has been synthesised for use in a novel, adhesive, biocompatible and biodegradable double crosslinked hydrogel network (DCN) for the effective closure and sealing of wounds. Aldehyde (CHO) groups are able to bond with native proteins on the tissue surface and act as a crosslinking site by reacting with the disulphide containing crosslinker 3,3'-dithiobis(propanoic hydrazide) (DTPH), forming a single crosslinked soft hydrogel network (SCN) with shear-thinning and self healing properties. The gel can then be further cured and strengthened with rapid UV-photopolymerization of the methacrylate groups to create a DCN. This two stage gelation and administration process of the hydrogel allows for easy in-situ application of UV crosslink-able pre-hydrogel solutions. This DCN hydrogel shows remarkable versatility as the storage modulus (G') has shown to be highly tuneable (10^3 – 10^5 Pa) by varying polymer concentrations, degrees of methacrylate substitutions and HA-MA-CHO:DTPH molar ratios to allow for application to many different wound environments. The hydrogel prepared showed high adhesion to porcine skin surpassing a burst pressure result for the commercially available tissue adhesive BioGlue by 52%. Along with these properties the DCN hydrogels also showed excellent cell viability.

Controlled Tough Bioadhesion with Ultrasound Zhenwei Ma[1], Claire Bourquard[2], Zu-hua Gao[3], Outi Supponen[2] and Jianyu Li[1]; [1]McGill University, Canada; [2]ETH Zürich, Switzerland; [3]The University of British Columbia, Canada

Tough adhesion of hydrogels and biological tissues has significant implications in engineering and medicine, but remains challenging to form and control. Here, we report an ultrasound (US)-mediated bioadhesion technology to achieve tough bioadhesion with controllability and fatigue resistance. Without chemical reactions, our strategy amplifies the adhesion energy and interfacial fatigue threshold between hydrogels and porcine or rat skin by up to 100 and 10 times. Combined experiments and theoretical modeling identify the key mechanism to be US-induced cavitation, which propels and anchors primers into tissues with mitigated barrier effects. The US effects are potent yet localized to enable spatial patterning of tough bioadhesion, on-demand detachment, and transdermal drug delivery. This work expands the material repertoire for tough bioadhesion and enables bioadhesive technologies with high-level controllability.

The US-mediated bioadhesion is achieved in two steps. We first apply the US to a primer solution/suspension of anchoring agents spread on tissue substrates with an ultrasonic transducer for a short period of time. Sequentially, we cover the treated area with a hydrogel patch with gentle compression. As a model system, we deploy a chitosan (Chi) solution and a polyacrylamide-alginate (PAAm-alg) hydrogel as the primer and the hydrogel patch, respectively. Our results show an adhesion energy of 1500 J m^{-2} obtained on porcine skin with the US treatment, more than 15 times higher than that of the no-US control. Our strategy is demonstrated with a large repertoire of materials. We confirm the adhesion enhancement by US with other hydrogels, including another double-network poly(N-isopropylacrylamide)-alginate (PNIPAm-alg) hydrogel and a single-network PAAm hydrogel. The same efficacy is observed with other anchoring primers such as proteins (gelatin) and nanoparticles (chitosan nanocrystals, aldehyde-functionalized cellulose nanocrystals). Besides skin, our strategy is applicable to various biological tissues, including buccal mucosa and aorta.

We then delve into the mechanism underlying US-mediated bioadhesion, where we combine experiments and theoretical modeling to substantiate the link between the US-mediated cavitation and bioadhesion. The US substantially enhances both the peak intensity of cavitation microbubble and bioadhesion. Fatigue fracture tests reveal a significantly enhanced interfacial fatigue threshold Γ_0 from ~5 J m^{-2} (no-US) to ~65 J m^{-2}. The results substantiate the existence of strong interfacial bonding, which typically only observed with covalent bonds, in contrast to often weak physical interactions such as entanglement resulted from interdiffusion. US also serves as a regulator for tough bioadhesion. As the US effects scale with the distance between the transducer and the tissue (d), simply maneuvering the US transducer could control the bioadhesion in magnitude and space. To understand and predict the spatially controlled bioadhesion, we conduct theoretical modeling on the acoustic field produced by the US transducer between the horn and the substrate. We extract the area on the substrate where the absolute pressure drops below the vapor pressure in every acoustic cycle, thereby enabling the formation of cavitation bubbles. At various d, we obtain drastically different pressure profiles on the tissue substrate, from which the regions impacted by cavitation are estimated. The simulation results agree with the experimental measurements. Besides the spatial control, we demonstrate that US can enable temporal control over bioadhesion by using a thermo-gelling gelation as anchoring primer and the heating effect of US.

Together, we report US-mediated bioadhesion to precisely control hydrogel bioadhesion in space and time. The universal applicability of our strategy promises impacts in broad areas ranging from human-machine interface and precision medicine.

1:45 PM SB09.02.02
New Adhesive Hydrogel Splint to Correct Malacic Trachea (Tracheomalacia) Vijay Kumar Rana[1], Ece Uslu[1], Sokratis Anagnostopoulos[1], Peyman Karami[1], Francois Gorostidi[2], Kishore Sandu[2], Nikolaos Stergiopulos[1] and Dominique P. Pioletti[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Le Center hospitalier universitaire vaudois (CHUV), Switzerland

Tracheomalacia (TM) is an illness in which the tracheal cartilage is too soft to ensure the mechanical support of the airways.[1] This results in an excessive and potentially lethal collapse and narrowing of the airways. Current treatment techniques including, tracheal reconstruction, tracheoplasty, endoluminal, and extraluminal stents, however, come with certain limitations.[2-4]
We will present a new and simple approach to correct TM where a (malacic) Trachea can be supported extraluminally by the adhesive hydrogel splint (patch). To this end, a new hydrogel formulation has been synthesized. We found that these hydrogel patches provide profound wet adhesion on the tracheal surface, thanks to a two-step photo-polymerization approach that help to anchor the surface much better than previously known adhesive hydrogels. A finite element model of a rabbit trachea was also developed to investigate the deformation and stress responses under maximum negative pressure with and without wrapping an adhesive hydrogel patch to it.
The numerical studies revealed that the hydrogel patch has the potential to preserve a more physiological shape of the trachea by constraining the membrane folding. Therefore, to validate the numerical model, and examine the potential use of the adhesive hydrogel, μ-CT and *ex vivo* experiments were also executed, respectively. To this end, few cartilage rings were removed from a healthy trachea to mimic the TM condition before executing these experiments in absence and presence of a hydrogel patch. At last, we could prove the hypothesis that airway collapse can be restrained by fixing the adhesive hydrogel splints superficially to a malacic trachea.
Interestingly, hydrogels developed herein also displayed outstanding wet adhesion on the surface of other soft tissues (skin, liver, heart, kidney, and lung), and inorganic surfaces (glass, wood, plastic, and ceramic *etc.*).

Stimuli-Detachable Adhesion of Hydrogels on Elastomer Substrate and Sequential Structural Change of the Soft Hybrids In Cho, Eunseok Heo, Hye Been Koo and Jae-Byum Chang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Fabrication of soft hybrid incorporating hydrogel and elastomers have huge potential in various research fields such as soft electronics and robotics, microfluidics, and tissue engineering. Recently, robust adhesion of hydrogel on diverse elastomer surfaces has been achieved by activating surface-adsorbed hydrophobic initiators to graft hydrogel polymer chains from the elastomer substrate. In addition, a recently established adhesion approach permits the separation of the adhesion between elastomers and hydrogels when exposed to light. However, chemical stimuli-detachable strong adhesion between hydrogels and elastomers has not yet been demonstrated. In this study, we present a novel method for adhering hydrogels to elastomer surfaces. To enable chemically-detachable adhesion, various hydrogels are immersed, dipped or brushed with hydrogel-precursor solution containing reversible chemical linkers. Topological adhesion of hydrogels and elastomers are then obtained with the assist of hydrophobic initiator contained in elastomer substrate. The proposed method allows the separation of attached elastomers and hydrogel, upon different chemical stimulation. We first demonstrate that this technology is applicable to a wide variety of hydrogels and elastomers. We then demonstrate the sequential folding and on-demand structural change of such soft hybrids by utilizing the detachable adhesion of various stimuli-responsive hydrogels to elastomer surfaces.

2:15 PM SB09.02.04
Design and One-Step Fabrication of an *In Situ* Formed Hyaluronic Acid-Based Tough Hydrogel with a Long-Short Chain Network Structure Rijian Song, Sigen A and Wenxin Wang; University College Dublin, Ireland

As the dominant component form of cells, extracellular matrix, tissues, and organs, hydrogels have been used in various biological and biomedical application areas, including wound dressings, drug delivery vehicles, tissue engineering scaffolds, soft robotics, and contact lenses. However, the high-water content of traditional hydrogels results in low mechanical properties, especially low toughness, making them unsuitable for most physiological load-bearing situations. Recently, intensive efforts have been devoted to improving the toughness property of hydrogels, such as constructing more homogeneous hydrogel networks, introducing reversible or irreversible bonds in the original hydrogel framework, and introducing structures in the hydrogel with folding, sliding, or high cross-linkage points. However, the above-mentioned tough hydrogels not only inevitably use bio-toxic monomers, crosslinkers or initiators, but also require a complicated preparation process. Hence, a new tough hydrogel with a simple preparation process and good biocompatibility has a high potential for bio-application. In this work, we hypothesized that the introduction of a single network with distinct chain lengths is able to improve the toughness of the hydrogel. Specifically, two structural features of tough long and short-chain (LSC) hydrogels were proposed in particular: (i) the skeleton of rigid hydrogel networks formed by short chains is relatively homogeneous, and (ii) some flexible long chains are connected with the rigid network skeleton. Here we report a universal example of LSC-hydrogels composed of biocompatible materials including thiolated hyaluronic acid (HA-SH), acrylated hyaluronic acid (HA-A), polyethylene glycol dithiol (PEG-DSH), and polyethylene glycol diacrylate (PEG-DA). In detail, PEG-DSH and PEG-DA act as long chains in the hydrogel network, while the HA-A and HA-SH act as short chains. Remarkably, the combination of long and short chains results in a multi-fold increase in the limit stress and toughness of the hydrogel, while retaining the advantage of extremely simple and safe in-situ gel formation. Most importantly, this simple and effective criterion for LSC-hydrogels can be extended to numerous classical single network (SN) - hydrogel systems and provide new directions for the design and preparation of tough SN-hydrogels.

2:30 PM SB09.02.05
Granule-Enhanced Viscoelastic Materials for Dynamic Biological Interfaces Jiuyun Shi, Yiliang Lin, Jiping Yue and Bozhi Tian; The University of Chicago, United States

The formation of the intimate interface between materials and dynamic biological systems serves as the basis for revolutionary disease diagnosis and treatment. However, the complexity of anisotropic structure, viscoelastic mechanics, and dynamic responsiveness of the native tissue pose significant challenges to creating adequate-contact and long-lasting interfaces for therapeutic delivery or biological signaling transduction. Here, we introduced a

viscoelastic dynamic granular hydrogel system which forms the dynamic biointerface with the biological tissues. Through the dynamic mechanical analysis, we revealed that the dynamic granular hydrogel system has viscoelastic behavior and environmental responsiveness. Furthermore, we demonstrated that the dynamic granular composite system has enhanced biological affinity and retention ability with the biological tissue after surface modification. Our results suggest that dynamic granular hydrogels are effective in treating ulcerative colitis and repairing skin wounds as regenerative medicine. Additionally, we proved that the dynamic granular hydrogels have the potential to be interfacial material for bioelectronic devices.

3D Ionic Microgel Printing of Degradable Ionic Junctions Ran Huo and Jianyu Li; McGill University, Canada

Ionotronics exhibit intrinsic deformability and ionic conductance that better match the human body mechanically and electrically compared to electronics. Ionic junctions are a unique and critical ionotronic component that possesses current rectification behavior analogous to electrical p-n junctions. Existing ionotronics and ionic junctions, however, are limited in electrical and mechanical performances and are difficult to process, optimize, and degrade. Herein, we report the design, fabrication, and characterization of degradable ionic junctions fabricated via 3D ionic microgel printing. Combining ionic microgels and a degradable secondary network, the ionic junctions feature high mechanical toughness (>1000 Jm^{-2}), high interfacial toughness, excellent electrical performance (current rectification ratio >100), and rapid degradation. Taking advantage of the intrinsic printability of jammed microgels, the ionic junctions can be 3D-printed into various shapes in high resolution with high fidelity. We further demonstrate the applications of ionic junctions in the form of a diode, a transistor, and a full-wave rectifier. By merging ionotronics, 3D printing, and degradable hydrogels, this work highlights high-performance sustainable ionotronics, which would impact broad areas ranging from wearables to human-machine interfaces.

3:30 PM SB09.03.02
Liquid-Infused Microstructured Bioadhesives Halt Non-Compressible Hemorrhage Guangyu Bao[1], Luc Mongeau[1], Christian Kastrup[2] and Jianyu Li[1]; [1]McGill University, Canada; [2]Versiti Blood Research Institute, United States

Uncontrolled hemorrhage accounts for more than 30% of trauma deaths. Despite tremendous research efforts, critical challenges remain in treating non-compressible and deep-narrow hemorrhages. Common strategies reliant on hemostatic agents alone to promote blood clotting are limited by slow clotting rate and coagulopathies. Alternative strategies are bioadhesive sealants that block the bleeding site physically. Removal of interfacial fluids is critical for adhesion formation and sealing performance of the bioadhesives. However, existing bioadhesives are slow and ineffective to remove the rapid pressurized blood at the interface due to their non- and nano-porous structures.

Inspired by the microstructured adhesives that adhere to bio-fouled surfaces in nature, here we propose new sealants based on *liquid-infused microstructured bioadhesives* (LIMBs) to halt non-compressible hemorrhage. Such bioadhesives can rapidly absorb and clot whole blood while forming strong bioadhesion, without the need for compression, to resist blood pressure and seal bleeding sites. We demonstrate a significantly improved hemostatic efficacy and biocompatibility of LIMB in rats and pigs compared to clinically used counterparts.

The optimized LIMB is porous, soft, tough, and stretchable. It contains macropores of ~200 μm that exceed the dimensions of blood components, such as red blood cells. Despite the porous structure, LIMB exhibits high fracture energy (>1500 J m^{-2}) and large deformability (stretch limit >6). These properties exceed soft tissues/organs such as cartilage and blood vessels. We partially fill the pores with adhesive functional liquid and leave some open. When being attached to the tissues, the capillary suction from the dry pores removes the barrier fluids from the interface, thereby enabling instant adhesion. The adhesive functional liquid stored within LIMB is then automatically transported to the interface to form strong, tough, and universal adhesion without the need for compression. Benefited by the dry matrix, LIMB can concentrate blood components and accelerate clotting, as evidenced by the blood clotting index used by many prior studies.

Drawing upon the excellent pressure-free adhesion and clotting ability, LIMB provides excellent efficacy in halting non-compressible and deep-incision hemorrhages. When being used as an implantable hemostat in a rat liver volume defect model (4 mm in diameter and 3 mm in depth), LIMB shows low blood loss (99.8 mg) and quick time to hemostasis (31.5 s), in contrast to the 517.1 mg and 165.8 s from SURGIFOAM, a commercial hemostatic gelatin sponge. LIMB also demonstrates very mild foreign body reactions, minimal inflammation, and allergy responses after being implanted in rats after 2 weeks. In a rat liver incision model (7 mm in length and 3 mm in depth), LIMB significantly reduced blood loss compared to non-structure bioadhesives, standard gauze, and Combat Gauze. In a pig liver incision model (15 mm in length and 10 mm in depth), the average blood loss for gauze and LIMB are 69.5 and 17.1 mL, respectively. 4 out of 6 pig injuries treated with LIMB stop bleeding within 10 min, but only 2 of 7 injuries treated with plain gauze succeed.

In conclusion, our new design leverages bioinspired architecture, tough adhesives, and liquid infiltration. The resulting microstructured bioadhesives can form instant and strong adhesion with bio-fouled surfaces without the need for compression. The bioadhesives are biodegradable, easy to implement, and stable for long-term storage. They show excellent biocompatibility and hemostatic efficacy compared to several existing hemostatic agents and bioadhesives, as demonstrated by the decreased blood loss in non-compressible and deep-and-narrow hemorrhages in small and large animal models. We anticipate that the reported design principle and the material system will galvanize the development and translation of bioadhesives and hemostatic materials to manage hemorrhage.

3:45 PM SB09.03.03
Optimizing a Minimally Invasive Reverse Thermo-Responsive Liquid Embolic Agent Polymer Treatment for Brain Aneurysms Evelyn Shue[1], Noah Fensterheim[2], Shaheer Khan[3], Dohyun Kim[4], Briana Poon[5], Lorenzo Verona[6], Elaina Heghes[7], Megha Gopal[8], Nakisa Dashti[8], Aaron Sloutski[8,9], Robert Wong[8], Daniel Cohn[9], Chandramouli Sadasivan[8] and Miriam Rafailovich[8]; [1]Richard Montgomery High School, United States; [2]Ida Crown Jewish Academy, United States; [3]Half Hollow Hills High School East, United States; [4]Seoul Foreign School, Korea (the Republic of); [5]Arlington High School, United States; [6]American School of Milan, Italy; [7]South Side High School, United States; [8]Stony Brook University, The State University of New York,

United States; [9]The Hebrew University of Jerusalem, Israel

Brain aneurysms are sac-like pathological dilations of intracranial blood vessels. Left untreated, they can rupture and cause fatal brain hemorrhages or ischemic strokes. Current treatments, like metallic implants, remain relatively ineffective, with unfavorable outcomes in 20-30% of cases or more [1]. This project seeks to develop an injectable, reverse-thermoresponsive (RTR), radiopaque, shape-conforming, crosslinkable, biodegradable liquid embolic agent (LEA). Made of pluronic polymer F88-DMA, contrast agent iohexol, and a crosslinker solution of ammonium persulfate (APS) and tetramethylethylenediamine (TEMED), the LEA easily injects through a catheter at room temperature, forms micelles at body temperature, leading to physical gelation, and chemically crosslinks via free-radical polymerization. The LEA should remain stable in the aneurysm to prevent further enlargement and allow wound healing. External stress should also not deform it. Before crosslinking, the F88-DMA polymer had a modulus of 28.13 kPa that increased to 142.10 kPa after crosslinking. Carotid arteries have an average wall shear stress of 0.85 ± 0.2 Pa, within the viscoelastic region of F88-DMA [2].

Various concentrations of TEMED and other additives were mixed with F88-DMA and tested *in vitro* to determine the optimal injectability and time for the polymer gel to solidify physically and crosslink chemically. The polymer gel must change phases at the optimal time so as to not solidify prematurely in the catheter or remain liquid too long in the aneurysm and get washed away by the bloodstream. Just as optimizing gel injectability is key, so too is optimizing the volume of the gel injected. Iohexol, an iodine-rich radiopaque contrast agent, was thus added into the LEA for visibility in angiography during the injection process.

Once injected and crosslinked, the gel is exposed to osmotic forces that promote swelling, potentially inducing aneurysm rupture. To prevent this, we added low concentrations of a four-armed polymer with crosslinkable methacrylate endgroups, known as tetramers. Placed in a static saline solution, we found that adding tetramer reduced gel swelling by ~50%.

Due to concerns over LEA-induced thrombogenesis, blood was drawn from a rabbit and mixed immediately with the APS/TEMED crosslinker. There was no thrombus formation even after an hour and APS/TEMED was thus found to be not thrombogenic. In further *in vivo* experiments, the LEA was successfully injected through a patient-sized microcatheter into a ligated rabbit carotid artery. The gel crosslinked and occluded the vessel for three weeks before explant, where the gel was recovered. Histology will be represented.

The LEA is biodegradable as a function of the patient-specific wound healing process such that the blood vessel returns completely to its original healthy state. An enzymatically degradable crosslinker, made of a peptide with a Gly-Leu motif in the center, was incorporated into the gel to bond with F88-DMA. When Matrix Metalloproteases (MMPs) were added, they cleaved the crosslinker's Gly-Leu motif, breaking it and triggering the liquefaction and disappearance of the LEA from the aneurysm. The peptide crosslinker could not induce chemical crosslinking absent APS/TEMED, but disturbance of this peptide alone proved sufficient to degrade the crosslinked gel.

Current results on radiopacity, injectability, stability, thrombogenicity, and biodegradability establish pluronic polymers and various additives as promising agents in the pursuit of an novel LEA brain aneurysm treatment. Future experimentation will test the effect of additives on the LEA's cytotoxicity and cell-adhesive properties.

4:00 PM SB09.03.04
Silk Embolic Material for Transcatheter-Directed Drug Delivery Jingjie Hu; North Carolina State University, United States

Transcatheter embolization is a minimally invasive procedure that uses embolic agents to intentionally block diseased or injured blood vessels for therapeutic purposes. Embolic agents in clinical practice are limited by recanalization, risk of non-target embolization, failure in coagulopathic patients, high cost, and toxicity. In this study, a silk-based embolic material (SEM) was developed and optimized to provide tandem integration of both embolization and the delivery of therapeutics. Natural silk was processed into fibroin proteins of varying lengths and was combined with charged nanosiliate disks to allow optimized mechanical property and injectability using clinical catheters. SEMs loaded with fluorochrome labeled albumin and Nivolumab, a widely used immunotherapy drug, showed a sustained release profile over 28 days in vitro. In a porcine renal survival model, drug loaded SEMs successfully embolized porcine arteries without recanalization and delivered both albumin and Nivolumab into the interstitial space of the renal cortex. Mechanistically, the delivery of therapeutics has been found to be optimal when the internal elastic membrane of the embolized artery was disrupted. Our results suggested that SEMs has the potential to be a next-generation biofunctional embolic agent to treat a wide range of vascular diseases.

Delivery of CAR-T Cells in a Transient Injectable Stimulatory Hydrogel Niche Improves Treatment of Solid Tumors Abigail Grosskopf, Louai L. Labanieh, Crystal M. Mackall and Eric A. Appel; Stanford University, United States

Adoptive cell therapy (ACT) has proven to be very effective in treating blood cancers, but traditional approaches to ACT are poorly effective in treating solid tumors observed clinically. Novel delivery methods for therapeutic cells have shown promise for treatment of solid tumors when compared with standard intravenous administration methods, but the few reported approaches leverage biomaterials that are complex to manufacture and have primarily demonstrated applicability following tumor resection or in immune-privileged tissues. In this talk, I will describe simple-to-implement supramolecular hydrogels for the controlled co-delivery of CAR-T cells and stimulatory cytokines that improve treatment of solid tumors. We develop Polymer-Nanoparticle hydrogels based on modified cellulose polymers and core-shell nanoparticles that interact to form an injectable hydrogel. The unique architecture of this material both simultaneously inhibits passive diffusion of entrapped cytokines, and permits active motility of entrapped cells to enable long-term retention, viability, and activation of CAR-T cells. We develop the formulation through novel in vitro studies and demonstrate its efficacy with cancer models in mice. The generation of a transient inflammatory niche following administration affords sustained exposure of CAR-T cells, induces a tumor-reactive CAR-T phenotype, and improves efficacy of treatment.

Optimization of Hydrogel Compositions to Enable the Ultra-Fast Immunostaining and Super-Resolution Imaging of Thick Tissue Slices Woonggi La, Junyoung Seo, Eunseok Heo and Jae-Byum Chang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Hydrogel is a soft, transparent, biocompatible material that is frequently employed in biological applications such as bioimaging and bioimplantable

devices. Hydrogels serve as scaffolds for protecting biological reactivity and storing position information of biomolecules, particularly in bioimaging. Expansion microscopy (ExM) is one of several imaging techniques that uses an electrolyte hydrogel to anchor all the proteins within biological specimens to polymer backbones and expand the entire specimens homogeneously to improve resolution. Another imaging technology, termed ELAST, employs hydrogels with long-chain polymers and entangles them with proteins, allowing for the elastic stretching of biological specimens without the formation of cracks in order to increase immunostaining speed. Recently, a hydrogel that permits the expansion and stretching of tissue has been reported. In this study, the composition of hydrogels is optimized to achieve a greater expansion factor, a more uniform expansion, and more stretchability. Using the optimized hydrogel, we demonstrate the staining of a 500-um thick specimen within a single day and the volumetric imaging of axon, myelin sheath, and neuronal marker (NF-L, MBP, MAP2) with a lateral resolution of 60 nm.

Multifunctional Injectable Hydrogel for *In Vivo* Diagnostic and Therapeutic Applications Wanghee Lee and Dae-Hyeong Kim; Seoul National University, Korea (the Republic of)

Injectable hydrogels show high potential for *in vivo* biomedical applications owing to their distinctive mode of administration into the human body. In this study, we propose a material design strategy for developing a multifunctional injectable hydrogel with good adhesiveness, stretchability, and bioresorbability. Its multifunctionality, whereupon multiple reactions occur simultaneously during its injection into the body without requiring energy stimuli and/or additives, was realized through meticulous engineering of bioresorbable precursors based on hydrogel chemistry. The multifunctional injectable hydrogel can be administered through a minimally invasive procedure, form a conformal adhesive interface with the target tissue, dynamically stretch along with the organ motions with minimal mechanical constraints, and be resorbed in vivo after a specific period. Further, the incorporation of functional nanomaterials into the hydrogel allows for various in vivo diagnostic and therapeutic applications, without compromising the original multifunctionality of the hydrogel. These features are verified through theranostic case studies on representative organs, including the skin, liver, heart, and bladder.

SB09.04.02
User-Demand Fast-Curable Ocular Glues Enforced by Multilength Tunable Networks Hyeseon Lee[1], Ajeesh Chandrasekharan[1], Keum-Yong Seong[1], Yeon Ji Jo[2], Samdae Park[3], Seonyeong An[1], Seungsoo Lee[3], Hyeji Kim[4], Hyungju Ahn[4], Sungbaek Seo[1], Jong Soo Lee[2] and Seung Yun Yang[1]; [1]Pusan National University, Korea (the Republic of); [2]Pusan National University Hospital, Korea (the Republic of); [3]SNvia, Korea (the Republic of); [4]Pohang Accelerator Laboratory, Korea (the Republic of)

Achieving fast and secure wound closure without ocular foreign body sensation is highly desired in ophthalmologic surgery. Sutureless approaches using tissue adhesives are gaining popularity, but their practical use is limited by the difficulty in controlling adhesion time and satisfying safety standards without compromising adhesive performance. Herein, we report user-demand hydrogel-forming ocular glues based on multilength photo-crosslinkable hyaluronic acid (HA), achieving firm tissue adhesion under wet and dynamic conditions and possessing cornea-like optical transparency. The HA-based photocurable glue (HA photoglue) quickly seals wounds upon nontoxic low-energy light exposure (320-500 nm, < 5s, < 1 Jcm^{-2}), and its mechanical and adhesive properties are improved by introducing short and long crosslinkable moieties into HA through one-step synthesis, forming multilength networks. Furthermore, the HA photoglue provides stable sealing in wet environments like ocular mucous surface, a clear vision with a light transmittance of more than 95% over the entire visible range, and a lubricating surface with minimal ocular sensation (generating less than 10% frictional force than suture groups). In a rabbit corneal incision model, the HA photoglue showed improved wound healing efficacy based on histological evaluation compared to control groups.

SB09.04.03
Hydrolysis-Driven Viscoelastic Transition in Triblock Copolyether Hydrogels with Acetal Pendants Jinsu Baek[1], Seyoung Kim[2], Byeong-Su Kim[1] and Soo-Hyung Choi[2]; [1]Yonsei University, Korea (the Republic of); [2]Hongik University, Korea (the Republic of)

While the hydrolytic cleavage of ester groups is widely exploited in degradable hydrogels, the scission at the midst of chain backbones can bring dramatic changes in the mechanical properties of the hydrogels. However, the predictive design of the mechanical profile of the hydrogels is a complex task, mainly due to the randomness of the location of chain scission. To overcome this challenge, we herein present degradable ABA triblock poly(ethylene oxide)-based hydrogels containing an A-block bearing acetal pendant, which provides systematically tunable mechano-temporal properties of the hydrogels. In particular, hydrophobic endocyclic tetrahydropyranyl or exocyclic 1-(cyclohexyloxy)ethyl acetal pendants are gradually cleaved by acidic hydrolysis, leading to the gel-to-sol transition at room temperature. Most importantly, a series of dynamic mechanical analyses coupled with *ex situ* NMR spectroscopy revealed that the hydrolysis rate can be orthogonally and precisely tuned by changing the chemical structure and hydrophobicity of acetal pendants. This study provides a new platform for the development of versatile degradable hydrogels in a highly controllable manner.

SB09.04.04
Rheo-SAXS Observation of Structural Change in Shear Thickening Polymer Gel Keishi Akada[1], Soichiro Okubo[2], Kazuya Tokuda[2], Koji Yamaguchi[2], Takamasa Onoki[2], Tatsuya Yamada[3], Syogo Tejima[3] and Jun-ichi Fujita[1]; [1]University of Tsukuba, Japan; [2]Sumitomo Electric Industries, Ltd., Japan; [3]Research Organization for Information Science & Technology, Japan

Background:
Shear thickening fluid (STF), often termed as a dilatant fluid, is a non-Newtonian fluid characterized by significant increase in viscosity when the applied shear rate above a critical value. It shows wide application prospects in shock absorption, body protection, and damper systems. However, these viscosity changes occur in a dynamic process, in which shear stress is applied, and the viscosity returns to its original state when the shear stress is removed. This reversible phase change makes it difficult to measure the dynamic microstructural changes that lead to the shear thickening phenomena. In this study, we performed a rheo-SAXS, which is simultaneous measurements of viscosity with small-angle X-ray scattering (SAXS) or ultra-small-angle X-ray scattering (USAXS) using an X-ray transmission solution cell. This real-time observation of the structural changes in colloidal silica solution showed the aggregation

process of polymers and compressing colloidal particles responsible for the ST.

Experiment:
The silica colloid sample was prepared by dispersing a silica sol (Snowtex ST-S, Nissan Chemical) with a particle size of 9 nm and PEG solution [1]. The viscosity and SAXS/USAXS were measured simultaneously using a rheometer (ONRH-1, Ohna Tech Inc.) in combination with a polycarbonate X-ray transmission Couette cell. The obtained spectra were resolved in the XY direction to elucidate anisotropic changes with respect to shear flow, and were plotted against the scattering vector Q. The experiments were performed at the Sumitomo Electric Beamline BL16 at the Kyushu Synchrotron Light Source Center and BL40XU, BL19B2 at SPring-8.

Results:
A viscosity measurement of the silica colloidal sample showed sharp increase of viscosity at a critical shear rate of 10 [1/s], indicating phase change of ST. SAXS spectra were acquired while rotating at several constant shear rate before and after ST transition, compared obtained spectral intensity. At shear above the critical shear rate, the spectral intensity centered at 0.01 1/nm increases in USAXS, indicating the formation of a floc of about 600 nm. SAXS spectra also showed similar anisotropy, with the 50 nm spacing intensity decreasing only in the velocity direction. The results suggest that the polymer network was restructured, forming larger flocs, and the silica clusters were compressed in the flow.

SB09.04.05
Conductive Hydrogels Embedding Three Dimensionally Connected Graphene Networks for Biomedical Applications Junggeon Park, Seungjun Lee and Jae Young Lee; GIST, Korea (the Republic of)

Conductive hydrogels afford efficient electrical communication with biological systems while providing soft and hydrated interfaces, which have garnered great attention for various biomedical applications, such as tissue engineering scaffolds and prosthetics. However, several issues, including high electrical properties with minimal incorporation of conductive components and simple fabrication of various shapes, remain a challenge. In this study, we developed novel conductive hydrogel system composed of three-dimensionally connected reduced graphene networks using graphene-coated agarose microbeads and thermal annealing. Differently charged graphene-coated agarose microbeads self-assembled to form granulate hydrogels, which can be easily handled and processed to produce various shapes of constructs. Subsequent mild heating allowed for the production of the conductive hydrogels (named thermally annealed graphene-channeled agarose hydrogel (TAGAH)) containing a three-dimensionally connected rGO network, which was formed via graphene rearrangement, thermal reduction, and agarose syneresis. TAGAH showed high electrical conductivity (~20 mS cm^{-1}) with a very small amount of graphene (~1.5 mg mL^{-1}), substantially low impedance (> 10-fold lower than that of controls), and tissue-like softness (~150 kPa Young's modulus). Various conductive constructs system could be easily fabricated by molding and 3D printing. *In vitro* cytocompatibility and *in vivo* tissue compatibility of these conductive hydrogels were confirmed by cell culture studies and subcutaneous implantation for 8 weeks. Moreover, potential biomedical applications of TAGAH-based materials as soft bioelectrodes, pressure sensors, strain sensors, and conductive tissue scaffolds were successfully demonstrated.

SB09.04.06
Reprogramming Factor-Based Injectable Hydrogels Containing Human Stem Cells for Cartilage Tissue Engineering Promotes 3D Cartilage Differentiation and Cartilage Regeneration Sumi Choi; Dong-A University, Korea (the Republic of)

Cartilage bears the load distributed in the joint and plays a pivotal role in stabilizing the joint through lubrication and shock absorption. Damage to the articular cartilage can accelerate joint degeneration and cause other joint diseases. Due to the nature of cartilage insufficient vascularization and lack of nerves and lymphatic vessels, the self-renewal process of articular cartilage rarely occurs after injury. Because non-human vertebrates have the potential to regenerate tissues such as bone, cartilage, muscle, nerve, and blood vessels, their signaling pathways and reprogramming factors have been investigated to induce chondrocyte differentiation from human stem cells. In this study, we specified chondrogenic factors in lizards capable of regenerating amputated tails. We identified the target molecule endoplasmin protein (ENPL, heat shock protein 90 kDa beta member 1) as a chondrogenic factor in 2D human tonsil-derived mesenchymal stem cells (hTMSC). Additionally, we designed a cartilage-mimetic hydrogel composed of hyaluronic acid and chondroitin sulfate for delivering ENPL and hTMSCs to damaged cartilage tissue. ECM-based 3D hydrogels can provide a mechanical and biochemical tissue microenvironment suitable for cartilage growth. The hTMSCs in the 3D hydrogel structure were successfully differentiated into chondrogenic cells. Additionally, a mouse osteoarthritis model confirmed the synergistic effect of cartilage regeneration of ENPL protein and bioactive hydrogels. This study demonstrates that ECM-based ENPL-equipped hydrogels can provide a therapeutic option for cartilage tissue engineering.

In this study, we present options for cartilage therapy of bioactive hydrogel-based scaffolds that induce in situ implantation, systems capable of forming cross-links, and stem cell chondrogenesis. Injectable hydrogels can provide a system for repairing and repairing damaged cartilage by delivering cells with minimal invasiveness to target sites of damaged tissues, including delivery of irregularly shaped areas. Here, we introduce an enzyme-mediated cross-linking method to fabricate injectable hydrogels. These enzyme-based reactions are suitable under cell-friendly physiological conditions. Natural proteins and tissues are rich in primary amines and imidazole groups and thiol groups that can bind phenolic moieties. Oxidation of phenol to ortho-quinone is the main function of tyrosinase (Ty). Because ortho-quinone is highly electrophilic, it can participate in various reactions such as Schiff-base reaction, Michael addition, and coupling reactions. In this regard, we designed a Ty-cross-linkable hydrogel by modifying hyaluronic acid (HA) and chondroitin sulfate (CS) with tyramine (TA). HA and CS are the components of the extracellular matrix (ECM), commonly used in tissue engineering, and can provide a biological and chemical environment for cartilage tissue. TA was conjugated to HA and CS using EDC/NHS chemistry for hydrogel crosslinking of HA and CS. Here, HA-TA and CS-TA generated by conjugating TA are advantageous for Ty-mediated crosslinking. Ty oxidizes the phenolic group of TA to form a quinone group. These reactive groups readily form covalent bonds with other chemical moieties such as amines, thiols, and imidazole groups. In this study, we show that TA-based hydrogels composed of ECM can provide cells and tissues with biocompatibility, cell compatibility, and a biomimetic environment. In addition, we targeted HSP90b1, which is related to the survival and proliferation of chondrocytes, by paying attention to the mechanism of lizard tail regeneration in which cartilage is regenerated instead of bone to induce cartilage differentiation. We demonstrate that Ty-based hydrogels incorporating the target protein ENPL can serve as strong candidates for cartilage regeneration with the added benefit of the biochemical response of ECM.

SB09.04.07
Injectable Fibrogel for Tissue Engineering Application Yanting Shen; The University of Hong Kong, Hong Kong

Hydrogels are valuable tools in tissue engineering and regenerative medicine due to their 3D structure, good permeability, and drug-releasing properties. In

particular, the injectable hydrogel has attracted considerable attention on account of its injectability with minimal invasiveness and usability for irregularly shaped sites. However, the scalable formation, together with the matching physicochemical properties and the controllable drug release rates for precise control over biophysical and biomedical cues to direct endogenous cells remain challenges. Here, we show that these shortcomings can be circumvented through an oil-free, biocompatible, biomimetic, and fully scalable fibrogel. In vitro, this fibrogel shows favorable biocompatibility and considerable vascularization abilities. The potential use of the fibrogel for advancing tissue regeneration is explored by a mice excision skin model showing that the fibrogel promotes wound healing with a rapid rate of new tissue regeneration and the appearance of de novo regenerated healthy tissue. The combination of injectability and tailorable properties of this fibrogel can be a promising approach in biomedical fields such as therapeutic delivery, medical dressing, and 3D tissue scaffolds for tissue engineering.

SB09.04.08
A Biomimetic 3D Glioblastoma Triculture Model Carolynn M. Brooks, Sawnaz Shaidani and David L. Kaplan; Tufts University, United States

Glioblastoma multiforme, or GBM, is an aggressive form of brain cancer that is hallmarked by highly immunosuppressive properties and therapeutic resistance. Recent studies have experimented with creating in vitro culture models of GBM tumors but are unable to adequately recapitulate the immunogenicity of the tumor microenvironment (TME). This may be due to a lack of multiple cell types, which are crucial to the heterogeneity of the microenvironment and GBM tumor characteristics. Expanding further upon the 3D bioengineered brain model established by Sood et. al, we proposed culturing glioblastoma cells, microglia, and astrocytes together to create a novel triculture model, first in 2D and then in a 3D porous silk scaffold supplemented with an ECM hydrogel. We have cultured the three lines at three different ratios to determine the optimal combination for harmonious proliferation in 2D. Quantitative viability and cytotoxicity assays (LDH, WST-1) were implemented to confirm survival and health of the cultures whereas qualitative immunostaining and fluorescent imaging were performed to observe cellular migration and proliferation. Once this optimal ratio was determined, the three cell types were seeded at four different total densities into porous 3D silk scaffolds infused with ECM hydrogels to observe spatiotemporal distribution of the cells over time (1 week and 4 weeks). Similar methods of analysis have been performed with the addition of two assays (CSPG ELISA, MMP assay) to quantify proteins associated with 3D culture characteristics. Further optimization of the GBM model will be determined through a drug screening implementing temozolomide, vincristine, and clomipramine to characterize the model's immunosuppressive response against different therapeutic agents. The successful establishment of this 2D and 3D triculture model will provide researchers with a comprehensive GBM model for potential investigation into other properties of the tumor microenvironment and future development of therapeutics to treat this deadly disease.

SB09.04.09
Tissue-Like Skin-Device Interface for Wearable Bioelectronics by Using Ultrasoft, Mass-Permeable and Low-Impedance Hydrogels Yoonsoo Shin[1,2] and Dae-Hyeong Kim[1,2]; [1]Seoul National University, Korea (the Republic of); [2]IBS (Institute for Basic Science), Korea (the Republic of)

Hydrogels consist of a cross-linked porous polymer network and water molecules occupying the interspace between the polymer chains. Therefore, hydrogels are soft and moisturized, with mechanical structures and physical properties similar to those of human tissue. Such hydrogels have a potential to turn the microscale gap between wearable devices and human skin into a tissue-like space. Here, we present material and device strategies to form a tissue-like, quasi-solid interface between wearable bioelectronics and human skin. The key material is an ultrathin type of functionalized hydrogel that shows unusual features of high mass-permeability and low impedance. The functionalized hydrogel acted as a liquid electrolyte on the skin and formed an extremely conformal and low-impedance interface for wearable electrochemical biosensors and electrical stimulators. Furthermore, its porous structure and ultrathin thickness facilitated the efficient transport of target molecules through the interface. Therefore, this functionalized hydrogel can maximize the performance of various wearable bioelectronics.

SB09.04.10
Fabrication of Skeletal Muscle Fibers Within Hollow Silk Matrices Madison Fletcher[1], Sophia Theodossiou[1,2] and David L. Kaplan[1]; [1]Tufts University, United States; [2]Boise State University, United States

The controlled flow and flexibility of coaxial needles allows multi-layered gels in the form of gel fiber scaffolds to be formed, with important utility in the field of tissue engineering. Coaxial needles can generate outer and inner layered hollow structures, allowing for the fabrication of macroscale crosslinked hydrogel fibers that are promising as scaffolds for muscle growth. To develop *in vitro* muscle fiber formation, the inner layer of the hydrogels support 3D growth and cell spreading of encapsulated myogenic cells. Silk fibroin (SF) from the *Bombyx mori* silkworm functions as a scaffold that allows cells to distribute throughout the core of the hydrogel. Our objective was to develop a core-shell muscle cell hydrogel system using SF as the shell and the inner channel as the cell-supporting component, to generate environments for the 3D growth and maturation of mouse skeletal muscle myoblasts (C2C12). We hypothesized that the addition of SF and extracellular matrix (ECM) materials would promote the long-term growth and survival of the cells for muscle-related outcomes.
Our methods first include culturing C2C12 cells in standard growth media. While passing confluent cells, two syringes were placed in a syringe pump and then attached to the inner (core) and outer (shell) ports of a coaxial needle using medical tubing. The core solution syringe was filled with the C2C12 cell suspension, collagen type 1 (Col1), SF, horseradish peroxidase (HRP) and hydrogen peroxide (H_2O_2), all suspended in standard growth media. The shell solution syringe was filled with sodium alginate (Na-Alg). A calcium chloride ($CaCl_2$) bath was used to crosslink the Na-Alg in order to form fiber-shaped gels. Fibers of desired length were cultured for up to 21 days in standard growth media. Fibers without SF/ECM components served as controls. Live-dead staining and light microscopy were used to assess cell viability following encapsulation.
The coaxial needle system generated mechanically stable core-shell fibers with distinct inner and outer layers with control over the contents of the layers and the length of the fibers. Na-Alg formed the outer shell (1.5mm diameter), while the inner conduit (0.8mm diameter) was filled with the C2C12 cell suspension. Rapid crosslinking due to the enzymatic reaction generated a structure that encompassed the core materials upon extrusion and held shape for 21 days with minimal leakage. The cross linked hydrogel fibers were sufficiently stable to generate 3 meter-long structures. Over time, the integrity of the outer layer's crosslinked hydrogel slowly decreased, but the addition of $CaCl_2$ in the growth media ameliorated this effect. At the same time, the cells suspended in SF rather than in just growth media resisted calcium toxicity under the processing conditions used. One day after extrusion, fluorescence images showed viable C2C12s that were distributed evenly throughout the core of the hydrogel fibers. The C2C12s proliferated over the 21-day period, measured through microscopy, with culture media changed every 4 days. After 5 days in culture, microscopy images showed cell alignment and developing matrix material, when compared to fibers without SF that showed more disordered cells.
This method of fiber preparation supports the survival and alignment of skeletal muscle cells in developing core-shell hydrogel myofibers for muscle tissue engineering applications. Future improvements of the method include better approximating the mechanical stimuli cells experience during *in vivo* growth.

SB09.04.11
TissueFab® Ready-to-Use Bioinks for the Fabrication of Tissue Constructs Kevin T. Dicker, Vinson Chu, Emma Hainstock, Megan Muroski and Gangadhar Panambur; MilliporeSigma, United States

3D bioprinting is a powerful enabling tool for regenerative medicine and drug discovery. Despite promising advancements in 3D bioprinting technology, a need still remains for high quality commercially available ready-to-use bioinks to empower these studies. In response, we have developed a platform of bioinks, *TissueFab*®, that are compatible with diverse widely studied cell types and bioprinting platforms. *TissueFab*® is a family of ready-to-use bioinks based on natural proteins and polysaccharides and synthetic polymers with high batch-to-batch consistency. These bioinks are designed for optimal printability and mechanical properties for micro-extrusion based bioprinting which we verified on the most popular commercial bioprinters thus demonstrating the printer agnostic characteristic of the bioinks. The bioinks were designed to photochemically crosslink with a wide range of compatible wavelengths of light. Separately, moving past photo-crosslinking, we have developed a class of ionically crosslinkable bioinks, Facile Curable, which avoid the use of light and photoinitiators to form a stable construct while maintaining high cell viability. *TissueFab*® bioinks were validated for high cell viability, proliferation and metabolic activity using C2C12 mouse myoblast cells, human mesenchymal stem cells (hMSCs) or human adult dermal fibroblasts (HDFa). For bone tissue engineering applications, we have shown that hMSCs bioprinted in *TissueFab*® - *Bone bioinks* show an increase in osteogenic differentiation. Additionally, *TissueFab*®- *Conductive bioinks* exhibit enhanced conductivity making them attractive for bioprinting electroactive tissues such as neural or muscular tissue. *TissueFab*® bioinks provide a robust tissue-mimetic platform for 3D bioprinting applications with both high printability and cytocompatibility to aide in addressing drug testing and tissue engineering challenges.

SB09.04.13
Investigating the Freezing-Thawing Process for PVA Hydrogels and Facile Screening of Effects of Additives Through Turbidity Measurement
Boonjae Jang, Jennie Paik and L. Jay Guo; University of Michigan, United States

Poly(vinyl alcohol) hydrogels are being investigated for wide applications in soft robotics, tissue engineering, wearable electronics, etc. due to their tunable mechanical properties. The freezing-thawing process is most widely used to obtain physically crosslinked PVA hydrogels by the formation of crystalline domains in the hydrogels. However, the freezing-thawing process is the most time-consuming process, and research on the process optimization of the preparation of PVA hydrogels is lacking. In this study, we show that it is possible to optimize the processing time of the hydrogel by controlling the freezing temperature, freezing time, thawing temperature, and thawing time, among various factors that affect gel characteristics during the freeze-thaw process. In addition, the gelation effects on the addition of various polyols or salts were compared and analyzed. We used the turbidity of the hydrogels by PVA crystals as a measure of the density and size of the crosslinked crystals, which can be correlated to the UV-Vis extinction spectra. Freezing temperatures by the reduction of freezing point were measured for various PVA solutions containing polyols or salts. Thawing at a temperature about 2 degrees lower than the freezing point for each PVA solution showed the highest turbidity. Moreover, the turbidity of the PVA hydrogel frozen for 30 minutes reached the maximum after 1-hour thawing and interestingly it showed similar turbidity with the PVA hydrogel frozen for 24 hours and thawed for 30 minutes. Thus, the processing time could be reduced significantly with optimized freezing-thawing conditions. Also, the turbidity of the PVA hydrogels containing various salts followed the order of the Hofmeister series due to the different interactions between ions and PVA chains. Additive polyols affected the turbidity of the PVA hydrogels followed such order: diethylene glycol > glycerol > 1,4-butanediol. The molecular size and hydrophobicity of the polyols might influence the interactions between polyols and PVA chains. This study facilitates the preparation of freeze-thawed PVA hydrogels and provides an effective screening method for the effect of various additives to obtain desired physical properties.

SB09.04.14
A Low Impedance, High Current, High Charge Density, Scalable and Soft Energy Converter Liu Hongzhen and Lizhi Xu; The University of Hong Kong, Hong Kong

Flexible energy conversion devices, especially those based on low-frequency mechanical energy, are crucial for developing flexible electronics. Here, we report a flexible power generation device that utilizes ionic streaming potential to generate electrical output. Taking advantage of the Li-ion anchoring ability of the oxygen-containing functional groups on the activated carbon cloth and the PVA hydrogel backbone, exploiting the difference in ion concentration caused by deformation, our device can generate an electrical output with the short-circuit current being up to 4 mA, and the power density reaching 425 mW per square meter. At the same time, the internal resistance is only 122 ohms. After 7500 cycles, the device can still maintain 97.38% of the peak current output. The working parameters, such as electrolyte concentration, frequency and speed of the mechanical driving force, and carbon cloth oxidation time, were systematically studied and optimized. When used to harvest mechanical energy, the device demonstrated outstanding charging capability, charging a 2F capacitor from 0.34 mV to 30.1 mV in 371 s at 80 kPa pressure. The device can power in vitro wearable devices and medical applications such as electronically controlled drug release.

SB09.04.17
Designing and Shaping Microfluidic Flow Profiles in Stokes Flow Regime with Deep Learning Zhenyu Yang[1], Zhongning Jiang[2] and Ho Cheung Shum[1]; [1]The University of Hong Kong, Hong Kong; [2]City University of Hong Kong, Hong Kong

The ability to shape flow profiles is critical for microfluidic fabrication of hydrogel fibers and particles with customizable structures and multiscale features. The flow profiles, referring to the lateral cross-sectional shape of the flow fields, can be transformed into diverse and complex shapes, depending on the flow and boundary conditions. The recently proposed inertialess flow profile engineering method deploys sequential steps in the channel to transform the flow profiles in Stokes flow regime, facilitating flow profile engineering. The steps with complex geometries are vital for diverse profile shapes; however, investigating the flow profiles and their transformations around such steps relies on iterative and time-consuming simulations or experiments. As a result, designing a flow profile with fully customized features remains computationally challenging.

Here we develop two deep neural networks for solving this forward design problem. The first model, based on variational autoencoder (VAE) architecture, takes the images of the step shapes as input and outputs the image of the transformed flow profiles. The model accuracy is metricized by the percentage of matched pixel values between the images of the predicted profiles and simulated profiles, and the test accuracy reaches 98.06%. Only minor differences can be visually identified between the predicted and observed profiles. Moreover, the model can predict the output flow profile of steps with unseen types of geometries, such as parallel steps or concave steps, with high accuracy, indicating the model have, to some extent, captured the underlying physical relationships between the step geometries and the output flow profiles.

The second model uses U-Net architecture to predict the profile transformations around a step. Before the training, the streamline data are compressed into transformation matrices, which only include the mapping of fluid element positions between the inlet and outlet profiles. The accuracy is evaluated as the percentage of matched elements in the transformation matrices between the predictions and the ground truth, and reaches 83% after 150 epochs of training. Plotting the predicted transformation matrices as the vector fields shows that the predictions can capture both the significant large-scale secondary flows as well as the small vertices. Moreover, the net transformation matrix of a step sequence can be computed by superposing the transformation matrices of the individual steps, enabling prediction of the output flow profiles of arbitrary step sequences and inlet flow profiles. With the current model accuracy, the flow profiles remain comparable to the simulation and experimental results after transformation by a sequence of 4 steps.
In conclusion, the VAE-based model can predict the flow profiles accurately, and can be generalized to unseen step topologies, while the inlet profiles and the number of steps are fixed. The U-Net-based model can be used to predict the flow profiles of multiple steps, with potential to further improve the

accuracy. We anticipate the model will allow predicting the flow profiles transformed by a large number of sequenced steps, thus significantly accelerating the design cycle of complicated flow profiles.

SB09.04.18
Electrothermal Soft Manipulator Enabling Safe Transport and Handling of "Living" Cell Sheets and Bioelectronic Devices Byoung Soo Kim[1,2], Min Ku Kim[3], Jonghwi Lee[4], Chi Hwan Lee[5] and Hyunjoon Kong[2]; [1]Korea Institute of Cermic Engineering and Technology, Korea (the Republic of); [2]University of Illinois at Urbana-Champaign, United States; [3]Hanyang University, Korea (the Republic of); [4]Chung-Ang University, Korea (the Republic of); [5]Purdue University, United States

Ultrathin materials made with "living" cells and microelectronic chips have emerged as significant technologies that improve the performance of tissue reconstruction, therapeutics, and healthcare monitoring. However, handling these thin and delicate materials remains a grand challenge because the external force applied for gripping and releasing can easily deform or damage the materials. This study presents a soft manipulator that can handle thin and fragile materials, such as "living" cell/tissue sheets and ultrathin electronic devices, without causing damage. The soft manipulator consists of a thermo-responsive, micro-channeled hydrogel, and a thin micro electric heater connected to an electrical power unit. Turning the power to the soft manipulator on and off makes the individual microchannels of the gel shrink and expand within 10 seconds and, in turn, lift or detach an object like a cephalopod's suction cup controlled by a bioelectric signal. This quick adhesion/detachment process is achieved by a pressure change through the anisotropically aligned microchannels of the gel with tissue-like softness. In particular, the soft manipulator enables the transportation of ultrathin and fragile cell sheets and thin film devices in both wet and dry conditions. This soft manipulator would be useful for handling a broad array of cell/tissue sheets and ultrathin electronic materials.

SB09.04.19
Digital Light Processing (DLP) Printing of MOF-Embedded Multi-Layered Hydrogel for the Localized Controlled Release of Anti-Cancer Agents Justin P. Edaugal[1,1,2], Erick L. Ribeiro[1,1,2] and Rigoberto C. Advincula[1,1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

According to the World Health Organization (WHO), cancer is currently the leading cause of global mortality, accounting for approximately 10 million deaths across the world in 2020. As a result, the research and development of novel oncologic treatment strategies have become a central topic of modern medicine. Despite the continuous effort, current clinical cancer treatment approaches still face several issues. Non-specificity associated with most current chemotherapy, for instance, along with their inability to deliver anti-cancer agents *via* a precise spatial-temporal controlled mechanism, often result in low therapeutic indices, as well as adverse side effects on healthy tissues. Metal-Organic Frameworks (MOFs) have become popular for applications in anti-cancer treatments, owing to their low cytotoxicity, high biodegradability, high biocompatibility as well as excellent chemical and physical stability. Moreover, the extensive variety of chemical and structural configurations arising from a library consisting of approximately 90,000 existing MOF compositions enable unlimited possibilities for their utilization in the rational design of hybrid systems with selective functionalities. Additive manufacturing, also known as three-dimensional (3D) printing, has revolutionized the biomedical industry, due to its ability to rapidly prototype complex 3D objects. Herein, we present the manufacturing of a scaffold-like multi-layered architecture composed of a graphene-based substrate interfaced with a Digital Light Processing (DLP)-printed hydrogel phase containing pH-responsive nanocarriers as a model system for cancer treatment *via* localized controlled release of chemotherapeutic agents. More specifically, the selected drug model, curcumin, was encapsulated within Zeolitic Imidazolate Frameworks (ZIF-8) structures (CCM-ZIF-8) and subsequently dispersed into a photopolymerizable poly(ethylene glycol) diacrylate (PEGDA)-based hydrogel. Finally, DLP was applied to yield a multi-layered CCM-ZIF-8/Hydrogel phase, which was interfaced with a graphene-based substrate to produce the pH-responsive drug release system. The delivery mechanism of chemotherapeutic agent is initiated upon contact of the CCM-ZIF-8/Hydrogel with the targeted area: the lower pH arising from cancer cells induces the decomposition of ZIF-8 phase, which proceeds layer-by-layer, resulting in the controlled release of the chemotherapeutic agents. In addition, the graphene-based substrate imposes a unidirectional diffusion of the drug toward the target area, while serving as a support for the layered printed CCM-ZIF-8/Hydrogel phase. Various structural and thermomechanical characterizations, such as Fourier Transform Infrared Spectroscopy (FTIR), Tensile Tests, Compression Tests, and Thermogravimetric Analysis (TGA), of the hydrogels, revealed the effects of curcumin-encapsulated ZIF-8 (CCM-ZIF-8) addition. Furthermore, in vitro drug release tests were performed, confirming the pH-responsiveness of the ZIF-8 MOFs.

SESSION SB09.05: Hydrogels for Biomedical Application II

Creation of a Hydrogel-Based Implant for Resurfacing of Articular Cartilage Benjamin Wiley; Duke University, United States

Replacement of damaged cartilage and subchondral bone with an equivalent synthetic construct would alleviate pain and improve mobility for millions of people. Key hurdles for this unmet need are the development of a hydrogel with a strength that exceeds that of cartilage and fixation of this hydrogel onto the surface of an articulating joint. This presentation will describe the first hydrogel with a tensile strength and compressive strength (50.5 MPa and 98.1 MPa) that exceeds that of cartilage (40 MPa and 59 MPa), and the first attachment of a hydrogel to a metal backing (which can integrate with bone) with a shear strength (1.98 MPa) that exceeds that of cartilage on bone (1.16 MPa). The high strength was achieved through reinforcement of crystallized polyvinyl alcohol with bacterial cellulose. To achieve an attachment strength 70% greater than that of cartilage on bone, freeze-dried bacterial cellulose was secured to a metal backing with an adhesive and a shape memory alloy clamp prior to infiltration and crystallization of the polyvinyl alcohol. The bacterial cellulose-reinforced polyvinyl alcohol was 3 times more wear-resistant than cartilage over 1 million cycles and exhibited the same coefficient of friction, whereas the coefficient of friction for annealed PVA increased to be 6.75 times greater than cartilage after 1 million cycles of wear. This work shows that BC-PVA hydrogel is a strong, wear-resistant material that will not damage opposing cartilage, and it can be secured to a metal base for integration with bone.

9:00 AM SB09.05.02
Low Voltage-Controlled Hydrogels for Drug Delivery Applications Ilaria Abdel Aziz[1], Johannes Gladisch[1], Sophie Griggs[2], Maximilian Moser[2], Magnus Berggren[1], Iain McCulloch[2] and Eleni Stavrinidou[1]; [1]Linköping University, Sweden; [2]University of Oxford, United Kingdom

Hydrogels emerged as promising actuators for a variety of applications, as tissue engineering, contact lenses and drug delivery, among others. In the latter, they represent a valuable alternative to standard pharmaceutical cues, as they can be placed in the proximity of the delivery region and exogenously or endogenously actuated. Indeed, interesting results showed controlled drug release triggered by pH, temperature, light and chemical changes. However, the physiological environment is highly dynamic, and changes in pH or temperature can be correlated to other reasons than the target of the drug delivery, thus the selectivity of these type of hydrogels is limited.
Electrically responsive hydrogels (E-hydrogels) represent a valuable alternative since the drug can be delivered on demand by an exogenous electrical stimulus. Some E-hydrogels have been proposed and characterized. Generally based on polyelectrolytes exposing fixed charges, the loading is driven by electrostatic interactions upon soaking the hydrogel in a solution containing the drug, and upon voltage addressing, the drug is then released. The materials proposed so far, as poly(2-(acrylamido)-2-methylpropanesulfonic acid), poly(acrylic acid), poly(acrylamide), chitosan and poly(2-hydroxyethyl methacrylate) (PHEMA) among others, showed promising results, though limited by high voltage and poor mechanical properties. We propose here a class of semiconducting organic polymers, based on polythiophene backbone and ethylene glycol (EG) side chains as a valuable alternative for E-hydrogels. When in contact with an electrolyte, upon electrochemical doping, ions from the electrolyte will enter the polymer matrix to compensate for the injected charges in the backbone. Upon reverse potential, the ions leave the polymer. This doping/de-doping mechanism is accompanied by a huge volumetric increase, up to 300% with respect to the initial values, due to ion intercalation and water intake, and we hypothesise that this volumetric increase could be used as a method for delivering big molecules or proteins. We show that the polymer exhibits excellent control ranging from 800-1000 Da, with release/leaking ratios up to 200%, and good control for bigger proteins in the range 5000-30000 Da with release/leaking ratios up to 30%, in the voltage window (-0.2, 0.5) V. The release fitting shows that the process is mostly driven by matrix swelling, thus confirming the deterministic delivery mediated by the voltage. Moreover, we show that pulsatile release is also possible, and a drug dose curve can be obtained by applying different potentials.
The proposed EG-side chain polythiophenes are a valuable alternative in the field of E-hydrogels, since they show excellent control over a large range of proteins, and they can be actuated within a low potential window (*i.e.* -0.2, 0.5 V).

9:15 AM SB09.05.03
Bioinspired Fabrication of Small-Diameter Blood Vessels Richard Y. Cheng[1,2,3], David Miranda-Nieves[1,2,3], Shashi Malladi[4], Yuming Zhang[4], Carolyn Haller[1,2], Torsten Meissner[1,2], Axel Guenther[4] and Elliot Chaikof[1,2,3]; [1]Beth Israel Deaconess Medical Center, United States; [2]Harvard Medical School, United States; [3]Wyss Institute, United States; [4]University of Toronto, Canada

Coronary artery bypass grafting is the most commonly performed cardiac surgery worldwide, but the standard of care remains the engraftment of patient-obtained veins that leads to stenosis or occlusion in nearly half of all cases after one year. This high failure rate has resulted in a demand for alternative strategies like tissue engineering which enable the formation of vessel-mimetic conduits with precise control over biomaterial composition and cell distribution. However, balancing vascular cell activity, biomaterial organization, and mechanical strength in these blood vessel mimetic conduits while maintaining long-term patency post-engraftment *in vivo* remains a significant challenge.

In response, the Chaikof lab and collaborators have developed a large-scale biofabrication process to quickly synthesize mechanically robust, free-standing, ultrathin biomaterial sheets as scaffold building blocks for vascular tissue engineering. Microfluidic extrusion, hydrodynamic focusing, and strain-induced pulling is applied to a naturally occurring type-I collagen protein solution, forming highly aligned sheets with physical dimensions of 1.9 µm thickness, 2.4 mm width, and >230 mm length. These sheets are then seeded with vascular smooth muscle cells, assembled into a tubular conduit with an inner diameter of 1.5mm via an automated rolling process, and subsequently endothelialized. Macroscopic brightfield imaging shows an open-lumen vessel with homogenous wall thickness conducive for unobstructed flow, and preliminary data obtained from multiphoton z-stack imaging reveals circumferential alignment of vascular smooth muscles with uniform distribution of endothelial cells in the lumen surface shortly after fabrication. Furthermore, incorporation of cell-viable biomaterial crosslinkers in the fabrication process improves the conduit mechanical properties of suture retention, burst pressure, and compliance to levels comparable to physiological arterial vessels.

Taken together, we report here a novel tissue engineering platform that enables the rapid and scalable production of “off-the-shelf” living engineered blood vessels incorporating primary vascular wall cells for prospective surgical engraftment. Current efforts are focused on investigating alternative cell sources compatible with the bioengineered vessel conduit, including genome-edited iPSC-derived vascular cells designed to evade the host immune system post-engraftment.

9:30 AM SB09.05.04
A Fast Gelation, Self-Healing Dynamic Hyaluronic Acid-Based Hydrogel for 3D Cell Encapsulation Melissa Johnson, Sigen A and Wenxin Wang; University College Dublin, Ireland

Dynamic hydrogels for three-dimensional (3D) cell encapsulation that better mimic the dynamic nature of the extracellular matrix have been developed as a result of advances in dynamic chemistry. Dynamic covalent hydrogels have emerged as the most promising biomaterials to overcome the constraints of current conventional hydrogel systems, such as static mechanical properties, irreversible linkages, difficulty in delivery and limited control over biophysical properties (i.e. porosity, degradation and strength). To address these limitations, a dynamic covalent hydrogel system based on aldehyde functionalised hyaluronic acid (HA-CHO) and thiolated hyaluronic acid (HA-SH) has been developed with tunable properties. The dynamic covalent chemistry of the thiol-aldehyde addition provides the hydrogel system with highly desirable rapid gelation and self-healing properties. Here we demonstrate that the molar ratio of the two functional groups (thiol and aldehyde) in the hydrogel system has a direct effect on whether a double crosslinked network or a single network forms. In order to improve the hydrogel mechanical properties, a higher thiol functional group ratio was used to increase the crosslinking density as thiol-aldehyde and disulfide crosslinking mechanisms produce a double crosslinked dynamic network. Moreover, the *in vitro* cell viability assessments of both functionalised materials (HA-CHO and HA-SH) show good biocompatibility. Overall, this work introduces the straightforward preparation of a new dynamic hydrogel system that has the potential to be an ideal 3D scaffold for culturing cells due to its excellent biocompatibility, self-healing, and fast gelation properties.

9:45 AM DISCUSSION TIME

9:45 AM BREAK

10:15 AM *SB09.05.06
User-Programmable Hydrogel Biomaterials to Probe and Direct 4D Stem Cell Fate Cole A. DeForest; Univ of Washington, United States

The extracellular matrix directs stem cell function through a complex choreography of biomacromolecular interactions in a tissue-dependent manner. Far from static, this hierarchical milieu of biochemical and biophysical cues presented within the native cellular niche is both spatially complex and ever changing. As these pericellular reconfigurations are vital for tissue morphogenesis, disease regulation, and healing, in vitro culture platforms that recapitulate such dynamic environmental phenomena would be invaluable for fundamental studies in stem cell biology, as well as in the eventual

engineering of functional human tissue. In this talk, I will discuss some of our group's recent successes in reversibly modifying both the chemical and physical aspects of synthetic hydrogel-based cell culture platforms with user-defined spatiotemporal control through a collection of bioorthogonal photochemistries. Results will highlight our ability to modulate intricate cellular behavior including stem cell differentiation, protein secretion, and cell-cell interactions in 4D.

10:45 AM SB09.05.07
Bioresorbable Origami Actuators for Intestinal-Retentive Drug Delivery Spencer Matonis, Bozhong Zhuang, Zeynep Temel and Christopher J. Bettinger; Carnegie Mellon University, United States

Introduction: The gastrointestinal (GI) tract provides a convenient, non-invasive access point for medical therapeutics and diagnostics. Ingestible devices have traditionally been limited to transient operation and rigid, inorganic structures, largely due to a lack of robust, biodegradable materials. As shown in this work, genipin-crosslinked gelatin (Gelapin) biopolymers offer a high degree of mechanical tunability and can be fabricated into a diverse range of functional geometries. Leveraging auxetic origami design and laser processing techniques, we demonstrate the potential for edible, self-deployable Gelapin actuators. Such structures can be fabricated into intestinal-retentive interfaces capable of packing up to ~10cm^2 of surface area into a standard "000" pill for future bioelectronic and drug-delivery platforms.
Methods: All raw materials were acquired from Millipore-Sigma (Milwaukee, WI, USA) and used as-received unless otherwise noted. For this study, genipin dissolved in ethanol and water was used to crosslink 300-Bloom, Type A porcine gelatin. Approximate crosslinking percentages were calculated based on the occupation of free amine sites using a ninhydrin assay. Varying amounts of glycerol plasticizer were incorporated into solution and the resulting biogels were dehydrated for 24 hours at 70°C. Auxetic origami designs were etched using a Rabbit CO_2 laser (Middletown, Ohio) to create hill and valley crease lines. For initiating the origami folds, a 3D-printed polymer mold was used to compress the etched substrates by 10% from their initial height. Mechanical and viscoelastic properties of biogel and bioplastic samples were evaluated using a tabletop RSA-G2 Solids Analyzer and Discovery HR 20 Rheometer by TA Instruments (New Castle, DE) along with a Instron Universal Testing System (Norwood, MA).
Results: In order to survey the mechanical tunability of gelapin as a function of crosslinking density, a variety of mechanical tests were done both in the gel and plastic state. Storage modulus of the hydrated biogel was measured in the linear viscoelastic region at a frequency of 1Hz as the sample crosslinked in-situ between parallel plates. After 36 hours, the un-crosslinked sample exhibited a storage modulus of 1.95kPa, while the fully crosslinked sample measured at 11.09kPa, an increase of 469%. A similar degree of mechanical tunability was demonstrated via uniaxial tensile tests of Gelapin bioplastic dog bones. These samples were prepared using glycerol as a plasticizer at constant loading (35% mass relative to gelatin) and laser-cut for testing. The resulting stress-strain plots show Young's modulus increasing from 32MPa to 417MPa and strain at failure decreasing from 963% to 108% between 0% and 100% crosslinking, respectively. This baseline mechanical data for Gelapin can be used to describe deployment due to elastic strain energy from a confined pill volume. Similarly, swelling kinetics can be used to identify deployment forces resulting from osmotic actuation in GI fluid. Gelapin biogels showed a nearly exponential decay in swelling capacity as a function of crosslinking with equilibrium mass changes shifting from +55% all the way to -4% (syneresis) over an extended 60hr period.
Conclusion: Here we have described thorough mapping of the Gelapin system's mechanical, rheological and swelling properties. Additionally, Gelapin bioplastics are demonstrated to be compatible with a highly scalable CO_2 etching process for the production of detailed, expandable origami structures. In future research, we aim to leverage this material knowledge in order to construct and evaluate a semi-empirical model for the bimodal deployment of gelapin origami actuators. This model will be applied to optimize geometric and material design parameters of an auxetic origami tube capable of dilating to a diameter of 25mm, while exerting sufficient radial pressure to be retained in the small intestine for prolonged periods of time (>8hrs).

11:00 AM SB09.05.08
Dynamic and Tunable Hydrogel for Extended Co-Delivery of Subunit Influenza Vaccine Olivia Saouaf and Eric A. Appel; Stanford University, United States

The robust material properties of a dynamic, self-healing, and injectable hydrogel make this drug delivery platform ideal for sustained release of subunit vaccine components to enhance the body's immune response to difficult vaccine candidates. Cargo spatial and temporal exposure in the body and immune cell interaction can be coordinated by tuning hydrogel dynamic and structural characteristics. We have designed a supramolecular polymer-nanoparticle (PNP) hydrogel whose composition can be altered to tune slow release of vaccine cargos into the body, enabling a more potent, durable, and high-quality immune response. The PNP hydrogel is formed by dynamic noncovalent interactions between PEG-b-PLA nanoparticles and dodecyl-modified hydroxypropyl methylcellulose polymers. Adjusting hydrogel formulation affects the diffusion and dynamic mesh size of the polymer network, affording precise control over the encapsulation and release of molecular cargo. In this presentation we will discuss the development of PNP materials, the dependence of cargo diffusivity on hydrogel composition, and the influence of cargo release on vaccine efficacy. We will describe the use of PNP hydrogels for sustained delivery of a subunit influenza vaccine comprising components of varying molecular weight and chemical composition. Characterization of cargo diffusivity in PNP networks lends an understanding of the release profiles of vaccine cargoes and a deeper knowledge of the dynamics of polymer-particle interactions in a supramolecular network. We will demonstrate the ability to modulate the material properties of our unique supramolecular hydrogel to produce an effective in vivo drug delivery platform.

11:15 AM SB09.05.09
Macroporous Hydrogels for *In Situ* Immune Cell Homing and Modulation Hua Wang; University of Illinois at Urbana Champaign, United States

The past decade has witnessed significant progress in the development of cancer immunotherapy, especially with the success of checkpoint blockades and T cell therapies. However, the low patient response of checkpoint blockades, poor efficacy of T cell therapies against solid tumors, and severe side effects in both have limited their wide application. These issues motivate the development of new immunotherapies with persistent tumor-specific humoral and T cell responses and reduced side effects, which lies in the ability to precisely modulate immune cells, especially dendritic cells (DCs) and T cells. In this presentation, I will introduce the use of immune cell-homing macroporous hydrogels for in situ recruitment and modulation of immune cells, and further development of potent immunotherapies.

In the first part, I will talk about DC-homing macroporous hydrogels for immunomodulation. We show that macroporous alginate hydrogels loaded with chemokines (e.g., GM-CSF) and azido-sugar nanoparticles can recruit and metabolically label DCs with azido groups *in situ*, which allows for their subsequent tracking and targeted modulation over time. Azido-labeled DCs were detected in lymph nodes for weeks, and could covalently capture dibenzocyclooctyne (DBCO)-bearing antigens and adjuvants via efficient click chemistry for improved antigen-specific CD8$^+$ T cell responses and antitumor efficacy against lymphoma and melanoma. We also show that azido-labeling of DCs allowed for *in vitro* and *in vivo* conjugation of DBCO-modified cytokines, including DBCO-IL-15/IL-15Rα, to improve priming of antigen-specific CD8$^+$ T cells. The cytokine conjugation approach enables continuous modulation of T cells during the T cell priming process and thus can improve the antigen-specific CD8$^+$ T cell response, which could bring therapeutic benefits for treating cancer, autoimmune disorders, and other immune-related diseases.

In the second part, I will introduce an injectable T cell-responsive macroporous hydrogel that enables *in situ* activation and expansion of T cells. The

macroporous gel is composed of a crosslinked polymeric network with macropores (~150 μm) that are large enough to home T cells. In the presence of T cells that can gradually disrupt the gel network surrounding the macropores, activation cues trapped in the network can be released for *in situ* activation and expansion of T cells. This T cell-responsive macroporous gel enables the expansion of functional T cells *in vitro* and *in vivo,* is stable over weeks upon subcutaneous injection, and can result in enhanced $CD8^+$ T cell response and antitumor efficacy. We further showed that the T cell-responsive macroporous gel enables *in situ* homing and expansion of adoptively transferred T cells, for improving the antitumor efficacy of conventional T cell therapies. This injectable, T cell-responsive macroporous gel provides an unprecedented platform for *in vivo* expansion of engineered T cells in a precisely controlled manner, for timely and more effective treatment of diseases.

11:30 AM SB09.05.10
Double Layer of Fibronectin-collagen Coating of poly(acrylamide-co-acrylic acid) Hydrogel Particles to Modulate Cell Migration Alfonso Pepe, Duy T. Nguyen, Diego I. Pedro, Griffin Golde and W. Gregory Sawyer; University of Florida, United States

The use of biomolecules as biomaterial coatings is recognized as a promising approach to modulate the biological response of different cells. Collagen (COL) and fibronectin (FIB) are the two most common extracellular matrix proteins (ECM) that have been widely used for the studies of cell adhesion and migration. However, the mechanistic difference between each protein or their synergy on cell migration is poorly understood. In this work, we investigated migratory behaviors of cancer spheroid models in 3-dimension (3D) as a function of extracellular matrix composition, cell adhesion, and mechanical properties of the medium.
In this work, an ensemble of liquid-like solid (LLS) conjugated with collagen type-I and fibronectin was developed. In brief, acrylamide monomer (AAm) 4 %w/v, bis-acrylamide (BIS) 0.3 %w/v and acrylic acid (AA) 1 %w/v hydrogel was prepared via free radical polymerization in pH 5.5 MES buffer (0.7 M). The polymerized hydrogel was mechanically disaggregated using a series of stainless-steel meshes of a selected size to create microgel particles. The microgel particle suspension was sorted and characterized with a mean of 80 μm and a standard deviation of 20 μm. The particles were activated in a solution of EDC and NHS. The activated microgel particles were conjugated with collagen I and fibronectin solutions in PBS, subsequently quenched with ethanolamine. The collagen modified microgels were co-conjugated with fibronectin by incubation with a fibronectin-PBS solution. The LLS was equilibrated with cell culture media for 1 h prior to the cell experiments.

Collagen and fibronectin were successfully detected on the LLS surface by immunofluorescence microscopy. The signal intensity profile shows strong correlation with protein concentration and cell adhesion. The results revealed that the intermolecular forces between the fibronectin and the collagen are sufficient to keep the fibronectin onto the collagen-coated particles. Furthermore, we reported a remarkable difference in invasive phenotype of breast cancer spheroids in 3D between the COL-LLS, FIB-LLS, and their respective compositions. The collagen-fibronectin (COL-FIB) complex, upon conjugated on to the LLS particles, facilitated stronger cell adhesion and spreading as measured with a bio-tribometer. A 3D invasion assay also demonstrated faster and more active migrators at the peripheral region of the tumor spheroids when cultured in COB-FIB-LLS. The cancer cells with invasive phenotype rapidly migrate deep into the 3D LLS matrix exhibiting stark contrast with COL-LLS or FIB-LLS alone where cells spread more gradually. The experiment also revealed a relationship between cell adhesion and migration velocity. It has been reported that mature adhesion complexes lead to reduced velocity. In our study, we demonstrated that the effect is abrogated by tunning the mechanical properties of the LLS microgels and protein concentrations. The results of this study revealed an underlying mechanism of COL-FIB complex that could enable more sufficient cell attachment and migration. An understanding on ell migratory behaviors in 3D within a well-designed and controlled ECM composition would enable much valuable insights in basic research.

SESSION SB09.06: Shape Morphing Hydrogels

Tuesday Afternoon, November 29, 2022
Hynes, Level 3, Room 310

1:30 PM *SB09.06.01
Photochemically-Driven Shaping of Thin Hydrogel Sheets Containing Light-Sensitive Supramolecular Complexes Ryan C. Hayward; University of Colorado Boulder, United States

The ability to precisely define the shape or motion of responsive polymers has wide ranging applications from soft robotics to biomaterials. Among the available stimuli to select from, light represents a simple, remote method of prescribing shape change with a high degree of spatial and temporal control. Our group, and others, have previously leveraged photothermal effects in temperature-sensitive hydrogels to drive shape change, self-assembly, and collective motion. However, photothermally addressable materials require constant illumination to maintain a shape change and suffer from decreased resolution due to thermal broadening. These limitations have stimulated work by numerous groups on photochemically-responsive hydrogels. While azobenzene and related photoswitches offer attractive properties including highly tunable lifetimes and excellent photostability, historically their modest change in polarity upon photoswitching has limited the light-induced response that can be achieved. To enhance this effect, our group has studied photochemically driven shape changes in thin hydrogel disks using host-guest interactions between azobenzene and cyclodextrin. Patterned illumination of the disks with ultraviolet light results in localized deswelling, giving rise to shapes with either positive or negative Gaussian curvature. The reversibility of the host-guest complexation allowed for the shapes to be erased with visible light and repatterned an arbitrary number of times. In addition, we demonstrate azobenzene derivatives that enable both swelling and deswelling of hydrogels entirely with visible light, allowing for increased penetration depth and improving compatibility with materials for cell and tissue culture.

2:00 PM *SB09.06.02
On-Chip Formation of Deformable Hydrogel 3D Architectures via Swelling-Driven Buckling Riku Takahashi[1], Hiroki Miyazako[2], Aya Tanaka[1] and Masumi Yamaguchi[1]; [1]NTT Basic Research Laboratories and Bio-Medical Informatics Research Center, Japan; [2]The University of Tokyo, Japan

Technology to reproduce the microstructure (channels, folds, etc.) and stimulating environment (mechanical stimuli, chemical stimuli, etc.) of living organisms in vitro is crucial for the fabrication of an organ-on-a-chip capable of advanced cell culture. In particular, if such a biological environment can be constructed on a solid substrate, including a sensor substrate, it can be developed as an organ-on-a-chip platform with potential applications in disease modeling and drug discovery through various types of data acquisition. Hydrogel is the best candidate as a base material because of its excellent permeability, biocompatibility, and ability to mimic the biological environment at the material level. On the other hand, the unique feature of gels, swelling, causes a volume mismatch between them and solid substrates, making it difficult to fabricate hybrid devices due to delamination or fracture.
In this talk, we introduce "buckle delamination", a method to fabricate three-dimensional (3D) architectures of hydrogel films on a chip by using swelling

as a driving force. This phenomenon is a type of instability induced by the mismatch between the volume expansion ratio of the thin film and the supporting substrate. This mismatch generates compressive stress, which causes part of the thin film to delaminate and buckle from the substrate, forming a hollow 3D architecture. First, we applied this phenomenon to hydrogel films and proposed a method to precisely control the architecture and position through microfabrication techniques. Using polyacrylamide gel and glass substrates as model materials, we have shown that by chemically controlling the adhesion pattern between the two materials, buckle delamination can be induced at arbitrary locations and continuous channel-like structures can be fabricated. Furthermore, by tuning the physical parameters of the hydrogel, the shape of the 3D architecture can be controlled based on patterns of instability. We then demonstrated that the channel-like architectures can work as a fluidic device. The device is based on a soft and flexible hydrogel film, which can passively expand and contract in the radial direction, like a blood vessel, in response to fluid flow. We have also demonstrated that the permeability and biocompatibility of this device allows for long-term culture of cells and the formation of vascular-like tissue in the channel. Finally, we will show that the architecture formation by "buckle delamination" is a processing method based on a universal physical phenomenon and that it can be applied to various types of swellable hydrogel. Notably, by using a stimulus-responsive gel film, the channel architecture formed on a solid substrate can be deformed quickly, largely, and bio-mimetically like an organ (e.g., peristalsis in the intestinal tract) in response to stimulus patterns. We believe that these results will be useful for designing devices that reproduce the dynamic in vivo environment on solid substrates, and may also contribute to the creation of organ-on-a-chip platforms and soft biomimetic robots.

2:30 PM SB09.06.03
Programmable Auxeticity in Hydrogel Metamaterials via Shape-Morphing Unit Cells Oliver Skarsetz[1], Viacheslav Slesarenko[2] and Andreas Walther[1,2]; [1]Johannes Gutenberg University of Mainz, Germany; [2]University of Freiburg, Germany

Mechanical metamaterials recruit unique mechanical behavior that is unavailable in bulk materials from a periodic unit cell structure with a specific geometry. However, such metamaterials can typically not be reconfigured once manufactured. Herein, we introduce shape morphing of a hydrogel metamaterial via spatio-selective integration of responsive actuating elements to reconfigure the mesoscale unit cell geometry to reach programmable auxeticity on the macroscale. Via thermal control, the unit cell angle of a honeycomb structure can be precisely programmed from 68° to 107°. This results in negative, zero or positive Poisson's ratio under applied tensile strain. This concept of shape-morphing hydrogel metamaterials via the addition of actuating struts into otherwise passive architectures offers a new strategy for reconfigurable metamaterials and extends applications of hydrogels in general. It can be readily extended to other architectures and may find applications in mechanical computing as well as soft robotics.

2:45 PM SB09.06.04
Preliminary Reconfigurable Nerve-Artery Microphysiological System for 3D Cell Culture and Immunostaining Selina Banerjee, Bryan Schellberg, Dylan Miller and Ryan Koppes; Northeastern University, United States

Tissue engineered microphysiological systems (MPS), also known as organs-on-chips, have recently emerged as a more patient-relevant and cost-effective alternative for disease modeling and drug discovery compared to traditional cell culture and animal models. Despite their increased functional relevance, most current MPS lack capabilities for analysis of individual components or layers through biological assays. Furthermore, current MPS rarely use 3D cell cultures to accurately mimic biological structures.

Here, we present a preliminary nerve-artery MPS. This novel MPS includes three removable layers: a three-chamber glass-bottom 3D cell culture layer which allows the contact of different cell types with GelPins (previously published by our lab) [1], with the middle 3D chamber in contact with a 2D cell culture layer through a semi-permeable membrane, and a removable media reservoir at the top of the assembly. The MPS also includes separate pipetting access ports to each chamber, which allows the specific addition and removal of cell culture medium, treatments, or reagents. This design allows specific endpoint analyses for each chamber, including immunostaining for the 3D hydrogel layer, and western blotting, flow cytometry, PCR, and immunostaining for the 2D layer. Furthermore, the glass bottom of the 3D hydrogel layer allows for high-resolution light and fluorescent microscopy of both the 2D and 3D layers, with the layers assembled or separated.

The manufacturing and assembly of the MPS include the use of stereolithography (SLA) 3D printing, laser cutting, and layer-by-layer assembly (as previously published by our lab) [2]. First, an SLA-printed clear resin piece is attached to a glass coverslip to form the bottom of the assembly. To form the three-chamber hydrogel cell culture layer, a Viton rubber gasket and modified GelPin [1] made of polyethylene terephthalate (PET) are laser cut and assembled with 3M 966 tape, and attached to the glass coverslip. Above the 3D cell culture layer is the 2D cell culture layer, which includes a laser-cut semi-permeable PET membrane. Above this 2D layer is the removable media reservoir layer, which includes a laser-cut Viton rubber gasket attached to a laser-cut polymethyl methacrylate (PMMA) piece. The 3D layer, 2D layer, and media reservoir are held together using flat head screws and nuts. Together, the three layers form a biomimetic structure to simultaneously model a nerve and artery: neurons can be cultured in the outer 3D hydrogel chambers to form the nerve component, and smooth muscle cells and endothelial cells can be cultured in the middle hydrogel chamber and the single-chamber 2D layer, respectively, to form the arterial component. To our knowledge, this design is the only nerve-artery model that includes 3D cell culture or an MPS.

As a proof of concept, F11 (mouse neuroblastoma - rat dorsal root ganglion) cells were encapsulated in 5% gelatin methacrylate (GelMA) hydrogel and seeded in the outer hydrogel chambers in the 3D layer of the MPS. The encapsulated cells were cultured in differentiation media for 2 weeks, fixed, immunostained for NeuN and actin, and imaged with an inverted fluorescent microscope. This study demonstrates that the MPS can be successfully used for longer-term 3D cell culture, immunostaining, and imaging experiments. Furthermore, the simple fabrication methods used to assemble the MPS can rapidly be modified to model other tissues or include other endpoint analyses, flow channels, or probes. Overall, this novel MPS has shown promising results for use as a nerve-artery model, and its applications and uses can be expanded with further research and development.

Hydrogels of Arrested Phase Separation Zhigang Suo; Harvard University, United States

We have developed a process that self-assembles a nanocomposite using a hydrogel-forming polymer and a glass-forming polymer. The process separates the polymers into a hydrogel phase and a glass phase. The two phases arrest at the nanoscale and are bicontinuous. Submerged in water, the nanocomposite maintains the structure and resists further swelling. We demonstrate the process using commercial polymers, achieving high water content, as well as load-bearing capacity comparable to that of polyethylene. During the process, a rubbery stage exists, enabling us to fabricate objects of complex shapes and fine features. We conduct further experiments to discuss likely molecular origins of arrested phase separation, swell resistance, and ductility. Potential applications of the nanocomposites include artificial tissues, high-pressure filters, low-friction coatings, and solid electrolytes. This talk is prepared on the basis of a paper co-authored with G. Zhang, J. Kim, and S. Hassan.

4:00 PM *SB09.07.02
Cavitating Hydrogels—From Molecular Connections to Buried Interfaces Alfred J. Crosby; Univ of Massachusetts, United States

Failure, or fracture, remains one of the most important, yet most challenging, topics in materials science. This challenge is especially true for soft materials, such as hydrogels and biological tissues. Understanding failure in these systems is critical for developing important technologies, from robust prosthetic materials to protective gear for mitigating debilitating injuries. However, the ultra-soft nature of these materials makes quantifying failure processes difficult. Here, we present two recent advances: 1) understanding how cavitation-based deformations lead to either reversible or irreversible damage in hydrogel materials, and 2) new cavitation-based methods for measuring materials properties of buried interfaces between ultra-soft hydrogel materials. For the first topic, we describe the results of a multi-university, multi-disciplinary study that combined the use of precisely-defined polymer networks, molecular dynamic simulations, and classical and new characterization methods to develop and validate of theoretical relationships between molecular network architecture and macroscale cavitation and fracture processes. For the second topic, we are motivated by the critical role that interfacial properties play in determining the failure of biological tissues, as well as ultra-soft materials that are designed to interface with these tissues. We introduce methods that provide straightforward, quantitative measurements of the elasto-adhesion length scale for ultra-soft hydrogel interfaces. These methods provide new means for characterizing interfacial properties within living systems, and they have added benefits of offering pathways for high-throughput characterization of hydrogel adhesion properties, in general. Collectively, the results and discussion presented here are important for enhancing our fundamental understanding of ultra-soft hydrogel materials and the mechanisms that control their failure across a range of size scales.

4:30 PM DISCUSSION TIME

4:45 PM SB09.07.04
Molecular Dynamics (MD) Simulations of Soil-Strengthening Nanocomposite-Polyelectrolyte Hydrogels Jerry Zhang[1], Vincent Wang[2], Anthony Zhu[3], Arkajyoti Sinha[4], Shoumik Saha[5], Dilip Gersappe[5] and Miriam Rafailovich[5]; [1]Minnetonka Senior High School, United States; [2]Irvington High School, United States; [3]Barrington High School, United States; [4]Lexington High School, United States; [5]Stony Brook University, The State University of New York, United States

Nanocomposite-polyelectrolyte hydrogels are gels formed from a mixture of charged polymer chains and nanofillers. They can absorb large amounts of water, mimic biological fluids/tissues, and more recently, they can potentially serve as a sustainable alternative to concrete for soil strengthening purposes. Despite the large number of studies on polyelectrolytes and their adsorption onto oppositely charged particles, little is known about the mechanism of network formation and structure of such charged hydrogels. Thus, we use molecular dynamics (MD) simulations to investigate the effect of charge on the gelation of our system and related properties including viscosity, network formation, cluster geometry, and polymer adsorption onto filler particles.

We use a coarse-grained approach, where nanofillers are modeled as rigid bodies of disk-like shapes. Polyelectrolyte chains are modeled as beads connected by finitely extensible nonlinear elastic (FENE) springs. All pairwise interactions are defined by the truncated and shifted 12-6 Lennard-Jones (LJ) potential. Systems also included uncharged solvent particles and free-floating univalent counterions for both nanofillers and polymer chains to ensure electroneutrality.

We vary the charge of both the filler particles and the polyelectrolyte beads independently. Upon reaching equilibrium, we use the Green-Kubo relation to calculate viscosity by integrating the stress-autocorrelation function (SAF), the step-strain test (SST) to determine the mechanical stability, the radial distribution function (RDF) of the polymers with respect to the fillers in order to measure adsorption, and finally, a network clustering algorithm (NCA) to test for cluster formation. If clustering occurs, we quantify cluster geometry by calculating the gyration tensor, allowing us to determine asphericity, acylindricity, and relative shape anisotropy.

Our initial results for systems with charge magnitudes of q=1 for both the polymer and filler beads show both the SAF and SST decaying to zero, implying gelation was not induced, while the RDF and NCA suggested that adsorption and clustering, respectively, also did not occur. We did observe increasing viscosity with charge magnitude, suggesting that larger charge magnitudes could induce gelation. Results also show that the cluster geometry of nanofillers is an important determinant of the final properties of the hydrogel where the assembly is mediated by polymer and nanofiller net charges. Our work will be able to determine structural information and conditions for hydrogel design. They will also enable experimental teams to manufacture and test nanocomposite hydrogels with the specific charge properties that our models predicted would exhibit enhanced behaviors.

We would like to thank the Morin Charitable Trust for funding this project as well as Prof. Miriam Rafailovich and the Garcia Research Program for making this work possible. We would also like to acknowledge the mentorship of Shoumik Saha and Prof. Dilip Gersappe for their guidance and support. All simulations were run on the Stony Brook University SeaWulf supercomputer.

Mucin Networks—A Mechanical Fuse that Protects Epithelial Cell Surfaces During Shear Diego I. Pedro, Alfonso Pepe, Duy T. Nguyen and W.

Gregory Sawyer; University of Florida, United States

Mucin dysfunction is implicated in many infectious and inflammatory diseases of the respiratory tract, the digestive tract, the reproductive tract, cancer, and the ocular surfaces. All moist epithelial surfaces are protected by a secreted layer of mucus, which is a low yield strength, high-water content, network of mucin glycoproteins. As a part of the innate immune system, these mucin networks provide hydration, protection, and help to exclude pathogens providing a reservoir for antimicrobial molecules. Although widely described as a “slippery” barrier on epithelial surfaces, the mechanics and self-healing properties of mucin network dynamics and their role in epithelial cell friction and shear are poorly understood. Experiments on self-mated epithelial cell surfaces at physiological contact pressures reveal shear stress limits of a mucin network, made of purified MUC2 and membrane mucins including MUC1 and MUC4[1]. Micro-rheological measurements using magnetic tweezers provide insights into the network rheology, and molecular biology techniques reveal thresholds for the production of proinflammatory cytokines and apoptosis.
In this work, hemi-spherical polyacrylamide hydrogel probes with a 2 mm radius of curvature and a shell thickness of 250 µm were used to maintain constant contact pressures ~ 1 kPa across the epithelial cell interfaces. The poly-acrylamide gels (water content ~ 87.5 %) were equilibrated in Keratinocyte Growth Media (KGM-Gold™). Bioconjugation of polyacrylamide with collagen type-I (0.4 mg/ml) was performed using 1mM Sulfo-SANPAH[2]. Glass-bottomed culture-dishes were coated with fibronectin for cell adhesion. Human Corneal Epithelial Cells (hTCEpi) were cultured for ~ 2 days to form a monolayer with >90% confluency on both the probes and the culture dishes. In situ biotribology experiments were performed at 37±0.2 °C, 5 % CO_2, and ~100 % relative humidity. A normal load of 400 µN was applied between the two surfaces. Friction force measurements were recorded on a custom fabricated biotribometer[3] with a 3 mm stroke length, and a sliding speed of 1 mm/s. Contact pressure was calculated by from the measured contact area and applied force. All microscopy was performed in situ on a Nikon A1R confocal microscope. Purified MUC2 at 5 wt% in KGM-Gold™ was continuously flowed to the sample to induce transport conditions reducing inflammation and cell death. The magnetic tweezers were used for micro-rheology following the design of Lammerding[4] with 6 µm superparamagnetic fluorescent bead.
Experiments with the reciprocal sliding of two hTCEpi epithelial surfaces revealed the upregulation and production of proinflammatory cytokines at shear stresses ≥ 40 Pa, and almost complete apoptosis and cell removal at 100 Pa. Experiments on self-mated epithelial cells showed friction coefficients that monotonically increased to µ>0.2 over 300 cycles without the addition of soluble MUC2. A 5 %w addition of MUC2 maintained low shear stress (t~40Pa) for over 300 cycles, and enhanced mucin protection. When transport conditions were induced, damage rate was significantly reduced, suggesting faster mucin-gel-self-healing phenomenon under this condition emphasizing the role of the self-healing time for appropriate mucin protection under shear. Magnetic-tweezers with microbeads revealed a definitive yield-stress and elasticity of the mucin network consistent with the measured shear stresses during sliding.
In this model, the fragile mucin network reduced shear stress, friction, and friction-induced damage, and it was found to self-heal faster under transport conditions.

9:15 AM SB09.08.03
Dynamic Covalent Crosslinking Strategies for Tunable Hydrogel Networks Rebekah Tan, Joey H. Wong, Xian Jun Loh and Kun Xue; Institute of Materials Research and Engineering, Singapore

Dynamic covalent systems are interesting as they are composed of bonds which show covalent character, but become reversible under environmental stimuli such as temperature or pH [1,2]. Boronic acids in particular can bind with cis-1,2 or cis-1,3 diols to form into boronate esters, and this is affected by pH and other diols [3,4]. As a building block in supramolecular engineering, boronate crosslinks can be used to dynamically crosslink onto polymers to generate hydrogel networks with tunable states and properties.

Hydrogel printing has the contrasting needs of a highly processable and printable hydrogel, and a higher mechanical strength post deposition [5]. To expand the repertoire of materials suitable for hydrogel patterning, we report versatile polymer networks comprising of polyvinyl alcohol crosslinked with PEG-diboronates crosslinkers at low ratios [6]. These pre-gel networks are highly processable and extendable: they can be pulled up into thin strands and used for patterning of thin lines, and show shear thickening at higher shear rates. The pre-gels can be easily converted into a hydrogel state by pH adjustment and show clear antibacterial effects. Valuably, the pre-gels can be integrated into a 3D printing setup to print programmable lines and shapes and subsequently converted into patterned hydrogels.This study demonstrates that dynamic boronate networks can switch between a processable state and a mechanically stronger state and could offer alternate strategies and possibilities for hydrogel patterning applications.

Due to its relative stability and reprocessability, dynamic covalent crosslinking of supramolecular units onto polymer chains is an alternative way to fabricate supramolecularly crosslinked polymers.We functionalised the PVA polymer backbone with the carboxylate functionality through boronate crosslinking. This enabled the formation of a suprapolymeric conjugate with dynamically attached carboxylate moieties, which could subsequently form into supramolecular crosslinked hydrogels via ionic and electrostatic crosslinks. When crosslinked by calcium, a stronger hydrogel was formed which could not self-heal. When the polyelectrolyte branched polyethylenimine (PEI) was added, a stable hydrogel was formed with antibacterial properties.

In summary, we have shown that dynamic covalent boronate crosslinking can generate pH-switchable hydrogel states for printing applications or can be used to construct a suprapolymeric conjugate in combination with secondary supramolecular interactions. Dynamic covalent crosslinks can act as building blocks for the fabrication of functional yet responsive hydrogel materials.

Degradation Controls Spreading and Interfacial Coverage of Nanogels at Soft Interfaces—Insights from Mesoscale Modeling Vaibhav A. Palkar[1], Devanshu Thakar[2] and Olga Kuksenok[1]; [1]Clemson University, United States; [2]Indian Institute of Technology Gandhinagar, India

Adsorption of nanogel and microgel particles onto liquid-liquid interfaces finds several potential applications. These particles are known to spread over the interface adopting shapes depending on the original size, shape, and crosslink density of the particles. In this work, we study controlled degradation of nanogels upon application of an external stimulus to dynamically control the topography of soft nanostructured interfaces. We use the Dissipative Particle Dynamics (DPD) simulation approach, along with an adapted form of the modified Segmental Repulsive Potential (mSRP) to characterize degradation and spreading of nanogels over the interface. To establish a baseline, we first simulate degradation of individual nanogel particles suspended in a solvent and track the evolution of particle size and shape via the gyration tensor up to the reverse gel point, where nanogel particles completely dissolve in the solvent. We show that the nature of the polymer-solvent interaction significantly affects the evolution of shape during degradation. Further, we simulate the adsorption and spreading of these nanogels onto the interface between two liquids and observe that this process is affected significantly by the strength of the repulsion between the two liquids. We compare the size and shape evolution of nanogels degrading at the interface with those degrading in the bulk and measure an extent of spreading during degradation. Our results indicate that controlled degradation of the nanogels results in an enhanced extent of interfacial spreading and provides a way to control interface topography at the nanoscale.

Three-Dimensional Stiffness Control of Double-Network Hydrogels by Bi-Ag Redox Reaction Ethan Frey[1], Sooik Im[1], Sam Cheeseman[2], Jinwoo Ma[1], Jan Genzer[1], Michael Dickey[1] and Vi Khanh Truong[2,3]; [1]North Carolina State University, United States; [2]Royal Melbourne Institute of Technology, Australia; [3]Flinders University, Australia

Connecting soft and rigid materials is crucial for numerous applications, including synthetic tendons and stretchable electronics. However, large gradients in stiffness can delaminate interfaces under strain. Gradual stiffness gradients allow stress to be distributed evenly to maintain adhesion. Previous work on stiffness gradients has been limited to stiffness control in only one dimension and often lacked precision. This work utilizes redox reactions in double network hydrogels to modulate the stiffness in three dimensions and form gradual stiffness gradients. Polyacrylamide-alginate hydrogels containing bismuth particles were reacted with silver nitrate to form silver particles and bismuth ions, which crosslinked the carboxylic groups of the alginate. Stiffness gradients were created by changing the exposure time to silver nitrate solution. This gradient in dynamic modulus was mapped by cutting the hydrogels into pieces and measuring each individually with a rheometer. Digital image correlation (DIC) analysis was used to create a 2-D map of strain level, confirming the gradient in stiffness and revealing that stiffness only increased at the locations of the bismuth particles. Therefore, stiffness gradients were additionally created by changing the particle distribution. This was done by altering the viscosity of the precursor solution and curing time to allow the particles to partially settle during curing. The resulting hydrogels actuated during the redox reaction due to localized stress on one side of the hydrogel. Lastly, the hydrogels exhibited excellent antibacterial properties due to the presence of bismuth and silver, both potent antibacterial agents in their nanoparticle and ionic form. Zone of inhibition testing and a colony-forming unit evaluation was performed to analyze these properties. In summary, this system allows for stiffness to be controlled in three dimensions, down to the size of individual bismuth particles. Therefore, these Bi-Ag double network hydrogels offer a solution for the fluid integration of rigid and soft materials, and their antibacterial properties could be helpful in many biomedical applications.

10:30 AM SB09.09.02
Autonomous Soft Robotics Using Chemical Fuels Giorgio Fusi[1], Daniele Del Giudice[2], Stefano Di Stefano[2] and Andreas Walther[1,3]; [1]Johannes Gutenberg-Universität Mainz, Germany; [2]Università degli studi di Roma “La Sapienza”, Italy; [3]Cluster of Excellence livMatS @ FIT - Freiburg Center for Interactive Materials and Bioinspired Technologies, University of Freiburg, Germany

Hydrogel actuators generate mechanical motion through volume changes in response to stimuli as varied as pH, heat, light or magnetic fields. Methods of controlling pH have primarily focused on sequential addition of reagents to alternately raise and lower pH, use of photoacids, or multi-component enzymatic reaction networks. We demonstrate the coupling of a one-molecule dissipative reaction network to a pH-responsive hydrogel actuator, leading to transient motion. Exploiting the rapid proton release upon addition of fuel, followed by spontaneous decarboxylation and proton consumption by the resulting intermediate species, transient pH drops in the timescale of minutes to days can be achieved. Matching reaction cycle timescale to the rate of gel (de)swelling results in an autonomous system where fully reversible contraction of gel actuators and bending of bilayer devices is obtained. Our results illustrate the use of a tunable chemical reaction network to control centimeter-scale hydrogel actuators and exploit their motion to generate mechanical force. Due to its simplicity and cyclability derived from its resistance to waste accumulation, this method of control is likely to prove attractive for a wide variety of pH-responsive hydrogel systems, and can be readily integrated into larger reaction systems and more complex device architectures displaying chemomechanical feedback.

10:45 AM SB09.09.03
Stimuli-Responsive Ion-Diffusive Ultrasoft Hydrogel for Zero-Powered Bioelectronics Sungwon Jung[1], Sangmin Lee[2] and Jinkee Hong[1]; [1]Yonsei University, Korea (the Republic of); [2]Chung-ang University, Korea (the Republic of)

Bioelectronics are emerging devices applied for human that are a promising solution for self-care and smart healthcare. Among them, non-invasive bioelectronics such as electrical stimulation patches are considered as the realistic and feasible medical applications for minimizing anxiety in patients with low immune responses or toxicity problems. Accordingly, multifunctional soft materials, for instances, skin-adhesive, conductive hydrogel for application to non-invasive bioelectronics are essential. Moreover, the number of self-powered system without using extra power source for bioelectronics also has been reported, however, there are still have limitations that require specific movement or environment.
Here in, we introduce a 1) stimuli-responsive ion-diffusive hydrogel (IDH) with optimized softness, skin-adhesive for bioelectronics and 2) a system capable of tissue vitalization by accumulating energy generated and lost spontaneously from humans contact with in daily life using. The IDH was synthesized by using polyacrylamide (PAAM), oxidized hyaluronic acid (OHA) and PEDOT:PSS with schiff-base and hydrogen bonding-based triple

network. By tuning the oxidation rate of OHA, optimized the mechanical property of IDH which has similar elastic modulus with human skin (~ 19.24 kPa) and shear adhesion strength (~ 57 J/m2) which is optimized mechanical properties for patients comfortability. Furthermore, the IDH has electrical stimuli-responsive ion loading/releasing properties because of reduction/oxidation of PEDOT:PSS which is capable for iontophoretic drug releasing bioelectronics. The IDH shows higher ion loading efficeincy inside to IDH when DC electric field is applied, and also shows higher ion releasing and penetration to porcine skin when the opposite DC electric field is applied.
The zero-powered system, called body-mediated energy loss conversion (BELC), is structurally designed system of stacked conductors and insulators. The BELC can convert energy loss from electronic devices and physical activity to usable energy via transfer through the human body as a medium. By applying IDH and the BELC system, body-mediated bioelectronics (BMB) patch was designed and fabricated. The BMB patch can internally concentrate electric field and various outputs during human activity (walking, running, typing on labtop, etc.) was measured (14.3 mV/mm of electric field output during running). Furthermore, iontophoretic ion-penetration through porcine skin during human activity was also investigated. The proposed multifunctional IDH is belived to be widely used for non-invasive bioelectronics and also BMB is expected to overcome the drawbacks of conventional bioelectronics and can pave the path to zero-powered bioelectronics with permanent operation.

11:00 AM SB09.09.04
Strong and Fast Hydrogel-Based Actuators by Electroosmotic Turgor Pressure Hyeonuk Na[1], Yong-Woo Kang[1], Chang Seo Park[1], Sohyun Jung[2], Ho-Young Kim[3] and Jeong-Yun Sun[4,5]; [1]Multi-Functional Soft Materials Laboratory Department of Materials Science and Engineering, Korea (the Republic of); [2]SOFT FOUNDRY, Seoul National University, Korea (the Republic of); [3]Department of Mechanical Engineering, Seoul National University, Korea (the Republic of); [4]Department of Material Science and Engineering, SeoulNational University, Korea (the Republic of); [5]Research Instituteof Advanced Materials (RIAM), Seoul National University, Korea (the Republic of)

Hydrogels are promising as materials for soft actuators because of qualities such as softness, transparency, and responsiveness to stimuli. However, weak and slow actuations remain challenging as a result of low modulus and osmosis-driven slow water diffusion, respectively. We used turgor pressure and electroosmosis to realize a strong and fast hydrogel-based actuator. A turgor actuator fabricated with a gel confined by a selectively permeable membrane can retain a high osmotic pressure that drives gel swelling; thus, our actuator exerts large stress [0.73 megapascals (MPa) in 96 minutes (min)] with a 1.16 cubic centimeters of hydrogel. With the accelerated water transport caused by electroosmosis, the gel swells rapidly, enhancing the actuation speed (0.79 MPa in 9 min). Our strategies enable a soft hydrogel to break a brick and construct underwater structures within a few minutes.

11:15 AM SB09.09.05
Strain Sensor with Self-Healing Ability Using a Dry-Resistant Hydrogel-Based Conductive Composite Jungyoon Seo, Taehoon Hwang and Hwasung Lee; Hanyang University, Korea (the Republic of)

Self-healing and conductive hydrogels had attracted great attention for applications as electronic skin and flexible strain sensors due to their excellent flexibility and strain-sensitivity. In particular, Poly(vinyl alcohol)(PVA)-based hydrogels were widely used for devices that require self-healing ability. However, traditional PVA-based hydrogels had limited long-term use because it is difficult to retain water in cold or hot environments. Here, We increased anti-freezing and anti-dryingperformance by introducing glycerol, BTCA(1,2,3,4-Butanetetracarboxylic acid), and SPA(sodium polyacrylate), thereby improving the safety of long-term use. Then, carbon nanotubes(CNTs) were introduced into the hydrogel, which assign conductivity to the hydrogel. The conductive hydrogel reliable recovery performance and superior self-healing ability without deterioration in electrical performance. The hydrogels were simply made of strain sensors and detected some real skin epidermis movements such as finger bending, wrist bending, facial movements changes. This work had the potential to beused to fabricate conductive, anti-drying/freezing, stretchable and strain-sensitive device applications.

SESSION SB09.10: Hydorgel Actuator, Sensor and Machines II
Session Chairs: Giovanni Bovone and Mark Tibbitt

Mechanoreceptor Inspired Iontronic Pressure Sensing for Humans and Machines Yuta Dobashi[1], Jerry C. Ku[1,1], Joel Ramjist[2], Victor X. Yang[1,2] and John D. Madden[3]; [1]University of Toronto, Canada; [2]Toronto Metropolitan University, Canada; [3]University of British Columbia, Canada

The human somatosensory network relies on ionic currents to sense, transmit, and process tactile information. We investigate hydrogels that similarly transduce pressure into ionic currents, forming a piezoionic skin. As in rapid- and slow-adapting mechanoreceptors, piezoionic currents can vary widely in duration, from milliseconds to hundreds of seconds. These currents are shown to elicit direct neuromodulation and muscle excitation, suggesting a path toward bionic sensory interfaces. The signal magnitude and duration depend on cationic and anionic mobility differences. Patterned hydrogel films with gradients of fixed charge provide voltage offsets akin to cell potentials. The combined effects enable the creation of self-powered and ultrasoft piezoionic mechanoreceptors that generate a charge density four to six orders of magnitude higher than those of triboelectric and piezoelectric devices. We explore the applications of these iontronic mechanotransduction effect in the context of both humans and machines - from implantable pressure-sensing hydrogels to bionic skins.

2:30 PM BREAK

SESSION SB09.11: 3D/4D Printing of Hydrogels

3:30 PM SB09.11.01
Dynamic Photomask Printer for Fabrication of Organs-on-Chip (OoC) Shu-Yung Nina Chang[1], Terry T. Ching[1,1,2] and Michinao Hashimoto[1,1]; [1]Singapore University of Technology and Design, Singapore; [2]National University of Singapore, Singapore

In this work, we developed a system to fabricate organs-on-a-chips (OoCs) using a prefatory fluidic chip and a do-it-yourself (DIY) photomask printer. The photomask printer allows direct photopolymerization of bioinks to create microfluidic channels in the prefatory chip, and the patterns of microchannels can be digitally and dynamically controlled. Existing OoCs are predominantly fabricated using soft lithography, whereby microfluidic chips were fabricated with a fixed channel design. Unlike the conventional OoC fabrication method, our system confers the flexibility to fabricate the desired microfluidic chip design *in situ* and use cell-laden hydrogel patterns as a part of the channel architecture of the OoCs.
In our DIY photomask printer, a high-resolution liquid crystal display (LCD) screen (with a pixel size of 32 μm × 32 μm) was used to project photomasks to create intricate microchannels smaller than 80 μm in horizontal dimensions in the OoCs. With sequential photopolymerization of hydrogels laden with different cell types *in situ*, we successfully patterned multiple cell types at precise locations on the multicellular OoCs (multi-OoC) to mimic the spatial organization of cells *in vivo*. As a demonstration, we fabricated multi-OoC to model vascularized tissues, where primary-cells-laden hydrogels and cancer cells-laden hydrogels were endothelialized with a layer of endothelial cells surrounding their exterior to form a barrier against the perfusing microfluidic channel. After culturing for 7 days, we observed the formation of tight junctions between the endothelial cells in our multi-OoCs. Disruption of these tight junctions was also triggered upon cytokine stimulation, resulting in the migration of metastatic cancer cells to the microfluidic channel. Secondly, the dynamic nature of our photomask printer enabled the designing of OoC *in situ* such that live images could be used to create a photomask accordingly. Using a live photomask, confinement of biological tissues in suspension culture, such as pre-formed cancer spheroids, was achieved in our system for perfusion culture. Such confinement would allow for easier visual monitoring compared to the conventional spinning culture of cell spheroids and organoids. Lastly, we demonstrated that the height of OoCs fabricated in our system was readily varied by changing the height of the spacer consisting of adhesive tapes. Such flexibility in our system allowed us to create OoC to mimic the hierarchical structure in blood vessels by varying the cross-sectional heights throughout the prefatory chip. In this design of OoCs, we achieved branching endothelial cells-laden fluidic channels with gradually decreasing heights, from 600 μm to 200 μm.
These demonstrations showed the potential of our system to create biomimetic structures by recapitulating the spatial organization of different cell types and the three-dimensional (3D) geometry of biological tissues on OoCs. The flexible and rapid OoC fabrication enabled by our system will contribute to increasing the efficiency of high throughput drug screening using biomimetic structures.

3:45 PM SB09.11.02
Stretchable and Shrinkable Hydrogel-Based Replication Using a Single 3D-Printed Structure via an Iterative Shrinking Process Eunseok Heo, Jun Chang Yang, In Cho, Hyun-Hee Lee, Yong-Jin Yoon, Steve Park and Jae-Byum Chang; Korea Institute of Science and Technology, Korea (the Republic of)

Recently, 3D printing has attracted significant attention in various fields as it can easily generate arbitrary 3D structures directly from a computer-aided design (CAD) model without any molds or templates. As a low-cost method for 3D fabrication, 3D printing has been widely employed in applications requiring sophisticated 3D structures, such as lab-on-a-chip in the diagnostic industry or patient-customized products in the biomedical field. However, low printing throughput has hindered the broader usage of this technology. To synthesize identical structures of different sizes or materials, each must be separately printed, increasing time and expense. Replication of 3D-printed structures via a molding process with size-tunable molds can be used to solve this issue, but it is limited to tapered or vertical profiles, such as microneedles or simple cylindrical shapes. Here, we demonstrate the generation of replicas of diverse sizes and materials, starting from a single 3D-printed template of complex shape. To achieve this, we use molds composed of stretchable hydrogel, which shrinks isotropically. Using the stretchability of the hydrogel, the 3D-printed structure is separated from the embedding hydrogel without crack formation. Then, polycaprolactone (PCL) fragments are introduced to fill the cavities of the hydrogel mold. The PCL-filled hydrogel structure is heated to 60 °C, a temperature at which the hydrogel mold shrinks as it dries, while at the same time, PCL melt and fills the cavities. This process can be repeated; diverse replicas with varying sizes and materials can be generated from a single 3D-printed template. Finally, we demonstrate the size reduction of the 3D-printed template with complex interconnecting geometries, which are not available with conventional molding methods.

4:00 PM SB09.11.03
Programming Differentiation of Neural Stem Cells with 4D Printed Multilayer Smart Scaffolds Yi Yang, Omar A. Khater, Nathan D. Gallant and Ying Zhong; University of South Florida, United States

Spinal cord injury (SCI) could permanently disconnect the central nervous system (CNS) and the body below it. It would cause different paralysis depending on the damaged segments of the spinal cord. The therapeutical method for SCI remains challenging due to the difficulties of neuron regeneration. Stem cells are promising to realize neuron regeneration due to their excellent differentiation potential. However, conventional ways for stem cell differentiation cannot control or guide the direction of the neural cells, making it difficult to be used in SCI therapy, as the spinal cord requires aligned neural bundles. Here, porous multilayer scaffolds that composites polydimethylsiloxane (PDMS) and poly(N-isopropylacrylamide) (PNIPAAm) layers were 4D printed. It imitates the extracellular matrix of neural stem cells in terms of strain and elasticity stimulation to enhance and guide PC-12 stem cell differentiation. Different printing parameters and surface treatment procedures were evaluated for the purpose of enhancing the polymer-cell adhesion. Various layer thicknesses and designs were investigated to understand the thermal-related reversible bending behaviors of the scaffolds. It was confirmed that by changing the temperature within the survival range of the cells, the 4D printed smart scaffolds can bend and recover reversibly, providing controllable strain on the cells at the desired frequency to program the differentiation behavior of neural stem cells.

Key word: 4D printing; PDMS; PNIPAAm; Neural stem cell; Cell culturing; Differentiation.

4:15 PM SB09.11.04
Hydrogel Based 3D/4D Printing Systems and Their Applications in Soft Robotics MD Nahin Islam Shiblee and Hidemitsu Furukawa; Yamagata University, Japan

Hydrogel actuators with soft-robotic capabilities, as well as biomimetic advanced materials with simple and programmable fabrication processes, are currently in high demand. In this work, we will demonstrate 4D printing phenomena using different hydrogel-based systems to create bilayer actuator systems. A variety of hydrogels, such as shape memory hydrogels, inter-crosslinking hydrogels, etc., have been developed and their physical properties have been characterized to understand their response behaviors under methodical application of water absorption and temperature. While shape memory-based hydrogel systems require two different compositions to create an actuating porotype, we have also successfully achieved 4D printed systems based on single inter-crosslinking hydrogels where single materials enable variable swelling degree resulting from printing conditioning. The deformation mechanism of the 4D printed structures has been studied by tuning of printing parameters, e.g. scan number, total UV light irradiation time, etc., and also by optimizing initiator concentration for the stereolithography printing process. These 4D-printed systems are designed to imitate living organisms that exhibit multi-directional actuation.

SESSION SB09.12: Composites Hydrogels
Session Chairs: Giovanni Bovone and Mark Tibbitt
Thursday Morning, December 1, 2022
Hynes, Level 3, Room 310

8:45 AM SB09.12.01
Bioinspired Structural Composite Hydrogel with a Combination of Mechanical and Thermal Properties Donghwan Ji and Jaeyun Kim; Sungkyunkwan University, Korea (the Republic of)

Hydrogels are water-filled three-dimensionally crosslinked polymer networks with completely different characteristics compared to typical materials like liquids, metals, ceramics, and plastics. Hydrogels have been utilized as soft robot components, flexible backbones of bioelectronics, conductive membranes, and artificial biological tissues. For these applications, developing hydrogels with a desirable combination of stiffness and toughness is a critical issue.
Since the development of soft yet tough double-network hydrogel, many studies have exhibited synthetic hydrogels applicable for soft tissues whose elastic moduli range from a few pascals to several kilopascals. Despite that, creating much strong, stiff, and tough hydrogels similar to load-bearing tissues, such as tendons and cartilages with elastic moduli in the MPa-to-GPa range, still remains challenging.
To achieve such mechanical property, in this study, we apply a bioinspired structure and fracture mechanisms into a double-network hydrogel and develop structural composite hydrogels. A natural structural composite, nacre, which consists of ductile polymeric matrices and stiff inorganic microplatelets (microsized tablets) in a layered structure, has mechanisms of an effective load transfer from the matrix to the platelet and fracture resistance through platelet pull-out. That leads to the combination of stiffness and toughness. Indeed, we had previously developed composite materials (a kind of plastic) and demonstrated the reinforcing effect and mechanism of layered inorganic microplatelets in polymer matrices of the material.
We expand this approach to a wet hydrogel system and present a bioinspired structural composite hydrogel composed of tough double-network polymer matrices and stiff alumina microplatelets assembled in a layered structure. To fabricate such hydrogel, we suggest a straightforward method, which is a reconstruction process comprising “drying-induced unidirectional shrinkage of a pre-gel” and “additional crosslinking with rehydration in an ionic solution”. During unidirectional drying/shrinkage, the pre-gel of the random compound becomes a thin film of layer-by-layer assembled microplatelets within highly densified polymer matrices; and then, subsequent crosslinking/rehydration fastens the densified layered structure with fully crosslinked polymer networks. During the process, the polymer–platelet interactions are also enhanced.
As a result, the structural composite hydrogel exhibited highly enhanced mechanical performance, withstanding more load and dissipating more energy along with a crack deflection and platelet pull-out. The resulting tensile strengths, elastic moduli (on the order of several MPa), and high fracture energies (up to 2 kJ m^{-2}) are comparable to those of the stiff load-bearing tissues such as the ligament and tendon. Such mechanically robust hydrogel with the densified polymer matrix and strong polymer–platelet interactions also exhibited high ionic conductivity. The conductive hydrogel containing cations, such as Li^{+} and Zn^{+}, was utilizable as a stable gel electrolyte almost without compromising mechanical performance. Further, the layered alumina platelets allowed the hydrogel to possess outstanding in-plane thermal diffusivity. When the hydrogel is introduced to serve as a gel electrolyte membrane, the hydrogel is expected to prevent rigid electronic components (electrodes) from inducing heat localization and thermal damage as well as to avoid a mechanical mismatch.

Nanoparticles Influence on Rheological Behavior of Poloxamer-Casein Hydrogels Louise L. Tundisi[1], Jéssica H. Fonsêca[1], Janaina Artem Ataide[1], Marcos A. D'Ávila[1], Daniel Kohane[2] and Priscila G. Mazzola[1]; [1]UNICAMP, Brazil; [2]Harvard Medical School, United States

Poloxamer 407 (P407)–Casein hydrogel was chosen to terbinafine-loaded polycaprolactone nanoparticles (PCL-TBH-NP). In this study, terbinafine hydrochloride (TBH) was encapsulated into polycaprolactone (PCL) nanoparticles, which were further incorporated into poloxamer-casein hydrogel in different addition order, to evaluate the effect of gel formation. Nanoparticles were prepared by nanoprecipitation technique and characterized by evaluating its physicochemical characteristics and morphology. The nanoparticles had a mean diameter of 196.7 ± 0.7 nm, PDI of 0.07, negative ζpotential (-0.7138mV), and high encapsulation efficiency (>98%). PCL-NP modulated terbinafine release in artificial sweat. Rheological properties were analyzed by temperature sweep tests at different addition orders of nanoparticles into hydrogel formation. Rheological behavior of hydrogels were evaluated, considering different concentrations of nanoparticles, and different addition orders. When nanoparticles were added to the final P407-Casein hydrogel (M1), a decrease in gelation temperature from 28ºC to 26 ºC ($p<0.05$) and below were observed. Above 0.4 mg/mL of nanoparticles, strong gels with modules almost temperature-independent were observed, and 0.4 mg/mL showed the highest storage modulus. In the second preparation method, where nanoparticles were firstly added to casein solution, followed by addition of P407 (M2), the gelation temperature also decreased: at 0.8 mg/mL of nanoparticles shifted from 28ºC to 20 ºC ($p<0.05$) the gelation temperature and had an increase in the storage module from 9.42 to 29.7kPa ($p<0.05$). The nanoparticle's addition to the hydrogel significantly influenced gelation temperature, the viscoelastic properties and provided stable gels at the two preparation methods. Moreover, the nanoparticle addition order leads to different rheological behavior for the same nanoparticle concentration; thus, a suitable nanoparticle concentration to improve hydrogel mechanical properties can be addition order dependent.

9:15 AM SB09.12.03
CARS Microscopy as an *In Situ* Characterization Technique for Living Composites Christopher Long, Patrik Johansson, Michelle Huang, Renato Nevarro, Michael Haney, Christy Munson, Tony Wyss-Coray, Sarah C. Heilshorn and Annika Enejder; Stanford University, United States

Tissue mimicking materials provide a physiologically relevant 3D environment for cell growth and tissue morphogenesis, shaped in a dynamic reciprocal interaction between the cells and host material. Hence, the matrix must be characterized together with the living cellular component as an integrated system. Traditional cell characterization techniques such as immunofluorescence microscopy are insufficient here, as they probe cell responses without correlating them to the characteristics of the matrix environment. Furthermore, the limited penetration depth of the UV/visible light probe beams and artifacts introduced by fluorophores make it to difficult to characterize 3D cell-matrix organizations and interaction mechanisms. Instead, multi-parametric techniques are required, which can characterize the host material simultaneously with the cells in 3D without physical sectioning. For this purpose, we have developed a robust imaging platform that incorporates spectral coherent anti-Stokes Raman scattering (CARS) microscopy on a standard confocal microscope. CARS microscopy is a label-free method that maps lipids and proteins in cells and the surrounding matrix by probing their inherent molecular vibrations. Through analysis of a broad range of vibrational signatures, resulting in spatially resolved spectral images, we simultaneously characterize the matrix meso-structure and the phenotypes of the resident cells. We have used this technique to study a unique class of recombinant biopolymer hydrogels, termed HELP gels, composed of a recombinant polysaccharide (**h**yaluronic acid) and a recombinant **e**lastin-**l**ike **p**rotein (ELP) crosslinked via dynamic covalent chemistry. HELP gels can encapsulate a variety of embedded cells, which alter their morphology and phenotype in response to matrix stiffness. Through CARS analysis of the polymer phase-separation within these hydrogels, we gained a mechanistic understanding of how to alter polymer hydrophilicity to fine-tune hydrogel structure and produce gels with specific mechanical stiffnesses. The mechanical tunability of these hydrogels makes them an attractive platform for developing *in vitro* models of human tissues and their diseased states.

Ongoing work is exploring these tunable HELP gels as brain mimetic matrices, leveraging CARS to simultaneously probe the dynamic meso-structure of the host gel and the phenotypes of the encapsulated cells based on their lipid profiles. HELP gels were formulated to match the stiffness of brain tissue and used to encapsulate human induced pluripotent stem cell-derived microglia-like cells (iMGs). Microglia are the resident immune cells of the brain, the activation of which is associated with a shift in metabolism and the accumulation of lipid stores. Cell genotypes characterized by metabolic dysfunction have been correlated with the progression of Alzheimer's disease (AD). By studying the lipid metabolism in HELP-encapsulated iMGs derived from AD-risk patients, detailed insights into the underlying mechanisms will be gained. We show that iMGs are viable in HELP gels and—in the manner of native brain microglia—accumulate lipid droplets, which are detected *in situ* using CARS microscopy given the unique vibrational signature of lipids. Furthermore, by encapsulating neurons and astrocytes in addition to microglia, we may evaluate lipid transport and metabolism between these cell types. To validate this *in vitro* model, samples of human brain tissue from healthy donors and AD patients were characterized by CARS microscopy and traditional immunofluorescence microscopy. Consistent with reports from others, we quantified a significant increase in lipid accumulation within the microglia of AD patients ($p = 0.05$). Taken together, these data demonstrate the usefulness of CARS microscopy to assist in the design, validation, and experimentation of tissue mimics as models of human disease progression.

Supramolecular Reinforcement of Polymer–Nanoparticle Hydrogels for Modular Materials Design Giovanni Bovone, Elia A. Guzzi, Stéphane Bernhard, Tim Weber, Dalia Dranseikiene and Mark W. Tibbitt; ETH Zürich, Switzerland

Moldable hydrogels can flow under applied stress (shear-thin) and reform a stable network (self-heal) when the stress is removed. An emerging class of moldable biomaterials are polymer–nanoparticle (PNP) hydrogels, which are formed from reversible intermolecular interactions between polymer chains and nanoparticles.[1] PNP hydrogels are used as injectable or extrudable materials in biomedical and industrial applications, however, the mechanical properties of PNP hydrogels are limited and network formation is restricted to interactions between specific combinations of polymer chains and nanoparticles.[2–4]

In this study, we developed a simple strategy to reinforce PNP hydrogels and expand the application spectrum of this class of materials.[5] We included α-cyclodextrin (αCD) in the hydrogel formulation as a supramolecular motif enabling mechanical reinforcement and modular design. Rheological measurements demonstrated that the addition of αCD improved the mechanical stability of PNP (CD–PNP) hydrogels in a concentration-dependent manner, achieving storage moduli up to $G' \approx 10$ kPa ($\omega = 1$ rad s^{-1}). The tested formulations retained the ability to shear-thin and self-heal. Our hypothesis is that mechanical reinforcement was caused by threading of αCD onto PEGylated nanoparticles and polypseudorotoxane formation, which enhanced nanoparticle–nanoparticle interactions.[6,7] We further leveraged these interactions to decouple mechanical properties from material functionality. We exchanged the structural polymers (hydroxypropylmethylcellulose, collagen, alginate, and methacrylated hyaluronic acid), and nanoparticles (block copolymer nanoparticles, gold nanoparticles, and iron nanoparticles), forming stable hydrogel networks ($\tan \delta < 1$, $\omega = 1$ rad s^{-1}) that were not possible to be fabricated without CD-reinforcement. CD–PNP formulations showed improved properties and tunability for 3D bioprinting and drug delivery applications and the application spectrum of this class of materials was broadened to electroconductive and magnetic applications.

Overall, supramolecular reinforcement improved PNP hydrogel mechanical properties and broadened the application spectrum without the need to re-engineer the network interactions. Reinforced CD–PNP hydrogels are a useful platform for applications where moldability, mechanical strength, and functionality are needed.

Hygroscopic Hydrogel Composites with Enhanced Sorption Kinetics Gustav Graeber, Leon C. Gaugler, Carlos D. Diaz, Xinyue Liu, Bachir El Fil, Xiangyu Li and Evelyn N. Wang; MIT, United States

Hydrogels are polymeric networks that can store large quantities of water. Their synthesis is scalable and economical, while their material properties are easily tunable. These qualities make hydrogels attractive materials for numerous applications related to energy and water. Recently, hydrogels that capture water vapor are receiving increased research interest. Such hygroscopic hydrogels can be used in sorption-based thermal energy storage, atmospheric water harvesting, dehumidification and passive cooling. For these applications, the specific water uptake of the material as a function of temperature as well as the sorption kinetics are important, since they translate into e.g., higher energy and power density, or increased water production. Sorption kinetics describe the rate at which the material can adsorb and desorb water vapor. While recent research on sorbents is mostly focused on optimizing the water uptake, sorption kinetics and material integration into devices are considered less. Here, we experimentally study various methods to enhance the sorption kinetics of hygroscopic hydrogels and their integration into practical devices. Combining confocal microscopy of the wet state and scanning electron microscopy of the dry state with dynamic vapor sorption studies, we correlate hydrogel synthesis parameters with material properties and sorption kinetics. Specifically, we investigate the fundamental effects of freeze-drying and molding, as well as the fabrication of hydrogel composite structures with enhanced heat transfer and mechanical stability. To this end, we integrate hydrogels (e.g., polyacrylamide or poly(*N*-isopropylacrylamide)) with hygroscopic salts (e.g., lithium chloride) and fin and foam structures (e.g., aluminum and copper). It is expected that these insights will allow hydrogels to realize their full potential in practical devices that address important challenges related to energy and water.

Tough Ionogels by Tuning Interactions Between Solvent and Polymer Networks Meixiang Wang; North Carolina State University, United States

Ionogels are compelling materials for technological devices due to their excellent ionic conductivity, thermal and electrochemical stability, and non-volatility. However, most existing ionogels suffer from low strength and toughness. Here, we report simple one-step methods to achieve ultra-tough and stretchable ionogels by tuning solvents (*i.e.*, ionic liquids)-polymer chains dipole-dipole interactions. In poor solvents, the polymer chains in the network can form phase separation that act as sacrificial bonds to toughen the ionogel. By contrast, in good solvents, the polymer chains are highly solvated and can form strong interactions (noncovalent crosslinks) with the solvent. These noncovalent interactions can be broken to dissipate energy and thus toughen the ionogels. The ionogels achieved by these strategies showed extremely high fracture strength (10-80 MPa), fracture energy (~24 kJ m^{-2}) and Young's modulus (50-1,000 MPa), while being highly stretchable (400-800% strain) and having self-healing and shape-memory properties. Importantly, these strategies are proved to be generalized, which offer a promising way to tough ionogel and may help to expand their applications.

10:45 AM SB09.13.02
Nonlinear Mechanics of Biopolymer and Tissue-Mimetic Hydrogels Jake Song, Serra Yesilata, Marcelo Garcia and Gareth H. McKinley; Massachusetts Institute of Technology, United States

While biopolymer gels made of rigid polymers such as fibrin and actin filaments have been reported to exhibit softening under compression and stiffening under extension, tissues (commonly consisting of cells embedded in a biopolymer network) have been reported to behave in an opposite manner and exhibit stiffening under compression and softening under extension. These findings naturally raise the question of whether such asymmetric nonlinear elastic properties of biopolymer gels and tissues might result in significant differences in how these materials fail under extensional and compressive loading conditions. We investigate this problem by performing extension-based and compression-based fracture tests on model gel systems that that exhibit different asymmetry in their nonlinear elastic properties. We share early lessons learned from our investigation, which sheds light on the fracture properties in biological materials and engineering principles for designing such properties in synthetic soft materials.

11:00 AM SB09.13.03
Spatially-Targeted Reinforcement of Hydrogel Microstructure by Cross-Linking of Double Network Hydrogels Using Femtosecond Laser Kaneto Tsunemitsu[1], Akira Watanabe[2], Hiroaki Onoe[1] and Mitsuhiro Terakawa[1]; [1]Keio University, Japan; [2]Tohoku University, Japan

Controlling elastic modulus as well as breaking stress is crucial for fabricating soft devices. Double network hydrogels (DN gels) have been reported to show high mechanical strength due to their unique network structure formed by two types of polymer networks. However, in the previously reported fabrication methods, DN gels were fabricated by cross-linking two different hydrogel polymers over the entire hydrogel. To the best of our knowledge, spatially selective formation of DN gel structures inside a hydrogel on a micrometer scale and the associated enhancement of local mechanical strength have yet to be demonstrated. In this study, we applied multi-photon polymerization (MPP) using a femtosecond laser to the cross-linking method of hydrogels and attempted spatially-selective formation of DN gels inside a hydrogel block. Hydrogels were prepared by the following two methods for comparison and evaluation. The first method was cross-linking of the 1st gel by UV irradiation followed by cross-linking of the 2nd gel by MPP using a femtosecond laser. By cross-linking the 2nd gel in a limited zone in the 1st gel, DN gel was formed in a spatially-selective manner. The second method was fabricating DN gels using MPP induced by femtosecond laser pulse irradiation for cross-linking of both the 1st and 2nd gels. This method was used to investigate spatially-selective changes in mechanical properties. As result, the stiffness changed in the DN gel where the 2nd gel was spatially-selectively cross-linked. The elastic modulus of the DN gel was higher than that of the single network gel. These results show that the mechanical properties have changed in the zone where the DN gel was locally formed. To demonstrate the potential of the method for soft robotics, we attempted to impart arbitrary mechanical strength in targeted locations and investigated the grasping property of a micro-object. We fabricated U-shaped gel tweezers and a glass bead with a diameter of 100 μm was grasped with the tweezers. The glass bead was slipped through the gel structure due to the significant deformation of the gel when only the single network gel was used because the structure was too flexible to transmit external force to the contact area with the bead. On the other hand, the glass bead was successfully grasped by the U-shaped structure with DN gel microstructures near the contact area with the glass bead, demonstrating the potential of the method for hydrogel-based soft devices.

Orthogonally Crosslinked Hydrogels to Improve Mechanical Strength and Broaden Applications of Thermo-Responsive Hydrogels Joey H. Wong, Valerie Ow, Jun Jie Chang, Xian Jun Loh and Kun Xue; Institute of Materials Research and Engineering, Singapore

Injectable hydrogels are highly attractive due to their minimally invasive administration to the body. Our group has previously used polyurethane thermogels as well as its component micelles in tissue engineering and drug delivery applications [1-3]. However, conventional injectable hydrogels normally possess poor mechanical properties, and deform and break under repeated loading [4,5]. To improve the mechanical strength and broaden the application of the polyurethane thermogels, we have utilized two different strategies leveraging upon orthogonal crosslinks.
Firstly, we prepared thermogelling polyurethane diacrylate (EPC-DA) hydrogels which are injectable and can be orthogonally photocrosslinked into fatigue-resistant implants. The thermogelation process occurs due to hierarchical physical self-assembly from micelles into hydrogels, and hence thermogels can serve as a dynamic source of polymeric micelles for further photocrosslinking [6].The hybrid-crosslinked poly(PEG/PPG/PCL urethane) diacrylate (EPC-DA) hydrogel has a dissipative micellar network and a secondary covalent network typical to strong hydrogels. The mechanical properties can be tuned by changing photocrosslinking conditions, and the hybrid-crosslinked EPC-DA hydrogels exhibited high stability and sustained release properties. In contrast to common injectable hydrogels, EPC-DA hydrogels exhibited excellent anti-fatigue properties with >90% recovery during cyclic compression tests, and showed shape stability after application of force and immersion in aqueous buffer for 21 days. The EPC-DA hydrogel formed a shape stable hydrogel depot in an ex vivo porcine skin model, with establishment of a temporary soft gel before in situ fixing by UV crosslinking.
Secondly, we covalently conjugated sodium alginate onto thermoresponsive polyurethanes, leveraging upon the ability of alginate to gelate with cations. We prepared hybrid polymers (EPC-Alg) that are responsive to both temperature and Ca^{2+}, and can form orthogonally crosslinked hydrogels which are non-toxic to cells. Higher alginate fractions increased the hydrophilicity and Ca^{2+} response of the EPC-Alg hydrogel, enabling tunable modulation of the gel stiffness and gelation temperature. The hydrogels could also encapsulate cell spheroids with high cell viability, demonstrating its feasibility towards 3D cell encapsulation in cell-based biomedical applications such as cell encapsulation and cell therapy.
In summary, we have demonstrated two differing strategies to strengthen thermo-responsive hydrogels for application as an anti-fatigue implant and for cell encapsulation.

Small Biomolecular Detection Based on Small-Signal Transconductance of Suspended Double-Network Hydrogels as Organic Electrochemical Transistors Alex C. Tseng and Toshiya Sakata; The University of Tokyo, Japan

Semiconducting double-network (DN) hydrogels are a promising materials platform for development of bioelectronics and biosensors, as the composite structure offers means for readily tailoring electrical, electrochemical, and importantly, mechanical properties to design device functions and improve biocompatibility. Previously, we demonstrated that DN hydrogels prepared by radical polymerization of acrylamide monomers in suspension with commercially sourced PEDOT:PSS (poly(3,4-ethylenedioxythiophene) complexed with poly(styrenesulfonate)) solutions are able to maintain the good electrical transport properties of PEDOT despite compositions of ~70% water by volume [1]. By incorporating phenylboronic acid (PBA) moieties in the polyacrylamide network, selective binding sites for biomolecules bearing vicinal diols (e.g., glucose or dopamine) were prepared. To obtain an electrochemical and non-enzymatic response to biomolecule concentration, we couple the PBA binding equilibrium with an electrocatalyzed peroxo pathway for O_2 reduction (ORR) on cathodically polarized PEDOT [2]. As the response signal does not require the target to be consumed, this detection scheme avoids the oxidizing conditions which may give rise to confounding signals from common interferents in biological assays (e.g. antioxidant species).
Simultaneously, increasing channel thickness and reduced volumetric capacitance in composite hydrogels motivates a shift towards application as a transducer with built-in amplification rather than as a typical ionic amplifier of Faradaic currents flowing from a sensitized gate electrode. By leveraging the mechanical strength of hydrogels, we fabricate organic electrochemical transistors (OECTs) with suspended channels on flexible polyimide substrates that enable 3D access for mass transport of analyte biomolecules and ions drifted by applied potentials. Accordingly, this configuration improves the OECT bandwidth by about two-fold thanks to a reduction in effective thickness. In conjunction with the use of a traditional reference/counter electrode pair, this enables the poising of small-signal (AC) transconductance measurements (via DC gate potential, AC amplitude and frequency) to directly probe at the rate of ORR with changes in PBA equilibrium. That is, the current of electrons supplied at the OECT drain for the regeneration of PEDOT catalyst is directly measured at a characteristic frequency for ORR. The resulting signal achieves sub-millimolar sensitivity for glucose in phosphate buffer, which is promising for non-invasive monitoring application.

SESSION SB09.14: Hydrogels in Health and Environment Applications
Session Chairs: Jue Deng and Jingjing Wu
Thursday Afternoon, December 1, 2022
Hynes, Level 3, Room 310

1:30 PM SB09.14.01
Large-Scale Production of Amphiphilic Magnetic Janus Particle with 3D-Printed Parallelized and Multiplexed Microfluidic Device for Oil Remediation Seonghun Shin[1], Seongsu Cho[1], Ryungeun Song[2], Hyejeong Kim[3] and Jinkee Lee[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Princeton University, United States; [3]Korea University, Korea (the Republic of)

Oil pollution in water is fatal to the ecosystem and threatens our health. To reduce the oil pollution, remediation materials have been used. However, the conventional remediation materials, such as chemical dispersants and oil absorbents, have limitations and other disadvantages. For instance, chemical dispersants are known to cause toxicity, and their performance relies on oil conditions, and water environments. Moreover, the use of oil absorbents results in a large amount of waste and secondary contamination. To overcome these problems, safer and more effective solid particle-based remediation materials have been developed to replace conventional remediation materials. However, these materials have not been used for industrial applications due to the problems such as labor-intensive device fabrication, complex processes for particle production and functionalization, and slow production rate.
In this study, we presented Amphiphilic Magnetic Janus Particles (AMJPs) as remediation material to resolve these problems. AMJPs are dumbbell-shaped and consist of bio-inert materials: PEGDA hydrogel part and PPGDA polymer part embedded with oleic acid coated Fe_2O_3 nanoparticles. AMJPs were produced in a single step with a 3D-printed microfluidic device and had amphiphilicity and magnetism without any functionalization step. To increase the production rate of AMJPs, we fabricated a parallelized droplet generator consisting of 10 droplet generation junctions connected via flow distributors. This device could produce particles 10 times faster than a single device while maintaining the same level of particle size dispersity. In addition, the device has modular connectors and can be multiplexed. This allowed us to multiplex 4 parallelized devices and boost the production rate by 40 times when compared with a single device while maintaining the single peak particle size distribution. We experimentally verified that AMJPs adsorbed to the oil-water interface for lowering surface energy and made the oil film into stable Pickering emulsions. We conducted experiments to quantify oil removal performance and confirm the versatility of AMJPs. We found that the volume of the remaining film of kerosene and mineral oil decreased by more than 96% at dosage of 750 mg/ml. Also, AMJPs could form o/w Pickering emulsion regardless of oil type, viscosity, water pH, and ion concentration. Especially for the oil, AMJPs could cover a very wide range of viscosity (1~10^5 cP). Further, we confirmed that AMJPs are recyclable and can capture and separate super heavy non-traditional crude oil in sea water. For industrial and practical applications, large-scale production of AMJPs would be an effective and versatile remediation material for oil adsorption and recovery.

1:45 PM DISCUSSION TIME

2:00 PM SB09.14.03
Hierarchical Composite Self-Sorted Gel Noodles Libby J. Marshall[1], Matthew Wallace[2], Najet Mahmoudi[3], Giuseppe Ciccone[1], Massimo Vassalli[1] and Dave Adams[1]; [1]University of Glasgow, United States; [2]University of East Anglia, United Kingdom; [3]ISIS Pulsed Neutron and Muon Source, United Kingdom

Multicomponent systems provide extra control over supramolecular systems and are an easy method for introducing functionality. For example, bioactive peptides can be incorporated into the gel network to improve cell culture viability. Here we discuss multicomponent systems composed of two structurally similar functionalised dipeptides: 2NapLG and 2NapFF. 2NapFF self-assembles into long 1D structures (worm-like micelles) at high pH (pH 10.5) and forms viscous solutions. The small-angle neutron scattering (SANS) data from 2NapFF is best fit to a hollow cylinder model at concentrations of 5 mg/mL and greater. 2NapLG forms spherical micelles in solution at high pH, giving non-viscous solutions. SANS data from 2NapLG are of low intensity and best fit to a power law only. Mixing these two components results in greatly increased viscosity compared to the individual components alone at the same concentrations. We have used a variety of techniques, including circular dichroism, SANS and NMR spectroscopy to investigate how these two components interact during self-assembly at high pH.

According to SANS data, the multicomponent systems form hollow cylinders with different radii and thickness to those formed by 2NapFF alone. We have used numerous NMR experiments to further investigate the interactions between 2NapLG and 2NapFF in solution at high pH. The integrals corresponding to protons on 2NapFF measured during ^{1}H NMR spectroscopy show decreased intensity in the presence of 2NapLG, suggesting that more 2NapFF molecules are in the assembled state in the multicomponent system. We were able to confirm that 2NapLG forms physical interactions with the structures formed by 2NapFF using nuclear Overhauser effect (NOE) NMR experiments. In samples of 2NapLG alone, we observed a positive NOE difference. This confirms that 2NapLG behaves like a small molecule in solution at high pH, i.e does not form persistent structures. However, in the presence of 2NapFF, a negative NOE difference was observed. This shows that 2NapLG does interact with the large structures formed by 2NapFF. What is perhaps most interesting is that a negative NOE difference was also detected on the aromatic protons. This was completely unexpected as the methyl and aromatic protons are very far apart on the molecule. This implies exchange with the micelles that is not observed in 2NapLG alone and within these structures, the methyl group is close enough in space to interact with the aromatic protons. For 2NapFF, the aromatic signal (most likely from the aromatic rings on the phenylalanine residues was selectively inverted. We observed NOE to other aromatic protons and to the CH_2 groups. The NOE difference is negative, as we would expect from the formation of worm-like micelles. No NOE was observed to protons on 2NapLG. This implies that the assembly between 2NapFF and 2NapLG is orthogonal, i.e. the two molecules are not intimately mixed within the structures.

2NapFF can be used to form supramolecular noodles. We expected that the 2NapFF/2NapLG multicomponent system would form mechanically superior noodles to 2NapFF alone according to data from viscosity and small-angle scattering experiments. This hypothesis was confirmed using nanoindentation. While 2NapFF forms supramolecular hydrogels on a reduction in pH, 2NapLG forms crystals under the same conditions. By exploiting this behaviour, we have formed crystals within supramolecular noodles the first reporting, to our knowledge, of such behaviour.

2:15 PM SB09.14.04
Bridge-Rich and Loop-Less Hydrogel Networks Through Suppressed Micellization of Multiblock Polyelectrolytes Jihoon Han[1], Saeed Najafi[2], Joan-Emma Shea[2] and Younsoo Kim[1]; [1]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [2]University of California at Santa Barbara, United States

Most ABA triblock polyelectrolytes-based physical hydrogels wherein the middle and end blocks are hydrophilic and charged blocks, form three-dimensional networks through micellar packing and generation of non-interlocked loops, resulting in decreased elasticity. This effect can be mitigated by maximizing the fraction of elastically effective bridges in the hydrogel network. Previous observations have shown that the ratio of bridges increases with increasing the relative length of the middle block and the concentration of ABA triblock polyelectrolytes [1]. However, despite the numerous efforts, there was a limit to maximizing the fraction of bridges based on the micelle structure [2]. Therefore, we aim to molecularly design block polyelectrolytes that can hinder the formation of neutral loops that are not involved in hydrogel elasticity and instead promote the formation of the mechanical links during the self-assembly process, which can result in hydrogels with higher elastic modulus. Herein, we report polyelectrolytes complex (PEC) hydrogels with network constructed by designing BABAB pentablock and BABABABAB nonablock polyelectrolytes with a structure that maximizes the entropy penalty of micellization. These polyelectrolytes directly self-assemble into branched and bridge-rich network units (netmers) instead of forming self-entangled independent micelles. As a result, netmers are hierarchically stacked to create a bridge-rich network, increasing hydrogel elasticity. Note that the synthesized BABABABAB nonablock polyelectrolytes had a larger number of blocks present in the BABAB pentablock polyelectrolytes; therefore, the gelation efficiency was maximized due to the larger degree of freedom and higher number of coacervate nodes. The more charge pattern of BABABABAB nonablock polyelectrolytes can promote the formation of crosslinks, and due to the structural advantages of the network, the mechanical properties of the hydrogel networks containing BABABABAB nonablock polyelectrolytes were greater than those of the conventional ABA triblock polyelectrolytes-based hydrogels. Furthermore, the shear modulus of the hydrogel significantly exceeds the theoretical value based on the phantom network theory of rubber elasticity, indicating that the topological constraints of netmer can promote the formation of entangled bridges, which play roles as physical crosslinks.

Energy-Autonomous Seawater Desalination by Thermo-Responsive Hydrogels Sebastian Seiffert; Johannes Gutenberg University Mainz, Germany

Water scarcity is one of the most serious global challenges of our time. One of the main solutions to address this challenge is water desalination. In this respect, forward osmosis (FO) has gained significant attention. For this purpose, thermo-responsive hydrogels containing ionic groups are a class of materials that can be potentially utilized as draw agent. The ionic groups induce the water flow in the process, and they also serve to block and thereby seperate salt. By increase of temperature above the volume phase transition temperature (VPTT) of the hydrogels, the hydrogels shrink, whereby the absorbed, purified water is recovered. Considering this effect, the idea of a membrane-free FO desalination process by ionic hydrogels has been introduced, in which hydrogels serve as both separation and draw agents. However, the use of thermo-responsive hydrogels in that approach is faced with different challenges such as (i) the significant detrimental effect of charged groups on the water recovery efficiency of hydrogels, and (ii) the need for designing FO agents with high salt rejection and water flow performance as well as with low fouling effect. Considering these challenges, we study the influence of the chemical composition, morphology, microstructure, and molecular architecture of charged, thermo-responsive hydrogels based on N-isopropyl acrylamide (NIPAAm) and sodium acrylate (SA) on the efficiency of FO seawater desalination in terms of salt rejection and water recovery. Based on these achievements, we aim to design a simple, efficient, and relatively non-expensive desalination process with a production capacity targeted to serve the demands of small villages via FO process.

PRESENTED ON-DEMAND ONLY: Cooperative Task Achievement by a Swarm of Active Matters Akira Kakugo; Hokkaido University, Japan

Cooperation is a strategy that has been adopted by groups of organisms to execute complex tasks more efficiently than single entities. Cooperation increases the robustness and flexibility of the working groups and permits sharing of the workload among individuals. Here, we demonstrate molecular transportation through the cooperative action of a large number of artificial molecular machines i.e. active matters, photoresponsive DNA-conjugated microtubules driven by kinesin motor proteins. Mechanical communication via conjugated photoresponsive DNA enables these microtubules to organize into groups upon photoirradiation. The groups of transporters load and transport cargo, and cargo unloading is achieved by dissociating the groups into single microtubules. The group formation permits the loading and transport of cargoes with larger sizes and in larger numbers over long distances compared with single transporters. We also demonstrate that cargo can be collected at user-determined locations defined by ultraviolet light exposure.

9:30 AM SB09.15.04
Giant Strain-Induced Crystallization in Ideal-Network Elastomers Chase Hartquist, Shaoting Lin and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Aligned crystalline domains can form in the amorphous network of elastomers when subject to large elongations. The increased crystallinity can effectively pin and blunt cracks, giving enhanced mechanical strength and fracture toughness. Strain-induced crystallization is reversible since ordered chains can disassemble during bulk retraction. However, the effect of strain-induced crystallization is limited in conventional elastomers by polydispersity, random network architecture, and dense chain entanglements. This work demonstrates that strain-induced crystallization in ideal-network elastomers can reach up to 50%, more than twice the effect of strain-induced crystallization reported in existing elastomers (e.g., 20% for natural rubber). Our experiments show that an ideal-network elastomer with a low polydispersity, high degree of homogeneity, and low chain entanglement density attains an amplified extent to which reversible hydrogen bonds form during stretching. This giant strain-induced crystallization simultaneously gives the ideal-network elastomer high fracture toughness and low mechanical hysteresis. We also show that the limiting stretch of ideal-network elastomers follows an abnormal scaling since giant strain-induced crystallization enables the material to stretch near its elastic limit. Polymer chains in the network display shorter initial end-to-end lengths, producing a higher elongation ratio when they straighten and break. We found that the ultimate stretch of an ideal-network elastomer follows the abnormal scaling, exceeding the established theoretical stretch limit, which is the square root of the number of monomers per chain. Ideal-network elastomers provide a foundation for the design of the next frontier of enhanced rubbery materials whose properties approach fundamental mechanical limits.

Finite Element Modeling of Coupled Swelling and Deformation of Biopolymer Thin Film Sanghamitra Debta, Pijush Ghosh and Ratna K. Annabattula; Indian Institute of Technology Madras, India

Polymeric gels are a three-dimensional network of physically or chemically cross-linked polymer networks that can absorb a considerable amount of water (sometimes 600 times their volume) without disintegrating. They are known for their broad applicability in the biomedical field. One of the unique characteristics of these polymeric gels is their responsive behaviour when exposed to external stimuli. The polymer film in this study actuates in the presence of water vapour. When the polymeric gels are made into thin films ranging from 100-200 μm in thickness and exposed to water vapour, they show reversible shape change. The reason for this is the diffusion of water vapour into the polymeric network, which leads to the deformation of the film. This reversible shape change has many potential applications in soft robotics.
In this work, a coupled swelling-induced deformation model is discussed based on the Flory-Huggins theory [1]. It considers the change in free energy due to the mixing of the water molecule with the polymeric network. Here, the change in material properties is incorporated by considering Young's modulus to be dependent on the concentration of the water vapour in the film [2]. Owing to the similarities between the diffusion and heat transfer equations, the inbuilt ABAQUS coupled temperature-displacement elements present in the ABAQUS material library is used to simulate the swelling-induced deformation of polymer thin film [3]. The finite element (FE) model results are corroborated with the experiments obtained for the stimuli-responsive cross-linked chitosan-water vapour system by comparing the folding path and curvature. The developed model can predict the behaviour and shape change of thin films in response to vapour and aid in developing and designing new material models for specific applications.

Stereolithography 3D Printing of Functional Hydrogel Nanocomposites Afra S. Alketbi, Aikifa Raza and TieJun Zhang; Khalifa University, United Arab Emirates

Hydrogels are recognized as one of the most promising functional materials, as they are dynamic, tunable, biocompatible, biodegradable, and capable of encapsulating large water content. On this basis, hydrogels and their composites are gaining tremendous popularity in various fields such as biomedical, food packaging and agriculture, water purification, sensing, and soft robotics, etc. However, hydrogels utilization is limited by the traditional processing methods, mainly molding for 3D geometries, which is a huge drawback for rapid product development. Moreover, molding techniques suffer from materials limitation as it allows only for a single material utilization. The limitation of conventional fabrication can be overcome by the recent advances in additive manufacturing, which enable the fabrication of complex three-dimensional and hybrid structures with enhanced functionality. Herein, we utilize stereolithography 3D printing to fabricate hydrogel nanocomposite through a novel approach. The direct 3D printing of composite inks, particles in ink, show limitations such as inhomogeneous particle distribution, agglomeration, and scattering of curing light, thus compromising the printed object quality and resolution. To avoid this, a new strategy is devised to introduce nanoparticles into the 3D printed hydrogels post the printing process. Metal salts as precursors of nanoparticles are added into the printing ink to develop different types of nanoparticles, including Fe_3O_4, NiO, and CuO, post the printing. The proposed method allows for the development of hybrid 3D structures in one device without compromising the printing resolution. The versatility of the proposed approach to fabricate 3D hydrogel composites using wide range of nanoparticles offers huge potential to practically utilize hydrogels for water, food and energy nexus.

Mechanically Reinforced Conductive Hydrogel Microfibers Prepared by Microfluidic Devices Gea Fitria, Arti Singh and Jinhwan Yoon; Pusan National University, Korea (the Republic of)

Fiber shape soft conducting materials have demonstrated their potential applications to be used in soft electronic systems. In this work, long hydrogel microfiber is prepared based on the coagulation of chitosan in cold water and simultaneous photopolymerization and photocrosslinking of acrylate. After further reinforcement of the chitosan chain in crosslinking agents, medium of the hydrogel microfiber was exchanged with the aqueous electrolyte solution. The resulting ionic hydrogel exhibits high stretchability and conductivity as well as dry-free properties. Owing to its mechanical robustness and ionic conductivity, we envision a highly stretchable soft electrode with the prepared ionic hydrogel microfiber, showing its potential for applications in soft electronics and wearable devices.

11:15 AM SB09.16.04
Wirelessly Operated Flexible Wound Infection Sensing Tag Based on Bioresponsive Hydrogel Ze Xiong and John S. Ho; National University of Singapore, Singapore

Wearable biosensors linked with smartphones provide an opportunity to detect pathophysiological events in real-time to notify patients and their caregivers. Such technology has the potential to transform the diagnosis, prevention, and management of chronic medical conditions by enabling continuous monitoring outside of traditional clinical settings. Chronic wounds represent one such condition where management is a major healthcare challenge, consuming over 5% of the healthcare budget. A key factor contributing to the inability of chronic wounds to heal is the presence of pathogenic bacteria, which secrete virulent enzymes that destroy host tissues and disrupt wound recovery. Prompt detection of wound infection is thus critical for clinical intervention to improve patient outcomes. However, current methods for detection either rely on subjective clinical assessments or time-consuming culture-based laboratory tests, leading to delays in the timely administration of proper treatment. Here, we propose and demonstrate a sensing technology, termed Wireless INfection Detection On Wounds (WINDOW), that detects bacteria virulence using a flexible, wireless, and battery-free sensing tag. This sensing tag is based on a custom DNA hydrogel (DNAgel) that provides a radio-frequency detectable response to deoxyribonuclease (DNase), an enzyme secreted by opportunistic pathogens. When exposed to extracellular DNase, the DNAgel is degraded via non-specific cleavage of DNA strands, resulting in the dissolution of the hydrogel. This changes the dielectric permittivity of the region above an interdigitated electrode and therefore modulates its capacitance. By connecting the electrode to an embedded system, this electronic signal can be read out in a wireless and battery-free manner at 13.56 MHz using near-field communication (NFC), a connectivity technology found on most modern smartphones for short-range communication and wireless power transfer. WINDOW has a thin and flexible form factor that enables it to be conformally embedded into wound dressings to wirelessly track virulence factor activity on demand. We demonstrate the potential of WINDOW for real-time detection of clinically-relevant amounts of *S. aureus* both *in vitro* and in a mouse wound model before the visible manifestation of infection. This technology may facilitate timely detection of wound infections for improved management of surgical or chronic wounds.

11:30 AM SB09.16.05
Developed Multi-Functional Hydrogel for Metal Ion Removal Pansilu E. Alwis and Thilini Gunasekara; University Of Sri Jayewardenepura, Sri Lanka

`High rates of metal and chemical consumption in industrial processes have resulted in a significant amount of waste, containing high levels of hazardous heavy metals in water resources. Because of their bio-accumulative, and toxicity, heavy metals cause massive environmental pollution. Heavy metals are toxic to almost all living species and are able to accumulate in the food chain, whereas excessive concentrations of other metals, such as magnesium and calcium, also have an influence on toxicity in humans and other animals. Therefore, such toxic metals must be removed by water purification. On that note, adsorption is an excellent approach to get rid of metals and metal ions. Hydrogel is an attractive adsorbent that can be used to eliminate contaminants from water bodies.
Water purification multi-functional hydrogel was synthesized from poly(acrylic acid) polyacrylamide copolymer and modified with urea to improve the adsorption efficiency of the hydrogel by increasing the active metal ion binding sites. Synthesized hydrogel (PAA-co-PAAm-modified with Urea) was characterized using FTIR, XRD, and TGA.
FTIR study confirmed polymerization, and urea modification in the hydrogel. The peak acquired due to the stretching vibration of the N—C—N bond was verified by the modification of the hydrogel with urea. The hydrogel's amorphous nature was confirmed by XRD analysis, which was revealed by broad peaks. On the TGA thermogram, there were five distinct stages of thermal decompositions related to weight losses of physically bound water, chemically bonded water, or lattice water, loss of $–NH_2$ as ammonia, release of H_2O, CO_2, and acrylic acid due to the breakdown of the C-C backbone and subsequent degradation of organic groups,
The developed hydrogel had the absorption capacities for the metal ions Cd(II), Co(II), Cu(II), Fe(III), Mn(II), Zn(II), and Mg(II) ions of 67.54 mg/g, 69.81

mg/g, 50.98 mg/g, 97.28 mg/g, 45.37 mg/g, 60.74 mg/g, 25.41 mg/g, and 67.09 mg/g respectively. Adsorption isotherm models and kinetic models of adsorption were also explored in the synthesized hydrogel. In kinetic determination, pseudo-first order, pseudo-second order, and particle diffusion kinetics models were investigated. In the pseudo-second-order kinetic model, adsorption of Cd(II), Co(II), Cu(II), Fe(III), Mn(II), and Mg(II) ions were well behaved. This suggests the adsorption was chemisorption, but the adsorption of Zn(II) ion was fitted to pseudo-first-order kinetics, indicating physisorption.
Freundlich and Langmuir isotherm models were investigated in the isotherm inquiry. The Freundlich isotherm model was used to fit the adsorption of Cd(II), Co(II), Cu(II), Fe(III), Mn(II), and Mg(II) ions, confirming that multilayer adsorption occurred. Nevertheless, the adsorption of Zn(II) ion followed monolayer adsorption and was fitted to the Langmuir isotherm model.
High amount of N functional groups of the hydrogel has increased the metal ion binding capacity and thus has yielded an excellent hydrogel for metal ion removal endeavors.

11:45 AM SB09.16.06
A Biomimetic Joint Model with Heterogenous Oxygen Environments Louis Ong, Indira Prasadam and Yi-Chin Toh; Queensland University of Technology, Australia

Crosstalk between subchondral osteoblasts and chondrocytes played significant role in OA pathogenesis. However, physiological coculture of osteoblasts and chondrocytes is limited by *in vitro* generation of differential oxygen concentrations across the cartilage-bone tissue interface. Chondrocytes in the cartilage require a low (1 %) oxygen environment while osteoblasts in bone tissues require normoxic (>9%) oxygen environment to maintain their tissue-specific functions. Current approaches to control oxygen gradients in microfluidic devices rely on diffusion gradients generated across a porous matrix using active gas networks, which is limited to monocultures and cannot mimic tissue interfaces with distinct oxygen tensions. Jammed packed microgels (JPMs) are a novel class of hydrogels that are formed by swelling aqueous solution in microgels which interact with each other via weak physical forces, resulting in their shear-yielding properties. However, the use of this class of hydrogels in tissue culture remains limited.
In this work, we demonstrated the use of polyacrylate JPMs to tune and mimic a heterogenous oxygen environment that mimics the tissue interface of the articular joint. We demonstrated the oxygen content tunability of the JPMs by functionalising the JPMs with two reducing agents: Oxyrase (oxygen reducing enzyme) and sodium sulphite, two common reducing agents used in anaerobic cultures. By optimizing the concentrations of reducing agents, we found that 0.1U Oxyrase (commonly used in anaerobic microbial cultures) could maintain a low oxygen level of 1.35 % for up to 48 hrs. The biocompatibilities of the JPMs for primary chondrocytes cultured in both normoxic and hypoxic JPMs demonstrated the JPMs, along with their functionalised reducing agents can support the viabilities of cell cultures. By controlling the type and concentration of the reducing agents, we demonstrated a host of JPMs with different oxygen contents, suitable for mimicking different physiological oxygen tensions. We further established patterning of JPMs with different oxygen content in a microfluidic device, mimicking a bone-cartilage oxygen tension. In situ oxygen sensing within the microfluidic device showed that we can establish and maintain physiological heterogenous oxygen level of cartilage (2% oxygen) and bone (10% oxygen) for 2 days within a cell incubator. On-chip hypoxic culture of primary human chondrocytes exhibited hypoxic response by upregulating hypoxic inducing factor alpha (HIFa), indicative of the hypoxic environment on-chip. Finally, we established co-cultures of allogenic pairs of patient-derived chondrocytes with osteoblasts under the heterogeneous oxygen environments. We showed that co-cultures under heterogenous oxygen physicochemical environment significantly enhanced chondrogenic phenotypes (i.e. increased aggrecan and decreased type I collagen expressions) as compared to coculture maintained under homogeneous oxygen levels without affecting the phenotypes of the osteoblasts within the co-cultures.
This work demonstrated the first instance of osteoblast-chondrocyte microfluidic co-cultures with patterned oxygen levels for up to 4 days. Chondrocytes cocultured under low oxygen environment with osteoblast exhibited enhanced chondrogenic expression compared to monocultures and co-cultures without oxygen control. This platform can potentially be utilized for further osteoarthritis (OA) drug screening applications.

12:00 PM SB09.16.07
Shape-Memory Ideal Polymer Networks with Giant Tunable Thermal Conductivity Chase Hartquist, Shaoting Lin, Buxuan Li, James Zhang, Gang Chen and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Since polymer networks are conventionally known as thermal insulators, strategies to enhance their thermal conductivity offer promising solutions to complicated thermal management problems. Thermally conductive polymer fibers and films have been processed by thermal drawing to achieve heightened measured thermal conductivities that match those of metals. However, dramatic thermal transport enhancement has only been shown using irreversible processing. Here we report ideal polymer networks that achieve giant tunable thermal conductivity. The thermal conductivity enhances by over four times its initial value in the stretched direction, from 0.3 $Wm^{-1}K^{-1}$ to 1.5 $Wm^{-1}K^{-1}$. This thermal conductivity change is reversible and can be tuned over many cycles. Crosslinks enable the material to quickly stretch and retract above the glass transition temperature, and the ideal-network architecture promotes chain alignment and stretchability. This shape-memory material retains the structure of the deformed configuration and becomes semicrystalline when cooled to room temperature. Structural characterization and molecular simulation indicate that stretching facilitates alignment of crystalline domains that contributes to bulk heat transport. These findings provide important steps towards realizing tunable, polymeric thermal switches for advanced applications of building materials, electronics, flexible devices, and heat exchangers.

10:30 AM SB10.01.01
America's Evolving Strategy in Advanced Functional Fabrics Michelle G. Farrington; AFFOA, United States

For E-textiles to truly make the shift from generating small volume products for highly specialized markets to a widely adopted toolkit of technologies used to enable products across a diverse set of applications, the industry must mature in a number of ways that go beyond the demonstration of new capabilities. Industry infrastructure development must be undertaken in order to support lower product development costs and faster time to market for e-textile products. These infrastructure elements include simulation environments, digital threads, and addressing standards gaps to name a few. Through collaborative R&D work enabled by a public-private partnership, AFFOA is resolving manufacturing technology gaps through investment in broad industry infrastructure development. Example projects combining government needs with industry driven technology roadmaps will illustrate the current methods our Institute uses to address technology and infrastructure gaps.

10:45 AM *SB10.01.02
Phase Segregated and Highly Conductive PEDOT-PSS for Textile Electronics—Wiring, WiFi, Radar, Electrochromic Color Change, Power Generation, Resistive Heating, ECG, EMG, EDA and Loudspeakers/Microphones Gregory A. Sotzing; University of Connecticut, United States

Polyethylenedioxythiophene-polystyrene sulfonate (PEDOT-PSS) has been shown to phase segregate at polyethylene terephthalate and nylon fabric surfaces in the presence of delustering agenst such as silica, titania, and alumina. This chemistry involves the formation of silicate, titanate and aluminate sulfonate esters with the polystyrene sulfonic acid to instil phase segregation leading to an enrichment of PEDOT sulfur at the air interface as observed by looking at the PEDOT (Sulfur):PSS (Sulfur) ratio using X-ray Photoelectron Spectroscopy (XPS). PEDOT-PSS sheet resistances were measured both in the DC, and even better in the AC. Electron microscopy of the fabrics show a continuous coating of PEDOT-PSS on each individual fiber of the textile, and current carrying aspects of the material could be analogized to Litz wire. Indeed, less PEDOT-PSS screen printed onto the fabric resulted in higher impedance at low frequencies while maintaining the impedance at higher frequencies. For DC application, we have explored the use of PEDOT-PSS fabrics for resistive heating, copper replacement in circuit to light a 60W incadescent bulb, circuit wires and resistors, and electrochromic (electronic color change) fabric prepared by an open-air method. For AC applications, work will be presented on wearable fabric WiFi, radar, power generation, electrocardiography (ECG), electromyography (EMG), electrodermal activity (EDA), and loudspeakers. As to fabric choice, these applications have been demonstrated on nonwovens such as polyester and nylon synthetic leathers as well as spandex (4-way and 2-way). With the many applications that PEDOT-PSS can provide, one can envision integrated fabric electronics where power can be generated, stored and then utilized by the fabric wearable sensory system and information transmitted via WiFi.

11:15 AM *SB10.01.03
PEDOT:PSS Fibers—Fabrication, Properties, Applications and Challenges Ruben Sarabia, Paula Alarcon Espejo and Matthew Weisenberger; University of Kentucky, United States

PEDOT:PSS is one of the most used conductive polymers in the field of electronic textiles due to its commercial availability, water-based formulation, high electrical conductivity, between others. Different fabrication techniques have been used to process PEDOT:PSS into fibers. The resultant fibers' properties are highly dependent on the process parameters. For example, the conductivity can vary from 0.1 S/cm to more than 4000 S/cm.
In this talk, we will discuss the current state of the art of electrically conductive PEDOT:PSS fibers and our work in this field. We will also talk about some of the potential applications of the fibers. Finally, current challenges such as scalability, stability or electrical contacts will be discussed.

11:45 AM SB10.01.04
Reel-to-Reel Fabrication of Smart Sensing Threads Ege Ozgul, Wenxin Zeng and Sameer R. Sonkusale; Tufts University, United States

There has been an emergence of thread based wearable and implantable devices due to their superior flexibility and ability to provide intimate tissue/organ interfaces [1][2]. In prior works, smart threads have been realized for sensing biomarkers of wound healing [1], sensing electrolyte levels in sweat[2][3], monitoring physical activity, and for sensing volatile gasses[2]. Even transistors have been realized on threads[2]. Sensing threads are realized through coating of functional inks using a manual dip-and-dry approach. However this results in non-uniform threads and uneven responses. This abstract addresses a key technological need to enable precise controlled coating of threads for any ink types. This is achieved using a custom built reel-to-reel dip-coating and drying apparatus, which is the focus of this presentation. For a specific case study, we propose the realization of stretchable strain sensing thread with remarkable uniformity (<4% error) over a meter long reel. Strain sensing threads are promising sensors for a wide range of wearable electronics applications. As their resistance depends on the tension, these threads can be used for measuring tension, pressure, and vibrations.
A benchtop reel-to-reel coating system has been designed for uniform coating of any functional inks on any thread type. The platform transfers the thread from one spool to another using two stepper motors driven by microcontroller at user-defined rate. During the transfer, ink is applied using a custom-built 3D printed cartridge. Ink formulation eventually dictates the functionality of smart thread. For proof of principle, we use a carbon ink to realize strain sensing threads The ink-coated thread is then heated and dried in a temperature-controlled heating chamber. During the fabrication process, the tension of

the thread is measured simultaneously, and a feedback loop is used to adjust the speed of the motor, so that the tension of the thread remains constant. This way, the thread is coated with consistent electrical properties along its length. Once the carbon layer dries, the carbon particles allow electrons to pass through and make the thread conductive.
To analyze the threads, multiple threads were coated with carbon ink under different tensions. Baseline resistance variation is less than 4% over meter long length. Then the electrical conductivity and strain sensitivity of each thread is measured, which ranges from 0.62 to 2.53 MΩ, a 277% resistance change when stretched and unstretched from 4 to 6 cm. We report multiple utilities for strain sensing threads thus realized, such as monitoring of physical activity, posture, arm/leg/finger movements and pressure. By changing the ink and the cartridge, one can coat other functional inks on threads such as chemoresponsive dyes to realize gas sensors, or semiconducting inks to realize transistors.

SESSION SB10.02: Health Monitoring
Session Chairs: Jesse Jur, Ruben Sarabia and Gregory Sotzing
Monday Afternoon, November 28, 2022
Hynes, Level 3, Room 311

1:30 PM *SB10.02.01
Health Monitoring with Electronic Textiles from Solution Processable Conducting Polymers Esma Ismailova; Mines St Etienne /BEL, France

In the last decade, there has been an increased use of organic electronics for biomedical applications. Bioelectronic devices made of conducting polymers show unique properties to interface with the human body and provide an efficient physiological monitoring. The development of state-of-the art organic electronic devices on textiles to promote their wearability and allow the democratization of health monitoring systems is rapidly becoming possible. Novel approaches are needed to evolve traditional microfabrication techniques to produce organic electronic textiles. The solution processability of conducting polymers offers excellent performances in devices fabrication on textiles preserving their stretchability, breathability and yielding ubiquitous systems. Examples of a “non-traditional“ micropatterning technique for cutaneous electrodes development on knitted textiles and traditional inkjet printing to directly design functional sensors on woven and non-woven fabrics will be showcased. These devices are designed to allow multimodal health data collection, which is essential in advancing technologies towards next generation of personalized diagnostics and therapies.

2:00 PM SB10.02.02
Sensing Floss—Saliva Diagnostics on a Thread Atul Sharma and Sameer R. Sonkusale; Tufts University, United States

Stress significantly impacts a patient's overall health; when stressed, the adrenal gland produces corticosteroids (such as cortisol) and adrenaline into the bloodstream. Cortisol negatively affects the regulation of various physiological processes such as carbohydrate metabolism and blood glucose levels. Long-term stress can disrupt homeostasis in the cardiovascular, renal, skeletal, and endocrine systems, leading to the development of chronic diseases. Moreover cortisol levels vary throughout the day. Because of its central role, continuous monitoring of cortisol levels in the human body is critical for health and wellness. Cortisol levels are often measured using immunochemical and analytical methods in blood, plasma, serum, oral fluid, sweat, and hair samples. Of these methods, saliva provides the most abundant, non-invasive source of cortisol biomarker. Towards the goal of routine stress-level examination, we engineer a thread-based electrochemical sensor for quantifying cortisol directly in saliva. The thread platform resembles a floss, which we define here as “sensing floss”. Threads offer the most flexible option for tissue-embedded sensing, microfluidics, and bioelectronics compared to other flexible platforms. This work demostartes the design of thread-based sensing floss both as a saliva sampler and for the realization of ultrasensitive and label-free electrochemical detection of cortisol in saliva using differential pulse voltammetry (DPV). To fabricate the cortisol sensing floss, a commercial gold-coated thread was used as a conductive base electrode surface to capture and strengthen the signal. The gold-coated thread was initially cleaned with isopropyl alcohol (sonication, 15 minutes) and plasma treatment (5 minutes), resulting in a smoother and cleaner surface for immobilization of the recognition element. The gold thread surface was then treated with dithiobis(succinimidyl propionate) (DSP, 4 mM in DMSO), formed a self-assembled monolayer, and rinsed with DMSO and phosphate buffer. Later, it was incubated with a designated concentration of cortisol-specific monoclonal antibody, mAb-cortisol (10 ngmL^{-1}) at 4°C for 4 hrs under a humid environment, and further incubated with bovine serum albumin (BSA) to incorporate an antifouling layer, and finally washed with buffer. The detection of the target analyte (cortisol) is based on the binding event between the cortisol molecule and the covalently immobilized mAb-Cortisol on the gold electrode surface, where an adopted conformation of the antigen-antibody complex alters the electron transfer rate at the electrode, resulting in a drop in measured current level. The surface topology and electrochemical properties of a cortisol-biosensor were studied using Fourier transform infrared spectroscopy, scanning electron microscopy, cyclic voltammetry, and electrochemical impedance spectroscopy. Under optimum experimental circumstances, the devised cortisol-biosensor demonstrated a dynamic range from 1.0 pg mL^{-1} to 1.03 ng mL^{-1} with a linear range of 1.0 pg mL^{-1} to 0.52 ng mL^{-1} and a limit of detection (LOD) of 1.0 pg mL^{-1} (S/N = 3) in cortisol spiked saliva samples. DPV measurements are carried out in the presence of a redox probe containing 1.0 mM Ferri/Ferro cyanide in PBS (0.10 M, pH 7.2, 0.10M KCl). Our results show that the sensing floss is capable of detecting cortisol in both spiked buffer media and saliva samples. The analytical figures of merit of the cortisol-sensing platform confirm that the designed sensing floss could be particularly successful for low-level detection and continuous monitoring of salivary cortisol. The sensing floss can be extended to detection of other biomarkers in saliva for variety of health indicators and disease conditions.

All PEDOT:PSS Fully-Textile Wearable Chemical Sensors Erika Scavetta, Beatrice Fraboni, Isacco Gualandi, Francesco Decataldo, Federica Mariani, Domenica Tonelli, Danilo Arcangeli and Marta Tessarolo; University of Bologna, Italy

Organic ElectroChemical Transistors (OECTs) are promising electronic platforms to realize chemical sensors since they can provide intrinsic signal amplification without the need of a freestanding reference electrode, they can operate at low power (< 100 µW) and can be easily miniaturized and adapted to non-flat, flexible and textile substrates. In addition, providing high sensitivity together with biocompatibility and low-cost, they could be proposed as analytical tools for the reliable detection of a wide range of low concentration analytes even in biological fluids such as sweat and wound exudate.
All poly(3,4-ethylenedioxythiophene):poly(styrene-sulfonate) (PEDOT:PSS) OECTs can be used as chemical sensors for the detection of redox analytes that are oxidized at PEDOT:PSS, such as ascorbic acid, dopamine, adrenaline or uric acid [1].
On the other hand, the selectivity issue must be addressed to allow the widespread use in real-life applications, through a proper functionalization of the gate electrode with molecules able to selectively interact with the target analyte [2, 3]. In this regard, pH or chloride sensors have been described by our

research group, entrapping iridium oxide or silver/silver chloride nanoparticles on the PEDOT polymer, thus developing two terminal sensors able to work without an external gate electrode.
One of the most appealing features of OECT chemical sensors is the possibility of realizing the whole device in a fully-textile form using easy scalable procedures thus allowing the development of a compact, lightweight, cost-effective, and easy to wear platform for monitoring healthcare and sport activities in real-time.
This contribution describes two examples of fully-textile wearable chemical sensors based on PEDOT:PSS OECTs. The first one is a multi-thread biosensing platform that can detect chloride ions (Cl^-) concentration and pH level simultaneously without interference. The textile sensors are simple threads, based on natural and synthetic fibers that show excellent sensitivity, reproducibility, selectivity, long term stability and the ability to work with small volumes of solution. The performance of the developed textile devices is demonstrated in artificial human perspiration to perform on-demand and point-of-care epidermal fluids analysis.
The second example of application is a fully-textile smart bandage for pH [4] and uric acid detection, to be applied for hard-to-heal wounds (i.e. severe and/or chronic) monitoring, where it is critical to constantly evaluate the healing stages and the overall wound condition.
The use of special medical-grade textile materials provides a passive sampling system, which enables the continuous, real-time and non-invasive analysis of wound fluid.

Garment Integrated Sensor Systems for Longitudinal Sleep Tracking Trisha L. Andrew; University of Massachusetts Amherst, United States

Chemical vapor deposition is a single-step processing method for forming functional polymer films on unconventional substrates, such as commodity textiles, and allows fabrication of rugged and sensitive fabric-based sensors for wearable electronics and smart farms. I will the detail the materials science and engineering advances made by my team during the process of assembling various garment-integrated sensor systems and plant-based sensors for longitudinal health monitoring in native environments. In particular, I will highlight our recent work in developing garments for portable brain activity monitoring and activity tracking, and systems for in-home sleep monitoring.

3:30 PM SB10.02.05
Stretchable, Breathable and Washable Textile Sensor for Human Motion Monitoring Lina Sanchez Botero, Anjali Agrawala and Rebecca Kramer-Bottiglio; Yale University, United States

Advancing the accuracy and ubiquity of in-situ human motion monitoring requires the development of soft wearable sensors that maximize wearer's comfort. To translate wearable sensing technologies beyond laboratory settings and into
real-world applications, it is important to develop light-weight, breathable sensors that can be seamlessly integrated into commercial clothing and interface directly with human skin without losing signal fidelity. Here, we report the fabrication of
a soft textile capacitive sensor capable of describing everyday human motions due to its high conformability and mechanical flexibility. Unlike established capacitive strain sensors, which usually rely on stretchable elastomers, our sensor is constructed out of thin films of breathable adhesive and fabrics. Our soft sensor exhibits good stretchability (>90%), excellent durability (repeating cyclic deformation > 5000 cycles), and high water-vapor transmission rate (~ 50g/h.m2) which allows sweat evaporation, an important parameter of comfort. Additionally, we verified that our sensor can function under analogous conditions to human body temperature and sweat (89% relative humidity and 35 °C) and function after washing. The sensor also shows highly stable capacitance over a high range of excitation frequencies (up to 1 MHz), facilitating its implementation with commercial circuitry. Furthermore, the manufacturing process of these sensors can be scalable and customizable at low cost, paving the way for the next generation of flexible and comfortable wearable sensors.

On Textiles Microfluidic Organic Biosensing via Additive Manufacturing Marina Galliani[1], Pooya Azizian[2] and Esma Ismailova[1]; [1]EMSE, France; [2]Leitat technological Center, Spain

Recent advances in personalized healthcare show a tendency to use biochemical sensing platforms built on wearable substrates to continuously monitor the presence and concentration of key metabolites in sweat. The seamless integration of sensors with microfluidic components defines the scope for the manufacture of future wearable point-of-care devices. The adjustable wicking properties of textiles and their fibril structure naturally allow for the absorption, diffusion, and storage of sweat. We present a scalable additive technique for a textile-based skin-mounted microfluidics development on clothes. Our new method allows the patterning of hydrophobic regions in non-woven fabrics, creating boundaries of hydrophilic micro-channels. Along these channels, a capillary flow allows a directed collection of sweat from the skin to the sensing receptor using only the wicking properties of the fabric. Digital printing techniques provide a direct method for high resolution and reproducible deposition of flexible materials. On this basis, we have fabricated microfluidic modules with different architectures for the collection, storage, and analysis of sweat. Directly printing an organic bioelectronic sensor onto microfluidics allows a unique integration strategy for a low-cost fabric-based sweat detection platform. The method presented here demonstrates a new approach for the monolithic integration of bioelectronic devices with sweat collection and analysis capability in textile garments.

4:00 PM SB10.02.07
Novel 3D Electrodes Embedded In Smart Garments for ECG Sensing Applications Vimanyu Beedasy[1,2], Patrick Smith[1] and Mark Catchpole[2]; [1]The University of Sheffield, United Kingdom; [2]Conductive Transfers Ltd., United Kingdom

Smart garments are becoming increasingly popular due to a rising demand for a wider range of functionality promised by the Internet of Things (IoT). Smart garments consist of embedded electronic components such as sensors that can be used for sensing applications to enable healthcare benefits where information such as heart rate, body temperature, levels of sweat, and even body pressure exerted over a particular area can be monitored. However, the integration of the sensor within the garment remains a key challenge to date, particularly for electrocardiogram (ECG) sensing applications as traditional electrodes must be fitted by a clinician in order to obtain an accurate ECG signal. These particular electrodes are often used in combination with a hydrogel to ensure contact with the skin, especially in regions of the body that are more susceptible to body hair, which can cause skin irritation and discomfort in the long term. In terms of functionality, the electrodes must maintain contact with the skin (even through hair follicles and around various body

morphologies) in order to ensure ECG signal fidelity. Additionally, the use of multiple disposable electrodes per patient raises the issue of sustainability in the long-term.

In this paper, we discuss a patent pending design of a smart garment consisting of 3D dry electrodes that are embedded for healthcare monitoring applications, bringing the advantage of reduced skin irritation. This garment was successfully prototyped using a combination of techniques, based on the screen printing process. Multiple layers of various functional materials were sequentially added to form a thin film circuit, about 100 µm thick, consisting of a stretchable conductive silver flake-based electrode surrounded by an equally stretchable ink encapsulant, and an adhesive layer which was used to embed the circuit into the garment under heat and pressure. During the heat transfer process, the encapsulation layer prevented ink dissipation into the synthetic fibres of the garment which could degrade the electrical performance of the electrodes.

The next process employed embossing to produce 3D electrodes consisting of “macropillars”. First, an iterative computational finite element analysis of the embossing process was done to identify high stress concentrations around the macropillars. The 3D features of the electrodes can be up to 4 mm in height; the use of stretchable inks and a stretchable fabric prevents failure due to stress and shear concentrations, and also due to inter-layer delamination. The embossing process was then performed under heat and pressure to permanently form the macropillars, resulting in the formation of 3D conductive electrodes.

The skin contact to the patient is also facilitated by using a compression garment combined with the 3D electrodes. Moreover, the placement of the 3D electrodes within the compression garment can be done according to the requirements of the patient given the bespoke nature of the 3D electrodes. For example, different electrode configurations such as EASI formation (5 leads), Fontaine formation (5 leads) or Lewis formation (5 leads) can be employed without being influenced by the natural body indentations and hair follicles as the combined usage of 3D electrodes and compression ensures contact with the skin. Further tests were performed according to ASTM standards to evaluate the influence of stretch on the electrical performance of the electrodes, and it was found that electrical resistance was stable up to 20 % strain, thereby ensuring a reliable signal and high signal-to-noise ratio.

One key application of this smart garment with 3D electrodes is for healthcare at home using IoT, especially since hospital at home offers significant cost savings over treatment in hospitals, particularly during post-operation recovery.

Wearable MXene-Bioelectronics for Diagnostics and Personalized Rehabilitation Raghav Garg[1,1,2], Nicolette Driscoll[1,1,2], Sneha Shankar[1,1,2], Todd Hullfish[1], Josh Baxter[1] and Flavia Vitale[1,1,2]; [1]University of Pennsylvania, United States; [2]Corporal Michael J. Crescenz Veterans Affairs Medical Center, United States

Real-time diagnosis of neural and neuromuscular diseases requires reliable and continuous monitoring. Wearable bioelectronics enable the necessary non-invasive electrophysiology sensing to study, diagnose, and treat neural and neuromuscular disorders. Multi-disciplinary advancements in materials, electronics, and biomedical engineering are enabling newer soft and flexible technologies for wearable electrophysiology sensing. However, current devices are limited by fabrication approaches that are expensive and do not scale, hindering immediate clinical translation.
Here we leverage safe and scalable liquid-phase processing of two-dimensional (2D) $Ti_3C_2T_x$ MXenes and infuse the nanomaterial into laser-patterned cellulose-polyester fabrics, to fabricate high-resolution bioelectronic interfaces (MXtrodes) for wearable electrophysiology sensing. Our fabrication paradigm allows the MXtrodes arrays to be highly versatile since their morphology, scale, and spatial distribution can be easy customized to be subject and application specific, giving them a major advantage over commercially available systems. Furthermore, MXtrodes exhibit low skin impedances without the need for any conductive gels, thereby increasing user compatibility and electrode stability. We demonstrate the clinical applicability of the MXtrode arrays by recording high-density surface electromyography (HDsEMG) patterns in the calf muscles during different tasks, from walking to controlled contractions. The high-density, high-sensitivity, and low-noise of the MXtrodes even during dynamic motions results in electrophysiology recordings with signal quality comparable with state-of-the-art commercial sensors, but with much higher accuracy and resolution. Our results underscore the application of MXene-based wearable bioelectronics in studying neuromuscular function and disease pathologies, as well as clinical rehabilitation paradigms.

4:30 PM SB10.02.09
Reusable Surface-Enhanced Raman Spectroscopy Membranes and Textiles via Template-Assisted Self-Assembly and Micro-/Nano-Imprinting Aditya Garg, Wonil Nam and Wei Zhou; Virginia Tech, United States

The development of wearable sensors for continuous real-time monitoring of human physiological status has attracted extensive research efforts. While significant commercial success has been made in wearable physical sensors for monitoring physiological parameters like heart rate and body temperature, wearable chemical sensors are still under intense research and development for applications in personal health management, including body biofluids analysis, wound monitoring, and human-centered environmental sensing of hazardous chemicals. Surface-enhanced Raman spectroscopy (SERS) has emerged as a powerful tool for ultrasensitive fingerprint recognition of molecules with considerable potential in wearable biochemical sensing. However, previous efforts to fabricate wearable SERS devices by directly treating fabrics with plasmonic nanoparticles have generated a nonuniform assembly of nanoparticles, weakly adsorbed on fabrics via van der Waals forces. Here, we report the creation of washing reusable SERS membranes and textiles via template-assisted self-assembly and micro-/nano-imprinting approaches. Uniquely, we employ a capillary force-driven self-assembly process to generate micropatch arrays of Au nanoparticle (NP) aggregates within hydrophobic microstructured templates, which are then robustly bonded onto semipermeable transparent membranes and stretchable textiles using a UV-resist based micro/nanoimprinting technique. Compared to previously developed wearable SERS devices, our fabrication technique offers several advantages: (1) good uniformity control of the spatial distribution and intensity of SERS hotspots, (2) good manufacturing compatibility with many types of delicate membrane/fabric materials due to the mild UV micro/nanoimprinting process at room temperature, and (3) strong mechanical bonding between Au NPs and the wearable substrates via a UV-cured resist. Due to the good mechanical robustness of the UV-resist immobilized Au NP aggregates, we could regenerate contaminated SERS hotspots using user-friendly detergent-water washing processes over multiple cleaning cycles without degrading the sensing performance. Moreover, we demonstrate that substituting conventional UV-resists with carbon nanotube-polymer composite resists can generate conductive wearable SERS devices, enabling electrochemical SERS for improved sensitivity and selectivity of detection in multi-analyte systems. Therefore, we envision that the template-assisted self-assembly and micro-/nano-imprinting approaches can help create wearable washing reusable SERS fabrics/membranes with advanced materials properties via polymer nanocomposites for specific needs in different biochemical sensing applications.

SESSION SB10.03: Energy Harvesting and Storage
Session Chairs: Hyun-Joong Chung, Patricia Dolez, Tushar Ghosh and Myung-Han Yoon

8:30 AM SB10.03.01
Silkworms as a Factory of Functional Wearable Energy Storage Fabrics Nageh K. Allam; American University in Cairo, Egypt

Feeding *Bombyx mori* larvae with chemically-modified diets affects the structure and properties of the resulted silk. Herein, we provide a road map for the use of silkworms as a factory to produce semiconducting/metallic natural silk that can be used in many technological applications such as supercapacitor electrodes. The silkworms were fed with four different types of chemicals; carbon material (graphite), sulfide (MoS_2), oxide (TiO_2 nanotubes), and a mixture of reactive chemicals ($KMnO_4/MnCl_2$). All the fed materials were successfully integrated into the resulted silk. The capacitive performance of the resulted silk was evaluated as self-standing fabric electrodes as well as on glassy carbon substrates. The self-standing silk and the silk@glassy carbon substrate showed a great enhancement in the capacitive performance over that of the unmodified counterparts. The specific capacitance of the self-standing blank silk negative and positive electrodes was enhanced 4 and 5 folds, respectively upon the modification with $KMnO_4/MnCl_2$ compared to that of the plain silk electrodes.

8:45 AM SB10.03.03
Washable Virus Blocking Textile for SARS-CoV-2 Powered by Human Body Triboelectric Energy Harvesting Minki Kang[1], Byung-Ok Choi[2,3,4], Nam-Hyuk Cho[5,5,6] and Sang-Woo Kim[1,4]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Samsung Medical Center, Sungkyunkwan University School of Medicine, Korea (the Republic of); [3]Samsung Medical Center, Korea (the Republic of); [4]Sungkyunkwan University (SKKU), Korea (the Republic of); [5]Seoul National University College of Medicine, Korea (the Republic of); [6]Seoul National University Medical Research Center and Bundang Hospital, Korea (the Republic of)

Effective mitigation technology to prevent the spread of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is required before achieving population immunity through vaccines. Here we demonstrate a virus blocking textile (VBT) which repulses SARS-CoV-2 by applying repulsive Coulomb force to respiratory particles, powered by human body triboelectric energy harvesting. We found that SARS-CoV-2 has negative charges and a human body generates high output current of which peak-to-peak value reaches to 259.6 μA at most, based on triboelectric effect. Thereby, the human body can sustainably power a VBT to have negative electrical potential and the VBT highly blocks SARS-CoV-2 by repulsing them. In acrylic chamber study, we found that the VBT blocks SARS-CoV-2 by 99.95 % and SARS-CoV-2 in the VBT is 13-times reduced. Our work provides the first technology that prevents the spread of virus based on repulsive Coulomb force and triboelectric energy harvesting.

9:00 AM SB10.03.04
Triboelectrification Induced Self-Powered Microbial Blocking by Harvesting Kinetic Energy from Human Motion Young Jun Kim and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

Conventional air-transmitted pathogen protection methods such as face masks typically involve obvious pressure drops and uncomfortable long-term wearing. Alternative methods, such as antimicrobial textiles can utilize the nanomaterial-modified functional fabrics for effective microbial prevention, whereas suffering from limited treatment throughput, high cost, and potential toxicity from nanomaterial release. Herein, we develop a novel microbial blocking textile using fabrics with opposite triboelectrification properties as the outer and inner layer that induces triboelectric charges by harvesting kinetic energy from human motion. The induced triboelectric negative charges at the outer layer on the microbial blocking textile achieve efficient air-transmitted pathogens blocking based on the electrostatic repulsion between the fabric and microbes. This self-powered triboelectrification-induced microbial blocking system with optimized material (PTFE and nylon) and structure (rib-knitted) achieves highly efficient microbial blocking (>95%) under a very high airflow of 2.0 m/s. Further, the pressure drop for the microbial blocking by this novel process is extremely low (<30 Pa). Our results demonstrate a promising method for rapid and self-powered air-transmitted pathogen blocking by involving triboelectric charges from human motion to meet vital needs to protect public health.

9:15 AM SB10.03.05
Investigation and Optimization of Direct-Write Printed Metasurfaces on Fabric Adria Kajenski[1], Guinevere Strack[1], Shahriar Khusrushahi[2] and Alkim Akyurtlu[1]; [1]University of Massachusetts Lowell, United States; [2]Notch Inc, United States

Wearable electronics covers a wide range of devices of varying complexity in a multitude of applications. Fabrication methods include weaving, embroidery, or direct-write printing. Printing has the advantage of coating individual fibers for seamless printed designs. Several printing processes can be used to fabricate wearable devices; however, direct-write printing is cost and time effective, producing consistent line widths using a variety of inks and substrates.

The RF metasurface is a passive device and is an example of a simple, wearable technology that can be produced via additive manufacturing. RF metasurfaces can be tailored by adjusting element shape or dimensions, providing reflection, transmission, or absorption within a frequency regime of choice. Here, a stop-band filter is designed at 5.8 GHz using an array of square loops. Textile substrate-based metasurfaces are versatile and have been used in various applications including anti-jamming and EMF shielding. [1]

The fabric-based printed metasurfaces are fabricated by direct-write printing two silver nanoparticle inks on single-sided polyurethane coated nylon substrates with thread masses of 70D and 200D, using a Nordson PRO4 dispensing system. The quality of the print heavily relies on a reasonable window of textile fiber thread mass and ink viscosity. Low viscosity inks printed on heavy thread mass fibers are more likely to introduce cracks and demonstrate fragility in tests. High viscosity inks are more forgiving and fully coat fibers, providing continuity regardless of thread mass. The textiles are subjected to wash and dry cycles, and mechanical testing of twisting, compression, and abrasion is performed. It is imperative to use a highly flexible ink resistant against mechanical distortion and resistance to wash and dry cycles. Lifetime of the textile metasurface is monitored over several months, demonstrating excellent longevity. Even when subjected to damage, the material may still perform depending on the number of defects and their location. RF performance and conductivity are used to assess the integrity of the wearable metasurface, and analysis of the failure mechanisms are conducted using SEM imaging. Quality and durability of the printed metasurface is dependent on the substrate type, thickness, and presence of a protective polyurethane coating. The protective coating on the reverse, non-printed side provides reinforcement, preventing ink from penetrating the fabric. This opens the possibility of printing on both sides, which can be used for introducing a second resonance, or in antenna applications for improving gain and bandwidth.

As part of this presentation, the performance and stability of the different inks on the different substrate thicknesses will be shown, and details of the ink and substrate interaction along with the mechanisms of failure will be presented. Details of the performance and durability of the metasurface samples will be demonstrated, and optimization of printing and testing processes will be reported.

[1] Printed Metasurfaces for Wearables A. Kajenski, S. Khushrushahi, G. Strack, and A. Akyurtlu; 2020 IEEE International Symposium on Antennas and Propagation and USNC-URSI Radio Science Meeting, Denver, CO 2022

9:30 AM BREAK

10:00 AM SB10.03.06
Thermally Drawn Multi-Material Fibers for Electronic Textiles Fabien Sorin[1], Andreas Leber[1], Chaoqun Dong[2], Hritwick Banerjee[1], Stella Laperroussaz[1], William Esposito[1] and Inès Richard[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland; [2]University of Cambridge, United Kingdom

Advanced functionalities integrated within fibers and fabrics are at the heart of the technological developments for electronic textiles. While functionalities are often added to the fibers or textiles via different deposition strategies, an emerging alternative approach relies in integrating materials and devices within the individual fibers. The thermal drawing process in particular, the technique used to fabricate telecommunication optical fibers, have experienced a series of materials and processing breakthroughs that have significantly expand the kind of materials and architectures that can be integrated into fibers. Flexible and even stretchable polymer fibers have been demonstrated to integrate metallic electrode arrays, electrically addressed semiconducting and piezoelectric domains, micro-channels, or textured surfaces with nanometer feature sizes. This provides fibers with novel advanced optical but also electronic and optoelectronic functionalities, with intriguing opportunities in energy harvesting and storage, fiber probes and optprobes, sensing, bioengineering and advanced e-textiles. In this presentation, we would like to introduce the vibrant field of multi-material fibers and highlight the several opportunities for the electronic textiles community. We will in particular present the fabrication approach, materials and achievable architectures offered by this process leading to novel electronic fibers and textiles (Adv. Materials 31, 1802348 (2019) (review paper from our group)). We will then discuss several recent results from our group starting with a first design that allows for the detection and localization of pressure along the fiber axis (J. Phys. D: Appl. Phys. 50, 144001 (2017)). We will then move to new designs based on the thermal drawing of thermoplastic elastomers, that enables to realize soft and deformable fibers (Adv. Mat. 30, 1707251 (2018)). We will show in particular electronic fibers and e-textiles that integrate conducting nano-composites (Adv. Funct. Mat. 30, 1904274 (2019)), and an innovative design where several liquid metal electrodes are co-drawn within an elastomeric cladding, forming distributed sensors based on transmission line principles (Nature Electronics 3, 316 (2020)). The achieved combination of pressure points localization and textile stretching enabled with only two contact points at a fiber end is unprecedented. We will also demonstrate similar soft fiber architectures and textile adapted for self-powered sensors and energy harvesters relying on the triboelectric effects (Nature Communications. 11, 3537 (2020)). We will conclude with the recent demonstration of the drawing of metallic glasses we could achieve, with feature sizes down to a few nanometers within a flexible fibers (Nature Nanotechnology 15, 875 (2020)), paving the way towards novel opportunities for fibers and textiles in bioengineering, sensing, electrochemistry (ACS Appl. Mat. and Int. 13, 43356 (2021)), and fabrics for the composite industry (Adv. Mat. Technologies 6, 2000957 (2021)).

10:15 AM SB10.03.08
3D Architecturing Strategy on a State-of-the-Art Liquid Crystal Spun Carbon Nanotube Fiber for Fiber-Shaped Supercapacitor with Ultra-High Electrochemical Performance Jeong-Gil Kim[1,2], Hayoung Yu[1,3], Jae Young Jung[1], Min Ji Kim[1,3], Hyeon Su Jeong[1] and Nam Dong Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Gwangju Institute of Science and Technology, Korea (the Republic of)

Fiber-shaped supercapacitors (FSSCs) are the most cutting-edge power sources for wearable electronics, however the essentially limited cylindrical space of fibers hinders high electrochemical performance, which should be overcome by the precise and systematic architectural process. Here, we suggest a simple but effective 3D architecture technique for fabricating FSSCs with high flexibility and electrochemical performance. Utmost liquid crystal spun carbon nanotube fiber (CNTF) is an ideal 1D core component that can achieve desirable properties demanded in FSSCs such as high conductivity and superior mechanical flexibility. GO is vertically composited to the surface of CNTF (VG@CNTF) by electrophoretic deposition process to fabricate a stereoscopic hybrid 3D structure. At this time, immediately depositing pseudo-capacitive active materials after the deposition of GO is a key process for maintaining the 3D structure of VG. Notably, the asymmetric FSSCs exhibit not only remarkable electrochemical performance of 65 Wh kg^{-1} at 100 kW kg^{-1} but also extraordinary flexibility and stability (capacitance retention of 98.60% at bending angles of 90° and 93.1% after 5,000 bending cycles). Moreover, the FSSC device integrated with common cotton yarn exhibits reliable performance even under harsh mechanically deformed environments. This study could lead to a breakthrough into the development of high-performance FSSCs for wearable applications.

10:30 AM SB10.03.09
MXene-Polymer Nanocomposite Fiber-Based Triboelectric Nanogenerator Md Mehdi Hasan[1], Md Sazid Bin Sadeque[1], Hilal Pecenek[2], Ilgin Albasar[1,3], Fatma Kilic Dokan[4], M. Serdar Onses[1,2,2] and Mustafa Ordu[1]; [1]Bilkent University, Turkey; [2]Erciyes University, Turkey; [3]TOBB University of Economics and Technology, Turkey; [4]Kayseri University, Turkey

Triboelectric nanogenerators (TENG) utilizes the universal triboelectrification effect to harvest ambient mechanical energy by coupling contact electrification with electrostatic induction. Ferroelectric polyvinylidene fluoride (PVDF) polymer improves triboelectric charge density by utilizing spontaneous polarization making this an excellent candidate for flexible TENG. 2D nanomaterials like MXenes improve triboelectric performance, thanks to abundant electronegative surface terminating groups and high surface area. Furthermore, MXenes significantly improve the output power of PVDF and its copolymer-based TENG by dielectric modulation through microcapacitor formation and microscopic dipole generation through interfacial polarization. Here, we present $Ti_3C_2T_x$ MXene-PVDF nanocomposite triboelectric fibers as energy-generating textiles by the scalable thermal fiber drawing. In this work, we will demonstrate three key outcomes: (1) rheological attributes for the successful drawing of nanocomposite fibers, (2) the effect of MXene addition and thermal drawing on the electroactive phase transition in fibers, and finally (3) the effect of MXene on the performance of TENG. The preliminary results of our fiber shows 2% increase in open-circuit voltage (upto 11.8 V), and 17% increase in short circuit current (upto 0.11 μA) upon 2.5 wt% of nanomaterials loading. The insights gained from this study will significantly contribute to our understanding of two-dimensional nanomaterials integrated fibers towards scalable fabrication of high-performance textiles.

10:45 AM SB10.03.10
Self-Powered E-Textile Based on Dynamic Schottky DC Generator Jun Liu[1], Yanbin Wang[2], Ruizhe Yang[1] and Tian Li[2]; [1]University at Buffalo, The State University of New York, United States; [2]Purdue University, United States

The growing demand for sustained power is one of the main challenges for wearable electronics, implantable devices, distributed sensors, etc., which are the critical elements for future Internet of Things (IoT) and Point of Care (POC). With recent advances in fabric materials and weaving techniques, low-power consumption sensor, wireless data transmission and cloud processing, the new era of Smart textile has come of age. However, the problem of powering smart textile system in the field at low cost, efficiently and for extended periods has remained unsolved. The Schottky DC generator is capable of generating a 3-4 orders' higher DC current density (10-100 A/m^2) compared to transient alternating current (AC) generation in conventional piezoelectric

or triboelectric nanogenerators, thus overcoming the power output limitation and frequency restriction in biomechanical energy harvesting. Moreover, the Schottky DC generation concept provide a new sensing mechanism for human activity monitoring with high electromechanical responsivity and multidirectional sensitivity. The flexible Schottky DC generator concept has recently been demonstrated and integrated with E-textile with conducting polymer system. In this talk, the original concept, recent progress, and future perspectives will be discussed.

11:00 AM SB10.03.11
Printed Photovoltaic Modules on Solution-Coatable Ultra-Thin Substrates for Mechanically Imperceptible Energy-Harvesting in E-Textiles
Mayuran Saravanapavanantham, Jeremiah Mwaura and Vladimir Bulovic; Massachusetts Institute of Technology, United States

Owing to the ultra-thin functional film thicknesses and intrinsically amorphous nature of emerging organic photovoltaics (OPV), they are well suited for integration into flexible/stretchable form-factors necessary to enable power-harvesting capabilities in e-textiles. To date, large scale demonstrations of such devices have primarily been on rigid glass or thick plastic substrates (>100 um), thereby limiting their conformal integration onto surfaces, a feature critical for their adoption into e-textiles. Recent reports of devices fabricated on ultra-thin (<5 um) substrates make use of intrinsically hard-to-scale chemical vapor deposition (CVD) or solution-coating methods employing high-temperature (>250C) imidization processes requiring a nitrogen-ambient environment. Herein, we report on a novel approach to prepare ultra-thin releasable polyester (PET) substrates in air-ambient conditions through a roll-to-roll compatible solution-coating process. Subsequently we demonstrate fabrication of fully-printed OPV modules on the substrates and their integration onto a high-strength (5kN/m tensile strength), light-weight (<15 g/m^2) composite fabric. Access to such coatable and ultra-thin substrates amenable to subsequent integration into e-textiles enables a platform not only suitable for energy-harvesting but any thin-film technology including displays, sensors, transceivers and compute elements.

11:15 AM SB10.03.12
Intrinsically Stretchable and Printable Lithium-Ion Battery for Free-Form Configuration Jeong Gon Son[1,2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

For next-generation wearable and implantable devices, energy storage devices should be soft and mechanically deformable, and easily printable on any substrate or active devices. Herein, we introduce a fully stretchable lithium-ion battery system for free-form configurations in which all components, including electrodes, current collectors, separators, and encapsulants, are intrinsically stretchable and printable. The stretchable electrode acquires intrinsic stretchability and improved interfacial adhesion with the active materials via functionalized physically crosslinked organogel as a stretchable binder and separator. Intrinsically stretchable current collectors are fabricated in the form of nanocomposites consisting of a matrix with excellent barrier properties without swelling in organic electrolytes, and nanostructure-controlled multimodal conductive fillers. Due to structural and materials freedoms, we successfully fabricate the several types of stretchable lithium-ion battery that reliably operates under various stretch deformations with capacity and rate capability comparable with non-stretchable battery over 2.5 mWh cm^{-2} at 0.5 C even under high mass loading conditions over 10 mg cm^{-2}, including stacked configuration, direct integration on both sides of a stretch fabric and application of various electrode materials and electrolytes. Especially, our stretchable battery printed on the stretch fabric also exhibits high performance and stretch/long-term stabilities in the air even when wearing and pulling.

11:30 AM SB10.03.13
Towards Green, Mass Customization of Electronic Fabrics Wenyu Wang, HaoTian Harvey Shi, Yan Yan Shery Huang and Ruishan Liu; University of Cambridge, United Kingdom

Traditional textile production has established fabrication processes of pre-treatment, dyeing, and finishing to obtain desired textile appearances and functionalities. Even though electronic textiles exhibit substantially enhanced functionalities than traditional textiles, their processing methods remain largely like those of traditional textiles, which include dip-coating, spraying, electrodeposition, or the use of coagulation bath. However, these processes often consume vast amount of water and energy, while producing significant amounts of chemical wastes. Here, we propose the integration of fibre spinning and 3D printing, which allows electrical functionalities to be embedded into/onto the microfibre structures on-demand. Tuning the spinning and print path of microfibres could generate customized patterns of e-fabrics. Such an on-demand, scalable method is foreseen to significantly reduce the chemical and material usage for e-fabric creation, as well as minimizing resultant waste generation.

1:30 PM *SB10.04.01
Emerging Technologies and Research in Electronic Textiles Tushar Ghosh; North Carolina State University, United States

The continued interest and growth in wearable and soft electronics devices have synergistically ushered in an entirely new area of innovative research and commercialization of e-textile products. Systems/devices in this category include multifunctional fibers and textiles with electronic capabilities having potential applications ranging from weapon systems to everyday textiles. The underlying science and technology of e-textiles are intertwined with many new and emerging fields such as nanotechnology, biomimetics, molecular electronics, etc. In this presentation, the general area of e-textiles will be introduced with an overview of the current state of the art and the challenges. More importantly, the presentation will focus on the complex challenges posed by the need for collaborative research in e-textiles involving multiple disciplines. The subsequent discussion will focus on the continuing effort at the SMARTextiles laboratory at N.C. State University to seamlessly integrate electronic functionalities directly into fibers and textiles to develop electrical devices such as sensors and actuators. In one of our ongoing research, tricomponent melt extrusion is being used to produce sensory fibers [1,2]. Once woven into a fabric, the fibers can be used as a sensor array to detect pressure, moisture, etc. In another research, an easy-to-manufacture, tunable, fully-textile sensor system that can detect pressure, humidity, or wetness is being studied [3,4]. Here capacitive pressure sensors are formed via a traditional sewing process with commercially available conductive sewing yarns. In both cases, the simple sensor design using conventional fabrication techniques resulted in practical and scalable methods of producing textile-based sensory arrays. The relationship between the sensor's physical, mechanical, and electromechanical properties, including hysteresis and sensory response, will be discussed. In addition to sensors, actuators are also essential for many e-textile applications. Therefore, we are exploring the movement and morphing in biological systems to develop advanced flexible structures [5]. For example, the nastic motion of plants in response to environmental stimuli, e.g., the rapid closure of the Venus flytrap's leaves, utilizes snap-through instabilities originating from the anisotropic deformation of plant tissues. In contrast, ballistic tongue projection of chameleon is attributed to direct

mechanical energy transformation by stretching elastic tissues in advance of rapid projection to achieve higher speed and power output. We have developed a bistable all-polymer laminate containing dielectric elastomers, which double as both structural and active materials. The electrical actuation of bistable structures obviates the need for continuous application of electric field to sustain their transformed state. The experimental results are qualitatively consistent with our theoretical analyses of prestrain-dependent shape and bistability. We are currently exploring similar fiber-based structures for textile applications.

2:00 PM SB10.04.02
A Heat-Based Self-Decontaminating Textile Material for Wearables Marquise D. Bell, Te Faye Yap, Kai Ye, Anoop Rajappan, Colter J. Decker, Yizhi J. Tao and Daniel J. Preston; Rice University, United States

The ongoing COVID-19 pandemic has caused severe shortages of personal protective equipment (PPE) and strained medical supply chains due to the disposable nature of PPE, which creates a need for constant replenishment to cope with high-volume usage [1]. To address this increase in demand, and to reduce the amount of waste generated by disposable PPE, we developed a reusable textile-based composite material that relies on dry heat decontamination [2], enacted through Joule heating of a conductive textile, to inactivate pathogens.

This wearable material is composed of four layers adhered to each other through a stacked lamination fabrication process which has been implemented in prior work to fabricate similar layered textile-based wearable devices [3]. The four layers that comprise this material are: (i) a plain-woven substrate textile infused with thermoplastic polyurethane on one side, (ii) a serpentine-patterned electrically conductive textile that enables Joule heating, (iii) an electrically insulating dielectric surface layer of thermoplastic polyurethane to prevent electrical contact with the wearer, and (iv) a thermally insulating base textile layer that interfaces with the wearer's skin to allow safe contact during the dry heat decontamination process. Through this facile and scalable fabrication approach, we created a wearable material capable of achieving the high surface temperatures (> 100 °C) required for viral inactivation within short time frames (< 5 s) while maintaining a comfortable temperature at the point of contact with the skin (< 30 °C).

The geometrical parameters of this material dictate its thermal performance for the inactivation of viral contaminants and can be predetermined, prior to fabrication, based on a desired level of virus inactivation. We quantified the inactivation efficacy of our composite material through experiments supported by analytical modeling predictions using a time-varying temperature profile [4], illustrating the effectiveness and practicality of our approach. We demonstrate how this material can be easily integrated into regular clothing (shown using gloves in this work) and can perform rapid dry heat decontamination, especially in untethered, on-the-go applications. This work provides a simple design and fabrication process for a composite textile material that enables quick and repeatable in situ dry heat decontamination with the ability to reduce waste created by disposable PPE and mitigate the risk of disruptions in supply chains.

2:15 PM *SB10.04.03
Development of Test Methods for Heating Textiles Patricia I. Dolez[1], Justine Decaens[2], Ikra Shuvo[1] and Shakil Mahmud[1]; [1]University of Alberta, Canada; [2]CTT Group, Canada

The integration of electronic and data processing functions within textile products has given rise to e-textiles. They can sense variations in the environment, either external or from the wearer, react by performing an action, and even adapt their properties. E-textiles offer major opportunities in healthcare, protection, and sportswear among others. However, in order to further develop this thriving E-textile industry sector, standardized testing and quality control methods are crucial for safeguarding product quality, regulating performance consistency, and ensuring consumer safety.

In the specific case of Joule heating textiles, several products have already reached the market. However, issues have been reported in terms of efficiency, durability and safety. The lack of efficiency may be associated with a higher response time, heterogeneous heat distribution, and/or irregular heating levels during repeated applications. In addition, different factors associated with daily life use can lead to a premature decrease in performance and ultimately reduce the lifespan of heating textile. Such factors can be mechanical (abrasion and repeated stretching and bending), related to textile care processes (laundering, ironing) and environmental (e.g. corrosion due to perspiration). Heating textiles may also create safety issues to the wearer due to short circuits, overheating, and fire incidents.

A test protocol has been developed to quantitatively assess the heating efficiency of heating textiles in a repeatable way. It uses thermocouples to measure the change in temperature at the surface of the heating textile during the heating and cooling phases. Various boundary conditions were applied with different fabrics/flexible materials simulating realistic use scenarios of heating textiles. The robustness of the test protocol was assessed with different heating textile structures: a conductive nonwoven fabric combining silver-coated nylon and polyester fibers; the same nonwoven fabric encapsulated with a polyurethane film; a heating fabric with an embroidered carbon fibre yarn; and a silicone rubber heating pad incorporating copper wires. Mathematical models were also developed to describe quantitatively the heating and cooling effectiveness of the heating textiles.

In terms of durability, the work focuses on five damaging conditions that are relevant to heating textile use in consumer products: abrasion, laundering, exposure to perspiration, repeated stretching, and repeated bending. The effect of these damaging conditions on the heating textile performance is studied using different types of Joule heating textiles – knitted, woven, nonwoven, embroidered/stitched/inserted, coated, and laminated. The conditions of the damaging treatment are selected to simulate realistic product use situations, e.g. in terms of the frequency and number of cycles of the bending and stretching motion and number of laundering cycles applied. The durability of the heating textile is assessed by comparing its heating performance after exposure to the damaging treatment with its initial efficiency. For the safety assessment, the test protocols characterize the propensity of the heating textile products to short circuits, ignition, and overheating.

The test and quality control protocols developed as part of this research aim to be reliable and robust as well as applicable to a wide range of Joule heating textiles with different structures. They are intended for Standards Development Organizations such as ASTM International and the International Electrotechnical Commission (IEC). We hope that they will contribute to lifting some of the barriers that currently limit the growth of the e-textile industry.

2:45 PM BREAK

3:15 PM *SB10.04.04
Protecting Firefighters and Donor Hearts by Smart Uses of Textiles Hyun-Joong Chung; University of Alberta, Canada

Textiles are extreme engineering materials that have been optimized mostly for clothing uses for thousands of years. The properties of the wonder materials are tunable by varying their fabric patterns, fiber/yarn composition, and constituting materials. In this talk, I will present two examples of utilizing textiles to protective human lives: (i) a wearable sensor that predicts the end-of-life of firefighter's personal protective garment and (ii) a textile-enforced elastomeric tube that facilitates blood circulation in an ex-vivo heart perfusion (EVHP) device for heart transplant surgery.
ANECDOTE 1: Firefighters' lives rely much on the performance of fire-resistant garments. While the garment is composed of textiles that perform exceptionally well in terms of maintaining mechanical robustness such as tear resistance, the performance of these textiles degrade slowly by aging. The major acceleration factors for the aging include high temperature, moisture, and ultraviolet (UV) light. The most serious problem of the aging behavior is that it is virtually undetectable; detectable consequences of the aging is the colour change of the textile, but tensile strength of the aged textile at the moment of detection is merely at the 20~30% of that of as-made ones. Whereas the performance limit of the protective textile is at ~50% of performance retention, the aging is a life-threatening problem for firefighters. In order to address the problem, our team is currently developing an end-of-life sensor of protective textiles. The wearable sensor is attached on the firefighter's protective garment, and undergoes the same life-experiences of the garment including high temperature, UV and water exposure, and laundering cycles. In the presentation, the design concept of the end-of-life sensor, which includes graphene-based conductive tracks and a sacrificial polymer layer, will be discussed. Understanding and quantifying the degradation of the sacrificial polymer is important. Here, we studied thermally- and hydrothermally-induced aging behavior of high performance polymers by quantifying the gradual loss of tensile strength and elongation at break. Time-temperature superposition principle was used as a framework to quantify the activation energy of degradation. Chemical degradation mechanism was studied by FT-IR with hypothesis-driven and machine-learning assisted methods to elucidate the vulnerable chemical bonding for degradation.
ANECDOTE 2: EVHP is an innovative technology in which a donor heart is kept alive and beating outside of the human body. During EVHP, the organ is kept near body temperature (37 °C) and perfusate (enriched blood) flows through the heart chambers, simulating physiological conditions. Currently, overly stiff tubing used in EVHP devices causes premature pressure wave reflection during heartbeat, which can increase risk of donor organ rejection. Use of aorta-inspired compliant tubing for EVHP devices, namely, RTV silicone elastomer tubes 'jacketed' by a sleeve of knitted fabric, was hypothesized to potentially mitigate this problem. We used a custom-built flow loop to pump fluid into sections of compliant tubing at known pressures and measured the response; our main finding was that the tubes deform rapidly as pressure initially increases, but eventually display 'self-regulation' behavior where their continued distension is tempered by the stiffening of fibres in the fabric. The experimental findings were supported by our 3-dimensional finite element simulations in ABAQUS using material coefficients obtained from uniaxial tensile tests of the tubing materials. Finally, we will showcase the efficacy of the fabric-jacketed tube in facilitating blood circulation in EVHP devices.

3:45 PM SB10.04.05
Smart Textiles in Extreme Environments Braden M. Li[1,2], Robin Dietrich[2], Alex E. Flynn[2], Alex Parkison[2], Deanna Sessions[2], Wilson Kong[2], Zachary Farrell[2], Rahel Rudd[1] and Christopher E. Tabor[2]; [1]Air Force Life Cycle Management Center, United States; [2]Air Force Research Laboratory, United States

The ability to impart "smart" functionality (i.e. stimuli responsiveness & sensing) coupled with the innate flexibility and comfort of textiles make smart textiles well suited to address the key challenges associated with developing the next generation clothing solutions to support emergency personnel (first responders, military, medics). It is not uncommon for these critical personnel to operate within extreme environmental conditions, ranging from dry arctic regions (-55°C) to hot / humid conditions. In this presentation, key material challenges and solutions will be shared that are being addressed within the US Air Force to enable next generation smart textiles in extreme conditions to better enable personnel to perform their duties by providing both physiological state awareness and mitigating detrimental states such as hypothermia and cognitive fatigue. Herein we discuss our efforts exploring the use of polymers with enhanced thermal properties coupled with printable liquid metal (EGaIn) inks to create conformable, flexible, and robust functional textile laminates suitable for applications such as active heating, electrophysiological sensing, and on-body data / power routing. These innovative material sets present new opportunities for additional textile-based wearable sensing, haptics, and augmented/virtual reality (AR/VR) applications that were previously unrealized due to intrinsic material limitations.

4:00 PM SB10.04.06
Ultra-Low Energy Adaptive Personal Thermoregulation—A Kirigami-Enabled Electrochromic Wearable Variable Emittance (WeaVE) Device Ting-Hsuan Chen[1], Yaoye Hong[2], Ching-Tai Fu[1,3], Ankita Nandi[1,4], Wanrong Xie[1], Jie Yin[2] and Po-Chun Hsu[1]; [1]Duke University, United States; [2]North Carolina State University, United States; [3]University of Southern California, United States; [4]California Institute of Technology, United States

Personal thermoregulation is of key importance for human skin temperature stabilization and personalized thermal comfort. However, a long-standing trade-off exists between tunable functionality, energy consumption, and wearability. Inspired by the mid-infrared electrochromic conductive polymers, we developed the first **ultra-efficient wearable variable-emittance device (WeaVE)**, enabling the tunable radiative heat transfer coefficient to fill the missing gap between thermoregulation energy efficiency and controllability.

WeaVE is an electrically driven, kirigami-enabled electrochromic thin-film device that can effectively tune the thermal radiation heat loss of the human body. The device can also maintain its cooling/heating state without energy input, thereby stabilizing the human body heat dissipation in response to varying ambient temperature with orders of magnitude less energy input compared to active devices or heating, ventilation, and air-conditioning (HVAC) systems. We also show that the kirigami design can achieve stretchability and conformal deformation under various modes of deformation and exhibits excellent mechanical stability after 1000 cycles. The integration of sensors and electronic control also enable programmable personalized thermoregulation. Our results show that **with less than 5.58 mJ/cm^2 energy input per switching, WeaVE provides 4.9 °C (8.8 °F) expansion of the thermal comfort zone, which is equivalent to a continuous power input of 33.9 W/m^2.** This is more than 1,000 times switching for a 1m^2 WeaVE with a typical smartphone battery, corresponding to months of usage. WeaVE provides an entirely new scheme to breaking the dilemma between conventional personal thermoregulation devices' functionality and energy consumption and maintaining the wearability requirement simultaneously.

4:15 PM SB10.04.07
Laser-Induced-Graphene Formation on the Kevlar Textiles for Wearable Electronic Devices Dongwook Yang, Han Ku Nam, Truong-Son D. Le, Younggeun Lee, Young-Ryeul Kim, Seung-Woo Kim and Young-Jin Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Wearable electronic devices are being widely employed in various situations, including firefighting, the military, fitness/well-being, and healthcare. One of the promising technology candidates for realizing wearable electronics is constructing conductive electrodes directly onto textiles or fibers. Direct laser writing can support the direct conversion of textiles into electrically conductive Laser-Induced-Graphene (LIG) by irradiating the intense laser beam for

converting specified precursor materials into LIG via photothermal reactions; this offers the more flexible design changes with faster manufacturing process. The introduction of ultrafast femtosecond lasers with shorter pulse durations could improve the patterning resolution while minimizing the unexpected material ablation. Kevlar is one of the fabrics having a high melting temperature so fits well for the successful synthesis of LIG using the ultrashort femtosecond laser pulses. We examined the electrical sheet resistance, surface morphology with an SEM, and chemical composition with a micro-optic Raman spectrum. After the characterization, we applied this patterning strategy to realize various wearable electronic sensors (e.g. strain sensors, temperature sensors, bending sensors) and energy storage devices on Kevlar. Textiles are made up of woven, nonwoven, and knit structures, each with its own set of physical properties.
A Yb-doped fiber femtosecond laser, power/polarization control optics, a Galvano scanner, beam-delivery mirrors, and a central control unit make up our direct-laser-writing system. At a 200-kHz repetition rate, the laser generates a repeated pulse train with a 1030-nm wavelength and a 350-fs pulse duration. For patterning of fabric strain sensors and energy storage devices, the laser's average power varied from 0.5 to 3 W while the beam-scanning speed varied from 10 to 30 mm/s. A Galvano scanner angularly scanned the laser beam, which was then focused on target fabrics with an f-theta lens. On-demand, the entire system was concurrently commanded to produce arbitrary patterns. For validating the physical and chemical characterization of LIG, sheet resistance, SEM, XRD, FT-IR, and Raman spectroscopy were conducted. Kevlar to LIG conversion in ambient air was achieved using femtosecond laser direct writing, which may be used in a variety of wearable devices. The resulting LIG is used to construct wearable strain sensors, bending sensors, temperature sensors, and supercapacitors based on the physical characteristics of different fabrics due to its features. The bending sensor is effectively realized for woven cloth. The TCR of the nonwoven temperature sensor is employed for monitoring body temperature, and the capacitance of the nonwoven supercapacitor is 12 mF/cm^2. The knit strain sensor is well established, and finger movements and human heartbeats were all detected. As a result of the direct conversion of Kevlar to LIG, LIG-based wearable sensors might be used in the military, firefighting, and sports sectors, among other things. Furthermore, we will investigate the possibilities of LIG production with ordinary fabrics, as well as the cleaning challenges associated with textile LIG devices.

4:30 PM SB10.04.08
Length Scale and Composition Dependent Large Deformation Mechanical Behavior of Hydrogen-Bonded Polymer Nanofibers Adwait Gaikwad and Pavan V. Kolluru; Texas A&M University, United States

There usually exists a trade-off between making a material ductile so that it can support large deformation and making it strong so that it can withstand large forces. Biological soft materials such as spider silk or collagen have inspired the use of a network of dynamic bonds (hydrogen bonding or metal coordination), which dissipate energy through rupture and reformation during the deformation, to simultaneously improve strength and toughness. Similarly, fabricating small nanoscale structures has also been reported to help overcome the strength-toughness trade-off. In this study, we systematically study the combined effect of structural length scale and hydrogen bond (H-bond) concentration on the mechanical behavior of polyvinylpyrrolidone (PVP) and tannic acid (TA) nanofibers. Using a unique submicron scale uniaxial mechanical testing with microelectromechanical system (MEMS), the elasto-plastic mechanical response of individual PVP-TA fibers was studied as a function of their fiber diameter and molar concentration of TA (i.e., effect of H-bond density). Our studies reveal a complex interdependence of nanofiber mechanical response on the fiber diameter and TA concentration. It was observed that elastic and plastic properties of PVP-TA nanofibers are very differently dependent on the fiber diameter and TA concentration, with the thinnest fibers being stiffer and more resilient, at lower TA concentrations, while thicker fibers show better elastic response at large TA concentrations. In contrast, the plastic deformation response of PVP-TA nanofibers was found to display a more complex, non-monotonic dependence of on fiber diameter and TA concentration. This presentation will outline these trends and infer the underlying role of the H-bonded network in controlling submicron scale mechanical behavior. The results of this study will effectively help develop novel hydrogen-bonded polymers with effective mechanical and functional responses.

4:45 PM SB10.04.09
Liquid–Metal-Superlyophilic and Conductivity–Strain-Enhancing Scaffold for Permeable Superelastic Conductors Qiuna Zhuang and Zijian Zheng; Hongkong Polytechnic University, China

Stretchable electronics find widespread uses in a variety of applications such as wearable electronics, on-skin electronics, soft robotics, and bioelectronics. Stretchable electronic devices conventionally built with elastomeric thin films show a lack of permeability, which not only impedes wearing comfort and creates skin inflammation over long-term wearing but also limits the design form factors of device integration. Liquid metal (LM) has recently been used as an advanced stretchable material for constructing stretchable and wearable electronics. However, due to the poor wettability of LM and the large dimensional change during stretching, it remains very challenging to obtain a high conductivity with minimum resistance increase over large tensile strains while maintaining adequate permeability.
To address the challenge, an LM-superlyophilic and stretchable fibrous thin-film scaffold is reported, on which LM can be readily coated or printed to form permeable superelastic conductors. In contrast to conventional LM-based conductors where LM particles are filled into an elastic matrix or printed on the surface of an elastic thin film, the LM can quickly infuse into the LM-superlyophilic scaffold (within seconds) and form bi-continuous phases. The LM-superlyophilic scaffold shows unprecedented advantages of an extremely high uptake of the LM and a conductivity-enhancement characteristic when stretched. As a result, the LM-based conductor displays and ultrahigh conductivity of 155,900 S cm^{-1} and a marginal resistance change by only 2.5 fold at 2,500% strain. The conductor also possesses a remarkable durability over a period of 220,000 cycles of stretching tests. The printing of LM onto the LM-superlyophilic scaffold for the fabrication of various permeable and wearable electronic devices is demonstrated.

Soft And Flexible Enzyme Fibers for Powering Wearable Devices from Body Fluids Shiqi Wu, Yi Ding, Wenyao Lei, Daniella Marie B. Gatus and Takeo Miyake; Waseda University, Japan

Wearable devices with biocompatible mechanical behavior have garnered much attention in field of power harvesting, biomedical sensing and others. Functionalized fibers could be used in wearable devices as several elements of display, sensor, medical therapy, and batteries. Here, we demonstrated a soft and flexible enzyme fibers for a biobattery in wearable devices.

The proposed fibers consist of an enzyme/Poly(1-vinylimidazole)-Osmium/carbon nanotube(CNT)/fiber for biofuel oxidation, and enzyme/multi-layered CNT/fiber for oxygen reduction. These fibers applied to the skin applications on cloth, bracelet, and semi-implantation of needle insertion.

SB10.05.02
High-Performance Textile Microsupercapacitors Based on Laser-Induced Graphene Composite Electrodes Soongeun Kwon, Hak-Jong Choi, Junhyoung Ahn, Hyungjun Lim, Geehong Kim, Kee-Bong Choi and JaeJong Lee; Korea Institute of Machinery and Materials, Korea (the Republic of)

Electronic textiles (E-textiles) have garnered extensive attention due to their extended usage in various applications such as sensors, actuators, and energy harvesting, and storage devices, and even displays. While individual functions of each E-textile have been separately researched, the energy storage device to power E-textiles should be integrated in the form of textile for practical applications. Microsupercapacitors (MSCs), thin-film energy storage devices, have received a great deal of attention as power sources for wearable, textile or stretchable electronic devices due to their fast charging capability, long life cycle, and good safety. Various ink printing techniques (screen printing, inkjet printing, 3D printing) have been employed to fabricate electrode patterns of textile MSCs. Even though these ink printing techniques are considered to be compatible with large-scale production, the preparation of inks based on high performance nanomaterials requires a costly, time-consuming and complicated process including high temperature synthesis or dispersion in an organic solvent. A cost-effective and facile textile MSC fabrication process without ink materials is thus required.
Laser-induced graphene (LIG), obtained by the direct laser writing of various types of carbon precursors, have widely researched as electrode materials of flexible microsupercapacitors with the advantages of 3D porous electrodes with high crystallinity, hierarchical porosity, and high surface area. However, these superior properties of LIG electrode were not applied in textile energy storage devices yet.
In this work, LIG-based textile MSCs (LIG-MSCs) were fabricated by thermal transfer printing. A LIG directly laser-written on a PI film was transferred onto the adhesive film area of textile substrates during thermal transfer printing. The electrochemical performances of the as-fabricated textile LIG-MSCs were investigated. Especially, LIG-MSCs based on LIG-metal composite electrodes exhibit fast ion transport for high-rate performance with capacitive rectangular shapes at high scan rates of up to 20V/s, suggesting outstanding rate capability among graphene-based textile MSCs. Moreover, LIG-MSCs demonstrated the possibility of practical usage as textile energy storage devices such as cyclic stability, a waterproof property, and control of the working voltage or capacitance by series or parallel connection.

SB10.05.03
Carbon Nanotube Textile Skin Electrodes for ECG Sensing Md Milon Hossain[1,2], Braden M. Li[1], Busra Sennik[1], Jesse S. Jur[1] and Philip Bradford[1]; [1]NC State University, United States; [2]Khulna University of Engineering & Technology, Bangladesh

Advanced carbon materials, metallic nanoparticles and conductive polymers are widely used for fabricating textile electrodes. Among the carbon materials, carbon nanotubes (CNT) demonstrate high aspect ratio, excellent mechanical properties, ultralight weight, good thermal and electrical properties. However, most of the electrodes fabricated using CNTs are composite film and lack breathability and comfort. Here we report the fabrication of CNTs wrapped textile yarns which are strong and flexible for different textile processing. We developed a textile processable yarn by wrapping CNTs over cotton and spandex yarn in a core-shell structure. The spandex core renders the yarn with high stretchability and ultra-conformability to the skin providing high reliability against mechanical deformation and motion artifacts. No adhesive and tethering required for our developed electrode to measure ECG and could be worn and washed as a regular textile. We demonstrated that the systematic design of the electrode will record comparable ECG signals of Ag/AgCl electrode in different body movement conditions.

SB10.05.04
OECT Based Lactate for Real Time Diabetic Wound Monitoring Yuchen Shao, Manisha Gupta, Jiaxin Fan and Paul Lavryshyn; University of Alberta, Canada

Diabetic patients have an increasing risk of developing the diabetic foot ulcer (DFU). If left untreated these wounds can lead to foot amputations. Clinical research has shown that real time monitoring of the lactate concentration helps guide therapy and improve patient outcome [1]. Blood tests for measuring lactate levels can provide only the systemic levels. We are developing a non-invasive and low-cost lactate biosensor which can provide the localized wound lactate levels and can provide continuous measurements to monitor the wound health.

In this research, we developed a 3D-printed lactate sensor on top of the flexible Kapton substrate. Organic electrochemical transistors (OECTs) are chosen for the biosensor because of its good performance for the ion-to-electron transduction and signal amplification. Sensors are fabricated using Optomec Aerosol Jet 5X printer with Au as the source and drain electrode, Pt as the gate, poly(3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) as the channel and polyimide as the insulator layer. The printed gate was first dropped casted with mixed chitosan and LoX. Functionalized sensors were stored under 4 degrees for 24hrs until they were fully dried and then washed with DI water and PBS solution. The device was measured in simulated wound fluid and has the response range from 500uM up to 5mM with a sensitivity of 117 uA/mM. Later, the layer-by-layer strategy was attempted according to the sequence nafion, chitosan and LoX, which exhibited a better range up to 10mM. Modifications to the functionalization method, such as carboxy-functionalized multi-walled carbon nanotubes (MWCNT) mixed with Tetrathiafulvalene (TTF), nafion, L-Lactate oxidase (LoX) and chitosan in acetic acid were dropped casted one after the other will be tried for further improvement. In addition, pH and extra reactions are also taken into consideration to help further correction for the lactate sensor. The results from the developed lactate sensor will be presented.
[1] Jia W, Bandodkar AJ, Valdés-Ramírez G, et al. Electrochemical tattoo biosensors for real-time noninvasive lactate monitoring in human perspiration. Analytical Chemistry. 85(14):6553-6560. doi:10.1021/ac401573r

SB10.05.05
Electrospun Fiber Laminate Triboelectric Nanogenerator for Acoustic Energy Harvesting Artis Linarts, Kaspars Malnieks and Linards Lapčinskis; Riga Technical University, Latvia

Triboelectric nanogenerators (TENG) are intriguing energy harvesting devices that convert mechanical energy into electricity and could power small portable devices or charge batteries [1]. Here we report acoustic triboelectric nanogenerator (A-TENG) consisting of polymer nanofibers made with electrospinning technique. A-TENG consist of up to 30 layers of polymer fibre mats with total thickness of200µm. Two polymers with opposed properties were chosen and with a custom made electrospinning device the fibres where collected on a rotating drum collector covered with a flexible electrode. Different triboelectric surface properties of laminate creates multiple triboelectric interfaces with dipole alignment across the volume of laminate; therefore this design allows electrical power generation in very low vibrations environments (40dB sound pressure).

The reported laminates in this study hold a great potential in the field of flexible triboelectric nanogenerator.

Smart Sensing Sutures for Real-Time Glucose Monitoring Mossab K. Alsaedi, Junfei Xia, Atul Sharma, Rachel Riccio, Rachel E. Owyeung, L. M. Romero and Sameer R. Sonkusale; Tufts University, United States

Real-time monitoring of glucose levels in living organisms is a key indicator of various biological processes. Specifically, monitoring glucose and other biomarkers in avian species (e.g. house sparrows) is a key indicator of the animal’s stress level. Current stress level monitoring methods are invasive and require multiple interactions with the animal (collecting blood samples at different time points). Therefore, a less invasive and continuous monitoring method is preferred.
Flexible bioelectronics have emerged in the fields of precision health and medicine as they offer seamless electronic-tissue interface in terms of physical contact and mechanical properties (comparable elastic moduli). Threads have previously been utilized in biomedical applications to realize thread-based transistors, biosensors, and even drug-delivery platforms. Threads’ one-dimensional, flexible characteristics ensure seamless integration with underlying tissues and organs better than two-dimensional, planar platforms and ensure intimate contact with tissue/organ surfaces, as exemplified by sutures. The fibers they are comprised of can be specifically chosen from biocompatible sources, such as silk and polylactic-co-glycolic acid (PLGA), to tailor their use more towards biomedical applications. Further, thread-based biosensors are small and light enough not to interfere with flight movement during continuous real-time monitoring.
In this study, we realize sensing sutures for glucose monitoring using electrochemical principles. We use a three-electrode system: the working and counter electrodes are made of medical-grade sutures while the reference electrode is a commercial Ag/AgCl (1 M KCl) electrode. The conductive layer on the working and counter electrodes is gold via solution-based electroless deposition and plating. This produces a more uniform and connected coating layer of gold on the thread’s rough, uneven surface. Compared to other conductive coatings, such as carbon which requires multiple coatings for adequate conductivity, electroless deposition of gold produces a more flexible conductive suture. Gold nanoparticles were synthesized, characterized, and deposited on the sutures. In addition to the conductive layer, an electron-mediating layer (Prussian blue) is electrically deposited and enzyme-chitosan bilayers are coated. Glucose oxidase, which is the enzyme immobilized in the enzyme-chitosan matrix, catalyzes the electron-producing reaction that glucose undergoes in the presence of oxygen and, as a result, alters the current in the system. At all steps, FTIR and SEM are utilized to confirm the presence and quality of each coated layers.
We demonstrate functionality of sensors by obtaining calibration curves and test data for real-time glucose monitoring, sensor stability, sensor repeatability, and analyte interference. The sensing sutures had a sensitivity value of 0.933 ± 0.115 nA/mM within a range from 0 mM to 54.9 mM glucose with an LOD value of 0.62 mM. They demonstrated successful real-time monitoring of change in glucose concentration over an operating period of 40 minutes and sensor stability of at least five days. In addition, the sensing sutures showed selectivity towards glucose even with the presence of other molecules, such as lactate. Tests and measurements were performed in 1X phosphate-buffered saline (PBS). Furthermore, future tests will be done using ex-vivo tissue models and in-vivo animal models. While glucose sensing has been reported, sensing sutures can be expanded to other analytes, such as lactate, electrolytes, chemokines, and metabolites.

SB10.05.07
Aptamer Functionalisation of Semiconducting Polymer Thin Films for Applications in Biosensing Organic Field-Effect Transistors William Neal, Matteo Palma and Christian Nielsen; Queen Mary University of London, United Kingdom

Point-of-care devices are a promising area of technology, with applications in personalised healthcare. Such devices aim at improving secondary preventative medical strategies, by detecting a disease before symptoms start to develop. Multipurpose, portable and easy-to-use sensing devices will increase the accessibility of diagnostics, resulting in earlier detection and treatment of disease. Integration into wearable technology would enable constant health monitoring, effectively minimising diagnostic times.
Developing upon initial work published within our group, we propose to incorporate favourable solution processable organic semiconducting polymers into a biosensing field-effect transistor. Functionalising a field-effect transistor with receptors, would allow for selective and amplified detection of analytes. Biomarker specific aptamers would endow the device with highly selective and chemically resistant sensing properties. However, receptor functionalisation of semiconducting polymers is challenging, as high-performance materials lack chemical groups exploitable for covalent attachment.
We will present foundational work carried out towards fabricating a biosensing platform. By blending a high-performance polymer (DPP-DTT), with a cross-linking agent (glutaraldehyde), the resulting polymer thin-films can be successfully functionalised with receptors. Primary amine terminated aptamers, in solution, react with glutaraldehyde, via a condensation reaction, covalently attaching the receptor to the surface. Successful thin-film functionalisation is observed in several characterisation techniques. Atomic force microscopy, X-ray photoelectron spectroscopy, fluorescent microscopy and water contact angle measurements are presented, as supporting evidence of the functionalisation of the receptor to the surface of the thin-film. Covalent attachment of the aptamer to the polymer was confirmed, as well as the accessibility of the aptamer binding to the target biomarker. Preliminary device architecture and polymer thin-film functionalisation strategies are presented, and once further optimised, combined to fabricate a sensor for detection of target biomarkers.

Fully Stretchable Sandwich Structured Textile-Based Triboelectric Nanogenerator with a Crepe Paper-Induced Surface Microstructure Kim Da Eun and Youn Tae Kim; Chosun University, Korea (the Republic of)

As various wearable devices are released, self-powered wearable energy harvesting technology is in the spotlight as a next-generation technology. Among them, research on triboelectric nanogenerator (TENG), which efficiently converts mechanical energy into electrical energy, is being actively conducted. In particular, the textile-based TENG is one of the most promising energy harvesters for realizing wearable devices and self-powered smart clothing. However, most of the existing textile-based TENGs generate energy only in the intentional vertical-contact mode, and have poor durability against twisting or bending deformation using metal materials.
This study, we propose a sandwich structured textile-based TENG (STENG) with a stretchability and fully flexibility for wearable energy harvesting. One side of stretchable textile is coated with micropatterned EcoFlex and used as a negative triboelectric material. The performance of power generation was improved by patterning the EcoFlex surface based on the microstructure of the crepe paper surface. The other side, acetate cloth tape is attached to the stretchable textile as a serpentine structure, and is used as a positive triboelectric material. Since this is a serpentine structure, it is possible to expand and

contract up to 50% in the lateral direction. The top of the acetate cloth is sewn with yarn to generation an air gap, which can generate energy even in stretching mode. That is, through friction between micropatterned EcoFlex and acetate, STENG harvests mechanical energy in the contact-separate, stretching, and rubbing modes. In addition, since all flexible materials are used, the structure is free from deformation. The output of 361.3 V and 58.2 μA in the contact-separate mode, the output of 166.1 V and 23 μA in the stretching mode, and the output voltages and currents of 119.5 V and 17 μA in the rubbing mode were observed. This is the result of 250% improvement in output performance compared to the flat EcoFlex-based STENG without nanopatterns. Finally, we successfully demonstrated the operation of the 135 LEDs using STENG's output without external power source. These findings could provide a textile-based power source with practical application in future e-textile and self-powered electronics.

SB10.05.11
A Coupled Electrochemical-Mechanical Analysis of Textile Battery Using Multi-Scale Modeling Dongwon Jang and Woong-Ryeol Yu; Seoul National University, Korea (the Republic of)

Textile battery is a novel fiber-shaped energy storage device that has the capability of flexibility fabricated by numerous yarn assemblies (i.e., woven fabric). Carbon fiber and polymer electrolyte are used for textile battery, each of which contributes to acting as an electrochemical electrode and transporting Li-ion with superior mechanical properties. It is difficult to predict effective electrochemical and mechanical behaviors of yarn-based whole textile battery due to complexity. Herein, we developed a simplified yarn model of textile battery comparing electrochemical and mechanical similarities between yarn scale and filament scale. First, electrochemical and mechanical homogenization methods were applied to the yarn model and visual modeling of carbon fiber and polymer electrolyte was implemented in the filament model. Comparison between homogenized yarn model and filament model was quantitatively carried out using 3D shape descriptors (compactness and cubeness) and a volume-averaged method, demonstrating high accuracy and efficient computational time of the homogenized yarn model. Next, a damage model under flexible condition (i.e., bending) was incorporated into the homogenized yarn model to consider external load effect on the electrochemical performance of textile battery. The effect of different bending conditions on the voltage profile and capacity of textile battery was investigated. Using the developed homogenized yarn model including damage, the electrochemical and mechanical performances of textile battery can be simulated, and detailed results will be presented at the conference.

SB10.05.12
Investigation of Reliability of a Flexible Pressure Sensor Based on a Polyethylene Carbon Composite - Velostat Anis Fatema and Aftab M. Hussain; International institute of Information Technology Hyderabad, India

Nanoparticle-based polymer composite materials are receiving attention for the development of sensors for various flexible and wearable electronic applications. However, it is important to test a material's reliability to validate the quality of the product and to ensure that the results obtained are accurate and repeatable. Flexible pressure sensors utilized in wearable and textile devices are subjected to continuous force and stress that may affect the sensor's response in the long run. Hence, reliability assessment is an essential factor to consider when designing any sensor. In this work, we have tested the reliability of a carbon-impregnated polymer composite named velostat, over repeated usage and bending cycles during the course of a year. It is an opaque conductive film of polyethylene impregnated with carbon particles, making it an electrically conducting composite material. It has been extensively explored because it is low-cost, thin, flexible, lightweight, and easy to fabricate. It works on the principle of piezoresistivity; the higher the pressure applied to the velostat, the higher the conductivity and the lower the resistance.
We evaluated the reliability of velostat by implementing this material into the design of a flexible pressure sensor array. The reliability assessment was performed on the pressure sensor array for one year. The sensor array was designed and fabricated as a multi-layer matrix structure. The top and bottom layers were the protective layers made of PVC sheets on which the conductive layers were pasted. The protective layers were transparent, thin, soft, and inexpensive. The thickness of the protective layers was 135±1 μm each. The conductive layers were conductive adhesive copper tapes. The copper electrodes were pasted in a crossbar architecture format and had a rectangular cross-section. The ends of the copper tapes were soldered with wires connected to the microcontroller. The thickness of copper tape with an adhesive layer was measured to be 60±1 μm. The middle layer was the piezoresistive material, velostat. Four copper electrodes were pasted on each protective layer. The size of each sensor pixel was 10 mm x 10 mm, and they were separated by a distance of 50 mm. Hence, it was a 4x4 sensor matrix with 16 individual pressure sensors and a total thickness of 434 μm (as measured by a Mitutoyo micrometer).
To analyze the reliability of the velostat-based pressure sensor, we conducted experiments for twelve months. In the first experiment, we tested the sensor's response every fortnight by applying a load of 1 kg to all sixteen sensors. We observed that with time, there is a change in the sensor response due to the non-homogeneous characteristics of the velostat. The sensor's response changed with an average standard deviation of 0.09 V. We also tested the sensor response to the application of higher loads by applying weights ranging from 1 kg to 12 kg every fortnight. We observed that there is less gradation in the resistance during the starting three months. As the molecules in the velostat start settling, the resistance shows more gradation on applying pressure and is closer to the ideal graph. We also evaluated the decay rate of the sensor. The decay rate is calculated by taking the sensor's response voltage ratio for all the weights. We observed that in the initial three months, there was a deviation in the decay rate by 0.11, which was reduced to 0.02 in the last six months' analysis.
The results obtained from the experimental tests for reliability show a practical possibility of implementing velostat-based pressure sensors in wearable and healthcare devices. The sensor mat is highly scalable and can be used in various applications like foot pressure monitoring, gait analysis, sitting posture recognition and correction, body pressure measurement, detection of bed sores, and many more.

SB10.05.13
Flexible Triboelectric Laminates—Energy Harvesters for Wearable Electronics Kaspars Malnieks, Andris Šutka, Linards Lapčinskis and Artis Linarts; Riga Technical University, Latvia

Triboelectric nanogenerator (TENG) devices have attracted considerable interest in the field of mechanical energy harvesting due to their low weight and mechanical softness. There are many innovative TENG devices from low-cost materials presented in the literature for mechanical energy harvesting from human motion, vibrations, wind, water flow, and waves[1].
Herein we report a new paradigm of triboelectric polymers – the triboelectric laminate – a volumetric material with electromechanical response comparable to the benchmark soft piezoelectric material polyvinylidene difluoride. The electromechanical response in the triboelectric laminate arises from aligned dipoles, generated from orientation of contact electrification in the laminates bulk volume. The triboelectric laminates where the polymer bilayers with different triboelectric properties are stacked to form laminates, together with the separator between each bilayer and for an electrodes we use flexible polyisoprene conductive carbon black composite. The dipoles are forming between sequential bilayers consisting of two different polymer fibres of different diameter. The loose interface between fibre bilayers ensures friction and triboelectric charging between two polymers. The electric output from the electrospun triboelectric laminate increases with increasing the density of bilayers.Triboelectric laminate generates Volumetric energy density of 21.13 $\mu J\ cm^{-3}$ and a peak average power density of 46.19 $\mu W\ cm^{-3}$ are observed from six layer laminate. Our material concept has clear benefits over the other flexible devices for mechanical energy harvesting. It does not require any poling procedures and electromechanical response is stable over 24 hours of continuous operation. Moreover, the electromechanically responsive material can be made from all types of polymers, thus providing ample of room for further improvements or functionalities such as stretchability, biodegradability, or biocompatibility. The concept of a triboelectric laminate can be

introduced into existing triboelectric nanogenerator form factors, to dramatically increase charge harvesting of a variety of devices.

This work has been supported by the European Regional Development Fund within the Activity 1.1.1.2 “Post-doctoral Research Aid” of the Specific Aid Objective 1.1.1 “To increase the research and innovative capacity of scientific institutions of Latvia and the ability to attract external financing, investing in human resources and infrastructure” of the Operational Programme “Growth and Employment” (No.1.1.1.2/VIAA/3/19/404)

Conductive Polymer Based Pressure Sensors for Optimization of String Instruments Practice Noemy Gagnon-Lafrenais, Pierre Kateb, Xin Zhou and Fabio Cicoira; Polytechnique Montréal, Canada

Repetitive movements in string instrument performance can lead to injuries such as tendonitis and muscular fatigue. It is believed that the pressure applied on a bow can influence the quality and magnitude of sound produced by the instrument. We are interested in exploring the correlation between the applied force at the hand and bow interface and the vibrations recorded on the stick of the bow.
Poly(3,4-ethylenedioxythiophene)polystyrene sulfonate (PEDOT:PSS):based[FC1] materials have been widely explored as potential candidates for precise pressure sensor[1]. Some recent applications, such as PEDOT:PSS polyurethane foam have been successfully demonstrated for a foot pressure sensor[2] .
In this project, we demonstrate a pressure pressuore sensor made of a PEDOT:PSS-based soft Organohydrogel which can be applied on the right hand at critical contact points whilst using a violin bow. The pressure sensor consists of an organohydrogel disk encapsulated in a transparent film. An interdigitated silver (Ag) electrode is printed on one of the substrates with an inkjet printer. The gel is a mixture of poly(3,4-ethylenedioxythiophene), ethylene glycol and tannic acid (PEDOT:PSS/EG/TA), which It has been demonstrated by our group that this material has a high conductivity of approximately 15 S/cm.
Cyclic compression tests have been realized on the organohydrogel. It has shown a response in resistivity for up to 7.5% strain for a 4 mm thick sample. The gel also showed moderate stability for up to 40 cycles. Moreover, we have been able to show that the designed pressure sensor has a response in resistivity to very subtle variations of pressure, while playing a two-octaves scales on the violin.
Future objectives are to study in more detail how the variation of applied force affects the resistance of the material. Furthermore, we wish to compare the effect of pressure on sound production by attaching a contact microphone to the bow. With these two sets of data, we will be able to build a model that will provide visual support when solving issues linked with string instrument practices. It will be a helpful tool in the optimization of sound production and the resolution of exceeding pressure that can link to injuries such as tennis and golfer’s elbow.

SESSION SB10.06: Functional Materials and Devices II
Session Chairs: Edwin Jager, Jesse Jur and Darren Lipomi

Hynes, Level 3, Room 311

8:30 AM SB10.06.01
Chip on a Fiber Toward the E-Textile Computing Platform Tae-Wook Kim; Jeonbuk National University, Korea (the Republic of)

Fiber electronics are of considerable interest for wearable applications and smart textiles, and they can facilitate communication and the interaction between humans and surroundings. As a basic element of functional textiles, the one-dimensional (1D) form of thread-like fibers offers high flexibility, isotropic deformations, breathability, and light weight in fabric structures. The 1D functional fibers can be further processed into two-dimensional (2D) textile and three-dimensional (3D) yarn configurations through traditional textile engineering techniques, such as twisting, weaving, sewing, knitting, knotting, and interlacing. Owing to such intrinsic merits, in recent years, fiber-based device components that perform optoelectronic functions, such as health/environmental monitoring, displays, sensing, energy harvesting, energy storage, electromagnetic shielding, and information processing, have been integrated directly into fabrics to demonstrate futuristic clothes. The existing electronic fiber platforms are generally composed of only one type of electronic component with a single function on a fiber substrate that is attributed to all around wrapping of an active layer on the entire fiber without patterning at the desired area on the surface of the fiber during the manufacturing process. Moreover, a precise connecting process between each electronic fiber is essential to configure the desired electronic circuits or systems into the 2D textile while minimizing the degradation of the device performance. Although assembly of those functional fibers can be used for recording, detecting, and readout data sequentially, similar to conventional integrated circuits and multifunctional devices on 2D wafers, both limitations on scaling down and difficulty in the configuration of the electronic circuit remain major obstacles for the implementation of practical electronic fiber systems. To impart multiple functions to the textile, the methods of inserting small electronic components into a fiber strand or yarn have been considered emerging candidates, enabling the implementation of a thermally drawn digital fiber and e-yarn. However, a limitation to the thermal drawing approach and the mounting of small components on the top surface of a filament is the low device density. A new strategy to fabricate a high-density electronic microfiber possessing multiple electronic components and circuits as well as maintaining excellent electrical performance has not yet been reported. In this work, we present a new electronic fiber platform that enables LSI of electronic device components on the surface of a 1D fiber, defined as a monofilament with a diameter of 150 μm. By using high-resolution maskless photolithography with a capillary tube-assisted coating method, multiple miniaturized device units are integrated onto a very narrow and thin fiber surface. As a proof-of-concept demonstration, basic electronic devices (field-effect transistors, inverters, and ring oscillators) and sensors (photodetectors, signal transducer, and distributed temperature sensors consisting of thermocouples) are fabricated onto the two different sides of the rectangular fiber. The chip on a fiber exhibits various electronic functions (UV detection and switching electrical signals in a single transistor, symmetric input/output behaviour in the n-type inverter, oscillation characteristics of 5-stage ring oscillator) and thermal sensing performance. We believe that our approach is one of the big steps to implement a high-density electronic fiber platform for integrated electronic textiles.

Continuous Wet-Spinning of Two-Dimensional Colloid Nanoplates into Fibers for Wearable Energy and Sensor Applications Tae Hee Han; Hanyang University, Korea (the Republic of)

The miniaturized fiber-based wearable devices are considered promising alternatives compared to conventional heavy three-dimensional (3D) and two-dimensional (2D) devices. Large-scale, straightforward wet-spinning of two-dimensional (2D) materials has emerged as a promising direction for processability to develop meter-long dimensional fibers. For example, graphene fibers (GFs) have great potential in future portable wearable electronics, which have gained considerable attention owing to high electrical conductivity, lightweight, tiny volume, outstanding mechanical flexibility, excellent

deformability, low cost, and the ability to be woven into smart textile fabrics. Herein this work, I introduce that GFs are derived from wet-spinning of graphene oxide (GO) dispersions which are demonstrated as safe electrodes for wearable energy and sensor applications. The Ni/NiO/GF sensors exhibit a 16-fold higher response to NO_2 gas and effective recovery characteristics. Furthermore, the Ni/NiO/GF with excellent mechanical flexibility and deformability were integrated into the commercial cotton fabric, thus demonstrating the feasibility of using the hybrid graphene fibers in wearable gas sensors. Additionally, hybrid metal oxide/GF all-solid-state supercapacitors exhibited an enhanced volumetric capacitance compared to pristine GF electrodes. The excellent performance and simple large-scale wet-spinning process pave the way for portable wearable electronics devices. Finally, I will introduce this wet-spinning strategy can be applied to another type of 2D nanosheets, such as MXene. By taking advantage of strong molecular interactions between MXene sheets, mechanically strong fibers can be fabricated by drawing the MXene gel. Because $Ti_3C_2T_x$ MXene fiber has dense lamella and a highly aligned multiscale structure, MXene fibers exhibit outstanding electrical conductivity and a high mechanical modulus compared with other MXene-based assemblies.

9:15 AM SB10.06.03
High Mobility Organic Electrochemical Transistors for Electronic Textiles Paula Alarcon Espejo[1,2], Ruben Sarabia[1,2], Maryam Shahi[1,2], Matthew Weisenberger[1,2] and Alexandra Paterson[1,2]; [1]University of Kentucky, United States; [2]Center for Applied Energy Research, United States

To date, PEDOT:PSS fibers demonstrate high electrical and thermal conductivity as well as exceptional mechanical properties making them promising candidates for use as fundamental building blocks of next-generation smart electronic textiles. Organic electrochemical transistors (OECTs) play an essential role in many bioelectronic applications. PEDOT:PSS is one of the most widely used channel materials in biocompatible OECTs due to its ability to facilitate mixed ionic and electronic conduction. Recently, the integration of PEDOT:PSS fibers in transistors has been a topic of interest due to its light weight, flexibility, and ability to integrate electronic functions in textiles. PEDOT:PSS fibers have potential to be used to obtain mechanical, electrical, chemical and thermal data for various environmental stimuli. One of the main challenges in OECTs device engineering is related to the contact interface between the semiconductor and the source-drain. Contact resistance affects charge transfer, lowering the performance in device operation and can lead to failure. In this work, we demonstrate the application of PEDOT:PSS fibers in OECTs and the performance of these devices based on the channel morphology and contact resistance.

Influence of Textile Architecture on the Electrical Resistivity of Inkjet Printed Ag Nanoparticle Inks Zixin Wang and Brian Derby; University of Manchester, United Kingdom

Textile substrates provide promising platforms for wearable technology that can provide both strength and flexibility making them potentially more comfortable to wear than rigid wearable alternatives. They can be made stretchable, breathable, and washable and are easily integrated into clothing. Inkjet printing is widely used to fabricate printed electronic devices and is also a common tool for patterning textiles. However, it is well known that the rough and porous textile surface makes it difficult to reliably print electrically conductive structures onto textile substrates. Here we report the use of X-Ray computed tomography (CT) to reveal the distribution of Ag ink after ink jet printing onto polyester textile substrates. CT images clearly show that the penetration of ink into the textiles is strongly influenced by the fibrous architecture of the fabric with capillarity confining the ink within the yarn tows running in the warp and weft directions of the weave. We have used image segmentation methods to identify connectivity of the silver objects after heat treatment and this demonstrates that connectivity, and hence electrical conductance, is less likely between tows running in each direction. This information shows that the electrical conductivity of a printed patch of Ag ink can be represented by a number of electrically independent Ag networks running in parallel and that the conductivity scales approximately with the size of the largest Ag network present.

Here we use CT imaging to analyse the distribution of Ag after printing and sintering in 6 different woven fabrics each made from the same polyester fibre with fibre diameter either 10 μm or 16 μm. Each fabric is a plain weave but with different yarn and fibre densities giving fabric weights in the range 80 – 450 $g.cm^{-2}$. We used a Fujifilm Dimatix 2800 to print 10 pL drops of a Ag nanoparticle ink at 10 μm drop spacing, with 5 layers of overprinting, to print identical patterns on each textile. After sintering at 150 °C the electrical properties of individual yarn tows in the fabric were measured using a 4-point probe. The printed fabric conductance values span three orders of magnitude, confirming the strong influence of fibre architecture on electrical properties. Image segmentation of the CT results from each fabric conclusively shows that the highest electrical conductance correlates with the presence of largest volume amongst the interconnected Ag objects. Three of the fibre architectures that show the highest electrical performance have equivalent conductivity values that are over an order of magnitude lower than that of bulk Ag and are also considerably lower than that achievable by inkjet printing Ag inks onto polymer film substrates. This work confirms that textile substrates can be used as substrates for printed conducting structures and that the fibre architecture controls the distribution of ink, the likely precision and resolution of deposition, as well as the conductivity of the printed structure.

10:15 AM SB10.06.05
Triboresistive Touch Position Sensors Younghoon Lee[1,2], Sungsoo Lim[1] and Jeong-Yun Sun[1]; [1]Seoul National University, Korea (the Republic of); [2]MIT, United States

Recent growing pursuit of skin-mountable devices has been impeded by the complicated structures of most sensing systems, containing electrode grids, stacked multilayers, and even external power sources. Here, a type of touch sensing, termed “triboresistive touch sensing”, is introduced for gridless touch recognition based on monolayered ionic power generators [1]. A homogeneous monolayer, i.e., ionic poly(dimethylsiloxane) (PDMS), generates electricity based on the electric field generated by touch. Voltages generated at each corner of the ionic PDMS rely on resistance between touch points and each corner, ensuring recognition of the touch positions without the need for electrode grid layers and external power sources. With notable advantages of high transparency (96.5%), stretchability (539.1%), and resilience (99.0%) of the ionic PDMS, epidermal triboresistive sensing is demonstrated to express touch position and readily play a musical instrument. A gridless system of triboresistive sensing allows rearrangement of the touch sections according to a given situation without any physical modification, and thus easily completes consecutive missions of controlling position, orientation, and gripping functions of a robot.

Lightweight and Flexible Flat-Knit Metasurfaces, Reflectarrays and Array Antennas Michael Carter[1], Leah Resneck[2], Younes Ra’di[3] and Nanfang Yu[1]; [1]Columbia University, United States; [2]North Carolina State University, United States; [3]The City University of New York, United States

Phased arrays and more generally metasurfaces are a ubiquitous class of optical devices that operate based on the local control of the phase response, and sometimes amplitude response, of individual antenna elements in an overall array ordered such that the collective phase response satisfies some required profile needed to shape an outgoing reflected or transmitted wavefront in a desired manner [1-3]. Lightweight, low-cost phased arrays and metasurfaces that are easily stowable and deployable are desirable for a number of terrestrial and space-based communications and sensing applications [4-5]. Textiles represent an appealing platform for lightweight, low-cost and flexible antennas and considerable research attention in the past few decades has been dedicated towards developing simple fabric-based wearable antennas for communications and on-body sensing applications [6-9]. Considerably less research effort has been dedicated towards fabric-based antenna arrays and more complex types of antennas, such as Yagi-Uda antennas, reflectarrays and other types of functional textile-based devices such as frequency-selective surfaces and integrated waveguides [10-12].

In this work we demonstrate a novel type of lightweight, flexible textile metasurfaces and array antennas made via flat-knitting; these include a metasurface lens, a metasurface vortex beam generator, and a Yagi-Uda antenna. The textile devices were fabricated using a Shima Seiki SRY123LP flat-knitting machine at the Zeis Textile Extension – Knitting Laboratory, NCSU. Two meta-unit archetypes based on different colorwork knitting techniques were used: a simple patch antenna archetype utilizing intarsia colorwork for the Yagi-Uda antenna and a more complex float-jacquard antenna archetype for the metasurface lens and vortex beam generator. Characterization of the device performance in the mm-wave frequency range was carried out at the Advanced Science Research Center, CUNY, and all three devices exhibit desired wavefront shaping capabilities. We compare the tradeoffs between intarsia and float-jacquard flat-knit metasurfaces and compare our flat-knit devices to traditional planar rigid metasurfaces and reflectarrays. Finally, we comment on extensions of this work towards quasi-3D and conformal flat-knit array antennas.

A Washable and Reusable Sensor System for Moisture Detection Ji-Tzuoh Lin and Cindy Harnett; University of Louisville, United States

This presentation investigates the integrity and repeatability of a washable system for moisture detection that integrates a polymer optical fiber (POF) with a consumer optical time-of-flight (ToF) sensor at the edge of an absorbent textile. Throughout the COVID-19 pandemic, disposable paper products have been in short supply, including diapers, paper towels, respirators, tampons, and incontinence supplies. Interest in washable and reusable products has soared. At the same time, there is a growing product roster of disposable electronic sensors for healthcare, such as moisture sensors in disposable diapers. These devices typically interface with a computer using resistive electronic traces and are not intended to be reused. Non-noble metal thin films, including the silver plating used in many e-textiles, corrode over time with exposure to water, losing their conductivity. All-polymer optical fiber based sensing methods promise a better washability outcome, as long as the materials can detect the signal of interest and can handle the mechanical stress of the wash-and-dry cycle. Better printable electronic materials, alloys, and soft composites are being developed, but soft optical sensors also have two key advantages versus electronic sensors: lower temperature sensitivity, and immunity to electromagnetic interference. The materials are deformable and often intrinsically stretchable, with similar mechanical properties to wearable stretch fabrics and soft robotic systems.

In the work reported here, a moisture sensor created from a plastic optical fiber (POF) is embedded in an absorbent bedding system that connects to a detachable optoelectronic readout module. This solution addresses the supply-chain challenge through reusability. The most popular type of plastic optical fiber (POF), polymethyl methacrylate (PMMA), is more suitable than glass fiber because of its flexibility and ability to recover from few-percent strains. However, PMMA is mildly hygroscopic. Fibers that absorb water can become brittle during the machine wash cycle, which soaks, rinses, and tumbles the fibers, resulting in fatigue on the fibers and ultimately breakage. Our approaches include three upgrades to commercial PMMA fibers. First, a waterproof coating is developed to mitigate damage to PMMA optical fiber caused by water absorption during the washing cycle. Second, a commercial embroidery machine is used to attach the fibers along paths in a nonwoven stabilizer layer with closely-spaced stitches, for well-distributed mechanical stress along the fiber. Third, PMMA is compared to alternative urethane-based fibers that have lower optical clarity but better stretchability for mechanical resilience.

A magnetic housing was also developed for quickly and uniformly assembling connectors onto the ends of soft waveguides, increasing the optical transmission of soft materials by improving their alignment with the optical source and detector. The connector provides a quick and repeatable reconnection to the sensor pad after the wash.

In the tests to be presented, PMMA fibers and other POFs are integrated into fabric pads, connected to junctions whose optical transmission changes in the presence of moisture, and the optical transmission in wet and dry conditions is tested with the magnetically-coupled optical source/sensor pair both before and after wash cycles. The integrity of the fiber is validated by comparing the wet/dry contrast intensity of the fibers before and after the wash cycle.

Direct Handwriting of All-Solution-Processed and Intrinsically Flexible Multicolor Perovskite Light-Emitting Diodes and Photodetectors on Textiles and Papers Junyi Zhao[1], Li-Wei Lo[1], Zhibin Yu[2] and Chuan Wang[1]; [1]Washington University in St. Louis, United States; [2]Florida State University, United States

Textiles and papers, made of percolation yarn- and fiber- networks, are commonly used in our daily life and they hold great potential to be platforms for next-generation flexible and wearable electronics. In this work, we report a versatile and ultra-fast mask-free fabrication strategy that enables direct handwriting of all-solution-processed halide perovskite optoelectronic devices onto papers, textiles (cotton, polyester, and nylon), and other unconventional

substrates including metal foil, plastic film, rubber balloon, vinyl glove, and even 3-dimensional surfaces such as glass vial or spheres. More specifically, we have developed and formulated universal electronic inks that could either be used in printing/coating machines or loaded into ballpoint pens for direct handwriting on target substrates. These electronic inks include poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and poly(ethylene oxide) (PEO) composite ink for transparent anodes, perovskite and polystyrene (PS)/ poly(methyl methacrylate (PMMA) composite ink for the photoactive layer, polyethylenimine (PEI) ink for the electron transporting layer, and silver nanowires ink for semi-transparent cathodes. The PEO component blended in the PEDOT:PSS conducting ink not only helped planarize the rough percolating yarn/fiber substrates, but also improved the conductivity and conformability of conducting film, thus leading to improved device performance and stability. By directly writing the above functional inks onto the substrate layer by layer, we have demonstrated high-performance multicolor light-emitting diodes (LEDs) with emissions covering the entire visible spectrum and photodetectors (PDs) in both a vertical photodiode configuration and a planar photoconductor configuration. The direct-drawn LEDs exhibited a brightness as high as 15,225 cd m^{-2} with a turn-on voltage of 2.4 V; and the PDs exhibited an on-off ratio over 10^4, a responsivity up to 132 mA/W, and a response time of less than 15 ms. Compared with existing microfabrication and printing processes, the direct handwriting approach allows high-performance optoelectronics being easily fabricated by untrained individuals in a time-efficient and cost-effective manner. The formulated inks buffered with handwriting technique are especially meaningful for early-stage demonstration and ideally suited for low-cost and large-area application scenarios such as E-Textiles, E-Packaging, and E-Papers with less stringent requirements on resolution. Additionally, the handwritten LEDs showed extraordinary robustness which could be bent to a 1 mm extreme curvature radius for over 5000 cycles without decay in performance. Overall, such low-cost and eco-friendly textile/paper-based LEDs and PDs could pave way for the integration of optoelectronics with wearable and human-machine interface applications.

Ultra-Lightweight and Ultra-Flexible PDMS/MWCNT Open-Cell Foam Nanocomposite BioSensors for Pressure Mapping Pardis Ghahramani, Kamran Behdinan, Hani E. Naguib and Zinan Cen; University of Toronto, Canada

Biomedical pressure-detecting sensors have attracted great interest in a wide spectrum of healthcare monitoring applications including injury prevention and motion analysis. However, current technologies in the market possess some drawbacks including low working pressure ranges, high hysteresis effects, and low recoverability in conditions where limited air ventilation exists such as shoe insoles, which adversely affect the performance of these sensors. To overcome these challenges, in this study a novel ultralightweight piezoresistive open-cell foam nanocomposite sensor which operates based on resistivity change in the material while an external force is applied to it, is designed and fabricated. Polydimethylsiloxane (PDMS)/multi-walled carbon nanotube (MWCNT) foam nanocomposite with two governing factors of porosity and conductive filler content was fabricated by a manufacturing approach that integrated solution casting and particulate leaching method. Mechanical properties of PDMS/MWCNT open-cell foam nanocomposite were characterized by the compression tests and its elastic and plastic behaviour were investigated. Experimental results indicated that samples with 60% porosity had higher energy absorption and mechanical strength than the samples with 70% and 80% porosities. Moreover, foam nanocomposites at the same porosities showed larger energy absorption and mechanical strength when they contained higher MWCNTs in their structure. PDMS/MWCNT foam nanocomposite demonstrated high flexibility, high compressibility up to 90%, and high recoverability in addition to limited mechanical hysteresis (less than 3%) without experiencing noticeable macroscopic damage which provides a great advantage over the similar piezoresistive sensors in the literature.

11:30 AM SB10.06.10
Self-Assembly in Supercritical Fluids—High Resolution Patterning on Curved and Flexible Surfaces Loren G. Kaake; Simon Fraser University, Canada

Organic electronic devices, especially those based on polymeric materials, offer the promise of highly flexible and stretchable circuitry and wearable electronics. However, manufacturing techniques for these promising devices has lagged behind materials development. Contrast this with small molecule devices on rigid substrates, where physical vapor deposition has already brought organic light emitting diodes into widespread use. Key advantages of this technique include thin film deposition without the need for complex in-situ chemical transformations as well as fine and highly reproducible patterning. We have developed a method of thin film formation that has all of the advantages of physical vapor deposition, while working with polymeric materials and enabling deposition on curved and flexible substrates. This technique leverages the unique properties of supercritical, near-critical, and/or subcritical fluids.[1] Counter to typical solutions, the saturation solubility of a solid solute first increases, and then decreases with increasing temperature near its critical point. We have leveraged this non-monotonic solubility behavior to deposit films onto a heated substrates. The decreasing solubility at the substrate surface simply precipitates the polymer from solution. Because the substrates are heated resistively, we can control the local heating by patterning resistive heating elements on the substrate. This we accomplished by performing photolithography on a substrate coated with indium tin oxide. When the lines were resistively heated, material deposited directly and selectively onto them. The technique also works when a thin polymer layer is inserted between the electrode array and the supercritical fluid, allowing the photolithographically patterned electrode array to serve as a patterning master for additive manufacturing onto thin and flexible materials. Moreover, the technique does not rely on line of sight mass transfer or cumbersome printing heads. We leveraged this advantage to deposit materials on to the curved interior of an elastomeric hemisphere approximately 3 mm in diameter.[1] The process will be shown to work with an aliphatic polymer and two types of organic semiconducting polymers.[2, 3] We postulate that this is a generalizable and scalable manufacturing technique that will become vital in the development of high resolution polymer circuitry.

Haptic Biomaterials for Two-Way Communication with Human Physiology Darren J. Lipomi; University of California, San Diego, United States

Human culture is replete with artifacts that interact with the senses of sight, hearing, taste, and smell. Material objects whose purpose is to produce a thoughtful or emotional response through the sense of touch, however, are rare. In this talk, I present my group's recent work on the intersection between the science of soft materials and the science of touch. This field, which we have named "organic haptics," combines active polymers, contact mechanics, and psychophysics. We are beginning to understand the ways in which stick slip friction, adhesion, and capillary forces between planar surfaces and human skin affect the ways materials produce tactile objects in consciousness as mediated by the sense of touch. This work, which combines human subject experiments, laboratory mockups of human skin, and analytical models accounting for friction, has led to several important observations. In particular, we have elucidated the mechanism by which humans can differentiate hydrophilic from hydrophobic surfaces when bulk parameters such as hardness, roughness, and thermal conductivity are held constant. We examined the role of relief structures in the skin—i.e., fingerprints—in determining the human ability to differentiate between surfaces. We have taken the insights from these psychophysical experiments to design new electroactive and ionically conductive materials to produce "actuator skins" whose goal is to produce realistic sensations for applications in tactile therapy, instrumented prostheses, education and training, and virtual and augmented reality.

Electromechanical Simulation for Predictive Design of Textile Electronic Systems Caitlin Knowles, Beomjun Ju, Kun Luan, Marissa Noon and Jesse S. Jur; North Carolina State University, United States

The electronic textile (e-textile) substrate has a substantial impact on the electrical performance, yet this impact is rarely evaluated in literature as fabrics have non-linear, anisotropic physical properties that are difficult to predict. The surrounding textile platform is therefore largely unexplored in its ability to enhance or degrade the electromechanical performance of the system. Cloth simulations generally require complex geometrical models and high computational expenditure. However, the recent emergence of particle-based 3D garment simulation in the apparel industry has allowed for rapid and increasingly accurate simulations. This work describes a methodology of predictive design and modeling of screen-printed interconnects using a particle-based 3D garment simulation tool. Specifically, the impact of various polyester-spandex substrates on the electromechanical performance was investigated and a simulation technique to predict the electrical resistance change with elongation was evaluated. A system-first testing method was developed to reliably assess the substrate impact on the system's electromechanical performance. The experimental set-up was then simulated using both particle-based and finite element simulation techniques. The relative resistance change ($\Delta R/R_0$) at 25% strain ranged from 8.2%-60.3% depending on the fabric substrate, with positive correlations between the electrical performance and the stiffness in the stretching direction. The same correlations were observed in the simulated stress and strain in the interconnect, providing evidence that the 3D simulation program can be used as a predictive platform for prototyping. The proposed method demonstrates the potential of particle-based, 3D garment simulation programs for a rapid, scalable, and accessible performance-predictive design of e-textile products.

Piezoelectric Fibers Endow Textiles with Acoustic Functionalities Grace H. Noel[1], Henry Cheung[1], Wei Yan[2] and Yoel Fink[1]; [1]Massachusetts Institute of Technology, United States; [2]Nanyang Technological University, Singapore

As hierarchical structures that contain multiple interfaces that serve as scattering points, textiles are traditionally thought of as structures that damp vibrations and sound. Harnessing the sensitivity of a piezoelectric composite in a fiber form factor, however, we introduce new ways for textiles to interact with sound by incorporating the "acoustic fiber" into fabrics. First, we weave an acoustic fiber into traditional fabrics to develop fabric microphones to capture sound. The acoustic fibers are created using a thermal drawing technique in which viscoelastic materials flow in a laminar regime, maintaining the cross-sectional geometry of the preform. In the fiber device, the piezoelectric domain of P(VDF-TrFE) with 20 wt% barium titanate nanoparticles is sandwiched between two carbon-loaded polycarbonate electrodes, each containing two copper wires that are fed in during the draw. The active layer and electrodes are encapsulated by a soft SEBS elastomer cladding. The measured d_{31} piezoelectric coefficient of the active domain of the fiber is 46 pC/N, which is more than double the values reported previously in literature (~20 pC/N). Coupling the acoustic characterization with laser vibrometry measurements, we deduce that the modulus of the fabric influences the curvature of the fiber, which is key to its electrical output. Through an axial bending mechanism, the fiber couples to the fabric to detect nanometer-scale vibrations in the fabric that result from the incoming acoustic pressure. In addition to fabric microphones, the acoustic fiber lends itself to many diverse applications. An array of fibers can be used to determine the direction of incident sound, and the fiber woven into a shirt can detect heartbeat and breathing rate. Additionally, rather than damping sound, textiles can be used as speakers, creating sound by applying a voltage to an acoustic fiber on fabric. Recent advances in these particular applications will be discussed.

3:30 PM *SB10.07.04
Electroactive Textile Actuators for Soft Exoskeletons and Wearable Haptics Edwin Jager; Linköping University, Sweden

Conducting polymers like polypyrrole can be electrochemically oxidised and reduced. These redox reactions are accompanied by a flow of counter ions and solvents from the electrolyte into or out of the polymer matrix to maintain charge balance and osmotic pressure resulting in a volume change of the conjugated polymer. This volume change can be exploited to fabricate electrochemically driven actuators in various formats from bending bilayer microactuators to macroscopic textile actuators. Yarn and textile actuators are fabricated by coating commercially yarns and fabrics with such conjugated polymers. First a thin layer of PEDOT (poly(3,4-ethylenedioxythiophene)) is applied to make the yarns or fabrics electrically conductive. Next, the yarns/fabrics are coated with the electromechanically active polypyrrole using electro-synthesis. Finally, the yarn/textile actuators are actuated by applying the appropriate redox potentials. To achieve in-air actuation, the yarns/fabrics are coated with ionogels, that function as the ion source/sink to drive the electrochemical reactions. Two ionogel coated yarns are assembled forming the anode/cathode pair of the electrochemical circuit enabling fully integrated, in-air actuation. Using advanced textile processing such yarn actuators are integrated into fabrics using weaving or knitting.These textile actuators can be integrated in garments such as soft exoskeletons and wearable haptic devices. The latest results of our textile actuators will be presented.

4:00 PM SB10.07.05
Inkjet-Printed Controllable Textile Strain Sensors for Human Motion Detection Beomjun Ju, Caitlin Knowles and Jesse S. Jur; North Carolina State University, United States

Flexible strain sensors have been attractive recently to detect and monitor human motion detection for an entertaining purpose like VR or AR, and medical purpose like rehabilitation. However, current strain sensors are not feasible to integrate with wearable platforms due to the complicated manufacturing and embedding issues. Electronic textiles (e-textiles) can be an attractive alternative to conventional rigid and bulky sensors because of intrinsic textile properties such as flexibility, stretchability, breathability, washability, and high durability under extreme deformations. This work presents a novel technique for developing textile strain sensors by only inkjet-printing of metal-organic decomposition silver ink on knit fabrics along with different directions (warp, weft, bias).

For material selection, we printed a 5×20 mm conductive pattern along with bias direction on knit fabrics having different tightness. The gauge factor increased from 0.16 to 19.7 according to the increase of the tightness factor of the fabrics from 2.35 to 3.46. This is related to the ink penetration depth depending on the tightness factor. Also, yarn-level structural changes while stretching showed direction-dependent behavior. This affected the relative resistance change and gauge factor because the number of contact points between conductive paths on the yarns changed during deformation. Stretching along with weft direction showed the lowest gauge factor for all fabrics, and there was a drastic resistance increase or instant off-state along with warp direction. Stretching along with bias direction combining both warp and weft direction showed a reasonable gauge factor. Also, the gauge factor of the strain sensors can be controlled by printing paths. The increase in the number of printing paths made the ink more penetrated and showed a lower gauge factor. This means that the printed pattern can work as a strain sensor or interconnect by arranging pattern directions and printing paths. Also, the knit-based textile strain sensors have a wide range of sensing performance up to 60 % due to high flexibility as knit fabric's own property.

For a use-case scenario in wearable technologies, we fabricated a full arm sleeve with two parts of printed conductive paths, including the strain sensor along with bias direction and interconnect along with weft direction, then connected to a readout circuit and Bluetooth data transmission system. The strain sensor-embedded armband showed the resistance change that can be translated to the strain by elbow motion. This allows for a full range of elbow motion to monitor the movement without having bulky equipment attached to the arm and should remain comfortable and breathable without hindering the effectiveness of the fabric. Also, we simulated the armband prototype using CLO 3D, which is commercial particle-based 3D garment simulation software, to predict the sensing performance of the developed sensors. Due to the facile process of directly inkjet-printing on fabrics, the developed textile strain sensors can be easily integrated with wearable devices for human motion detection. Thus, they have huge potential in practical and manufacturable applications.

Perfusable Knits—Knitted Silicone Tube for Wearable Device Atsushi Takano and Michinao Hashimoto; Singapore University of Technology and Design, Singapore

Background. Wearable devices with embedded fluidic channels have demonstrated reconfigurable applications as fluid-based sensors and actuators (e.g., conductive ink, liquid metal and compressed air). Methods for fabricating flexible constructs with fluidic channels are essential for the development of wearable devices with advanced functions. Currently available fabrication methods are primarily based on soft lithography and three-dimensional (3D) printing, however, which are yet suboptimal in terms of fabricating embedded fluidic channels in large surface areas with complex 3D structures.

Contribution. We present an alternative route to fabricate channel-embedded, flexible constructs by knitting silicone tubes and structural yarns, which we termed perfusable knit (PK). Silicone tubes serve as both the structural components (i.e., the part constituting the textile and garments) and the functional components (i.e., the part where functional fluids are infused or perfused).

Techincal achievement. PK was fabricated with a manual knitting machine using commercially available silicone tubes with 2-mm outer diameter (OD) and 1-mm inner diameter (ID). Fabrication of two-dimensional (2D) textile and three-dimensional (3D) wearable devices was readily achieved by this approach. We identified knitting gauges and patterns of knitting (e.g., jersey, rib and garter) suitable for the fabrication of 3D knitted structures. Inlay knitting with an automated knitting machine was also demonstrated to integrate silicone tubes with the textile, which served as another platform to handle liquid embedded in the textile. Tensile tests confirmed that the elongation of the textile knitted with silicone tubes was anisotropic in terms of stretchability. The textile made of the silicone tube filled with conductive ink exhibited deformation-specific electrical responses that can be used for motion sensing. Crucially, the mechanical anisotropy affected the electrical responses exhibited by embedded conductive inks. As a demonstration, a wearable force sensor in the form of a mitten consisting of silicone tube, acrylic yarn, and conductive fluids were developed for motion sensing of the finger using electrical resistance.

Significance. Overall, we developed a unique fabrication method for flexible and wearable devices by directly knitting perfusable silicone tubes. We envisage that PK will provide alternative routes for the design and fabrication of 3D wearable devices containing functional fluids, allowing for the sensing of electrical and chemical signals using sensors integrated into garments.

E-Textiles Power Modules—Removing the Reliance on Conventional Batteries S.P. Beeby[1], Sheng Yong[1], Nick Hillier[1], Junjie Shi[1] and Mahmoud Wagih[2]; [1]University of Southampton, United Kingdom; [2]University of Glasgow, United Kingdom

Whilst research into electronic textiles (e-textiles) has led to ever-increasing levels of functionality and integration, the supply of power is typically limited to the use of conventional rigid batteries. Improved integration enables electronic systems to be hidden within a textile and become invisible to the user but the supply of power has not kept pace with these developments and the reliance on batteries compromises the concealed nature of the system as a whole. Removing the reliance on traditional batteries requires alternative energy supplies and/or textile-based energy storage devices (supercapacitors or batteries).

Power can be supplied by a variety of energy harvesting technologies that can convert ambient sources of energy into electrical power. Sources of power include the kinetic energy associated with the physical displacement of, or strains within, a textile. Thermal energy can be captured from temperature gradients across a fabric and solar energy in the form of light incident on the surface of the fabric can also be harvested. In addition, wireless power transfer (WPT) offers the potential to capture electromagnetic energy. These energy sources could be used to power e-textile systems directly or, more likely, to recharge textile-based energy storage devices.

This talk presents an overview of energy harvesting, WPT and energy storage devices explored at the University of Southampton. Kinetic energy has been harvested from textiles using piezoelectric, ferroelectret and triboelectric transduction mechanisms. Thermal energy harvesting has previously been demonstrated using printed thermoelectric generators. Thin film organic and dye sensitised photovoltaic cells have also been realised on textiles. WPT research includes flexible textile antennas developed to capture radio frequency electromagnetic waves and textile-based coils used to transfer energy using resonant inductive power transfer. Examples of textile-based supercapacitors and batteries will also be presented. Finally, textile power modules that

combine mechanical and RF energy harvesting power sources with the textile-based energy storage will be demonstrated. The talk will highlight the challenges and constraints that arise when working with textiles and discuss the future work required remove the reliance on conventional batteries.

Battery-Free, Tuning Circuit Inspired Wireless Sensor Systems for Detection of Multiple Biomarkers in Bodily Fluids Jinghua Li; Ohio State University, United States

Tracking concentration of biomarkers in biofluids can provide crucial information about health status. However, the complexity and non-ideal form factors of conventional digital wireless schemes impose challenges in realizing bio-integrated, lightweight, and miniaturized sensors. Inspired by the working principle of tuning circuits in radio frequency electronics, our recent study reports a class of battery-free wireless biochemical sensors: in a resonance circuit, the coupling between a sensing interface and an inductor-capacitor oscillator through a pair of varactor diodes converts a change in electric potential into a modulation in capacitance, resulting in a quantifiable shift of the resonance circuit. Proper design of sensing interfaces with bio-recognition elements enables the detection of various biomarkers, including ions, neurotransmitters, and metabolites. Demonstrations of “smart accessories” and miniaturized probes suggest the broad utility of this circuit model. The design concepts and sensing strategies provide a realistic pathway to building bio-integrated electronics for wireless biochemical sensing.

9:15 AM *SB10.08.05
Two-Dimensional Field-Effect Heterostructures for Wearable and Textile Electronics Felice Torrisi; Imperial College London, United Kingdom

Solution processing of graphite and other layered materials provides low-cost stretchable inks enabling electronic textile devices [1]. However, the limited quality of the two-dimensional (2d) material inks, the complexity of the layered arrangement, and the lack of a suitable dielectric 2d material ink [2] has impeded the fabrication of active field effect devices on fabric based on fully-printed 2d heterostructures. In this talk I will demonstrate fully inkjet printed 2d material active heterostructures with graphene, MoS2 and hexagonal-boron nitride (h-BN) links (Fig 1a), and use them to fabricate all inkjet printed flexible and washable ambipolar, n- and p-type field effect transistors (FETs) on textile, reaching a field effect mobility of µ ~ 105 ± 29 cm2 V-1 s-1 on polyester fabric, at low operating voltages (< 5 V) (Fig. 1b). The devices maintained their performance even under ~ 4% tensile strain and showed stable operation for periods up to 2 years, indicating the two-fold role of the h-BN layer as a flexible dielectric and encapsulant. Finally, I will show how hybrid inkjet-printing of 2D and organic semiconducting inks enables all-printed complementary logic circuits [4] on rigid and flexible substrates. The viability of our process for printed and textile electronics is demonstrated by fully inkjet printed electronic circuits, such as reprogrammable volatile memory cells, complementary inverters, and OR logic gates with graphene/h-BN FETs.

Semiconductor Fibers for Smart Clothing Gang Wang; State Key Laboratory for Modification of Chemical Fibers and Polymer Materials, Donghua University, China

Semiconductor devices in the form of fibers and fabrics have important applications in the fields of information and communication, medical care, human-machine interface etc. How to obtain good flexibility and weavability while maintaining excellent semiconductor performance and then integrate industrial weaving technology is the key to realize its application in the field of wearable smart fabrics. And the introduction of fiber structure through shear processing is an effective way to achieve this. In the field of semiconductor hybrid fiber and integrated fabric electronics, our work is mainly carried out in the following three aspects. First, design high-performance semiconductor printing ink. By regulating the aggregation and rheological properties of semiconductor polymer molecular chains, we obtained the printing ink with excellent printing and semiconductor performances. Second, prepare large-area and high-oriented flexible thin film transistor devices by microfluidic printing. Based on the idea of multi-dimensional hybrid design, we built the high-precision microfluidic printing equipment. Through shearing and manifold design, we realized the printing preparation of nanofiber-based flexible transistor arrays. Thirdly, construct single-fiber logic devices. The micro-nano structure regulation idea that make fibers by microfluidic shear and proton exchange was proposed to realize the continuous preparation of semiconductor hybrid fiber at the kilometer level, obtaining signal amplification, logic operation and other functions, and also exploring the application in smart clothing.

9:30 PM SB10.09.02
Electromechanical Properties of Wearable and Flexible Pressure Sensing Fabrics Enabled by Integrating Yarn Sensor into Textile Structure for Compression Textiles Yiyi Yang, Xiao Tian, Ben Niu and Tao Hua; The Hong Kong Polytechnic University, China

Compression textiles are functional textiles that can apply pressure to specific areas of the human body for a variety of purposes, which are commonly made by using extensible and elastic woven and knitted fabrics. When the extended fabric is worn, such as on a cylindrical shaped limb, internal stress will be generated in the fabric, and thus the resultant interfacial pressure will be exerted onto the body. In this regard, an elastic strain sensing fabric can be used

to measure the resultant pressure. However, there is very limited literatures on the study on such strain/pressure sensing fabrics as well as the dependence on the influencing parameters. In this study, a pressure exerting and sensing fabric was firstly developed by integrating yarn based polydopamine-enhanced strain sensor into elastic woven fabric substrates via advanced weaving technologies. Herein the fabrication and characterization of the strain/pressure sensing fabrics were demonstrated, and the effects of woven fabric structure and parameters upon sensing outcomes were investigated. To find out the most appropriate parameters for fabric substrates, the fabrics in three different structures with varied densities were developed. Fabrics which perform the best in the elastic and recovery test were chosen as the substrates, in which the yarn-based sensors were integrated into for fabricating strain/pressure sensing fabrics. The mechanical and electromechanical properties of the strain/pressure sensing fabrics under both unidirectional tension and a curved form were evaluated by using a newly setup of a test protocol. Consequently, the pressure-displacement and electrical resistance-displacement curves as well as the resultant electrical resistance-pressure were obtained to characterize the fabric sensor developed in terms of electromechanical properties. The experiment results show that the fabric pressure increases with the increase of press depth, and thus the increase of the electrical resistance of extended sensing fabrics, presenting good sensing performance including sensitivity, hysteresis as well as repeatability. Moreover, the results have further revealed the effects of fabric substrate parameters on the sensing properties, including fabric density and applied fabric pretension. The sensing fabrics also show very good stability under 2000 press-release cycles, indicating the ability to enable a continuous monitoring on the applied pressure. In addition, the fabrication of these sensing fabrics was relatively convenient. Therefore, it is expected to be compatible with industrial manufacturing for fabricating flexible and large-area fabric-based sensors for various applications in a foreseeable future.

Fibrous Supercapacitor and Hydroelectric Nano-Energy Generator Using Silk-Based Conductive Textile Byungil Hwang; Chung-Ang University, Korea (the Republic of)

With the acceleration of technological advances in flexible and wearable electronics, there are needs for a highly reliable wearable energy storage and harvesting system. Fibrous supercapcaitor and hydroelectric nano-energy generator are promising candidates for the power sources of wearable electronics due to their flexibility and seamlessness to human body. To fabricate the fibrous energy storage and harvesting system, the development of reliable fibers that can supply electrical power even under harsh external damages. In this study, highly conductive and reliable silk yarns are developed utilizing an Ag nanowire, multi walled carbon nanotubes (MWCNT, 3 – 7 walls), and poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) composite coating. The conductive silk yarn electrodes are fabricated via a sequential dip-coating process of silver nanowires, multi walled carbon nanotubes (MWCNT, 3 – 7 walls), and poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS). The composite-coated silk yarn electrodes are stable under cyclic bending as well as under washing in water. Due to the synergetic effect of the three conducting materials, an excellent electrochemical performance is obtained resulting in high volumetric energy and power densities of 8-13 mWh cm^{-3} and 8-19 W cm^{-3}, respectively. A yarn-type supercapacitor is demonstrated by integrating composite-coated silk yarn electrodes with a hydrogel electrolyte, showing a promising stability as evidenced by the retention of over 94% and 93% of the specific capacitance after 90 degree bending and stretching. In addition, the conductive fibers are applied to hydroelectric nano-energy generator. Transpiration driven ion conduction through the conductive fibers generates electrical current more than 4,000s by dropping water. The potential of the fibrous hydroelectric nano-energy generator to operate a small wearable device is demonstrated. The developed fibrous supercapacitor and nano-energy generator with the excellent mechanical and electrochemical stabilities will be a promising candidate for a sub-energy storage/harvesting system of the next generation wearable electronic devices.

10:05 PM SB10.09.04
Effects of Super-Elastic Dielectric Yarn in Multi-Yarn Knits for a Highly Stretchable Strain Sensor, Resistor and Interconnect in a Single Knit Hong Yee Low[1,1,1], Ujjaval Gupta[1,1], Pei Zhi Chia[1,1], Ying Yi Tan[1,1], Jun Liang Lau[2] and Gim Song Soh[1,1,1]; [1]Singapore University of Technology and Design, Singapore; [2]Rehabilitation Research Institute of Singapore, Singapore

Multi-yarn knitting is a promising approach to achieve electrically functional textile. Through computer numerical control (CNC) knitting, multiple yarn types can be knitted in a single knitting process hence the properties of the knitted fabric are the results of complex interplay between the intrinsic properties of the yarns (or combination of yarns) used and the knit structures (loop length and stitch patterns). Much research in CNC knitting has focused on the development of functional yarns, particularly electrically conductive yarns. Such yarn has been incorporated in the form of electrically conductive knit pattern and have been demonstrated as strain/stretch sensors, piezoelectric and capacitive sensors for wearable and non-wearable applications. Current approaches have focused on improving the sensitivity and repeatability through specially formulated yarn as a single conductive component in the knit, however, are generally limited in the form of simple geometry such as stripe and patch.
In this work, we report the design and fabrication of strain sensor, electrical interconnects and resistor distributed within a single piece of the knitted soft wearable in a single knit job. The strain dependent electrical resistance pattern for the sensor, interconnect and resistor are greatly contrasting. In a strain sensor, it is desirable to produce a large change in resistance for enhanced sensitivity. On the other hand, an interconnect or a resistor should produce negligible change in resistance when stretched, with further requirements for interconnect to have low electrical resistance while resistor to have high electrical resistance. The vastly different electrical characteristics of the knit was achieved through the mechanical coupling between electrically conductive and dielectric yarns.
In multi-yarn knitting, the type of mechanical coupling between yarns of dissimilar properties depends on the intrinsic properties of the yarn and the stitch pattern. The stitch patterns are a unit cell of knitting instructions that repeat periodically to form a knitted fabric. It has been determined that a high ratio of the Young's modulus of the conductive yarn (E_c) to that of the dielectric yarn (E_d), $>10^3$ is an important enabling factor. In a knitted textile, the super-elastic dielectric yarn functions to control the electrical contact points in the conductive yarn (negligible stretchability) in the following manner: enables periodic contact points formation and breaking in the conductive yarn during stretching of the textile (strain sensor). The dielectric yarn also preserves the original contact points in the conductive yarn during stretching of the textile (interconnect and resistor) and prevents the formation of contact points (resistor) in the conductive yarn during stretching of the textile. Through the above design approach, a highly stretchable all knitted electrical components of sensors and a network of interconnects in the form of a knee brace has been achieved. As a soft wearable, the knitted sensorised knee brace is in close contact with the skin, allowing the customization of the sensor placement based on skin strain measurements. Through user tests, knee joint motions

obtained from the knee brace with knitted electrical components have been validated with image capture motion sensing data (VICON).

10:20 PM SB10.09.05
Uni-Active Material Comprised Triboelectric Nanogenerator for High-Performance Wearable Electronics Anand Babu and Dipankar Mandal; Institute of Nano Science and Technology, India

The demand for energy and portable electronics is in full swing with the rapidly increasing population of the world. Self-powered devices and sensors are working like the panacea to full fill this gap. Owing to its low cost, broad choice of materials, and easy fabrication techniques, triboelectric nanogenerator (TENG) is a promisingly viable technology for fabricating self-powered devices/sensors. Fundamentally, the working principle of the TENG is based on the combined effect of contact electrification and electrostatic induction. Surface area, roughness, and charge density of the contacting surfaces are the key player in determining the overall performance of TENG. Conventionally, two dielectric materials with different triboelectric natures are used to fabricate the TENG. However, the choice of a combination of different materials based on their charge density is one of the prime challenging tasks. Here, we have proposed an effective way to fabricate a TENG with a single (unit) material only (abbreviated as U-TENG), comprised of electrospun nylon-11 nanofibers with different triboelectric natures. The triboelectric nature of the nylon-11 nanofibers is tuned by changing the voltage polarity in the electrospinning setup. Technically, there is a change in the surface potential by using the alternate voltage polarity (positive and negative polarity), which leads to generating different charge density, and subsequently gives rise to a change in work function, a critical factor in defining the triboelectric nature, this is a key factor in designing U-TENG. The tuning of surface potential or, say, the tuning of triboelectric nature of the materials by using alternate voltage polarity also shows promising results for other polymers as well. Owing to its high sensitivity, U-TENG has immense capability to be successfully implemented as a self-powered wearable sensor, which is demonstrated as an ultrahigh sensitive acoustic sensor with a very high mechanoacoustic. Owing to its high sensitivity in the low-to-middle decibel (60–70 dB) sounds, U-TENG is plausibly capable of distinguishing different voice signals depending on the condition of the vocal cord. The effective voice recognition ability of U-TENG indicates that it has a high potential to open an alternative pathway for medical professionals to detect several diseases such as neurological voice disorder, muscle tension dysphonia, and vocal cord paralysis related to the voice without using any chemical/invasive technique.

7:00 AM SB10.10.01
Electrically Conductive nylon/poly(pyrrole) Nanotubes-Based Composite Fibers Prepared by Wet-Spinning Kiran Rana; Indian Institute of Technology Delhi, India

Wearable electronic textiles and camouflaged textiles are technologically important materials that are critical for the future growth of technical textiles. For these applications, flexible polymer-based conducting fibers are absolutely necessary. Towards this, various materials like intrinsically conducting polymers (ICPs), MXenes, and metallic and CNT/graphene-based materials have been used as electrically conductive fillers in the polymer matrix. Among these, ICPs are promising materials as they are lightweight, dispersible, and easy to synthesize. However, the blend of the conjugated polymers with spinnable polymers has usually yielded poor electrical properties in the past.
In this study, it was hypothesized that the anisotropic nanostructure of ICPs may provide a better connecting network and may yield improved electrical properties of the blends. In order to investigate this, we have synthesized anisotropic nanostructures of poly(pyrrole), viz. poly(pyrrole) nanotubes (PPyNT), and blended them with nylon-6 to obtain solution spun composite fibers. The composite fibers, thus obtained, showed good DC electrical conductivity of up to 10 S/m at a low percolation threshold. This study further investigated the effect of loading of PPyNTs on the mechanical and electrical properties of the conductive composite fibers.

SESSION SB11.01: Biologically Programming Materials I
Session Chairs: Neha Kamat and Ben (Keith) Keitz
Monday Morning, November 28, 2022
Hynes, Level 3, Room 305

10:30 AM *SB11.01.01
Control of Enzymatic Membranes Monica Olvera de la Cruz, Curt Waltmann and Jeremy Wang; Northwestern University, United States

Aggregates of proteins in cells mediate cell interactions and organize the local environment to promote specific cellular functions including synthesizing molecules. I will discuss advances in designing aggregates that mimic cellular protein aggregates by modifying protein interactions and/or by using synthetic molecules to organize enzymatic proteins in non-biological environments. The assembled membranes are capable of making useful chemicals and breaking down toxins.

11:00 AM SB11.01.02
Developing Controllable Synthetic Cells Michael Booth; University College London, United Kingdom

Synthetic cells, lipid membrane-bound compartments that mimic living cells, are a promising technology for studying living systems and as drug delivery vehicles. However, real-world application of synthetic cells requires methods of controlling their function for spatiotemporal activation and to reduce off-target effects. My group are developing methods to externally control these soft biomaterials with multiple stimuli, including light, temperature, and chemical signals. We are using our 'remote-controlled' synthetic cells to mimic living processes and form controllable interfaces between living and non-living materials. Current advances include the development of a dual light-activated cell-free AND gate and the light-activated communication between synthetic cells and bacteria.

11:15 AM SB11.01.03
Greasing Protein Wheels—Harnessing Post-Translational Lipidation for Bioinspired Materials Science and Engineering Davoud Mozhdehi; Syracuse University, United States

Advances in recombinant DNA technology have expanded our ability to design and produce protein-based materials with superior control over the biomacromolecule's length, sequence, and structure. Despite these positive attributes, proteins still lack the chemical diversity of their synthetic analogues due to the limited repertoire of canonical amino acids. This limitation restricts the available chemical design space (and thus the function) of protein-based biomaterials. In our quest to overcome this evolutionary constraint, we are inspired by a solution offered by Nature: leveraging specific chemical transformations to modify proteins with non-proteinogenic building blocks, a process called post-translational modification (PTM), which expands the chemical diversity of the proteome by more than two orders of magnitude.

Our focus is to reprogram PTMs to synthesize *de novo* designed hybrid biopolymers with programmable self-assembly. In this talk, I will discuss our recent work on leveraging post-translational lipidation to create genetically encoded amphiphiles with temperature-programmable assembly. Though the chemical biology of lipidation is under intense investigation, protein lipidation remains a major, untapped resource in our synthetic, biomaterials, and therapeutic toolkit. Facile, scalable, and inexpensive lipidation of proteins is currently an unmet synthetic capability. Lipidated proteins cannot be produced by genetic code expansion methods due to the stringent preference of ribosomes for amino acid-derived motifs. Alternatively, their multi-step convergent semi-synthesis is laborious and technically challenging. To address these challenges, we have developed operationally simple, high yield biosynthetic routes for the production of lipidated proteins that facilitates their production to study their materials properties.

I will demonstrate that the effect of lipidation on the assembly, nano-morphology, and material properties of lipidated proteins diverges significantly from experimental results and theoretical predictions of structurally related materials such as amphiphilic polymers and peptide-amphiphiles. Our working hypothesis is that the molecular syntax of lipidated proteins encodes for interactions that are absent in synthetic polymers and short peptides. Specifically, the large molecular surface of lipids enables them to contact multiple segments of peptide chains, and these nonnative interactions synergize/interfere with the ability of proteins to fold, resulting in distinctive functional consequences. Revealing this "*molecular syntax"* will enable the development of the next generation of biomaterials and therapeutics that rival the exquisite hierarchy and capabilities of biological systems.

11:30 AM SB11.01.04
Membrane-Based Artificial Neurons for Brain-Like Signal Processing at the Edge of Biology Michelle Makhoul-Mansour, Joshua Maraj and Stephen A. Sarles; the University of Tennessee, United States

Bottom-up synthetic biology has transformed the design and modification of custom biomolecules and living cells. It also provides paths for developing functional biomolecular materials for use in applications such as targeted drug delivery, tissue regeneration and even smart, wearable bioelectronics. In contrast to traditional electronic components that are heavy, non-biocompatible, and power hungry, synthetic biomolecular materials are soft, biocompatible, and leverage similar structures and transport properties of biological cells. These are needed to improve sensing and signal processing functions at the biotic/abiotic interface: the *edge of biology*. Specifically, synthetic biomolecular materials would benefit from the adaptive properties of memristors and neuromorphic devices that enable brain-like signal processing, in-memory computing capabilities, and activity-dependent plasticity. Recent research directions in this field intend to bridge the gap between modern day computing and biological tissues by carefully engineering new neuromorphic devices inspired by how the brain processes and stores information.

A new type of two-terminal, neuromorphic device—a *biomolecular memristor*—has been introduced by Sarles *et al*. Biomolecular memristors are

assembled at the interfacial bilayer of lipid-coated aqueous droplets dispersed in oil using the droplet interface bilayer (DIB) technique. DIB membrane-based devices are highly modular and scalable, can be functionalized to various types of stimuli, and offer tunable memristance and activity-dependent plasticity. Herein, we examine new functionality of biomolecular memristors doped with voltage-activated ion channels: spontaneous voltage spiking (self-regenerative pulses akin to action potentials in nerve cells) upon injection of a DC current. We hypothesize that spontaneous spiking voltages can be generated in response to injected DC currents due to the combined effects of membrane capacitance and voltage-dependent ion channel gating that show negative differential resistance (NDR). Preliminary results show that NDR can be achieved in DIBs using alamethicin peptides and protamine introduced on one side of the membrane. Spiking behaviors are examined by injecting DC currents and measuring the resulting changes in membrane voltage. The addition of NDR, a property of "active" devices, to DIB memristive elements can improve the storage density and reduce power consumption through local amplification in neuromorphic circuits. Our goal is to build a scalable material system of biomolecular *neuristors* that emulate the "leaky integrate and fire" and nonlinear dynamic functions of neurons. This brings us a step closer to enabling spiking neural networks (SNNs) functionality for real-time spatio-temporal data processing at the edge of biology using soft, compatible bioelectronic materials.

11:45 AM SB11.01.05
Poster Spotlight: Membrane Fusion—How Cubic Lipid-siRNA Constructs Escape the Endosome Lining Zheng and Cecilia Leal; University of Illinois at Urbana-Champaign, United States

Small interfering RNA (siRNA) silences gene expression and has shown great potential in medical applications. However, intracellular delivery of siRNA remains a great challenge. Lipid nanoparticles have been one of the most successful siRNA carriers to date, but their delivery efficiency is limited due to low endosomal release. We have shown that cubic structured lipid nanoparticles (cubosomes) loaded with siRNA - cuboplexes, show greater siRNA knockdown compared to traditional lamellar structured liposomes. In this work, we aim to elucidate the reason behind this difference in delivery efficiency. We will show confocal microscopy (CF), flow cytometry and live cell imaging data demonstrating higher cellular uptake of cubosomes compared to liposomes. CF, fluorescent based fusion assays, cryogenic transmission electron microscopy and dynamic light scattering measurements indicate that compared to liposomes, cubosomes are more prone to fuse and form aggregates with endosomes, which implies a stronger pore forming capability that leads to siRNA escape. These results support our suggestion that cubosomes can lower the free energy required to promote endosome pore formation and establish a topologically active delivery mechanism.
*This work is supported by the NIH (1DP2EB024377-01).

11:50 AM SB11.01.06
Poster Spotlight: Controlling Material Properties via Transcriptional Regulation of Extracellular Electron Transfer (EET) from *S. oneidensis*
Gina Partipilo[1], Austin J. Graham[2] and Ben (Keith) Keitz[1]; [1]University of Texas at Austin, United States; [2]University of California, San Francisco, United States

Extracellular electron transfer (EET) is an anaerobic respiration process in bacteria that couples carbon oxidation to the reduction of extracellular metal species. Though performed by a wide variety of microbes, the model organism *Shewanella oneidensis* directs EET through a well-defined protein pathway, the Mtr-pathway. EET from the gram-negative, genetically tractable bacteria can serve as a link between the biotic and abiotic by directing the reduction of a suitable metal catalyst. Through engineering the proteins in the Mtr-pathway, we can exert metabolic and genetic control over a variety of synthetic transformations, not limited to atom-transfer radical polymerization (ATRP) and Cu(I)-catalyzed alkyne-azide cycloaddition (CuAAC). As a result, EET and the Mtr-pathway can serve as tunable handles for materials formed via these chemistries. Simple buffer gates controlling the transcription of Mtr-pathway genes allows for material formation to "turn-on" the reaction with an inducer molecule. A buffer-NOT gate allows for induction to "turn off" the reaction. Utilizing higher complexity genetic circuits, a series of two-input logic gates can be employed to control material stiffness and conversion. The PEG-hydrogels stiffness can be predictably controlled with the two-input gates utilizing both CuAAC and ATRP. Furthermore, the material stiffness appears to closely mimic the synthetic biology rules traditionally measured with fluorescence. This indicates that more existing synthetic biological circuits can be employed to control material properties. Our results investigate the applications of biocatalytic EET for use in engineered living-materials with a higher degree of computation. Furthermore, controlling material properties through a bacterial interface allows for a high degree of control in complex environments. Utilizing a small molecule system, EET-catalyzed CuAAC fluorescently labelled live mammalian cell membranes without harming cell viability. These results indicate that there may be an opportunity for applying these computational hydrogels as scaffolding for wound repair or cell differentiation, as changes in the environment can allow *S. oneidensis* to actuate changes to material properties.

11:55 AM SB11.01.07
Poster Spotlight: Engineering the Extracellular Matrix with DNA-Based Devices for Modulation and Force Sensing Applications Peter E. Beshay, Melika Shahhosseini, Carlos Castro and Jonathan W. Song; The Ohio State University, United States

It is well appreciated that reciprocal communication between cells and the surrounding extracellular matrix (ECM) can modulate the properties and the behavior of both the ECM and cells to influence both form and function. For example, modulation of the mechanical properties of the ECM by cells is believed to significantly influence the progression of certain diseased tissue such as fibrosis, healing wounds, or the stroma of tumors, all of which are known to exhibit ECM remodeling through the cross-linking of fibrillar collagen and/or deposition of non-collagenous ECM. In addition, interstitial flow through the ECM plays a major role in modulating cancer metastasis by redistributing chemokines, leading to chemotaxis, or through the activation of cell-surface mechanosensors, such as focal adhesion proteins, that promote cell motility. Current advances in Atomic Force Microscopy (AFM), and Magnetic Resonance Imaging (MRI) provided significant insights on the effect biophysical forces on disease progression. However, those techniques do not provide insights into effect of remodeling the same tissue sample nor provide a direct way of measuring the forces exerted by interstitial flow in the ECM. Here, we present a hybrid system that utilizes microfluidic devices and DNA-based nanoscale devices that will enable manipulating properties and measuring biophysical forces in the ECM at a sub-cellular level.

DNA-based molecular sensors have been of particular interest for studying cell interactions due to their high tunability, sensitivity and easy integrability into various biological systems. However, measuring cell-ECM interactions due to fluid flow using these sensors has yet to be achieved. Here, we present a DNA origami-based force probe that is capable of measuring fluid flow forces in the ECM. The probe, which is about 100 nm in size, consists of two barrels of DNA connected by six flexible linkers; allowing the device to fluctuate between open and closed states. Probe fluctuations is then reported using single molecule Förster resonance energy transfer (smFRET). The dynamics of the probe and its force sensitivity can be tailored by changing the interaction strength between its linkers. To enable the measurement of fluid flow forces in the ECM, we demonstrate our ability to anchor our probe to the fibers of collagen I-based hydrogels. We also present a three-channel microfluidic device comprising an "interstitial space" channel sandwiched between two "vessel" channels as a mean for applying physiologically relevant fluid flows. This microfluidic device can hence mimic interstitial fluid flow on the ECM by applying different pressure gradients on its channels. The integration of the DNA-engineered ECM with this microfluidic system will enable the spatiotemporal measurement of interstitial flow forces in the ECM, allowing for studying the effect of these forces on cancer cell motility and metastasis.

SESSION SB11.02: Engineering the Biotic/Abiotic Interface
Session Chairs: Ben (Keith) Keitz and Seunghyun Sim
Monday Afternoon, November 28, 2022
Hynes, Level 3, Room 305

1:30 PM *SB11.02.01
Self-Healing of Biomineralized Engineered Living Building Materials Elizabeth Delesky, Rollin Jones, Sherri Cook, Jeffrey Cameron, Mija Hubler and Wil V. Srubar III; University of Colorado Boulder, United States

Living building materials (LBMs) are an emergent class of structural materials that leverage the biomineralization capability of microorganisms within sand-hydrogel scaffolds to produce living, load-bearing structures. In this study, we produced LBMs using a physically crosslinkable hydrogel-sand scaffold and two microorganisms with different biomineralization pathways—*Synechococcus sp.* PCC 7002 (photosynthetic) and *S. pasteurii* (ureolytic)—and investigated their self-healing capacity. Our results reveal that both *Synechococcus sp.* PCC 7002 and *S. pasteurii* demonstrated exceptional viability within all LBMs for more than 20 days. LBM prisms were pre-loaded to 40% of their structural capacity in compression or flexure. Damaged LBMs containing *Synechococcus sp.* PCC 7002 exhibited a full rebound of their original compressive and flexural strengths, respectively, after three days of healing at 50% relative humidity (RH) (*i.e.*, ambient conditions). In contrast, LBMs containing *S. pasteurii* exhibited marginal recovery of their original compressive and flexural strengths, respectively, after three days of healing at 50% RH. The compressive and flexural strengths of all LBMs fully rebounded after seven days of healing at 50% RH. Results substantiate that the self-healing ability of the hydrogel alone plays a critical role in facilitating healing of LBMs, as evidenced by high rebounds in compressive and flexural strengths by the hydrogel-sand scaffold after three or seven days of healing 50% RH.

2:00 PM SB11.02.02
Surface-Adhered Biomembrane Networks Formed on High Energy Surfaces of SiC and Al_2O_3 Ruslan Ryskulov[1], Esteban Pedrueza Villalmanzo[1,2], Aldo Jesorka[1], Lin Xue[3], Elif Köksal[3], Karolina Spustova[3] and Irep Gözen[3]; [1]Chalmers University of Technology, Sweden; [2]University of Gothenburg, Sweden; [3]University of Oslo, Norway

Reservoirs of lipid molecules, specifically onion shell vesicles, spread on high energy surfaces, e.g. Al_2O_3, to form a stack of molecular films (double bilayer). Eventually, the spreading lipid exhausts the reservoir, and rising tension ruptures of the films [1]. Gözen and later Köksal *et al*. discovered that this disruptive process generates a network of nanotubes, which redistributes lipid material in order to alleviate local tension (Marangoni flow), and vesicles grow from the tubes [2,3]. We have shown that local heating accelerate the growth and transformation of containers, and initiates their fusion. Similar processes might have occurred in warm environments on the Early Earth. Our current work aims to utilize this system and **control** soft matter **transformations with IR light** to design and construct reconfigurable chemical reaction networks (CRNs) on engineered surfaces.
In the context of the origin of life, the formation of the earliest primitive compartments and their transformation to biological cells is not known in detail, and is a subject of intensive research. Köksal *et al.* suggested the involvement of solid high energy surfaces as source of energy for autonomous shape transformations of lipid assemblies, protocell and nanotube network formation, and encapsulation of solutes therein. Such surface-supported networks of vesicles and soft nano-conduits might have functioned as primitive CRNs in the prebiotic world. Their simplicity and ease of formation inspired further development as a soft matter reactor nanotechnology. We combined an inverted laser induced fluorescence microscope with a focused 1470 nm IR-B laser and a spatial light modulator (SLM) for generating designed irradiation patterns (digital holography) in order to elevate the temperature locally at the surface and simultaneously observe lipid film transformations.
Membrane compartment formation, growth, and merging was accelerated by local heating with an IR fibre. We developed an *in situ* temperature measurement setup and confirmed consistency with conditions in warm natural environments, such as the “Lost City” hydrothermal vents (~70°C) [4]. Thermocouple absorption of IR energy was taken into account. The actual temperature in the proximity of the fibre ending (distance to the protocell) was determined by linear approximation. We further employ thermally evaporated SiC surfaces for improved adhesion control, which allows for efficient MLV spreading into double bilayer structures and rapid growing of protocells colonies [5], even without additional fusogenic agents, such as Ca^{++} ions. Further research aims to implement chemical/enzymatic reactions within such networks in order to gain new insights into possible protocell development scenarios in the context of the origins of life.

2:15 PM SB11.02.03
Hierarchal Coatings of Biological Building Blocks via Self-Limiting Electrospray Deposition Sarah Park[1], Lin Lei[1], Kelly Kyker-Snowman[1], Darrel Dsouza[1], Robert Zipkin[2], Emran Lallow[1], Joel Maslow[3], Hao Lin[1] and Jonathan Singer[1]; [1]Rutgers University, United States; [2]MedChem 101, United States; [3]GeneOne Life Science, United States

Electrospray deposition (ESD) is a spray coating process that utilizes a high voltage to atomize a flowing solution into charged microdroplets. These self-repulsive droplets evaporate as they travel to a target grounded substrate, depositing the solution solids as thin films. These thin films can be utilized in biomedical applications including drug and therapeutics delivery in addition to the fabrication of medical implants and biosensors. Our lab has categorized various modes of ESD, including self-limiting electrospray deposition (SLED). In SLED, the material arrives onto a target as a dried spray, carrying a charge that eventually begins to repel itself over time. The charged spray is redirected to regions that are uncoated such that manipulation of the electrostatic repulsion, hydrodynamic forces, and evaporation kinetics can be employed to conformally cover 3D architectures with micro-coatings. The generated coatings are hierarchical, possessing either nano-shell, nanoparticle, or nanowire microstructure, which can be smoothed through further post processing. We envision SLED as being a replacement for dip or conventional-spray coating, where its greatest advantage would be the potential for much higher materials utilization. While many studies have presumed high efficiency in ESD, this is rarely quantified. Here, we show how architecting the local charge landscape can lead to SLED coatings approaching 100% deposition efficiency on microneedle arrays and other complex substrates of relevant

therapeutics with the building blocks and signals for synthetic biology, including DNA vaccines, proteins, amino acids, bioactive small molecules, and biocompatible conductors.

2:30 PM SB11.02.04
Screening Methods for Hydrophobins and Peptides as Potential Promoters of Polymer Adhesion Mark T. Kozlowski, Jose A. Wippold and Joshua A. Orlicki; U.S. Army Research Laboratory, United States

Bacterial cell surface display libraries have been adapted to identify potentially promising proteins and peptides with adhesive characteristics against an array of diverse substrates. The peptide display libraries were screened using methods previously developed by the Army Research Laboratory to find promising peptide sequences that interacted strongly with substrates such as gold or ITO nanoparticles. The current work combines peptide display with microfluidic approaches to screen material substrates (e.g. polymers, metals) that may exhibit weaker interactions than those probed previously. In addition to the display of a peptide library, a class of natural surfactants known as hydrophobins have been expressed on the bacteria surface. Hydrophobins are used by fungi to breach air-water interfaces when colonizing new environments, and have already been shown to adhere to highly non-polar surfaces, such as Teflon or polystyrene.
Progress towards identifying proteins and peptides that promote bacterial adhesion to diverse polymer substrates and demonstration of microfluidic-based methods for obtaining semi-quantitative data on binding affinity with reasonable throughput will be discussed. This work will ultimately merge the screening tools of synthetic biology approaches to address long-standing challenges in materials science, providing new insights for probing adhesion.

2:45 PM BREAK

Programming Microorganisms to Assemble Macroscopic Living Materials Sara Molinari, Robert F. Tesoriero, Esther Jimenez and Caroline Ajo-Franklin; Rice University, United States

Challenged by a changing climate, dwindling natural resources, and a growing global population, we need advanced, renewable materials that meld the sustainability of biological materials with the functionality of conventional materials. To help address this need, my research group creates sustainable and environmentally-responsive living materials by seamlessly integrating conventional materials with living systems. One major effort in our group is to engineer microorganisms to grow into multifunctional, hierarchically ordered macroscopic materials by introducing non-natural extracellular matrices. Living materials synthesized by organisms, such as bones and shells, exhibit remarkable mechanical properties due to their hierarchical assembly of hard and soft components across the nanometer to the micron scales. While engineering macroscopic analogs to these materials would open new frontiers, there is currently no bottom-up route to do so that enables control of the composition, hierarchical structure, and properties of living materials. In this talk, I will describe our approach to constructing such hierarchically ordered materials by programming bacteria. We report growth of macroscopic materials from freshwater bacteria that display and secrete an engineered self-interacting protein. This protein formed an extracellular de novo matrix and assembled cells into hierarchically-ordered, centimeter-scale materials. We showed that the mechanical, catalytic, and morphological properties of these materials can be tuned through genetic modification of the self-interacting protein. Our work identifies novel genetic tools, design and assembly rules for growing macroscopic materials with both wide-ranging mechanical properties and customizable functions. We anticipate the modularity of this approach will permit the incorporation of different protein polymers in the de novo matrix, thus allowing to generate materials with a variety of desired compositions, structures, and properties. We envision specific matrix properties that can be combined synergistically with existing cellular functions to greatly expand the opportunities for biological materials in human health, energy, and the environment.

3:45 PM SB11.02.06
Secretion-Catalyzed Assembly of Protein Biomaterials on a Bacterial Membrane Surface Qi Xie and Stephen D. Fried; Johns Hopkins University, United States

Protein-based biomaterials have historically played a key role in tissue engineering, and additional exciting applications as self-healing materials and sustainable polymers are emerging. Their fibrous forms are often the most applicable. Over the past few decades, recombinant expression and production of various fibrous proteins from microbes have been demonstrated; however, the resulting proteins typically must then be purified and processed by humans to form usable fibers and materials. Here, we show that the Gram-positive bacterium Bacillus subtilis can be programmed to secrete silk through its translocon. Surprisingly, we discover that this translocation mechanism drives the silk proteins to assemble into fibers spontaneously on the cell surface, in a process we call secretion-catalyzed assembly (SCA). Furthermore, these fibers form self-healing hydrogels with minimal processing. This work provides a blueprint to achieve autonomous assembly of protein biomaterials in useful morphologies directly from microbial factories.

Advancing New Living Materials by Understanding Assembly Principles Robert F. Tesoriero[1,1], Sara Molinari[1], Dong Li[2], Kathleen Ryan[3], Paul Ashby[2] and Caroline Ajo-Franklin[1]; [1]Rice University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Berkeley, United States

Like natural materials such as wood and bone, engineered living materials (ELMs) require specific conditions to facilitate proper assembly. By elucidating these assembly parameters in relation to the mechanism of material formation, we become able to better understand a material's potential application space. Our research group has recently developed the first example of a *macroscopic* **b**ottom-**u**p ***de novo*** **e**ngineered **l**iving **m**aterials (**BUD-ELMs**) in the bacterium *Caulobacter crescentus*[1]. To understand and optimize the conditions that promote proper material assembly, we grew BUD-ELM cultures under various shaking conditions. We have found that this material not only requires shaking to assemble from planktonic culture, but also that the assembly process is sensitive to specific shaking conditions. To describe these conditions under a single parameter, we developed the modified volumetric power input ($P_{v,a}$), which takes into account both the sheer forces experienced by the culture and the size of the air-water interface onto which the material forms. By analyzing the resulting size of material samples grown under different $P_{v,a}$ values, we were able to determine an optimal $P_{v,a}$ range for maximum material formation. Additionally, we used this model to predict the optimal shaking conditions for larger flasks sizes, demonstrating the potential to scale up cultures for increased material production. By interpreting this data in conjunction with Western blot analysis and atomic force microscopy, we propose that during BUD-ELM assembly, *Caulobacter* cells adhere to a secreted BUD-protein matrix that forms at the air-water interface. Based on this mechanism, we hypothesized that this sequential assembly process would allow for integration of non-engineered bacterial species into the material's structure. To explore this concept, we developed a co-culturing approach for BUD-ELM-forming *C. crescentus* and the model cyanobacterium *Synechocystis* sp. PCC 6803. We observed the stochastic incorporation of live *Synechocystis* cells within the material by fluorescence microscopy. This result not only provides further support to our proposed assembly mechanism, but also enables a novel platform for photosynthetic, co-cultured ELMs. By further engineering *Syenchocystis* cells, we hope to expand this platform to provide a novel class of ELMs with reduced nutrient requirements, increased lifespan, and user-defined functionality.

Transforming Natural Microbial Biofilms into Functional Materials Sarah M. Glaven[1], Lina Bird[1], Brian Eddie[1], Isabel Baker[1] and Meghna Thakur[2]; [1]U.S. Naval Research Laboratory, United States; [2]George Mason University, United States

Autotrophic bacteria form biofilms and use inorganic energy sources (e.g. gases, minerals, and electrodes) to fix carbon dioxide (CO_2). Such living materials could be developed as catalysts for biosynthesis, where CO_2 is captured and transformed into useful biomolecules. The problem is that autotrophic bacteria are difficult to grow under laboratory conditions and often rely on syntrophic partners whose contribution to growth cannot be reproduced in pure culture, rendering them genetically intractable. In order to develop autotrophic marine bacteria for technological use, tools to genetically manipulate them directly, without the need for standard laboratory isolation and cultivation, are required. In this talk, I will describe my team's work toward *in situ* genome editing of autotrophic bacteria in an electrode biofilm. I will present recent results demonstrating a CRISPR-based genome editing tool called INTEGRATE in two different biofilm-forming marine bacteria, *Marinobacter atlanticus* and "*Candidatus* Tenderia electrophaga". *M. atlanticus* is a heterotrophic testbed strain that forms biofilms on electrordes and is being used to optimize INTEGRATE for marine bacteria. "*Ca.* Tenderia electrophaga" is an electroautotroph, growing only from CO_2 fixation and electron uptake from an electrode, that exists in a consortia of ca. 20 other species, including *M. atlanticus*. Insertion of a fluorescent marker protein into *M. atlanticus* biofilm cells was tracked in real-time using confocal microscopy, yielding approximate transformation efficiency in mature biofilms. Biofilm transformation protocols developed with *M. atlanticus* were applied to "*Ca.* Tenderia electrophaga" to show, for the first time, successful genome integration of a fluorescent marker protein in an uncultivated electroautotroph. Genetically modified "*Ca.* Tenderia electrophaga" was stable after further enrichment, however, further editing was required to provide a selective advantage over the natural strain. This work represents the first step towards *in situ* genome editing of microbial communities that form electroactive biofilms as an approach towards developing living catalytic materials for CO_2 fixation.

SESSION SB11.03: Poster Session

SB11.03.02
Interfacial Assembly of Bacterial Microcompartment Shell Proteins in All Aqueous Emulsions Dharani Abeysinghe[1], Eric J. Young[2,3], Andrew T. Rowland[1], Cheryl A. Kerfeld[2,3] and Christine D. Keating[1]; [1]The Pennsylvania State University, United States; [2]Michigan State University, United States; [3]Lawrence Berkeley National Laboratory, United States

Compartmentalization is one of the most rudimentary hallmarks of living systems as it is essential to localize chemical species and functional components and to maintain biochemical gradients. Artificially designed 'protocells' (*i.e.,* elementary compartments from which living cells could have evolved from) are used to gain better insights into the role of compartmentalization. All aqueous emulsions formed through liquid-liquid phase separation (LLPS) have emerged as a compartmentalization strategy through which to assemble protocells. Examples include complex coacervates and aqueous two-phase systems. Furthermore, researchers have combined LLPS with lipid self-assembly to create lipid-based membrane-bound protocells. Similarly, self-assembling proteins could offer an alternative approach for making synthetic cell membranes, as evidenced by the existence of natural protein-based organelles and vesicles such as bacterial microcompartments (BMCs). Exploiting the interactions between such protein assemblies and LLPS provides new avenues to make responsive membrane-bound protocells with customizable properties. BMCs are 40 to ~600 nm protein containers formed by a semi-permeable protein shell surrounding an enzymatic core which allows bacteria to compartmentalize key metabolic pathways. The shell facets are composed of hexamer-shaped protein building blocks that associate laterally by shape complementation and weak electrostatic forces. Because of their self-assembly properties, BMC shell proteins are promising building blocks that can be repurposed to design novel nano to micron-scale higher-order protein architectures. In this study, we examined the assembly and positioning of BMC shell proteins when they are combined with a polylysine/polyaspartate coacervate system. Confocal fluorescence imaging showed that BMC shell proteins adsorb at the interface between the coacervate droplets and the dilute continuous phase. Our findings highlight the importance of electrostatic interactions between BMC shell proteins and polycations which can be tuned by varying the polycation/polyanion charge ratio. Functional properties of these protein bound compartments (*e.g.,* permeability, compartmentalization of enzymatic reactions) were also investigated. This study provides insights in establishing a prototype for a new class of proteinaceous protocell chassis for compartmentalizing functionality.

SB11.03.03
Poster Spotlight: Controlling Material Properties via Transcriptional Regulation of Extracellular Electron Transfer (EET) from *S. oneidensis*
Gina Partipilo[1], Austin J. Graham[2] and Ben (Keith) Keitz[1]; [1]University of Texas at Austin, United States; [2]University of California, San Francisco, United States

Extracellular electron transfer (EET) is an anaerobic respiration process in bacteria that couples carbon oxidation to the reduction of extracellular metal species. Though performed by a wide variety of microbes, the model organism *Shewanella oneidensis* directs EET through a well-defined protein pathway, the Mtr-pathway. EET from the gram-negative, genetically tractable bacteria can serve as a link between the biotic and abiotic by directing the reduction of a suitable metal catalyst. Through engineering the proteins in the Mtr-pathway, we can exert metabolic and genetic control over a variety of synthetic transformations, not limited to atom-transfer radical polymerization (ATRP) and Cu(I)-catalyzed alkyne-azide cycloaddition (CuAAC). As a result, EET and the Mtr-pathway can serve as tunable handles for materials formed via these chemistries. Simple buffer gates controlling the transcription of Mtr-pathway genes allows for material formation to "turn-on" the reaction with an inducer molecule. A buffer-NOT gate allows for induction to "turn off" the reaction. Utilizing higher complexity genetic circuits, a series of two-input logic gates can be employed to control material stiffness and conversion. The PEG-hydrogels stiffness can be predictably controlled with the two-input gates utilizing both CuAAC and ATRP. Furthermore, the material stiffness appears to closely mimic the synthetic biology rules traditionally measured with fluorescence. This indicates that more existing synthetic biological circuits can be employed to control material properties. Our results investigate the applications of biocatalytic EET for use in engineered living-materials with a higher degree of computation. Furthermore, controlling material properties through a bacterial interface allows for a high degree of control in complex environments. Utilizing a small molecule system, EET-catalyzed CuAAC fluorescently labelled live mammalian cell membranes without harming cell viability. These results indicate that there may be an opportunity for applying these computational hydrogels as scaffolding for wound repair or cell differentiation, as changes in the environment can allow *S. oneidensis* to actuate changes to material properties.

SB11.03.04

Nucleic Acid-Templated Growth of Iron Oxide Nanoparticles for Colorimetric Cell Detection Yoonbin Ji; University of Seoul, Korea (the Republic of)

With the recent development of nucleic acid nanotechnology, DNA-based materials have been considered for biosensing probe materials with their stability and programmability. Moreover, the hybridization of DNA materials with inorganic materials such as gold, silver, or iron oxide was also drawn attention for exploiting their exceptional functionality. However, the conjugation of biomolecules with inorganic molecules was expensive and laborious. Here we introduce the novel method for fabricating DNA/iron oxide nanoparticle (IONP) hybridized structures by using charge interaction between nucleic acid and metallic cations for co-precipitation reaction. DNA microstructure fabricated via the well-known rolling circle amplification (RCA) method was highly porous and negatively charged and could act as active sites for IONP growth reaction. Synthesized DNA/IONP hybrid showed core-shell structure with homogeneously covered iron oxide particles on a single DNA microparticle. Rationally designed DNA template with aptamer sequence, aptamer-DNA/IONP exhibited specific cancer cell targeting ability and was easily observed by colorimetric assay via Prussian blue staining.

SB11.03.05
The Regulation of RNA Polymerization and the Synthesis of Sponge-Like RNA Particles by Viscosity Moon S. Hyun and Jong Bum Lee; University of Seoul, Korea (the Republic of)

By utilizing a wide range of biological activities of RNA, RNA nanotechnology has advanced significantly for its prospective medicinal applications. However, the heterogeneity between individual patients and disease still calls for personally optimized nanoparticle design to enhance clinical outcomes. Therefore, RNA nanostructures manufactured via rolling circle transcription (RCT)-based enzymatic RNA self-assembly have gotten much interest as a possible way to control the nanoparticle design and improve the therapeutic RNA loading capacity. Here, we used viscosity to modulate enzymatic RNA polymerization and investigated how viscosity influences the synthesis of sponge-like RNA particles by modifying enzyme activity and molecular interactions between reaction components. The increase in viscosity under reaction circumstances resulted in a slower rate of RNA polymerization, indicating that viscosity regulates polymerase activity. Furthermore, when the solution viscosity increased, the inorganic crystallization of magnesium pyrophosphate, which serves as a structural foundation for sponge-like RNA particles, was reduced. As a result, the size of the sponge-like RNA particles decreased as the solution viscosity increased. In addition, in excessively viscous circumstances, the sponge-like structures vanished. Finally, the size of the sponge-like RNA particles was fine-tuned by modulating the template DNA to monomer rNTP ratio utilizing another previously described size reduction approach. Depending on each patient and disease, the needed size of the sponge-like RNA particles will be varied. As a result, we proposed novel ways to precisely manipulate the size of sponge-like RNA particles to meet various personalized demands.

SB11.03.06
Poster Spotlight: Engineering the Extracellular Matrix with DNA-Based Devices for Modulation and Force Sensing Applications Peter E. Beshay, Melika Shahhosseini, Carlos Castro and Jonathan W. Song; The Ohio State University, United States

It is well appreciated that reciprocal communication between cells and the surrounding extracellular matrix (ECM) can modulate the properties and the behavior of both the ECM and cells to influence both form and function. For example, modulation of the mechanical properties of the ECM by cells is believed to significantly influence the progression of certain diseased tissue such as fibrosis, healing wounds, or the stroma of tumors, all of which are known to exhibit ECM remodeling through the cross-linking of fibrillar collagen and/or deposition of non-collagenous ECM. In addition, interstitial flow through the ECM plays a major role in modulating cancer metastasis by redistributing chemokines, leading to chemotaxis, or through the activation of cell-surface mechanosensors, such as focal adhesion proteins, that promote cell motility. Current advances in Atomic Force Microscopy (AFM), and Magnetic Resonance Imaging (MRI) provided significant insights on the effect biophysical forces on disease progression. However, those techniques do not provide insights into effect of remodeling the same tissue sample nor provide a direct way of measuring the forces exerted by interstitial flow in the ECM. Here, we present a hybrid system that utilizes microfluidic devices and DNA-based nanoscale devices that will enable manipulating properties and measuring biophysical forces in the ECM at a sub-cellular level.

DNA-based molecular sensors have been of particular interest for studying cell interactions due to their high tunability, sensitivity and easy integrability into various biological systems. However, measuring cell-ECM interactions due to fluid flow using these sensors has yet to be achieved. Here, we present a DNA origami-based force probe that is capable of measuring fluid flow forces in the ECM. The probe, which is about 100 nm in size, consists of two barrels of DNA connected by six flexible linkers; allowing the device to fluctuate between open and closed states. Probe fluctuations is then reported using single molecule Förster resonance energy transfer (smFRET). The dynamics of the probe and its force sensitivity can be tailored by changing the interaction strength between its linkers. To enable the measurement of fluid flow forces in the ECM, we demonstrate our ability to anchor our probe to the fibers of collagen I-based hydrogels. We also present a three-channel microfluidic device comprising an “interstitial space” channel sandwiched between two “vessel” channels as a mean for applying physiologically relevant fluid flows. This microfluidic device can hence mimic interstitial fluid flow on the ECM by applying different pressure gradients on its channels. The integration of the DNA-engineered ECM with this microfluidic system will enable the spatiotemporal measurement of interstitial flow forces in the ECM, allowing for studying the effect of these forces on cancer cell motility and metastasis.

SB11.03.08
Anisotropic Nanofiber-Laden Hydrogel as Guidance to 3D Cell Orientation Cholong Choi, Suntae Kim and Chaenyung Cha; UNIST, Korea (the Republic of)

Along with continuous research in biotechnology, there is a growing demand for cell culture platforms that can provide a more biological microenvironment to induce complex cell behavior. The extracellular matrix (ECM) controls chemical signals and stores cytokines and nutrients beyond the structural support of tissue. It also serves to control the physical signals mediated by the integrins and has structural diversity. On the other hand, in conventional plastic substrates such as flasks and well plates, cells are attached to the surface and cultured so the behavior of cells can be explored only by the response to chemical signals such as growth factors. To mimic various biological tissues, an extracellular matrix environment suitable for each cell activity must be served.
The three-dimensional hydrogel culture system can control mechanical properties within a physiological range by controlling crosslinking density of polymer. Hydrogel can also provide a microenvironment that mimics natural surroundings for cell growth. However, overall hydrogel structures were difficult to control the fine physical properties of the cell niche. The limitation of controlling the local environment around cells can be studied by introducing other nanomaterials within hydrogels.
Electrospun nanofibers are widely used as scaffolds in tissue engineering that they are easy to fabricate and can simulate the structure of natural proteins derived from ECM. The other advantage of introducing nanofibers is that the porosity of the hydrogel can be maintained and the stiffness of the local area is controlled by the fiber density. Moreover, nanofibers can recreate the topographical heterogeneity of ECM architectures.
In particular, aligned structures of connective tissue can be easily found across soft tissue, skeletal muscle, heart tissue, and cancer tumor. From a microscopic point of view, the aligned structure affects angiogenesis, ECM reconstruction, and, electrical signal propagation in neurons. From a macroscopic point of view, it supports tendon loading, transmits muscle force, and is used to determine the malignant prognosis of tumors.

However, the traditional strategy to control the direction of cell migration is to give a chemical or physical cell adhesion gradient that would change cellular fates. Moreover, mimicking anisotropy in a three-dimensional structure still has been a challenge.
Hence, this research demonstrates to regulate the orientation of cells along gelatin nanofibers aligned under an external magnetic field. This work establishes a new multifunctional scaffold strategy that mimics the aligned three-dimensional fiber structure of various nature tissues with independent control of physical and chemical properties.

SB11.03.09
Programmable Nanofibers as a Platform for Engineered Living Materials Hoda Hammad and Anna Duraj-Thatte; Virginia Tech University, United States

Innovation in material sciences has been the primary driver of significant changes in human history. Over the course of evolution, living cells -unicellular or multi-cellular- have tailored their pathways to synthesize complex materials responding to different environmental stimuli. Autonomous growth, self-organization, self-repair, responsiveness, and other characteristics of these living systems opened a different paradigm at the interface between material science and biological engineering. Inspired by nature and living systems, synthetic biology aims at using biological systems to perform user-defined functions.Through genetic engineering, synthetic biology extended its impact into material science. Living cells have been utilized as bio-factories producing programmable materials tailored to biotechnological applications ranging from biomedical to agriculture fields. Incorporation of the engineered living cells into materials enabled novel functionalities such as self-healing, autonomous assembly, adaptivity, and self-regeneration that synthetic materials lack. Therefore, synthetic biology paved the way for active, dynamic, and functional biomaterials. Our advanced understanding of bacterial systems highlighted them as an ideal chassis for pioneering the living materials field. The majority of the bacteria, inherently, exist as biofilms endorsed in an extracellular matrix composed of polysaccharides, proteins, nucleic acids, and other biomolecules. The ability of bacterial biofilms to self-assemble into higher-order structures has made them an attractive programmable platform for engineered living materials (ELMs). The current knowledge of genetic tools on model organisms such as *E. coli* made it an ideal organism for genetic prototyping in the field of ELMs. We will discuss different engineering techniques and synthetic biology tools that leveraged the power of the native curli system, the primary structural protein component of the *E. coli* biofilm, as a protein scaffold in different ELMs applications.

SB11.03.10
Poster Spotlight: Membrane Fusion—How Cubic Lipid-siRNA Constructs Escape the Endosome Lining Zheng and Cecilia Leal; University of Illinois at Urbana-Champaign, United States

Small interfering RNA (siRNA) silences gene expression and has shown great potential in medical applications. However, intracellular delivery of siRNA remains a great challenge. Lipid nanoparticles have been one of the most successful siRNA carriers to date, but their delivery efficiency is limited due to low endosomal release. We have shown that cubic structured lipid nanoparticles (cubosomes) loaded with siRNA - cuboplexes, show greater siRNA knockdown compared to traditional lamellar structured liposomes. In this work, we aim to elucidate the reason behind this difference in delivery efficiency. We will show confocal microscopy (CF), flow cytometry and live cell imaging data demonstrating higher cellular uptake of cubosomes compared to liposomes. CF, fluorescent based fusion assays, cryogenic transmission electron microscopy and dynamic light scattering measurements indicate that compared to liposomes, cubosomes are more prone to fuse and form aggregates with endosomes, which implies a stronger pore forming capability that leads to siRNA escape. These results support our suggestion that cubosomes can lower the free energy required to promote endosome pore formation and establish a topologically active delivery mechanism.
*This work is supported by the NIH (1DP2EB024377-01).

SESSION SB11.04: Designing and Printing Living Materials I

Tuesday Morning, November 29, 2022
Hynes, Level 3, Room 305

8:45 AM *SB11.04.01
Shape-Morphing Living Composites Taylor H. Ware; Texas A&M University, United States

Stimuli-responsive polymers respond to their environment without requiring motors, sensors, or power supplies. Notably, the stimulus-response of many synthetic smart materials is derived wholly from physical properties, and as a result, these materials require powerful stimuli, such as heat, to induce shape change. By comparison, the stimulus-response of living organisms can be triggered by weak physical stimuli or specific biochemicals. We will discuss fabricating living yeast –hydrogel and bacteria-hydrogel composites capable of undergoing programmed shape change. As the cells are higher in modulus (~100×) than the gel, cell proliferation results in a macroscopic shape change of the composite. Importantly, genetic manipulation of the cells enables the stimulus that induces shape change to be controlled. For example, we will discuss composites where volume change on exposure to a single biochemical (L-histidine) is 14× higher than volume change when exposed to highly similar biochemicals (D-histidine and other amino acids). The use of this shape-changing material for future applications in drug delivery and sustainable manufacturing will be discussed.

9:15 AM SB11.04.02
Bacterial Patterning of Soft Materials Ismar E. Miniel Mahfoud and Ben (Keith) Keitz; The University of Texas at Austin, United States

Extracellular electron transfer (EET) is an anaerobic respiration mechanism through which electroactive microbes interact with and influence their environment. Using membrane-bound cytochromes, these organisms deposit electrons onto external electron acceptors such as metals and metal oxides. By controlling the expression and activity of EET proteomic elements, it is possible to use electroactive microbes as actuators that confer biological control over abiotic material properties. For example, we have shown that electrons produced by EET-capable organisms can activate exogenous metal catalysts, resulting in radical crosslinking of hydrogel precursors. Additionally, we have also created genetic logic circuits that predictably regulate EET pathway genes and EET flux in *Shewanella oneidensis* in response to one or more chemical inducers. With the development of these fundamental logic gates, we envision more complex architectures that would allow for spatiotemporal control of hydrogel crosslinking.

Communities of bacterial cells communicate by secreting chemical signals that act on others in the population in a concentration-dependent manner, usually leading to transcription of specific genes. By engineering strains to utilize these systems, gene expression can be tuned in a spatiotemporally dependent manner. These patterning circuits can spatially control transcription of EET-relevant genes and can be used to pattern crosslinkable materials,

such as hydrogels.

To the end of developing this technology, we have engineered *Shewanella oneidensis* “sender” cells that, under control of an inducible gene circuit, secrete a diffusible signal. We have also engineered “receiver” cells that express GFP in the presence of the signal. In petri-dish based assays, when fully induced sender cells are placed on top of a lawn of receiver cells and allowed to incubate, a circular “halo” of fluorescence is observed within the signal diffusion gradient produced by the sender cell population. We have found that we can modulate the size and intensity of the fluorescence pattern by varying the induction level of the sender cells. Using image analysis, we were able to quantify the intensity, size, symmetry, and consistency of the pattern.

The experiment was then repeated with receiver cells that express a key EET pathway protein instead of GFP. A colorimetric reporter of Iron(II) allowed visualization of a “halo” of EET-driven Iron(III) reduction that was very similar in size and shape as the fluorescence experiment, indicating not only spatiotemporal control of EET gene expression, but visual and genetic predictability of EET patterns using the fluorescence system. Future experiments will involve more complex genetic logic within receiver cells to create more intricate patterns as well expanding the reduction substrate scope to dyes and crosslinkable material precursors.

This technology will lay the groundwork for the engineering of living materials that can react to and interact with complex environments in applications such as chronic wound healing, tissue engineering, device fabrication, and the modeling of developmental signaling systems. Finally, this work will more broadly contribute to the development of EET as a universal interface that allows bacteria to confer genetic control over a large range of material properties.

9:30 AM SB11.04.03
Programmable Microbial Foundry for Functional Living Materials Avinash Manjula-Basavanna; Northeastern University, United States

Living cells have the unparalleled ability to produce materials under ambient conditions from abundantly available benign components. This remarkable manufacturing capability of living cell is harnessed in the emerging field of Engineered Living Materials for various functional applications. In this talk, I will present our recent efforts to program the microbial foundry to produce the AquaPlastic [1] and the Microbial Ink [2].

AquaPlastic is a novel bioplastic produced from engineered microbial biofilms and it biodegrades to ~90% in just 45 days. AquaPlastic is resistant to organic solvents, strong acid, and base, which can be further utilized to form the protective coatings on various 1D and 2D substrates. AquaPlastic can also be molded, healed, and welded by using water. This work on AquaPlastic paves the way for packaging and coating applications, and to build a sustainable world.

Microbial Ink is a new class of bioink produced entirely from the genetically engineered microbes by a bottom-up approach. The shear-thinning property of the Microbial Ink coupled with its high viscosity, high yield-stress and shape fidelity facilitated the extrusion-based 3D printing into multi-layered architectures. The Microbial Ink was further programmed by using rationally designed genetic circuits in microbial cells to produce; A) Therapeutic Living Material – On demand secretion of an anticancer drug, B) Sequestration Living Material – Selective removal of toxic moieties and C) Regulatable Living Material – To control the number of cells by inducing (on demand) cell death. This work enables unprecedented avenues to manufacture macroscopic Functional Living Architectures and showcases advanced capabilities of Engineered Living Materials.

9:45 AM BREAK

10:15 AM *SB11.04.04
Freeform Printing of Complex Living Materials Using a Low-Cost DIY 3D Bioprinter Anne S. Meyer; University of Rochester, United States

3D printing of engineered bacteria is an evolving field that employs the tools of synthetic biology to express desired proteins and peptides while maintaining control over the shape and spatial organization of the resultant biomaterials. Previous bacterial 3D printers have been limited to producing low aspect ratio prints that become unstable and collapse under their own weight at greater heights. By leveraging open-source hardware and software, we have designed and modified a low-cost, commercial 3D printer into a bacterial bioprinter that can print complex, free-standing structures with high aspect ratios. To print complex structures with sharply defined edges, a novel syringe mount was designed with retraction functionality that pauses bio-ink extrusion during non-printing periods. Our new printer deposits bio-ink within gel slurries with viscoplastic properties, allowing delivery of bio-ink gellification agents immediately upon printing. This technique allows us to print stable, high aspect ratio (15:1), free-standing structures with sharper resolutions and internal cavities. A challenge to bioprinting is providing a supply of fresh nutrients and exchanging waste byproducts to support the health of the embedded microbes without damaging the printed structures. To address this, we developed a method to incubate the bioprints within a stable agarose-based gel slurry that permits diffusion of nutrients. Bioprints of engineered *Escherichia coli* strains incubated within a nutrient-infused slurry for seven days demonstrated 100-times higher colony-forming units compared to bioprints incubated without added nutrients, suggesting that nutrients diffuse through the slurry to increase viability of bacteria within bioprints. Printing complex structures by combining a low-cost 3D printer with a nutrient delivery method will enable the printing of complex biomaterials with extended functional lifespans and novel applications, including enzymatic degradation, multifunctional sensors, biofilm applications, and more.

10:45 AM SB11.04.05
Printing and Characterizing RNA Gradient Generators Moshe Rubanov, Pepijn Moerman and Rebecca Schulman; Johns Hopkins University, United States

Living organisms detect and produce gradients for a variety of different tasks, including morphogenesis[1,2], chemotaxis[3,4], and distributed computation[5]. Synthetic gradient generators have been developed to recreate the spatially heterogenous chemical environments seen in biological systems. Some previously developed methods for gradient generation include using droplet mixers, hydrogel secretion, membrane channels, and pipette injectors[6]. However, these methods generally create gradients that are difficult to reproduce, are transient (lasting no more than 2 hours), introduce convection, or are difficult to model. Stable gradient generators have been reliably produced using microfluidic convection-based microchannels[7] which produce gradients using a replenishing reservoir of a source and sink. However, convection-based microchannel gradients are difficult to integrate into multiple independently produced gradients capable of interacting with each other within the same chamber. Additionally, the gradient generator developed produces RNA, which can be coupled to fluorescent reporters and to control downstream dynamic processes[8,9]. To build a tunable RNA gradient generator, we anchor transcription templates within hydrogel posts photopatterned within a microfluidic flow cell. These posts act as a chemical source, constantly producing RNA. The RNA diffuses out of the hydrogel posts where it is degraded in solution. We use T7 RNAP and RNase A/T1 to drive local RNA transcription

and global degradation, respectively. Tuning the location and size of the hydrogel posts, along with T7 RNAP and RNAse A/T1 concentrations, enables the building of a tunable set of RNA gradients. To measure these gradients, we use hydrogels with attached "reporter" complexes that react with the RNA and produce a fluorescent signal. Multiple photopatterned source hydrogels could also be used to form more complex additive gradients, more closely recreating environments in cell populations[2]. This platform makes it possible to direct local self-assembly of nucleic acid responsive nanostructures and nanoparticles, and for the study of complex microenvironments in cell cultures.

Yeast Biomaterial for Environmental Remediation Christos E. Athanasiou; Georgia Institute of Technology, United States

Traces of heavy metals found in water resources, due to mining activities and e-waste discharge, pose a global threat. Conventional treatment processes fail to remove toxic heavy metals, such as lead, from drinking water in a resource-efficient manner when their initial concentrations are low.
In this talk, we will present how by using a yeast biomaterial we can effectively remove trace lead from water via a rapid mass transfer process, achieving an uptake of up to 12 mg lead per gram of biomass in solutions with initial lead concentrations below 1 part per million. Furthermore, we will discuss our efforts on using advanced experimental and computational characterization techniques to investigate the lead adsorption mechanisms, and present our discovery that lead adsorption is linked to a significant increase in yeast cell wall stiffness. These findings open new opportunities for using environmentally friendly and abundant biomaterials for advanced water treatment targeting emerging contaminants.

1:30 PM *SB11.05.01
Genomically Recoded Organisms—Living Foundries for Producing Programmable Biomaterials Farren J. Isaacs; Yale University, United States

Materials produced from synthetic chemical processes provide access to a broad range of chemical structures yet are constrained by the lack of sequence-defined polymerization methods. In contrast, biological systems employ sequence-controlled processes to synthesize biomolecules, in which the molecular information encoded by nucleic acids is converted into sequence-controlled protein polymers. However, nature is constrained to a small set of organic monomeric building blocks, the 20 canonical amino acids, thereby limiting the chemical diversity of polymeric biomaterials. Advances in synthetic biology permit the genetic encoding of synthetic chemistries at monomeric precision, enabling the synthesis of programmable proteins with tunable properties. Here, I describe the design and construction of genomically recoded organisms (GROs) possessing open coding challenges. These open codons, together with engineered translation machinery, enable site-specific and multi-site nsAA incorporation in proteins at high yields and purity where multiple identical nsAAs provide the dominant chemical and biophysical properties to proteins or biopolymers. Finally, I will describe the production of sequence-defined biomaterials with applications in highly-conductive protein nanowires and functionalized biotherapeutics. The use of GROs to produce multifunctional, structurally complex materials can be expanded toward the development of a programmable new class of genetically encoded biomaterials with diverse chemistries and broad applications for new classes of enzymes, materials, and therapeutics.

Dynamic Optical Systems Inspired by Cephalopods Georgii Bogdanov, Nikhil Kaimal, Atrouli Chatterjee, Alon Gorodetsky and Aleeza Farrukh; University of California, Irvine, United States

Cephalopods (e.g., squids, octopuses, and cuttlefish) have captivated the imagination of both the general public and scientists alike due to their sophisticated nervous systems, complex behavioral patterns, and visually stunning coloration changes. By drawing inspiration from the structures and functionalities of tunable cephalopod skin cells, we have designed and engineered human cells that contain reconfigurable protein-based photonic architectures and, as a result, possess tunable transparency-changing and light scattering capabilities (1). In turn, we have visualized the refractive index distributions of analogous engineered cells with three-dimensional label-free holotomographic microscopy techniques, and as a consequence, we have developed a detailed understanding of the relationship between their global optical characteristics and subcellular ultrastructures (2). We have moreover extended these efforts to the predictive engineering of the refractive indices and light-scattering properties of multiple self-assembled protein-based platforms, both *in vitro* and *in vivo* (2,3). Finally, we have developed improved chemical and genetic strategies for manipulating the sizes, numbers, and refractive indices of our subcellular structures (4). Our combined findings may facilitate an improved understanding of cephalopod camouflage mechanisms and lead to the development of unique tools for applications in biophotonics and bioengineering.

The Influence of Rhizobium tropici Produced EPM Biopolymer on Green Bush Bean Root and Plant Growth Shirley X. Yu[1], Huiting Luo[2], Youyou Zheng[3], Zihan Wang[4], Melany Fernandez[5], Miriam Rafailovich[2], Marcia Simon[2], Stephen Walker[2], Jay Gao[2] and Steven Larson[6]; [1]Collingwood School, Canada; [2]Stony Brook University, United States; [3]Asheville School, United States; [4]Mulgrave School, Canada; [5]Suffolk County Community College, United States; [6]Army Engineer Research and Development Center, United States

With the increase in severe weather events due to climate change, plant development both aboveground (providing vegetation cover) and belowground (enhancing root systems) is crucial in limiting soil erosion. Traditional chemical fertilizers do allow for these developments but have environmental consequences from polluting waterways to disturbing the natural biodome. Hence, much effort is currently being invested in finding alternative means to enhance plant growth and mitigate soil erosion through the application of environmentally sustainable materials. A Rhizobium tropici (R. tropici) derived biopolymer has been reported as an effective, biodegradable additive to reduce soil erosion. We, therefore, chose to study its effectiveness for root and stem/leaf growth of plants in the early stages of development, starting from the germination of the seeds through the initial growth of leaves and shoots. The plants used were green bush beans due to their relatively short germination time of 7-12 days which allowed us to see the effects of the fertilizers within a short period of time.
Two biopolymer fertilizers, both ethanol precipitable materials (EPM) derived from R. tropici bacteria ATCC strain under the same cultivation environment and procedure but grown in two laboratories, were tested. Green bush beans were divided into five groups: control (tap water) and four EPM treatments. The EPM treatments consisted of the combinations of 50 mg/L EPM1 (from the first lab), 50 mg/L EPM2 (from the second lab), 100 mg/L EPM1, and 100 mg/L EPM2. The beans underwent 10 days of germination and then were transplanted into soil for 3 weeks of further watering with tap water or EPM solutions daily. Mass measurements were used to investigate whether the EPM biopolymer influenced the growth of the roots versus the stems and leaves differently. As such, the green bush bean plants were removed from the soil for roots and plant analysis after 3 weeks of transplantation. The soil was washed off and the plants were dried completely to ensure that the mass was only of the intended roots and stems/leaves. The effects of each treatment were recorded by measuring the masses and lengths of the roots and stems/leaves individually. Mass measurements were used to investigate whether the EPM biopolymer influenced the growth of the roots versus the stems and leaves differently.
Watering bush bean seeds with EPM concentrations as low as 50 mg/L and 100 mg/L produced a small increase in the germination rate: from 87% to 93% for seeds grown for 10 days in a moist environment. The root mass of the plants treated with the EPM solutions increased compared to the control by 29% to 71% (for EPM1) and by approximately 14% (for EPM2). The plants treated with either of the EPM solutions have a mass of stems and leaves that is higher than the control by 45% and 58% for EPM1 and EPM2, respectively. Furthermore, the result shows that there was a 21% to 43% increase in plant height for plants treated with EPM solution. EPM1 and EPM2 solution treated plants showed enhancement in both root and stem/leaf mass compared to the control, but the EPM1 solution was better for root development and EPM2 solution was better for stems and leaves development—consistent with plants typically preferring either root or leaf production. These results suggest that the EPM biopolymer stimulates bush bean plants to develop a denser root structure and a larger leaf and shoot system, which enhances plant survival. Taken together, these results may explain the reported increase in resistance to soil erosion when biopolymer was used to irrigate different berm slope sites.
We would like to thank the US Army Corps of Engineers (ERDC) for their support (W912HZ-20-2-0054) in this research, Dr. Michael Sadowsky for providing the Rhizobium tropici CIAT 899 (UMR 1899) strain, and the Morin Charitable Trust for the funding.

Living Material Systems with Multilayered Genetic Circuits for Biomedical Nanomaterials Urartu Seker; Bilkent University, Turkey

We have developed self-actuating genetic circuits for nanomaterial synthesis using a protein based scaffolding. The self-actuated living material systems can sense the environmental signal, process the signal using the sensor gene circuits, process the gene circuits and create an output which the final nanomaterial scaffolding biofilm protein.[1] In the follow-up study we have focused on nanomagnet synthesizing and tumor colonizing living material systems. The high cancer incidence grows the demand for efficient cancer diagnostic tools with minimized side effects nowadays. Developments in this aspect bring magnetic nanoparticles (MNPs) for biomedical applications due to their stability, biocompatibility, and magnetism properties. In nature, magnetic nanocrystals are synthesized in certain organisms, including many bacteria, which help their spatial orientation and survival by sensing the earth's geomagnetic field. This work aims to convert *Escherichia coli* to accumulate magnetite, which can further be coupled with drug delivery modules. For that, we designed bacterial machines in a way to accumulate magnetite using genetic circuitries hiring Mms6 with iron-binding activity and essential in magnetite crystal formation. Our work demonstrates that the combinatorial effect of Mms6 with ferroxidase, iron transporter protein, and material binding peptide enhances the paramagnetic behavior of the cells in magnetic resonance imaging (MRI) measurements. Alternatively, cellular machines are also engineered to display Mms6 peptide on the cell surface via an autotransporter protein[2] providing easy synthesis conditions that showed augmented MRI performance. Our findings are promising for endowing a probiotic bacterium, able to accumulate magnetite intracellularly or extracellularly, serving as theranostics agent for cancer diagnostics via MRI scanning, drug delivery, and hyperthermia treatment.[3] The study was supported TUBITAK 115M108

Programmable Living Materials with Engineered Spore-Forming Bacteria and Synthetic Macromolecules Seunghyun Sim; University of California, Irvine, United States

In this talk, I will present the Sim lab's recent efforts in developing programmable living materials with engineered spore-forming bacteria, Bacillus subtilis, and synthetic macromolecules. Programmable aspects of these living materials, both in terms of genetic engineering of B. subtilis and molecular-level control in synthetic polymers, will be discussed. I will also highlight unique properties and characteristics of these living materials.

3:45 PM SB11.06.03
Genetic Logic Gates Enable Patterning of Amyloid Nanofibers Recep E. Ahan, Cemile E. Ozcelik, Ebuzer Kalyoncu and Urartu Seker; Bilkent

University, Turkey

Many biological structures contain spatially organized materials produced by cells. Appearance of organized materials in distinct kingdoms indicates that organized materials provide advantages against natural selection. There are many examples of biological process which harvest the power of unique feature of spatially organized structures. Here, we developed recombinase enabled logic gates to synthesize organized materials in *E. coli*. The gates can utilize to record exposure of environmental signals and adjust to synthesize certain types of CsgA based fibrillous biofilm materials. Composition of fibrillous/cell biofilm material can be regulated by user-defined signals. We envision that recombinase based genetic circuits provide available route to the control composition and spatial organization of living materials.

The study was supported by TUBITAK Grant Numbers 114M163 and 216M127. U.O.S.S. thanks the TUBA-GEBIP Award. E.K. thanks TUBITAK BIDEB Graduate Fellowship.

Chemically Modified *Bifidobacterium bifidum* for Cancer Immunotheranostics Using Photothermal Therapy Sheethal Reghu and Eijiro Miyako; Japan Advanced Institute of Science and Technology (JAIST), Japan

Conventional cancer therapies face a myriad of shortcomings which has hampered their widespread application. Bacteria-driven cancer therapy has emerged as a very promising therapeutic strategy, offering numerous advantages such as high selectivity, specificity, and high-targeting efficiency. They possess numerous unique mechanisms for treating cancer that are unachievable with standard methods.[1]
In this project, we report the modification of an anaerobic bacteria, *Bifidobacterium bifidum*, which exhibits an innate anticancer efficiency. [2] The bacteria were modified by incorporating a photothermal agent, indocyanine green with cremophor EL, by incubation process.[3] Cremophor EL, an FDA-approved polyoxyethylene castor oil derivative, commonly used in poorly water-soluble drugs was added to indocyanine green molecules for encapsulation thereby forming indocyanine green with cremophor EL nanoparticles. After overnight incubation with *Bifidobacterium bifidum*, indocyanine green with cremophor EL molecules penetrated the bacterial membrane forming the modified bacteria, thereby changing their color from white to green. These modified bacteria were capable of absorbing light in the near-infrared (NIR) region thereby making them provide an excellent photothermal conversion efficiency. Characterization of these chemically modified bacteria was carried out using UV spectroscopy, transmission electron microscopy, fluorescence spectroscopy, and confocal microscopy to determine their absorption range, structural and morphological changes, and to elucidate their mechanism resulting in their modification. Furthermore, they exhibited low toxicity and high temperature elevation in *in-vitro* studies with and without laser irradiation. *In vivo* studies were conducted in syngenic tumor mice models to study the tumor targeting efficiency using colon26 cancers. The modified anaerobic bacteria were intratumorally injected and their accumulation was observed solely in the hypoxic environment inside the tumor leaving other organs, and their distribution was determined using an NIR fluorescent imaging system. Additionally, the treatment of these colon cancers was carried out by photothermal therapy, by irradiating the tumors at 0.7W using an 808nm NIR laser after 24 hours of intratumoral injection. The application of photothermal therapy was observed by the temperature elevation caused by the NIR laser on the tumor surface resulted in excellent anticancer efficiency causing the disappearance of the tumor after a few days. The blood test results in tumor mice models also revealed that the modified bacteria were completely non-toxic and biocompatible in mice. Various tissue staining techniques were also carried out to explain the mechanism of tumor suppression. In summary, this study demonstrates a very simple mechanism of nanoengineering the bacteria without any complicated genetic manipulation, rather a much simpler process to modify bacteria to increase their efficiency at the same time maintaining their morphology, function, and structure. This study demonstrates the potential for bacteria therapy in cancer theranostics as they can provide a paradigm-shifting knowledge for the development of next-generation anticancer agents by nanoengineering the bacteria.

Biochemical Networks for Controlling the Growth and Metamorphosis of Soft Materials Rebecca Schulman; Johns Hopkins University, United States

Complex cellular behaviors such as motion and division are directed by far-from-equilibrium chemical networks that regulate the assembly and reconfiguration of a cell's architecture at the molecular scale. The ability to program the evolution of synthetic materials using designed chemical networks in fashions similar to the way biological networks regulate a cell and tissue architecture could be a route to building radically new materials that could grow into specific shapes, heal, or adapt to their environments. Building and improving these systems might also provide new perspectives on the structural organization of cells and tissues and on the genetic and signal transduction networks that regulate these cell and tissues' structures and therefore, functions. We have been developing synthetic components that dynamically assemble and change the shapes of biomolecular materials, specifically hydrogels and semiflexible polymer networks, and corresponding synthetic chemical networks that can regulate these materials' dynamic assembly. I will describe how different biomolecular signals can induce different dynamic polymerization and depolymerization processes in these materials and how chemical networks can be coupled to these materials to induce dynamic material behavior. To understand what new behaviors can arise in these systems when their chemical networks become large and complex, we have recently developed integrated synthetic in vitro genetic regulatory networks consisting of oligonucleotide templates, T7 RNA polymerase and an RNase. These networks can consist of tens of different interconnected network elements and could be used to build synthetic regulatory networks of complexities comparable to those of simple viruses or those that construct macromolecular complexes inside cells.

Diblock Polypeptide Hydrogels as Bioinks for 3D Printing in Tissue Engineering Muireann Cosgrave; Royal College of Surgeons Ireland, Ireland

The use of 3D printing in tissue engineering (bio-printing) has rapidly increased throughout recent times, namely due to its ability to construct more complex, cell-viable 3D structures.[1] Hydrogels are a prominent choice for bio-ink formulations as they can be engineered to simulate the native extracellular matrix (ECM).[2] Furthermore, their mechanical properties can be altered to optimize printability and cytocompatibility properties. For particular applications, the choice of hydrogel used in bio-printing processes encompasses several important considerations, particularly that its strength is stable and suitable for the printing process, whilst also being comparable in strength to that of the native tissue it is replacing.[2]
Here we present a range of amphiphilic star-shaped diblock co-polypeptides consisting of methacrylamide functionalized poly(L-glutamate)-b-(L-leucine) with different star architectures. The hydrophobic side chains of the L-leucine blocks drive the self-assembly of the polypeptides in water, spontaneously forming stable hydrogels. The mechanical properties of these materials are readily tuned by varying the star architecture and the monomer feed used. They also possess shear-thinning and self-recovery properties, indicating their suitability for extrusion based 3D printing. Complex 3D printed structures can be readily generated and then photo-crosslinked using visible light (405 nm) in the presence of comonomers. Printed hydrogels show good biocompatibility and represent viable bio-ink material platforms for tissue engineering.

Skin-Actuator Interactions for Vibrotactile Haptic Applications Jin-Tae Kim, James E. Colgate and John A. Rogers; Northwestern University, United States

Recent advances in skin-integrated vibrotactile haptic devices offer the capability of realizing a sense of touch, not only at the fingertips but across all regions of the body in virtual settings. However, many challenges lie ahead for creating realistic tactile interactions, owing to the complexity and lack of understanding of our somatosensory system and associated skin-actuator interactions. Here, we experimentally explored nearly all types of off-the-shelf vibrotactile sensors including an eccentric rotating mass (ERM), linear resonant actuator (LRA), tactor, and piezoelectric actuator interfacing directly to the skin surface and skin-like materials. Non-intrusive optical methods, including 3D Digital Image Correlation (DIC), Particle Tracking Velocimetry (PTV) and Eulerian Video Magnification (EVM), were implemented to decipher important continuum mechanic properties relevant to mechanoreception, including strain and acceleration at different depths in a skin phantom. Additional parameters, such as contact area, power input, frequency, and viscoelasticity, as well as customized perception tests, are considered to further correlate skin-actuator interactions and tactile perception. These findings will provide reference data for model validations and optimal strategies for developing next generation haptic devices.

10:45 AM SB12.01.02
Bioinspired Robotic Cutaneous Sensor System for Softness Detection Haotian Chen, Ivan Furfaro and Stephanie P. Lacour; Ecole Polytechnique Federale de Lausanne, Switzerland

Softness perception is a unique feature of the human skin, which is very useful during object manipulation tasks. However, this distinctive function relies on the skin deformation under pressure, and is hard to mimic in traditional robotic technology.
Although some research groups have developed several compliance sensing modules based on flexible or stretchable electronic technologies, the interaction between a soft artificial device and a target object, in terms of Young's modulus, is rarely considered. Specifically, when the target material is stiffer than the sensor, a large deformation occurs in the device while there is negligible deformation on the contacted object. Conversely, a softer object may deform more than the soft sensing module itself. As a result, even under the same external pressure, the deformation of the sensor depends on the difference in Young's moduli of the materials forming the target object and the sensor. Such variation could cause significant errors in the measurement and thus, hinder the correct characterization of the compliance.
Inspired from the human tactile system, we report on liquid metal-based soft sensor modules for softness detection. Each sensing unit comprises a strain sensor and a pressure sensor to measure deformation and pressure simultaneously. We propose an analytical mechanical model to describe the interaction between the soft sensor and the soft target, and simulate the system using finite element modeling. Following a calibration, we successfully distinguished engineering materials such as rubber and hydrogel and some biological tissues including chicken chest and heart. Next we prepared a 4x4 sensor matrix and successfully quantified the compliance and spatial distribution of several objects. This softness sensing technology may be implemented in applications such as robotic palpation or precise teleoperation.

11:00 AM SB12.01.03
A Nanomesh Pressure Sensor for Monitoring Finger Manipulation While Avoiding Interference with Human Sensations Sunghoon Lee, Tomoyuki Yokota and Takao Someya; The University of Tokyo, Japan

An ultimate goal of biological information measurement is to monitor states of a living body in a non-invasive, continuous and accurate manner without disturbing the natural functions or activities of the living body. Because sensors in direct contact with biological tissues are inevitably exposed to physical disturbances caused by physical contact, considerable efforts have been made to minimize the effects of sensors. In temperature measurement, for example, it is necessary to reduce heat capacity or thermal conductance of sensors in order to suppress the effect of heat transfer from the object to the sensor. In addition, because our living body is soft and has a three-dimensional structure, it is required to use soft and/or flexible sensors to reduce the effects from modulus differences, and to achieve the stable contact to the curved objects. Recent development of soft and flexible pressure sensors has enabled to detect biological information such as human pulse or intraocular pressure, and human motions.

To continuously monitor biological information over a long period of time, sensors are required to exhibit a high mechanical durability. Soft and flexible pressure sensors allow an operation in bent or twisted states. The use of ultra-thin substrates and CNT/graphene nanofibers reduces a mechanical stress to sensors in the bent state, and results in an accurate detection of pressure with a bending radius of 80 μm. Recently, pressure sensors using porous PDMS or microstructured PDMS with Ag-NW coating have maintained a high pressure sensitivity (20 kPa^{-1}) without a damage under large pressure loads in MPa range. Furthermore, the use of rubber or textile gloves to protect the sensors significantly improves the durability of sensors, because such thick and durable materials prevent the sensors from causing mechanical damage to external forces.
However, there still remain challenges to achieve practical durability of sensors while maintaining a natural skin sensation. When the thickness of the material applied to the skin is reduced, the skin can sense external changes more easily. However, thin materials are vulnerable, because the force required to penetrate and/or break the material, is proportional to the thickness of the material. Furthermore, thin materials are easily scraped off against surface frictions. In order to improve the frictional durability while maintaining the overall thickness thin, it is necessary to reduce a friction coefficient of the surface materials to reduce scraping, or to introduce rigid protective materials to minimize a plastic/rubber deformation of the surface materials. However, such approaches cause a difference with the surface of a normal finger and an influence on the sensation due to a difference in mechanical properties with the skin.

Here, we present extremely durable nanomesh pressure sensors that can be attached on human skin without affecting human senses. The nanomesh sensors are ultra-thin (10 μm) and lightweight, and all layers are composed of nanoporous structures. The sensors exhibit a high mechanical durability against lateral pressures such as shearing or friction, as well as vertical pressing. The performance of sensors can be maintained without a significant degradation or breaking, although the surface of sensor was directly rubbed while pressing with a high pressure of more than few hundreds kPa.

11:15 AM *SB12.01.04
Fibers and Meshes Designed as Artificial Muscles Andreas Lendlein; University of Potsdam, Germany

Fibers from shape-memory polymers (SMP) can be programmed to shrink, twist, bend or even knot themselves upon exposure to heat. Their integration in textiles can enable complex macroscopic motions or lead to changes in haptics or diffusivity of water vapor. Here (sub)micron fibers and meshes are presented, which were prepared by electrospinning. Fiber meshes from crosslinked semi-crystalline polymers exhibited a thermally-controlled actuation capability, which could be used to reversibly adjust pore diameters in polymer filters [1]. The fiber diameter has been identified as effective design parameter with regard to actuator performance. A high degree of molecular orientation could be obtained by processing for small diameter fibers. The angels between stacked layers, in which fibers are aligned in parallel, and the covalent interlinking at fiber contact areas are relevant design parameters for the fabrication of fiber meshes with anisotropic actuation capabilities [3]. Finally, electrospun meshes from degradable shape-memory polymers [4] have been explored as epicardial patch system, which can guide postinfarct myocardial remodeling processes [5].

Ultra-Soft Transducers with Organic Electronics for Skin-Sensor Systems Takao Someya[1,2], Tomoyuki Yokota[1], Sunghoon Lee[1] and Kenjiro Fukuda[2]; [1]The University of Tokyo, Japan; [2]RIKEN, Japan

Extremely soft and lightweight electronic devices can acquire biological signals such as pressures [1,2], blood pressure [2], electrocardiogram [3] on the skin, cell sheets, and textiles with minimized uncomfortableness when attached and without sensory interference. Combining such ultra-soft sensory systems with an ultra-lightweight or wireless power supply makes it possible to realize self-powered transducers [5,6]. We will report recent progress of the ultra-flexible organic photonic system and the nanomesh based skin sensors. To realize the air-stable organic photonic system, we developed the ultra-flexible organic light emitting diode with inverted structure. The lifetime of the OLED is longer than 1 week. In addition, we realized the self-adhesive nano sheet which was reinforced by polymer nanofiber. We succeed to monitor the ECG signal for a one week by attaching the nano-sheet electrode. [1] S. Lee et al., Science, 370, 966-970, (2020). [2] J. Zhong et al., Adv. Mater. 34, 2107758 (2022). [3] T. Yokota et al., Adv. Mater. Technol. Doi: 10.1002/admt.202200454 [4] S. Lee et al., Nat. 2:30 PM SB12.02.03
High-Resolution Piezo-Resistive Film Based on Aligned Nickel Particle Network for Mimicking Receptor Systems of Human Skin Hanul Kim, Seongdae Choi, Jiseok Seo and Yongtaek Hong; Seoul National University, Korea (the Republic of)

Electronic skin (E-skin), which is electronics that mimic the properties of human skin, has recently received increasing attention owing to its various applications, such as the human-machine interface and health monitoring devices. For the E-skin to interact with its surroundings in the same way as real human skin does, it is necessary to develop skin-like flexible sensors capable of detecting most of the physical contacts and physiological activities of the human body. Hence, a flexible pressure sensor for E-skin applications is required to detect external pressure at various levels to cover the entire pressure range in our daily life. In addition, as tactile receptors are distributed all over human skin in high density, a pressure sensor array for mapping high-resolution pressure distribution is also needed. To date, many studies focused on the pressure performances of a single sensor, attaining high sensitivity through additional microstructures. However, their pressure response quickly reached the saturation region at the level of simple touch and showed limitations in achieving high-resolution arrays due to crosstalk effects from the adjacent pixels. Organic field-effect transistor (OFET) based structures also have been adopted to overcome the crosstalk effect, but they used high cost and time-consuming processes such as photolithography or evaporation process.
In this work, we demonstrate a facile fabrication of flexible piezoresistive film based on anisotropically aligned micro-sized Nickel (Ni) particles embedded in polydimethylsiloxane (PDMS) composite. First, we prepare an uncured mixture of Ni/PDMS and place between the two strong magnets. Using the ferromagnetic property of Ni particles, whole particles in the film are aligned in the direction of a vertical magnetic field. After the curing process, filamentous conduction paths of Ni particles are formed, enhancing the pressure sensitivity and minimizing crosstalk effects compared to the film with randomly distributed Ni particles. To obtain the pressure sensor array, electrodes are deposited on the top and bottom sides of the film by spray-coating silver nanowire (AgNWs) ink. As the sensing pixels are defined at the intersection of top and bottom electrodes, the resolution of the sensor array can be adjusted by the pitch of the deposited electrode array up to 100dpi, which far exceeds the receptor density of human skin. This system is advantageous in imitating the receptor systems of human skin that have different densities for each body part. Using a resolution-varying read-out circuit that includes top and bottom electrode arrays with multiple pitches ranging from 0.25 mm to 1 mm, we can present an identical pressure distribution at various spatial resolutions using a single piezo-resistive sheet, detecting the same way as the human hand which has 4-fold difference in receptor density. The sensor can also detect a broad pressure range of up to 373kPa in high sensitivity, covering the entire pressure stimuli associated with human activities.

High-Efficiency Stretchable Light-Emitting Polymers from Thermally Activated Delayed Fluorescence Wei Liu[1,2], Cheng Zhang[1], Juan J. de Pablo[1,2] and Sihong Wang[1,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

Stretchable electroluminescent (EL) polymers are the key components for realizing skin-like displays and optical bio-stimulations, which can offer unique functionality for information visualization, wirelessly signal/power transmission, and medical therapies. However, in contrast to other types of stretchable devices, such as sensors and transistors, stretchable EL devices have lagged behind in terms of combining high stretchability with high EL efficiency. All stretchable emitters reported to date have been based on “first-generation” EL polymers that can only harness the singlet excitons with a theoretical quantum yield of 25%. In this work, we present a material design concept for imparting the stretchability onto “third-generation” EL polymers that can harness all the excitons through thermally activated delayed fluorescence (TADF), thereby with a theoretical near-unity quantum yield. Our novel design concept for such stretchable light-emitting polymers is the backbone insertion of flexible, linear units between TADF units, which, as shown both experimentally and theoretically, provides very effective strain dissipation for stretchability without causing any sacrifice to the EL performance. Therefore, enabled by the highly efficient TADF processes and extraordinary stretchability, record-high external quantum efficiency (EQE) is achieved even at 100% strain. Besides, the concept is generalizable to achieve blue-green-red full-color stretchable light-emitting polymers. Demonstrated by the fully stretchable organic light-emitting diodes (OLEDs), the stretchable TADF polymers provide an unparalleled path towards achieving all the desired EL and mechanical characteristics, including high efficiency, brightness, switching speed, stretchability, and low driving voltage.

3D-Stacked Thin-Film Transistors for Simultaneous Detection of Pressure and Temperature Youngmin Jo and Sungjune Jung; Pohang University of Science and Technology, Korea (the Republic of)

Deformable sensors can be conformally attached to a curvilinear surface, so they can detect stimuli successfully. They have been widely investigated in electronic-skin applications such as soft robots and prostheses. Due to emerging nanotechnology and materials science, various deformable sensors have recently been developed. Fabrication of sensors using thin-film transistors (TFTs) is one of the primary development trends. The sensors have shown some advantages such as improvement in sensitivity and minimal crosstalk. However, the TFTs are affected by temperature T, which causes a T-responsiveness of the sensor which is intended to detect some stimulus, not T. To detect an accurate stimulus regardless of T, the T influence must be calibrated. Although a multi-functional sensor with T calibration was proposed, their calibration methods required T sensors that used poly(vinylidene fluoride-co-trifluoroethylene). To utilize the calibration method widely, a more-general T sensor must be used for the calibration method. In this study, we demonstrate

a multi-functional sensor that can detect pressure *P* and *T* synchronously. The multi-functional sensor is composed of a *T* sensor and a *P* sensor. A *T* sensor is fabricated using organic thin-film transistors (OTFTs). On the *T* sensor, a *P* sensor is fabricated using OTFTs and a piezo-resistive sheet. The *T* sensor is influenced by only a change of *T*, whereas the *P* sensor is influenced by a change of both *P* and *T*. To produce accurate *P* information regardless of *T*, the current value of the *P* sensor is calibrated using the *T* value produced from the *T* sensor. Finally, the multi-functional sensor is attached to a robotic gripper and the gripper with the sensor successfully holds and lifts a hot cup.

3:45 PM SB12.02.06
Controllable Degradation Conductors for Soft Robotic Tactile Skin Pietro Cataldi, Lorenzo Natale and Athanassia Athanassiou; Italian Institute of Technology, Italy

Materials employed in tactile sensors for robotics are typically an engineered version of current rigid, bulky, and long-lasting materials for electronics.[1] Thus, they are not suitable for flexible and motile parts of robots and do not mimic the human or animal skin that is soft, flexible, and biodegradable.[2,3] As a result, the development of tactile sensors that are conformable, lightweight, and produced with degradable and readily available materials is crucial.[3]

Among various technologies, capacitive sensors have been successfully employed to build sensorized skins for robots. The main challenge in adopting this technology is the need for conductors and dielectrics materials with appropriate properties. While biobased and biodegradable dielectrics such as biopolymers and natural polymers, like proteins, are abundant, conductors that degrade after performing a specific function are unavailable.[4]

We propose electrical conductors with a controllable degradation, finely controlled through the material formulation. We show that the degradation can be tuned from minutes to months, depending on the composition. This unique technology is suitable for applications where long-term stability is crucial, such as robotic skin and those requiring environmentally controlled degradation, such as bioresorbable transient electronics. The conductors display Ohmic I-V curves and sheet resistance in the order of 10 Ohm/sq. They can be applied as a coating to various flexible dielectric substrates. We assembled such conformable electrical conductors with degradable dielectrics to build soft capacitive tactile sensors that exhibit tunable degradation. Such soft haptics sensors can be designed ad hoc to sensitize various parts of the robots, from the fingers to the feet. Indeed, depending on the Young modulus of the dielectric used to build the capacitors, different degrees of deformation can be achieved at a specific load applied (from grams to kilograms). This artificial skin is assembled as human mimicking robotic skin for the iCub humanoid robot, the flagship open-source robot developed by the Italian Institute of Technology.[1]

4:00 PM *SB12.02.07
Tactile Sensitivity to Molecular Scale Phenomenon—New Routes for Fine Touch Charles Dhong; University of Delaware, United States

For the sense of sight or hearing, displays and speakers can recreate a wide variety of scenes and sounds. For touch, however, haptic devices cannot recreate the variety of sensations from our everyday experiences. The ability to recreate rich and accurate tactile sensations could have broad implications in human machine interfaces, soft robotics, and disability rehabilitation. While most haptic devices rely on reconfigurable bumps or electrical stimulation, we explore how tactile sensations can be created through materials chemistry.

A challenge to rationally controlling touch is that fine touch is a complex mechanical event where the finger, a deformable and heterogeneous interface, slides across an object, generating friction. These mechanical vibrations from friction are the source of mechanical stimuli which ultimately lead to a tactile percept. In this talk, we describe our efforts to modulate friction through surface chemistry to generate tactile sensations. Through mechanical testing and novel analysis, we can predict whether or not humans can discriminate between two coatings, which allows us to rapidly screen through materials prior to human testing. Using this platform, we show that humans can perceive molecular level differences—even when supported on relatively smooth silicon wafers. These molecular level phenomena range from single atom substitutions in silane-derived monolayers, to the degree of crystallinity in polystyrene films. Our materials chemistry-based routes are complementary to many existing haptic actuators and could broaden the variety of tactile sensations generated in haptic devices.

4:30 PM SB12.02.08
Flexible High Sensitivity Tactile Sensors for Electronic Skin Applications Antonello Mascia, Andrea Spanu, Annalisa Bonfiglio and Piero Cosseddu; University of Cagliari, Italy

Nowadays, in an increasingly interconnected world, where the daily monitoring of various bio/physical parameters is growing rapidly, electronic devices and sensors are permeating everyday life. In this context, flexible and conformal materials and systems have allowed a dramatic growing of bio-integrated electronic systems for monitoring different parameters and, particularly, epidermal electronic is a new field of application in which electronic devices can be transferred directly onto the skin.
To fulfill this aim, device architectures that can match the mechanical properties of the human skin have to be developed. Moreover, it is necessary to develop a procedure that allows to transfer onto the skin such devices in a reliable way, while preserving their performances.
In this work we report a tattoo-like electronic systems, that can be easily fabricated on sub-micrometer thick plastic substrates and employed for the detection of several parameters. The proposed system has been fabricated on a plastic carrier, coated with a water-soluble material acting as sacrificial layer. At the top of such structure, an ultrathin film of Parylene C is deposited through a large area deposition process. This procedure is compatible with the fabrication of several kinds of electronic devices, such as sensors or electrodes for the monitoring of electro-physiological parameters.
We have used such approach for the fabrication of high sensitivity transistor-based tactile sensors, employing a Sub-micrometer Channel Organic Charge Modulated Field Effect Transistor (SC-OCMFET). This architecture represents a versatile tool for the realization of a wide range of sensing applications, from bio/chemical to force/pressure sensing. The proposed device is based on a floating gate organic transistor, capable to be operated at low voltages thanks to an ultra-thin, hybrid dielectric. In order to achieve sensitivity to pressure, a piezoelectric thin film, namely PVDF, is coupled with the sensing area of the device. In this way, when a pressure is applied on the PVDF, the charges induced in the piezoelectric film led to a variation of transistor threshold voltage and a current variation can be detected as a result of the applied pressure. The signal of the piezoelectric material is thus locally amplified by the short-channel transistor. As the device sensitivity depends on the ratio between the sensing area and the channel area of the transistor, a reduction of the

channel length can lead to a significant increase in the sensor sensitivity. We herein propose an easy and reproducible approach for the fabrication of sub-micrometer SC-OCMFETs that does not require expansive and time consuming high resolution techniques, and that allowed us to achieve very high sensitivity, if compared to the previously reported planar devices. Moreover, this approach, allows at the same time to dramatically reduce the area occupied by the amplifying transistors, which is very important when dealing with the fabrication of arrays and matrices of tactile sensors. The fabricated devices are capable to detect very small stimuli, with an impressive sensitivity, and can detect forces within a range from 0.01 up to 1 N and pressures below 100 Pa. Moreover, since the PVDF is also a pyroelectric material, temperature variations ranging from 10° up to 45 °C could be also detected. Interestingly, since the responses of the device to the two different physical stimuli are characterized by marked differences in sensitivity and response time, it is possible to employ the same device for the fabrication of multimodal tactile sensing systems. The highly flexibility of the developed structure, and the easiness of the employed process, make this solution very interesting for the fabrication of multimodal, highly compliant artificial skin.

4:45 PM SB12.02.09
A Conformable Thermo-Actuated Tactile Display Arianna Mazzotta[1,2], Silvia Taccola[3], Ilaria Cesini[1], Russell A. Harris[3] and Virgilio Mattoli[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Scuola Superiore Sant'Anna, Italy; [3]University of Leeds, United Kingdom

Conformable electronic devices have the capability to adhere to non-flat surfaces without changing their properties and performances. They are therefore able to easily comply with the multiple deformations of the human skin allowing imperceptibility, high comfort level, and continuous use for the user. In addition to several other sensorized devices, conformable electronics could be used to provide stimuli to the human body, for example through the development of tactile displays for visually impaired people or for human-machine interfaces.
In this work, we propose a conformable and disposable thin haptic display capable of providing vibro-tactile sensations. The device consists of a matrix of unit cells that can be selectively activated in order to reproduce Braille characters and/or complex dynamic information. This new device exploits the low thermal capacity of thin conductive films that allow the generation of fast, controlled, and localized heat flow. Each unit cell is characterized by a printed micro serpentine-shaped resistor that can heat up due to the Joule Effect.
Each resistor is inside a small chamber containing air. In particular, the upper wall of this chamber consists of a deformable PDMS membrane that swells - following the applied pulsed voltage - thanks to the thermal expansion of the air. The soft display can be attached to human skin using double-sided medical tape so that this movement elicits a vibro-tactile sensation on the skin.
Finite Element Simulations were first conducted in order to verify that the chosen geometry permitted localized heating with consequent swelling of the membrane. A process of Aerosol Jet Printing technique allowed the fabrication of the very small serpentine-shaped resistors by directly printing silver nanoparticle ink on a 25 µm Kapton substrate. The printing parameters identified were used to achieve a good trade-off between a high resolution of the designs (70 µm line-width) and a suitable level of conductivity. The next steps of the fabrication allowed us to create closed volumes of "trapped" air at the level of the resistors by techniques including plasma treatment and spin coating. After the assessment and optimization of the fabrication process, the device was assessed by functional tests that revealed a fast activation time of each cell (in the order of tens of ms), low working voltages (< 10 V), and an output force above the perception threshold at that working frequency.
This conformable soft display has multiple benefits. Firstly, the printing techniques offer great versatility and fast prototyping for the design of specific applications. Secondly, owing to its low thickness, the display conforms to the skin, increasing the level of perception of tactile sensation. Moreover, the presented working principle allows the fabrication of a light, flexible, and low-voltage device, paving the way for the development of a fully-portable haptic device in the future.

SESSION SB12.03: Materials I

Graphene-Based Intrinsically Stretchable Two-Dimensional-Contact Electrodes for Highly Efficient Organic Light-Emitting Diodes Huanyu Zhou[1], Shin Jung Han[1], Amit Kumar Harit[2], Dong hyun Kim[2], Dae Yoon Kim[3], Yong Seok Choi[3], Hyeokjun Kwon[1], Kwan-Nyeong Kim[1], Gyeong-Tak Go[1], Hyung Joong Yun[4], Byung Hee Hong[3], Min Chul Suh[5], Seung Yoon Ryu[2], Han Y. Woo[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Graphene Square, Korea (the Republic of); [4]Korea Basic Science Institute, Korea (the Republic of); [5]Kyung Hee University, Korea (the Republic of)

Intrinsically stretchable organic light-emitting diodes (ISOLEDs) are becoming essential components of wearable electronics. However, the efficiencies of the ISOLEDs have been highly inferior to their rigid counterparts, which is due to the lack of ideal stretchable electrode materials that can overcome the poor charge injection at one-dimensional metallic nanowire/organic interfaces. We demonstrate highly-efficient ISOLEDs that use two-dimensional-contact stretchable electrodes (TCSEs) that incorporate a graphene layer on top of embedded metallic nanowires. The graphene layer modifies the work function, promotes charge spreading, and impedes inward diffusion of oxygen and moisture. The work function (WF) of 3.63 eV is achieved by forming a strong interfacial dipole after deposition of a newly-designed conjugated polyelectrolyte with crown ether and anionic sulfonate groups on TCSE; this is the lowest value ever reported among ISOLEDs, which overcomes the existing problem of very poor electron injection in ISOLEDs. Subsequent pressure-controlled lamination yielded a highly efficient fluorescent ISOLED with an unprecedently high current efficiency of 20.3 cd/A, which even exceeds that of an otherwise-identical rigid counterpart. Lastly, a three-inch five-by-five passive matrix ISOLED was demonstrated using convex stretching. This work can provide a rational protocol for designing intrinsically stretchable high-efficiency optoelectronic devices with favorable interfacial electronic structures.

Good and Bad Elastomers for Stretchable Gold Nanowire Composites Samuel Lienemann[1], Ulrika Linderhed[2,1], Ioannis Petsagkourakis[2,1], Nara Kim[1], Valerio Beni[2] and Klas Tybrandt[1]; [1]Linköping University, Sweden; [2]RISE, Sweden

Soft and stretchable electronic materials for wearables and implants can have a demanding set of requirements, including biocompatibility, specific mechanical and electromechanical properties, long-term stability, and good electrode performance. To meet these requirements, we have over the years developed stretchable gold nanowire-based conductors for a variety of applications, such as implantable electrode arrays, organic thermoelectric generators, and organic supercapacitors and batteries. Different types of elastomers can be advantageous for certain applications based on their properties

and processing. However, when using different elastomers together with gold nanowires we have noticed huge differences in electromechanical performance of the composites, despite similarities in Young's modulus of the elastomers. Here I present our investigation into the causes of these major variations by comparing the performance, properties, and behavior of 5 different elastomer systems of similar modulus in combination with gold nanowires. The findings have implications when choosing elastomers for stretchable electronic composites and provide support for the interpretation of variations in electromechanical performance.

Sustainable Materials and Design Approaches for Soft Electronics and Robotics Martin Kaltenbrunner; Johannes Kepler University, Austria

Modern societies rely on a wide range of electronic and robotic systems, with emerging stretchable and soft form factors enabling an ever more intimate integration of the digital and biological spheres. These advances however often take their toll on our ecosystem, with high demands on energy, contributions to greenhouse gas emissions and severe environmental pollution. Mitigating these adverse effects is amongst the grand challenges of our society and at the forefront of materials research. The currently emerging forms of soft, biologically inspired electronics and robotics have the unique potential of becoming not only like their natural antitypes in performance and capabilities, but also in terms of their ecological footprint.
This talk introduces materials and methods or soft systems that facilitate a broad range of applications, from sustainably powered, transient electronic skins to metabolizable soft robots. Based on highly stretchable biogels and degradable elastomers, our forms of soft electronics and robots are designed for prolonged operation in ambient conditions without fatigue, but fully degrade after use through biological triggers. Electronic skins provide sensory feedback such as pressure maps, strain, temperature and humidity sensing. Recent advances in 3D printing of biodegradable hydrogels enables omnidirectional soft robots with multifaceted optical sensing abilities. Tackling the challenge of autonomous operation, soft, stretchable and biodegradable batteries are introduced that power wearable sweat sensors. Pushing the boundaries further, design concepts that exploit mechanical instabilities for fast actuation in soft robotics systems to environmentally friendly cooling systems based on the giant elastocaloric crystallization effect are demonstrated.

9:00 AM SB12.03.04
Material and Device Designs in Biomimetic Polymer Electronics Sihong Wang; The University of Chicago, United States

The vast amount of biological mysteries and biomedical challenges faced by humans provide a prominent drive for seamlessly merging electronics with biological living systems (e.g. human bodies) to achieve long-term stable functions. Towards this trend, one of the key requirements for electronics is to possess biomimetic form-factors in various aspects for achieving long-term biocompatibility. To enable such paradigm-shifting requirements, polymer-based electronics are uniquely promising for combining advanced electronic functionalities with biomimetic properties. In this talk, I will introduce our new molecular design, chemical synthesis, and physical-processing concepts for polymer semiconductors, which enabled the incorporation of multiple biomimetic properties with advanced electronic functionalities. Fundamental understandings that have been obtained about the structure-property relationship in these unprecedented material designs are serving as the foundation for opening up this new research direction for polymer semiconductors. Furthermore, enabled by these new materials, we have also created new device designs and fabrication processes for building unprecedented functional devices (i.e., sensors, LEDs, transistors) that are intrinsically stretchable with unperturbed performance when operating conformably on human bodies. Collectively, our research is opening up a new generation of electronics that fundamentally changes the way that humans interact with electronics.

9:15 AM SB12.03.05
Molecular-Scale Design of Piezoelectric Core-Shell Nanofibers for Wearable Electronic Devices Application Guangshuai Han, Yining Feng and Na Lu; Purdue University, United States

Wearable electronics as a viable mean to realize human-machine interaction have been developed and evolved over the centuries. Polymer-based piezoelectric materials, which can conformably covert human motions to electrical signals, exhibit excellent potential in the application of wearable electronics. However, the discovery and design of functional composites with high piezoelectricity and long-term stability is a significant challenge. Limited study has focused on theoretical modeling approaches to design high-performance polymer-based piezoelectric materials. Herein, we adopt the molecular dynamic approach to design a core-shell structure polyvinylidene fluoride (PVDF) based composite with enhanced crystallinity and electroactivity. Based on the results from the molecular dynamic simulation, the strong intermolecular interaction among the hydrogen bonding is an effective strategy to enhance the crystalline phase of the PVDF. In addition, we synthesized the nano-fibrous composites using the sol-gel method with a piezoelectric shell structure and conductive core structure. The optimized core-shell structure and enhanced crystallinity were confirmed by the experimental characterization results. The as-fabricated flexible piezoelectric devices exhibit significantly enhanced piezoelectricity with a 4 times increase in signal intensity. This unique core-shell structure of piezoelectric nanofibers opens up broader applications such as the Internet of Things and the human-machine interface. Moreover, this work could provoke a new approach for accelerating the design and discovery of functional materials for wearable electronics by using molecular dynamics simulation.

9:30 AM SB12.03.06
Chip-Less Wireless Electronic Skins by Remote Epitaxial Freestanding Compound Semiconductors Yeongin Kim[1,2], Jun Min Suh[1], Jiho Shin[1], Yunpeng Liu[1], Hanwool Yeon[1,3], Kuan Qiao[1], Hyunseong Kum[1,4], Chansoo Kim[1], Han Eol Lee[1,5], Chanyeol Choi[1], Hyunseok Kim[1], Doyoon Lee[1], Jaeyong Lee[1], Jihoon Kang[1], Sungsu Kang[6], Jihoon Kim[6], Sungkyu Kim[7], Joshua Perozek[1], Kejia Wang[1], Yongmo Park[1], Kumar Kishen[1], Lingping Kong[1], Tomas Palacios[1], Jungwon Park[6], Min-Chul Park[8], Hyung-jun Kim[8], Yun Seog Lee[6], Kyusang Lee[9], Jiyeon Han[10] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Cincinnati, United States; [3]Gwangju Institute of Science and Technology, Korea (the Republic of); [4]Yonsei University, Korea (the Republic of); [5]Jeonbuk National University, Korea (the Republic of); [6]Seoul National University, Korea (the Republic of); [7]Sejong University, Korea (the Republic of); [8]Korea Institute of Science and Technology, Korea (the Republic of); [9]University of Virginia, United States; [10]Amorepacific R&D Center, Korea (the Republic of)

Health monitoring platforms based on electronic skins have included flexible/stretchable sensors, electronic circuits, and skin-compatible adhesive patches. They have applications in biophysical tracking of fitness and wellness, and clinical management. The broader use of e-skins in our daily lives can be boosted by the capability to communicate data wirelessly. A major shortcoming of conventional wireless e-skins is rigid integrated circuit (IC) chips, such as near-field communication (NFC) and radio frequency identification (RFID) chips. Those IC chips compromise overall flexibility. Also, the data accuracy of analog-to-digital converters (ADCs) in IC chips are dependent on power consumption. The power constraint in wireless e-skin systems often leads to reduced sensitivity of sensing data converted by ADCs. Thousands of transistors in IC chips generate a lot of heat and consume significant power, leading to reduced wireless distance. Chip-less wireless e-skin sensors based on inductor-capacitor (LC) resonators have been reported, but their applications are limited to pressure and strain sensing with relatively low sensitivity because of the limitations of capacitive sensor designs.

We report a chip-less wireless e-skin technology based on surface acoustic wave (SAW) sensors. Our wireless SAW e-skin shows high strain sensitivity (the minimum detectable strain of 0.048 %); low energy consumption (3.7 nJ/measurement); versatility as a sensing platform for strain, UV, and ion

concentrations in sweat; and long-term wearability of one week. The excellent piezoelectricity and single-crystallinity of our ultrathin freestanding membrane of gallium nitride (GaN) on soft patch enable wireless communication without IC chips. The ultrathin GaN epitaxial layers are grown on graphene-coated GaN substrates by remote homoepitaxy and are easily released from the weak graphene-GaN interface by 2D material-based layer transfer (2DLT) process. These results present routes to cheap, low-power, high-sensitivity, and versatile platforms for wireless health monitoring devices.

9:45 AM BREAK

10:15 AM SB12.03.07
Characterization of Elastomers and Elastomer-Based Sensors in Extreme Environments Elze Porte[1,2], Sophia Eristoff[1], Anjali Agrawala[1] and Rebecca Kramer-Bottiglio[1]; [1]Yale University, United States; [2]University College London, United Kingdom

Soft devices for assistive action or health monitoring can improve wearer comfort compared to their more rigid counterparts. These devices may be used in extreme temperature and humidity conditions around the world or in extraterrestrial settings. Extreme low humidity and temperature conditions can be experienced towards the poles and extreme high humidity and temperature in hot climates towards the equator. Robots in these extreme environments are exposed to very different conditions than to the lab environments in which they are developed and tested. However, limited data is available on the material characteristics of commonly used elastomers in soft robots at different temperature and humidity conditions. This lack of knowledge can lead to unexpected behavior of the system and ultimately failure.
In this study, we characterize four commonly used elastomers in soft robotics (Ecoflex, Dragon Skin, Smooth-Sil, and Sylgard) in a temperature range of -40°C to 80°C and humidity range of 5% to 95% RH. We performed pull-to-failure, stiffness, and stress-relaxation tests, using image tracking techniques to determine the true stress and strain of the soft materials. We manufactured capacitive sensors with Dragon Skin and Smooth-Sil as base materials and carried out electromechanical characterization, measuring the capacitance response to tensile strain in the different environmental conditions.
We found that both the mechanical behavior of the elastomers and the electromechanical behavior of the sensors depend on the environmental conditions of operation. All elastomers show temperature dependent behavior, with typical stiffening of the material and a lower strain at failure with increasing temperature. The stress-relaxation behavior was most sensitive to sub-zero temperatures, with both reduced and increased relaxation observed. No clear trends were observed between the mechanical behavior of the elastomers and humidity conditions. The capacitive sensors exhibited changes in performance that related to both humidity and temperature conditions. A nonlinear relationship was found between the capacitance of the sensors and the temperature conditions. The capacitance was found to be decreasing with temperature between 0°C and 80°C and to be increasing with temperature between -40°C and 0°C. The humidity response of the sensors resulted in a slightly lower capacitance at low humidity and a slightly higher capacitance at high humidity.
The results from this study show that the environmental conditions of operation need to be considered in the design of a robotic system. The potential change in stiffness, failure point, and relaxation of the materials can affect design choices such as the used materials, range of motion, and power requirements. The temperature and humidity dependent sensor performance means that sensor output can only be accurately read with knowledge of the environmental conditions in which they operate. In conclusion, this study provides essential insights into elastomer behavior for the design and successful operation of soft robotic systems for wearable applications outside of a lab setting.

10:30 AM *SB12.03.08
Laser Induced Graphene for Soft Electronics, Sensors and Functional Surfaces Francesco Greco[1,2]; [1]Scuola Superiore Sant'Anna, Italy; [2]Graz University of Technology, Austria

Laser Induced Graphene (LIG) is a porous conductive carbon material produced by laser-induced pyrolysis of various polymer precursors. LIG fabrication on polyimide was first described in 2014 and ever since the research on this material has attracted much attention, especially for its technological applications. An infrared or other (UV, vis) laser sources are used to this purpose. The photothermal pyrolysis process allows for fast and maskless scribing of circuits onto insulating precursors in ambient condition, thus enabling new developments in flexible/stretchable/wearable electronics, electrochemical sensors, energy harvesting and storage, soft robotics, among others.[1–4]
Here, we present some results of our group on: 1) fundamental Investigation of LIG, its structure and properties; 2) technological applications in soft electronics, sensors, functional surfaces.
The LIG morphology and properties (especially conductivity) can be tuned by varying the laser fluence and adjusting the rastering parameters. This results in various LIG types: a flat porous LIG, a dense forest of long carbon nanofibres bundles or a "sponge" structure. A corresponding variation in crystal structure, defects, and surface area is observed. The adoption of a UV laser source with a galvo scanner head enables the reduction in size of scribed features down to 5-10 mm width, with an overall improvement of LIG homogeneity. Also, by locally changing the oxygen content of the atmosphere at the scribing beam spot, a dramatic change of surface wettability is obtained. Tunable wettability over the full range of water contact angle is achieved from superhydrophilic (0°) to superhydrophobic (>150°). Patterns with high wettability contrast can be created, opening the way to various applications in self guiding of fluids over surfaces and biomimetic fog harvesting. Applications in soft, wearable sensors and supercapacitors are obtained by embedding of LIG in thin stretchable elastomers (PDMS, medical grade Polyurethane). These include: stretchable connectors, skin contact electrodes for electrophysiology, sensors for temperature and strain/pressure monitoring, wearable electrochemical sensors for monitoring of urea, tyrosine, pH in sweat.[4,5] Also, we coupled LIG/PDMS with stimuli responsive polymer hydrogels deposited by initiated chemical vapour deposition (iCVD). These were investigated as soft actuating structures with thermal- and moisture-triggered response.[6] Most recent advancements include the investigation of sustainable approaches to green electronics and sustainable soft robotics . Several bioderived polymers and raw natural materials (e.g. agricultural and food industry waste, shells, etc) are studied as suitable precursors for LIG and LIG based sensors.

Selective Transformation of PEDOT:PSS into Highly Conductive Hydrogels by Laser-Induced Phase Separation Daeyeon Won, Deog-Gyu Seo, Seung Hwan Ko and Junhyuk Bang; Seoul National University, Korea (the Republic of)

Engineering conductive hydrogels with high electrical conductivity and mechanical stability in aqueous environments are important in research fields such as bioelectronics, e-skin, and energy devices. Especially, bioelectronics has actively adopted conductive hydrogels as bio-interfacing electronic material owing to similar natures to biological tissues. The softness and high water contents of hydrogels can minimize mechanical mismatch with biological tissues that can potentially realize long-term medical diagnosis or treatment such as neural signal recording and nerve stimulation.

The most commercialized conducting polymer, Poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) is a promising candidate for the fabrication of conductive hydrogels based on its electrical conductivity and electrochemical properties. However, fabricating PEDOT:PSS hydrogels still has critical issues in aqueous instability and poor electrical conductivity. “Phase separation method” that redesigns the arrangement and crystallinity of PEDOT:PSS binary system has been rapidly studied to achieve high conductivity with aqueous stability. Ironically, most of the phase separation additives are cytotoxic and require a long detoxification process. Moreover, high-resolution patterning techniques of PEDOT:PSS hydrogels are required for bioelectronics, but conventional processes are limited by low resolution or process complexity such as inkjet printing and photolithography.

We introduce a novel biocompatible manufacturing process that overcomes such limitations explained above. Through the laser-induced phase separation of PEDOT:PSS, the phase distribution of binary PEDOT and PSS was dramatically reconstructed. The micro-patterned PEDOT:PSS hydrogels achieved high electrical conductivity and aqueous stability with 6-μm spatial resolution. We further demonstrated stable neural signal recording and stimulation with PEDOT:PSS hydrogels electrodes fabricated by laser.

Laser-Induced Liquid Metal-Graphene Composite for Stretchable Electronics Sooik Im, Ethan Frey, Adam Bachmann, Jan Genzer and Michael Dickey; North Carolina State University, United States

Gallium-based liquid metals have been extensively studied in the soft-matter community due to their intrinsically soft and stretchable properties with excellent electrical and thermal conductivity. Liquid metal particles are especially of interest because their electrical properties can be tuned using external stimuli to rupture their 3 nm-thick oxide layers. In one of these methods, a focused laser beam provides photothermal energy to sinter liquid metal particles, making conductive paths. However, this process requires high laser power to achieve high electrical conductivity because liquid metal has low absorption of infrared (IR), the wavelength at which the laser is operated.
Here, we increased the IR absorption of liquid metal particles by coating them with poly(amic acid). After the coating, the power required to sinter the liquid metal particles dropped by half. During the laser process, the poly(amic acid) was converted to graphene flakes, known as laser-induced graphene. As a result, liquid metal-graphene bilayers formed. We were then able to pattern the bilayers on hard substrates as well as transfer them to soft substrates. The transferred layers are stretchable, maintaining electrical conductivity.

11:30 AM SB12.03.11
Omnidirectionally Stretchable Electronics Substrate Film Having Negative Poisson’s Ratio Using Auxetic-Structured Glass-Fabric Reinforcement Yung Lee, Junho Jang, Hyunhwan Lee and Byeong-Soo Bae; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Nowadays, as the application of electronic devices is broadening into portable, deformable, and wearable forms, non-rigid material-based electronics with free form factors are required. To realize the wearable and stretchable devices, stretchable substrate is an essential component. Elastomers are widely used as the substrate of stretchable electronics due to their high stretchability and resilience. However, the elastomeric substrates suffer from severe distortion during stretching because of their high Poisson’s ratio (PR), which is a demerit for its usage such as a display substrate. In addition, there has been limitation to wearable devices because of the different behavior with human skin that expands along multiple direction with 1-degree of freedom bending of joint. To overcome these, meta-structures having negative PR (NPR), namely the auxetics, has been propsed. Though, general auxetic materials exhibit NPR characteristic by transversal expansion of empty spaces upon elongation, which hinders its usage as a substrate because of the structural discontinuity and a limited practical area.
Here, we propose an omnidirectionally stretchable substrate film without any discontinuity and empty spaces on the surface using an auxetic-structured selective reinforcement with glass-fabric into elastomeric matrix. The film is composed of two domains: i) auxetic-structured glass-fabric reinforced domain that induces NPR characteristic and ii) pristine elastomer domain that induces resilience and surface continuity. To achieve an ideal NPR characteristic (i.e. theoretical maximum value of unfilled auxetic structure) while maintaining a continuous surface, the two domains should have a substantially different elastic modulus. To investigate the effect of modulus difference between two domains and geometrical parameters of auxetic structure such as thickness, shape, and dimension, an experimental study is performed using digital image correlation (DIC) analysis. By modifying the mechanical properties of component materials and auxetic structure, a controllable PR between -1 to 0.5 is achieved. The optimized glass-fabric reinforced substrate exhibits NPR characteristics with maximum NPR value of -0.95, stretchability of 20% with 10,000 cycles of repetition. The proposed substrate also exhibits high thermal stability (>350°C), dimensional stability (<50 ppm/°C), and low surface roughness (R_a < 100nm), showing its capability to high temperature and solution processes. We demonstrate the omnidirectionally stretchable substrate as a wearable biosensor platform such as ECG sensor, providing stable conformal contact to human joint. Having NPR, the substrate expands omnidirectionally under uniaxial extension like a human skin. We also fabricate a distortion-free stretchable light-emitting devices using the omnidirectionally stretchable glass-fabric reinforced substrate.

Soft Neuromorphic E-Skin Zhenan Bao; Stanford University, United States

In this talk, I will discuss our approach toward a monolithically integrated soft e-skin.

2:00 PM SB12.04.02
Innate Self-Sensing Capability for Fiber-Reinforced Soft Actuator with Only Essential Components Hwajoong Kim[1], Seungbeom Noh[1], Jinho Kim[1], Seonggyu Lee[1], Gyowook Shin[2], Chankyu Lee[3], Yonglae Park[2] and Jaehong Lee[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]University of California, United States

Soft robots are emerging as next-generation robotics due to their high mechanical compliance, large deformation resulting from excellent stretchability and flexibility, and outstanding adaptability to various shapes and surface morphology. To effectively control such soft robots and actuators in practical applications, a sensing system that can monitor their movements and deformation in real-time is fundamentally essential. Nevertheless, most of previously reported soft actuators do not provide real-time physical feedback signals or provide only limited physical feedback signals, due to the lack of a sensing

system. Consequently, it is difficult to maintain accurate and consistent actuation under unintended external loads in practical applications. In this regard, research on the feedback control system of soft actuators using additional sensing components such as soft strain, bending, and pressure sensors has been intensively studied. However, such additional sensing components can interrupt the operation of soft actuators due to mechanical and structural mismatching between the sensor components and soft actuators. Moreover, the additional sensing components make the entire actuating system highly complicated. Therefore, soft actuators with self-sensing capability that can sense their movements themselves without additional sensing components are required.
Here, we present pneumatic fiber-reinforced soft actuators with self-sensing capability by using only their essential components: an elastomeric chamber, axial strain-limiting fiber, and two radial expansion-limiting fibers. The self-sensing fiber-reinforced soft actuator is designed to monitor their deformation itself by winding two inextensible conductive fibers around the elastomeric chamber in a double-helical structure. The wound conductive fibers simultaneously perform two roles: radial expansion-limiting fibers for the actuator and fiber-based capacitive bending sensor. Based on the capacitive bending sensor inherently embedded in the soft actuator, we demonstrated that the bending deformation of the soft actuators was successfully measured during the operation of the actuator. An analytical prediction and a FEM simulation model were developed to explain the correlation between the mechanical and electrical behavior of the soft actuators. Moreover, negligible hysteresis and outstanding stability were observed against repeated pressurizing-releasing cycles (10,000 cycles). Based on the self-sensing capability, we verified the closed-loop feedback control of the fiber-reinforced soft actuator, which provides a stable and accurate actuation independent of unintended external loading. Finally, stable picking of various objects under external loading was demonstrated by designing the gripper system. To the best of our knowledge, this is the first demonstration of a self-sensing soft actuator that leverages an essential component of the actuator also as a sensor, eliminating any mismatch between the actuator and sensor.

2:15 PM SB12.04.03
Human Hand-Inspired Stiffness-Tunable Soft Gripper Formed by the Split-Brushing Adhesion of Diverse Hydrogels Hye Been Koo, Eunseok Heo and Jae-Byum Chang; Korea Institute of Science and Technology, Korea (the Republic of)

Humans, animals, and even insects interact with the environment via their grippers having various morphologies and functions. In contrast to other grippers found in nature, the functions of human hands are unique. Even when heavy objects are placed on them, their high stiffness prevents deformation. In addition, they are flexible, allowing the fingers of hands to bend easily to grab various objects. Various attempts have been undertaken in recent years to mimic the morphologies and functions of human hands using hydrogels. However, the majority of present hydrogel grippers are limited since they are readily deformed but their stiffness is insufficient for lifting heavy objects or supporting huge loads. These two features, high stiffness and ease of bending, are challenging to obtain with a single hydrogel system, as finger stiffness must be low for bending to be possible. In this paper, we demonstrate a hydrogel gripper whose stiffness can be easily adjusted by temperature from a few to hundreds of megapascals. This gripper is comprised of various hydrogels with distinct functionalities, including a hydrogel with high stiffness, a hydrogel with temperature-dependent stiffness change, and a hydrogel with temperature-dependent volume change. In order to build this hydrogel gripper by integrating these three hydrogels, we present a unique hydrogel adhesion approach, which we refer to as split-brushing adhesion, which enables strong adherence between various hydrogels. The only trigger that can activate this hydrogel gripper is temperature. We demonstrate that the bending of the fingers of this gripper can be regulated by temperature and that the bent fingers are stiff, allowing them to grasp heavy things.

Electronic Skins for Healthcare and Virtual Reality Stephanie P. Lacour; EPFL, Switzerland

Skin-interfaced electronics are becoming powerful tools for applications in human-machine interaction and digital capture of human movement and physiology, which offer promising perspectives in e-health applications. We report on microfabricated electronic skins prepared with silicone and liquid metal conductors. Based on a combination of soft lithography, directional patterning, thermal evaporation or spray coating of gallium, the soft technology enables a range of designs and geometries that can be used to form liquid metal-based stretchable electronic conductors. The versatility of the technology enables a palette of sensor designs that can offer transparency (T > 89%), large metallization density (2/5 µm line/gap), and high electromechanical performance (strain > 10 %, > 100k cycles). We will illustrate the technology capability demonstrating soft sensors for minimally invasive hand tracking, closed-loop soft actuation control and softness sensing.

3:30 PM SB12.04.05
Soft Skin-Attachable Full-Spectrum Tactile Stimulator Based on Laterally Multilayered Dielectric Elastomer Actuators Siyoung Lee[1,2], Jonghyun Son[1], Geun Yeol Bae[3], Giwon Lee[1], Mihai Duduta[2] and Kilwon Cho[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]University of Toronto, Canada; [3]Kumoh National Institute of Technology, Korea (the Republic of)

Haptic (e.g., Skin-stimulation) technology has been applied based on garments such as gloves, vests, and suits for virtual reality and augmented reality (VR/AR) to provide users with the most natural and realistic feeling. To provide more comfortable wearability and immersive experience, conventional electromagnetic actuators, are relatively heavy, bulky, and stiff, should be replaced with thin, soft, light and skin-attachable skin-stimulating devices. Dielectric elastomer actuators (DEAs) are the suitable candidates for soft haptics, because they are composed of soft dielectric polymer and can rapidly respond over a wide frequency range. However, they have still significant challenges to the realization and commercialization of skin-attachable stimulators. First, the operating voltage for actuation should be lowered from typical operating voltages of several to tens of kilovolts for DEAs. Secondly, at low operating voltages, DEAs should exhibit significant and variable displacements exceeding the thresholds for activation of the mechanoreceptors in the skin dermis. Thirdly, DEAs should also realize diverse actuations with various frequencies and temporal patterns to provide a realistic experience for users to distinguish the textures by feeling dynamic vibration.
Here, we report a low-voltage-driven and skin-attachable DEA-based stimulator that covers the full perception range of all mechanoreceptors on human skin and that can be worn comfortably and reliably on a human finger. We realized the low-voltage operation (~ 200 V) of DEAs by exploiting the novel design of multilayer DEAs in which hundreds (~900 layers) of elastomer layers with thin dielectric distance (10 µm) and compliant electrodes are laterally aligned. The laterally multilayered DEA (LMDEA) can be fabricated in a single process including sophisticated photolithography and secondary sputtering, which is much simpler than the complicated and time-consuming stacking process for previous multilayer DEAs. Further, to enhance the actuation performance, we harnessed the low young's modulus and high permittivity of ionic liquids into the dielectric elastomer layer. The fabricated LMDEA showed significant contractive displacement (i.e., 160 µm as static and 55 µm as 200 Hz dynamic displacements) in the frequency range up to 800 Hz at the operating voltage of 200 V which is much lower than those of previous DEAs. Moreover, the structural/material design enables LMDEAs to have a high actuation force of more than 200 mN at the same operating voltage and to show high operation stability with no electric breakdown but high electrode conductivity based on stable impedance values during a duration test (> 0.7 million cycles).
The finger band skin-stimulator consisting of two LMDEAs and a needle was skin-attachable on the finger due to the thinness (35 µm) of the LMDEAs. The needle connecting to the contracting LMDEAs generated mechanical stimulation (up to 30 times) greater than the threshold displacement of human skin for various frequencies (1 ~ 200 Hz) at an operating voltage within 200 V. Also, we demonstrated that the skin-stimulator can apply various

vibrational stimuli to the human skin by varying the magnitude, frequency, and even pattern of the applied voltage. Therefore, LMDEAs show the significant potential for use in haptic communication, human machine interfaces for VR/AR, touch therapy, and beyond.

3:45 PM SB12.04.06
Stretchable Strain Sensor Enabled Smart Clothing for Motion Capturing Applications Zinan Cen, Fraser Robinson, Goldie Nejat and Hani E. Naguib; University of Toronto, Canada

Motion capturing technologies provide insightful information of the human body and has a wide range of applications including in virtual reality, sport analysis, physical rehabilitation, and socially assistive robotics. Conventional motion capture methods using camera systems fall victim to varying light conditions and occlusion, therefore usually requires studio settings. Such limitations motivated research in obtaining motion data through on-user sensors such as inertial measurement units (IMU). However, IMUs are rigid, have high power consumption, and suffer from signal drift, all of which restrict the capability of IMUs for long term usage. With recent development in nanomaterial, highly sensitive strain sensors with large working strain range have been fabricated. Their low power consumption, lightweight, and ability to conform to curved surfaces show great potential as an alternative for motion capturing applications. In this paper, we designed a stretchable strain sensor enabled smart clothing that is capable of monitoring upper limb movements of the users. Each strain sensor is composed of a highly stretchable elastomer layer and a conductive layer. The elastomer layer is made from a thermoplastic polyurethane (TPU) fibrous mat fabricated via electrospinning. Carbon nanotube (CNT) ink is dispensed onto the elastomer layer and air dried to form the conductive layer. As the sensor is stretched, discontinued phase of CNT is formed across the conductive layer reducing the density of conductive pathways, which increases the resistance of the sensor proportional to the strain experienced. Smart clothing was developed by attaching multiple stretchable strain sensors at various locations that maximize strain during motion. A convolution neural network (CNN) model was developed to estimate the joint angles of shoulders and elbows using strain signals from the smart clothing. To address the non-linear and hysteretic behavior of the sensors, signals in past time steps were included in the input to the CNN model. The functionality of the smart clothing was demonstrated through the integration with a socially assistive robot (SAR) to provide dressing assistance. Namely, smart clothing on the user is used for joint angle mapping, which are then classified into different dressing steps. The completion status of each dressing steps allows the SAR to provide appropriate instructions to the users. Experiments validated the performance of the joint angle mapping model, and dressing action classifier.

4:00 PM SB12.04.07
Encoding of Tactile Information in Hand via Skin-Integrated Wireless Haptic Interface Kuanming Yao, Jingkun Zhou, Lidai Wang and Xinge Yu; City University of Hong Kong, Hong Kong

Vivid haptic feedback is still a remaining challenge in truly immersive virtual/augmented reality (VR/AR). Since the tactile sensitivity among different individuals and different parts of hand within a person varies widely, a universal method to encode tactile information into faithful feedback in hands according to the sensitivity features is urgently needed. In addition, existing haptic interfaces worn on the hand are usually bulky, rigid, and tethered by cables, which is a hurdle for accurately and naturally providing haptic feedback.
Here we report a soft, ultrathin, miniaturized and wireless electrotactile system (WeTac) that delivers finely controlled current pulses through the hand to induce tactile sensations as the skin-integrated haptic interface. It's featured with a compact driver unit that can be wirelessly controlled by a mobile device via Bluetooth, and the battery is wirelessly rechargeable, which gets the driver unit rid of any tethering cables or cords, and allows the user to do activities without any bounding feelings. The WeTac could be worn on hands to provide programmable spatio-temporal electrotactile feedback patterns through a thin, soft hydrogel-based hand patch, which has 32 stimulation pixels over the palmar side, with a high spatial resolution of 1.8 pixel/inch^2 in average and 4.5 pixel/inch^2 in densest area. Compared to other electrotactile device with denser array, WeTac has a wider coverage range (whole hand) than simply on the fingertip.
To make it more universally fit to general public users, we investigated the thresholds features among different groups of people. It’s found that although the general distribution patterns are similar (the fingers are much more sensitive than the palm, especially the fingertips), people's threshold levels are closely related to gender, age, job and personal experiences. Thus it's necessary to customize stimulation strength according to specific user's threshold. By detailed investigation of an individual's threshold maps at different electrical parameters, suitable stimulation parameter combinations are acquired for personalized feedback tuning in VR/AR or human-robotic interaction scenarios. Pressure distributions for actions like grasping a tennis ball and a virtual mouse running across the palm can be correctly projected with high spatiotemporal resolution by specified algorism. It can also help to feel the pressure of a robotic hand when the user controls it to touch an object. This illustrates the potential of our device in realizing faithful and vivid virtual touching in various applications for boosting a more immersive experience in virtual world (i.e. Metaverse). We believe that skin-integrated wireless haptic interface could also assist the development of other fields in the future, like remote control of robotics, sensory feedback from prosthetics, catastrophe alerting, skill training, education, etc.

Materials-Enabled Stretchable, Flexible and Wearable Electronics and Their Biomedical Applications Nadeem Qaiser and Vincent Tung; King Abdullah University of Science and Technology, Saudi Arabia

The pursuit of state-of-the-art stretchable, flexible and wearable electronics has changed our daily-life activities. To achieve the desired stretchability designs that can stretch due to topology and intrinsically stretchable materials significantly impact the efficacy of IoT and IoE applications [1,2]. As the mechanics of these devices dictate the overall response of the devices, the geometrical topology of interconnects such as serpentine and lateral spiral play a decisive role. Likewise, various materials, including copper and carbon nanotubes, have proved their great performance for identical devices while encapsulating in flexible polymers. Therefore, these stretchable designs and materials play an important role in bio-related flexible devices. Currently, wearable and flexible electronics analyze sweat, glucose, blood pressure, and other skin conditions. However, localized jaw-bone swelling called parotid swelling caused by some viruses has never been tracked before. This work reports carbon nanotubes (CNTs)-based piezoresistive sensing patch encapsulated in a highly flexible polymer and can record muscle deformations in real-time. The developed patch offers an excellent gauge factor (~16) for

in-plane stretching and spatial expansion with low hysteresis. We fabricated the pneumatic actuator that experienced volumetric expansion and thus redefined the gauge factor to calibrate the volumetric muscle expansion. Moreover, we employ a Bluetooth-low-energy system that can send information about muscle activity in real-time to a smartphone app. We utilized COMSOL calculations to reveal the mechanical robustness of the patch. The experiments showed the sensing patch's greater cyclability, making it a great choice for personal healthcare, i.e., monitoring the real-time POC of human muscle swelling. Likewise, another application of copper-based stretchable interconnect is in thermal therapy. Thermal therapy is widely used to treat arthritis- the stiffness or pain of human muscle/bone. This work reveals the copper-based stretchable thermal patch that can digitally control the temperature of the patch, making it an excellent device for thermal therapy. We have used a CMOS-compatible nano/microfabrication scheme to make the thermal patch encapsulated in polyimide, making it flexible. The developed thermal patch gives a safe range of heating, can be stretched to fit any part of the body, and be wirelessly controlled. Our results have shown the exciting applications of copper and CNT-based smart patches, opening doors to various futuristic bio-medical applications.

Triboresistive Touch Sensing—Grid-Free Touch Point Recognition Based on Monolayered Ionic Power Generators Younghoon Lee[1], Sungsoo Lim[1] and Jeong-Yun Sun[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Research of Institute Advanced Materials, Korea (the Republic of)

Recent growing pursuit of skin-mountable devices has been impeded by complicated structures of most sensing systems, containing electrode grids, stacked multi-layers, and even external power sources. Here, we introduce a type of touch sensing, termed triboresistive touch sensing, for gridless touch recognition based on monolayered ionic power generators in Fig. 1. A homogeneous monolayer, i.e. ionic PDMS, generates electricity based on the electric field generated by touch. Voltages generated at each corner of ionic PDMS relied on resistance between touch points and each corner, ensuring recognition of the touch positions without need for electrode grid layers and external power sources. With notable advantages of high transparency (96.5%), stretchability (539.1%), and resilience (99.0%) of the ionic PDMS, epidermal triboresistive sensing was demonstrated to express touch position and readily play a musical instrument. Gridless system of triboresistive sensing allowed to rearrange touch sections according to a given situation without any physical modification, and thus easily completed consecutive missions of controlling position, orientation, and gripping functions of a robot.

SB12.05.03

A Strategy Reducing Interfacial Stress by Placing Pores Around Serpentine Electrodes for Highly Durable Stretchable Electronics Seungkyu Lee, Jun Chang Yang and Steve Park; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The development of stretchable electronic devices has brought great attention to next-generation wearable devices such as electronic skins (E-skins) and electrical tattoos.[1] In the field of wearable technology, there is a growing demand for soft electronics in health monitoring and various types of applications such as the Internet of Things and soft actuators, VR/AR.[2-3] The stretchable functional electronics has been adopted for increasing durability under stretching by using intrinsically stretchable materials and structural dynamics designs. Especially, many research about gaining stretchability through structural designs such as serpentine interconnects and kirigami structure have been reported.[4-6] Among the various structural designs of stretchable electronics, the "island-leg" design represents a widely used strategy, and bridge-modified interconnects in the middle area (i.e., trenches) between non-stretchable elements such as islands provide stretchability and flexibility. However, these devices are susceptible to mechanical failure such as fatigue breakdown of ductile materials and brittle material destruction, and peeling of adhesive interfaces. A delamination occurs due to mechanical mismatch (i.e., modulus, stretchability) between the serpentine and the elastomer substrate. Therefore, device stretchability is reduced because the material can reach the limit locally in smaller macro variants. Here, pores near the serpentine electrode can be proposed to effectively improve stretchability and durability of stretchable electronic system. The system configuration includes a serpentine and a pore with a convex oval design around it. The serpentine electrode made of the designed polyimide reduces the von mises stress between the interface and the electrode. The T-shaped pores in the substrate absorb the stress concentration near the serpentine electrode, which is prone to microcracking. The pores presented in this study have an effect of reducing stress by about four times compared to electrodes without pores. Experimental measurements and finite element analysis (FEA) on island bridge designs using interconnects between serpentine electrode and substrates confirm the validity of substrate pore strategies. Furthermore, the various applications such as heater, display, and e-skin are demonstrated.

High-Power Photonic Skin for Wearable Photodynamic Therapeutics of Skin Cancer Yongmin Jeon[1], Eou-Sik Cho[1], Sang Jik Kwon[1], Ye Ji Shin[1], So Yeong Jeong[2] and Yongjin Park[2]; [1]Gachon University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Conformal and soft bioelectronic devices with various form-factors based on soft functional materials such as 2D materials and organic materials recently have been receiving considerable attention and research is actively being conducted. Among various soft bioelectronic devices, extremely thin and ultraflexible photonic skin type opto-bioelectronic devices have the advantage of superior wearable and bio-compatible characteristics. On this basis, they are being utilized in wearable biosignal diagnosis applications including skin-type pulse oximetry and wearable treatment devices such as skin-type phototherapeutics. However, the previous 2D material, thin film organic material-based photonic skin, has disadvantages of high operational voltage (>10 volts) and low output power, and problems such as high heat generation and long treatment time of several hours or more in applications such as photodynamic therapeutics have occurred.

In this talk, I will show a high-power photonic skin of 100mW/cm^2 or more under 8V through structural and optical design of an OLED in the form of parallel vertical stacking. This high-power photonic skin has a folding reliability of 350um, which is the level of skin wrinkles, based on ultra-thin properties of 10 micrometers, and also has reliability properties allowing it to be washed with water. In parallel stacked OLED based photonic skin, the shape of the wavelength, the output, and the luminous efficiency could be optimized by adjusting the thickness of each stacked OLED layer. In order to confirm the possibility of photodynamic therapeutics application using this low-voltage, high-output photonic skin, singlet oxygen generation efficiency was confirmed by measuring the singlet oxygen generation ratio, which was improved roughly four-fold compared to a previously reported OLED. In addition, the therapeutic effect of reducing cancer cell viability in melanoma cancer cells was confirmed even after a short irradiation of only 30 minutes. In conclusion, the possibility of application of photodynamic therapeutics to various skin cancers and bacteria using high-power photonic skin was confirmed.

A Wearable System for Detecting Hand Motion Using Strain Sensors Sangmin Lee[1], Dongbin Jo[1,2] and Wanjun Park[1]; [1]Hanyang University, Korea (the Republic of); [2]Samsung Electronics Co., Ltd., Korea (the Republic of)

A wearable system for detecting hand motion is presented using strain sensors with carbon–based nanomaterials. The system can detect hand gestures with data obtained from ten sensors, and sign language gestures can be converted to English alphabet letters through a mapping process. Most of the conventional motion detecting methods are image–based methods, however these approaches have limitations with large and burdensome peripheral devices, and due the influence of surrounding environment such as light and shadow. Therefore, there is a need for a detecting system which can operate without influence of environmental factors and which could be worn on the body, in order to take advantages such as accurate motion detection and portability. Our carbon–elastomer composites sensor applied to this system shows excellent stretchability characteristics providing no discomfort while moving when attached to the human body, and has excellent durability without deterioration in performance even after long cycles. Finally, a wearable system was demonstrated, so that the 26 English alphabet sign gestures could be translated into letters real time.

Development of Kirigami-Based Stretchable Electronics for Wearable Electronic Devices Bongkyun Jang[1], Sejeong Won[2], Hyeon-Don Kim[1], Jaehwa Lee[2], Jaegu Kim[1], Hak-Joo Lee[2] and Jae-Hyun Kim[1]; [1]Korea Institute of Machinery and Metals, Korea (the Republic of); [2]Center for Advanced Meta-Materials, Korea (the Republic of)

Stretchable electronic devices are electronic circuits fabricated onto stretchable substrates. So far, many researchers have applied elastic materials such as silicones or polyurethanes to stretchable substrates. A design of kirigami patterns based on mechanical metamaterials can provide the substrates with high stretchability. These mechanical metamaterials are artificial mechanical structures that exhibit unconventional mechanical properties that originated from their structures rather than their compositions. Especially, auxetic metamaterials show a negative Poisson's ratio that enables a lot of applications in soft robotics, medical devices, and stretchable electronics. Nano and microscale fabrication technology can contribute to the fabrication of kirigami-based mechanical metamaterials since nano and microscale structures can realize the appropriate properties of metamaterials that are suitable for the specific application. In this study, we developed the fabrication process of stretchable electronic devices using kirigami patterning of polymeric substrates. We designed and fabricated the distortion-free micro-LED (Light Emitting Devices) display using flexible electronic circuits and kirigami technology. In addition, we demonstrated the wearable and skin-attachable biomedical devices of stretchable micro-LED for phototherapy and beauty. These fabrication technologies can contribute to the manufacturing of stretchable electronics for free design form factors.

SB12.05.08
Broadband Mechanoresponsive Liquid Metal Sensors Md Saifur Rahman, Julia Huddy, Andrew B. Hamlin and William J. Scheideler; Dartmouth College, United States

Stretchable electronics have the fundamental advantage of matching the complex geometries of the human body, providing novel opportunities for real-time biomechanical sensing. We report a new method for high frequency AC-enhanced resistive mechanical sensing that leverages the deformability of liquid metals to enhance low-power detection of mechanical stimuli in wearable electronics. The fundamental mechanism for this enhancement is the geometrical modulation of the AC skin effect, which induces current crowding at the surface of a liquid metal trace. We apply 1-50 MHz excitation in combination with DC sensing to quantitatively pinpoint mechanical modes of deformation such as stretching in-plane and compression out-of-plane that are otherwise impossible to distinguish by traditional methods. This novel sensing method, which we explore by FEA simulations, is experimentally employed in a glove to simultaneously detect various hand gestures and tactile forces as well as a respiratory sensor band to monitor breathing rate. In addition to this multifunctionality, we show how this AC sensing modality can enable high SNR readout at 100X lower power consumption compared with DC, enabling a new generation of efficient wearable radio-frequency (RF) systems for haptics and biomedical sensing.

SB12.05.09
Tissue-Adaptive Bionogel Based on Piezo-Driven Ion Confinement for Mechanical Biosignal Acquisition System Jihong Kim, Joo S. Kim, Hanbin Choi, Dong J. Kim, Bokyung Kim and Do Hwan Kim; Hanyang University, Korea (the Republic of)

As advancements in management remain insufficient for chronic patients, death per cardiovascular disease has perpetually increased, becoming a global encumberment today. For the effective approach towards the challenges of healthcare technologies in this field, the use of implantable bioelectronics shows optimistic potential to precisely monitor the mechanical biosignals (blood pressure, respiratory rate) in real-time. However, since conventional bioelectronics commonly use rigid metal and inorganic materials, a mechanical mismatch occurs between the bioelectronics and soft tissues, resulting in

low sensitivity and signal-to-noise ratio (SNR). To overcome these concerns, the tissue-level modulus of soft materials (e.g., hydrogel and ionogel) is critical for the development of implantable bioelectronics. Despite the fact that the soft hydrogel can firmly adhere to tissues, the impaired long-term stability caused by dehydration of solvent, and ion exchange between biological ions and synthetic ions leads to erroneous monitoring of biosignals.

In this talk, we propose a novel design of biocompatible ionogel (Bionogel) exploiting a piezo-driven ion confinement structure that prevents ion exchange and enables precise mechanical biosignal readout. To introduce mechanosensitive characteristics to the proposed design of the ion confinement structure, we develop soft Bionogel composed of hydrogen-bonded choline-based ion pairs on the surface of functionalized gold particles (AuNPs) embedded into chitosan biopolymer matrix. Unlike the phenomenon of the ion transfer at the interface between hydrogel and tissues, our Bionogel is capable of minimizing ion exchange by capturing ions. Such confined ion pairs can be dissociated under mechanical stimuli, resulting in reversible ion pumping. Notably, our Bionogel-based mechanotransducer exhibit exhibits exceptional mechanosensitivity ($S = 14.60\text{-}10.18\ kPa^{-1}$) over a wide range of pressures (0 – 100 kPa). Furthermore, cell (Human Dermal Fibroblast) viability and cytotoxicity tests performed on Bionogel signify the enhanced biocompatibility compared to the conventional iongel and conducting polymer. As a result, we believe that the successful integration of the Bionogel-based mechanotransducer into the implantable bioelectronics capable of perceiving subtle signals from the human body can serve as a blueprint for the development of the next-generation health monitoring system.

SB12.05.12
Long-Term *In Vivo* Operation of Implanted Cardiac Nanogenerators in Swine Jun Li; University of Wisconsin--Madison, United States

Implantable nanogenerators (i-NG) provide power to cardiovascular implantable electronic devices (CIEDs) by harvesting biomechanical energy locally eliminating the need for batteries. However, its long-term operation and biological influences on the heart have not been tested. Here, we evaluate a soft and flexible i-NG system engineered for long-term in vivo cardiac implantation. It consisted of i-NG, leads, and receivers, and was implanted on the epicardium of swine hearts for 2 months. The i-NG system generated electric current throughout the testing period. Biocompatibility and biosafety were established based on normal blood and serum test results and no tissue reactions. Heart function was unchanged over the testing period as validated by normal electrocardiogram (ECG), transthoracic ultrasound, and invasive cardiac functional measures. This research demonstrates the safety, long term operation and therefore the feasibility of using i-NGs to power the next generation CIEDs.

SB12.05.13
An Intrinsically Stretchable Multi-Biochemical Sensor for Sweat Analysis Using a Photo-Patternable Silicone Elastomer Seungwan Kim[1,1], Joohyuk Kang[2], Injun Lee[1,1], Wonryung Lee[2] and Byeong-Soo Bae[1,1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Patterning of stretchable materials such as PDMS, Ecoflex, which is widely used in stretchable electronics, is a necessity in methods to fabricate multi-layer of stretchable integrated circuits. Nevertheless, previous patterning methods for stretchable materials, such as soft lithography and laser lithography, can leave residues or damage on the underlying layer. Fabrication of sophisticated and multi-functional stretchable biosensors requires development of an intrinsically stretchable material that can be directly patterned without any effect on the primary layer.
Here, we developed Photo-patternable Ecoflex (PPE) to directly integrate intrinsically-stretchable nanocomposite. We used benzophenone as a photo-inhibitor to hinder cross-linking of Ecoflex by the radical reaction, so that Ecoflex could be patterned using photolithography. PPE was then combined with the stretchable silver (Ag) composite as an encapsulation layer by using a direct patterning process. The homogeneous interface between encapsulation and conductor contributes to efficient strain energy dissipation, so at 250% strain, stretchable electrodes with PPE encapsulation showed 50% higher electrical conductance than stretchable electrodes without PPE encapsulation. Using this PPE integrated stretchable conductor, we fabricated an intrinsically stretchable and multi-chemical sensor that can monitor the levels of pH, glucose and lactate in sweat. All sensors showed durability (i.e., $\leq$ 10% change at 50% strain and $\leq$ 15% change over 1000 cycles at 20% strain). Finally, the intrinsically stretchable device was demonstrated to continuously monitor the glucose and lactate levels in human sweat. The measured glucose level was quantified as 70 mg/dL in the fasting state and 100 mg/dL after food intake. The measured lactate level was from 5 mM to 16 mM during exercise. Both measurements were consistent with those from commercial essay kits.

SB12.05.15
Electrolyte-Gated Synaptic Transistor for Artificial Electronic Skin Through Bioinspired Skin-Healing Snail Secretion Kyungho Park, Dong Hyun Choi, Jusung Chung, Kyungmoon Kwak, Jong Bin An, Jae Seong Han and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

The sense of touch is an important way the human body interacts with the environment, enabling to accurately perceive, grasp, and manipulate a variety of objects. However, most studies for tactile sensing lack learning and memory functions, making active and direct interaction with the environment difficult. Recently, by inserting a neuromorphic computing system that mimics the functions and information processing of the biological nervous system into the conventional electronic skin (E-skin), many researchers have attempted to implement a future E-skin that can simultaneously perform cognition, learning, and memory. For the realization of artificial synapses required for neuromorphic computing systems, electrolyte-gated synaptic transistors (EGSTs) have been studied due to various advantages such as low power consumption, printability, and the opportunity to fabricate novel device architectures. However, biocompatibility must be considered for application to artificial E-skin.
Herein, we propose EGSTs using snail secretion as the electrolyte, which is a biocompatible and skin-healing material suitable for natural skin for artificial E-skin. To fabricate snail secretion EGSTs, we deposited indium gallium zinc oxide (IGZO) channel by radiofrequency (RF) magnetron sputtering on a heavily boron-doped silicon wafer with a thermally oxidized 120 nm thick silicon dioxide film, as the substrate. Thereafter, indium tin oxide (ITO) electrodes as the source and drain were also deposited by RF magnetron sputtering process via shadow mask consisting of a width/length ratio of 1000/150 μm. For activation of IGZO and ITO film, they were annealed at 300°C in the air for 1 h. Finally, snail secretion was dripped on the top of the IGZO channel.
Snail secretion including glycolic acid, allantoin, and mucin, which were skin-healing functional materials, contains a large number of hydroxyl groups, which can promote the transfer of protons (i.e., hydrogen ions) through temporary hydrogen bond formation. Therefore, it is suitable for the implementation of biological synapses. To verify the biological synapses, we confirmed the anticlockwise hysteresis characteristic of snail secretion EGSTs under the gate voltage (V_G) sweep ±3.0 V. A negative threshold voltage (V_{th}) shift from −0.32 to −0.66 V was observed. The negative V_{th} shift could be caused by protons trapped at the interface between the IGZO and snail secretion. It could be predicted by the synaptic weight of biological synapses. Therefore, to investigate the synaptic weights, we measured the paired-pulse facilitation (PPF) characteristics of snail secretion EGSTs. PPF means that a larger second excitatory postsynaptic current (EPSC) is triggered when the second pre-synaptic spike pulse is applied before the first EPSC is recovered to the initial value. When paired pre-synaptic spikes with a pulse width of 10 ms apply with a time interval (TI) of 10 ms, the PPF index, defined as the amplitude ratio between the second EPSC (A_2) and the first EPSC (A_1), was 168.8%. And, to confirm the learning-forgetting (L-F) characteristics of our devices, we conducted consecutive 100 positive pulses (V_G of 1 V, TI of 10 ms) and followed by 50 negative pulses (V_G of −0.75 V, TI of 10 ms). As a

result, it was confirmed that our device has precise control for L-F by observing its linear characteristics. Finally, we measured the spike rate dependent plasticity characteristics of our devices, which can be judged on the ability of the artificial E-skin to be subjected to a stimulus applied to a certain abnormality. When 800 nA was set as the threshold, the 30 pulses applied at 10, 20, and 25 Hz did not exceed the threshold, but the threshold was exceeded at 50 Hz. These results could be recognized as pain by repeated and strong stimulation in the artificial E-skin. Therefore, we believe that snail secretion EGSTs will contribute to the development of improved artificial E-skin.

SB12.05.16
Bioactive and Antimicrobial Patterned Nanofibers Scaffold for Skin Regeneration and Wound Healing Shrouk M. Abdo and Nageh K. Allam; American University in Cairo, Egypt

Chronic wounds have created a global burden on the patient and health care systems as severe non-healed wound complications may lead to limb amputation and quality of life. Current research on Wound care and skin regeneration has been focused on developing practical therapeutic approaches for chronic wound management. Specifically, there is a need to create a wound dressing material that can promote cells growth, migration, and distribution across the wound area and provide protection. Moreover, they should be able to deliver drugs and bioactive molecules, which promote wound healing and tissue regeneration. Electrospun nanofibers (NFs) have shown great potential as functional wound dressing material. Aligned, crossed, and fine diameter fibers are advantageous for wound healing. In this regard, the present study used poly(glycerol-sebacate) (PGS) and polycaprolactone (PCL) mixture with benign solvents to form PGS/PCL electrospun nanofibers (NFs) on ground collector and mesh-like collector. This process produced randomly aligned PGS/PCL NFs and organized crossed PGS/PCL NFS, which resemble the basket-mesh pattern of collagen fibrils in the skin tissue. Under the scanning electron microscope, the fibers collected on the mesh collector showed organized crossed fibers with smaller diameter distribution than the randomly aligned fibers collected on the ground collector. Uniaxial mechanical testing indicated that the patterned fibers have significantly improved mechanical properties. Further elements were added to the structure to promote wound healing through Hyaluronic acid (HA) coating. To provide antimicrobial property, zinc oxide (ZnO) nanopowders have been added to the polymers mixture. HA coating was realized through scaffold surface activation by sodium hydroxide (NaOH) to improve the surface polarity and allow hydrogen bonding with HA. The ZnO nanopowder was fabricated via the microwave-assisted

method. Fourier-transform infrared spectroscopy (FTIR) and Energy-dispersive X-ray spectroscopy (EDX) have been used to confirm the successful addition of HA and ZnO to the structure. Water contact angle showed that HA-coating had improved the hydrophilic property of the scaffold as well as water-up take capacity. In vitro biocompatibility test using fibroblast cell line L929 indicated that 2% (w/w) ZnO has no cytotoxicity on the cells, and HA-coating promotes cells viability. In-vitro wound healing assay showed that the scaffold could improve cells migration to the scratch area, and HA-coating made it more significant. Colony-forming unit assay (CFU) showed a significate antimicrobial activity of the nanofibers loaded with ZnO after 12 hours against gram-negative E. coli. Synergistically, the crossed scaffold loaded with ZnO and coated with HA was proven to have an antimicrobial property and improves cells viability and migration, which are required for wound healing and skin regeneration.

SB12.05.17
Autonomous Self-Healable Ionoconductor for User-Customized Electronics Yong Min Kim; University of Seoul, Korea (the Republic of)

Implementing self-healing capabilities in a deformable platform is one of the critical challenges for achieving future wearable electronics with high durability and reliability. Conventional systems are mostly based on polymeric materials, so their self-healing usually proceeds at elevated temperatures to promote chain flexibility and reduce healing time. Here, we propose a new ionic cluster (IC)-driven self-healable ionoconductor composed of rationally designed copolymers and ionic liquids. After complete cleavage, the ionoconductor can be repaired with high efficiency (~90.3%) within 1 min even at 25 ºC, which is mainly attributed to the dynamic formation of ICs between the charged moieties in copolymers and ionic liquids. By taking advantage of the superior self-healing performance, stretchability (~1130%), non-volatility (over 6 months), and ability to be easily shaped as desired through cutting and re-assembly protocol, reconfigurable, deformable light-emitting electroluminescent displays are successfully demonstrated as promising electronic platforms for future applications.

SB12.05.18
Stretchable Li-Ion Battery Using Origami Scale Structure for Untethered Soft Robots Myoung-Ho Kim[1,2], Minsub Oh[1], Hoo-Jeong Lee[2] and Seungmin Hyun[1,3]; [1]Korea Institute of Machinery and Metals, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]University of Science and Technology, Korea (the Republic of)

In recent years, technology of soft robotics has emerged as an important issue for the robot industry. Compared to conventional industrial metallic robots in controlled environments, soft robots are highly expandable in responding to non-standardized environments. Due to these characteristics, it is expected to be used not only in daily life, but also in specific applications such as treatment of disease and disaster relief. The development of a structure that is free to deformation with energy source is also essential to improve the technology. The integration of flexible structure and energy supply is very important to reduce the waste of space and weight of soft robots for versatility and portability. However, there are many difficulties due to the absence of batteries with high reliability under deformation. In this study, we propose a novel geometric structure for stretchable devices, created by folding well-defined two-dimensional patterns with cutouts to produce an extremely stretchable structure with superior reliability and bi-axial deformability. The structure is designed to mimic the hinge of a snakeskin so that its unit cells do not interfere with each mutual movement enabling stable deformations without mechanical damage. In addition, to maximize areal density and stretchability, the optimal shape of unit is determined. The unit-based geometric structure is applied to a stretchable Li-ion battery and constructed of hexagonal pouch cells and parallelogram interconnections. In situ electrochemical characterization confirms that the performance of the battery is maintained under dynamic deformation with a stretching ratio of 90% and a 10-mm-radius bending curvature, guaranteeing a long-lasting cycle life. Finally, the geometrically designed structure-based battery is applied to movable robots, crawling and

slithering, with dynamic bi-axial deformations and can be pivotal role in the development of flexible electronics including human-friendly wearable electronics and soft robots.

SB12.05.19
UV-curable Acryl-Polyurethane for Human-Compatible Flexural 3D Printing Structures Won Bin Lim, Ji-Hong Bae, Jin-Gyu Min, Ju-Hong Lee, Min-Ji Seo and PilHo Huh; Pusan National University, Korea (the Republic of)

An acryl-functionalized urethane prepolymer series with various compositions were synthesized using polyethylene glycol (PEG) and hexamethylene diisocyanate (HDI). Optimizing blending formulation for human-compatible 3D printing structures was based on MTT assays for cytotoxicity. The MTT assay was used to determine the biocompatibility of acryl-urethane (AU) resin for mammalian HaCaT cells. In the case of polyol, the most important component of the resin, treatment with poly(tetramethylene ether) glycol (PTMG) and polycaprolactone diol (PCL) induced concentration-dependent cytotoxicity, whereas PEG showed no cytotoxic effect. AU resin was designed by the addition of 2-hydroxyethyl methacrylate (2-HEMA) as a suitable material for digital light processing (DLP) 3D printing. The optimizing photo-initiator and additive were selected by UV-spectroscopy. The formulation containing the UV-curable AU resin and photo-curable additives was exposed to 405 μm UV radiation to produce the 3D structures. The effects of the photo-initiator/multifunctional acrylate value and UV absorptive power on the 3D printing performance were evaluated in terms of the mechanical properties and dimensional resolution. The surface properties of the 3D structures were tuned by controlling the photo-initiator type and composition in the AU resin. The resolution quality of the 3D printed wearable bands showed distinct differences by UV curing time, viscosity, and exposure amount. Overall, this UV-curable AU resin can be a promising prepolymer for the DLP printing of flexible photo-resin for biocompatible and photo-curable applications.

SB12.05.20
Passive 3D Printed Fully Elastic Pill for Sampling of Gut Microbiome Ruben Del Rio Ruiz, Rachel E. Owyeung and Sameer R. Sonkusale; Tufts University, United States

Technologies capable of noninvasively sampling the luminal content of the GI tract have the potential to improve our understanding of the role of microbiome in health and various medical conditions. Microbial conditions in the gut are typically inferred from the analysis of fecal DNA and fecal metabolites [1]. This approach is inadequate for characterizing the microbiome upstream of the distal colon [2, 3]. To gain new insights into the many beneficial functions of the gut microbiota, it is essential to sample in different locations in the gut, particularly organs located upstream of the colon. Orally ingestible medical devices for gut engineering have been reported for sensing and diagnosis [4]. Most devices are rigid, and some require complex fabrication and assembly techniques. Our prior work on ingestible pills for sampling the gut microbiome [3] relied on a passive osmotic pump and was validated in animal models. However, the design suffered from leakage and post-sampling contamination due to the lack of a closing valve. Here, we describe the development and testing of an ingestible, fully elastic, lightweight, biocompatible, battery-less, 3D-printed, micro-engineered pill for sampling the gut microbiome. The pill is locked with an automatic closing valve which utilizes highly hydrophilic sodium polyacrylate beads, both as an absorbent for passive suction, and for locking the intake when the beads are swollen, and sampling is completed. Results from in-vitro experiments show that the flexible elastic pill is capable of sampling reliably with negligible leakage and contamination.
Stereo-lithography (SLA)-based 3D printing was used to fabricate the ingestible device using a bio-compatible/photo- curable elastic resin (50A) using a Form 2 printer. The pill was designed and fabricated in two sections: The bottom case has two-sided elliptical inlets and two internal microvalves for closing of the inlets autonomously. The top case is utilized as a shield for the pill once the beads are inserted. Three sodium polyacrylate beads are inserted in the pill. Upon exposure to fluid, the beads swell and mechanically push on the microvalves to close the inlets. The pill is then placed inside a pH-sensitive enteric coating to delay sampling until it enters the small intestine, where the coating dissolves in the higher pH environment. Natural peristaltic motion ensures mobility to the pill through the GI tract without any active motion.
The pill's sampling performance was tested by measuring the time required to acquire sample from the same buffer solution. Results show that within 20 minutes beads were fully swollen and microvalves locked both inlets, preventing additional sample acquisition. Finally, rigorous contamination tests were performed by submerging post-sampled pills in Rhodamine B dyed DI water for 30 minutes and 16 hours. Dye uptake by the pill was measured using UV-Vis spectroscopy. Results show no measurable contamination, indicating that the automatic closing valve worked as expected.
In summary, this abstract describes a flexible battery-less ingestible device for sampling intestinal microbiome from the small intestine with a self-closing mechanism to prevent contamination and leakage. Future research will focus on adjusting the composition of the enteric coating to control the location of sampling in the GI tract.

All-Solution Processed Conformable Strain Sensor for Precise Muscle Movement Detection On Skin Surface Hayun Kim, Cheayoung Lee, Hyunjun Yoo and Yongtaek Hong; Seoul National University, Korea (the Republic of)

With the development of more precisely controlled artificial skin, soft robotics and human-machine interfaces, highly sensitive sensors to detect skin surface deformation has gained tremendous significance for their wide range of use in various fields such as device operation control, motion tracking and advanced interface. To keep pace with these trends, many studies have been introduced to suggest the next generation sensor for precise mapping of skin surface deformation. Over the past few years, major research has been conducted to measure and interpret bioelectric signals such as electrocardiography (ECG) and electromyography (EMG). These studies succeeded in obtaining accurate data by analyzing the signals generated by the human body, but when the size of the target muscles becomes smaller or the number and size of sensor electrodes become smaller, the accuracy of data decreases rapidly, making it difficult to obtain valid information. Also, for the EMG signal with a small signal-to-noise ratio (SNR), it was almost impossible to specify the exact point of signal occurrence, which is critical in real-time signal monitoring. Therefore, a reliable sensor capable of measuring the real-time movement of the skin without interfering with the fine movement of the muscles is highly desirable for next-generation electronics requiring immediate and close measurement of small and minor input signals.
In this work, we propose an all-solution processed skin-conformable strain sensor that is highly reliable for low-strain skin deformation sensing. Our strain sensor is facile and large-area compatible based on the spray coating method, maintaining high cycle stability and moderate resistance by taking advantage of both silver nanowire (AgNW) and carbon black (CB) blended as a sensing material. A mixture of AgNW and CB dispersed in ethanol is spray-coated on the polyimide film. After vaporizing the solvents, polydimethylsiloxane (PDMS) is poured onto the sensor film, and the entire substrate is spin coated. After annealing, sensor film is embedded into PDMS and easily detached from the polyimide (PI) film. The fabricated sensor shows high cycle stability of over 6,000 cycles under repeated 5% strain with excellent linearity and gauge factor over 20. At the same time, the thickness of the sensor is under 300 μm, assuring high conformability and precise detection of skin deformation. To further demonstrate the feasibility of our sensor toward precise muscle movement deformation, data obtained from our sensor attached to the human muscle was compared to the actual skin deformation rate measured with a 3D

digital image correlation (3D-DIC) device. Our sensor has succeeded in precisely tracking deformation at a given location without interfering with muscle movement. This study provides a new pathway to map skin deformation especially in the single muscle movement with a low deformation rate under 5%, which is clearly distinguished from other sensors applied to large strains such as joint flexure. Furthermore, our sensor can be applied to any type of deformable substrate with potential applications such as wearable devices, soft robotics and advanced user interface. The detailed methods and results will be discussed later.

This work was supported by the Technology Innovation Program (No.20008801, Development of muscular function management solution based on electronic skin with EMG IMU and Strain sensor) funded By the Ministry of Trade, Industry & Energy(MOTIE, Korea).

Stretchable and Biodegradable Batteries with High Energy and Power Density Doris Danninger and Martin Kaltenbrunner; Johannes Kepler University Linz, Austria

Realizing a sustainable, technologically advanced future will necessitate solving the electronic waste problem.[1] Biodegradable forms of electronics offer a viable path through their environmental benignity. With both the sheer number of devices produced every day as well as their areas of application ever increasing, new concepts of degradable batteries able to sustain the high power demands of modern electronics must be developed. Simultaneously, integration of electronics in close interaction with its user or powering soft robotic devices necessitates high degrees of compliance, rendering stretchable batteries indispensable. With the first stretchable battery demonstrated by our group in 2010, we since advance such concepts towards environmentally benign materials.[2] We demonstrate a concept for merging intrinsically stretchable materials with engineered stretchability by kirigami-patterning on a component level. With this method, we achieve high-power biodegradable batteries with reversible elasticity up to 35% when stretched uniaxially and 20% for biaxial extension. Using a combination of molybdenum metal foils, a molybdenum trioxide paste and magnesium metal foils as electrode materials, a peak power output of 196 µW cm^{-2} and an energy density of 1.72 mWh cm^{-2} is realized. The biodegradable batteries are used to power an on-skin biomedical sensor patch, enabling monitoring of sodium concentration in sweat. We designed a flexible circuit board in a small form factor allowing the collection of sensor data, while solely being powered by our biodegradable battery. The whole device is non-obtrusive and comfortable to the wearer. This concept provides a versatile route for high-power biodegradable batteries, enabling untethered soft electronic devices in a sustainable future.

A Highly Flexible, Non-Flammable Li-Ion Battery via Co-Optimization of Electrode Cohesive and Adhesive Strength Guangqi Ouyang; University of California, Los Angeles, United States

With the development of flexible and wearable electronics, the thickness of current wearable devices can scale down to hundreds of microns and the flexibility of the devices can be less than 1 mm bending radius [1]. Therefore, to match the progress of wearables, the design of flexible batteries needs to consider form factor, flexibility. However, traditional batteries (i.e. Coin cell, pouch cell, cylindrical cell) have not scaled down in a similar manner as their device counterparts, which makes the final size of the integrated system is limited. In addition, regarding flexibility, traditional battery structures fail to match the flexibility of devices they power, compromising the advantage of wearable devices. In past few decades, researchers have developed various types of flexible batteries for powering wearable biomedical devices, including fibrous batteries, and rubbery batteries. However, they are still limited in flexibility, stability, and output performance.

According to research [2,3], a battery fails during flexing in two modes: cohesive failure and adhesive failure. As for the cohesive mode, stress concentration and propagation happen within electrode layers due to its complex particle-network structures, which causes non-uniform Li intercalation and deintercalation processes. As for the adhesive failure mode, electrode layers delaminate from current collector layers, thus significantly increasing their contact resistance. Both modes strongly hurt battery stability and electrochemical performance.

Based on our previous work[4], we demonstrate a “land-bridge” electrode design to reduce cohesive stress concentration within electrode layers and a “Site-pinning” approach to increase adhesive strength between electrodes and current collectors. The coupled optimization of these two methods gives the battery achieve > 1000 times bending under 5 mm bending radius, 1 mAh/cm^2 capacity density, < 300 um total thickness.

First, as for “land-bridge” design, a 8x8 electrode matrixes are casted on a 600 nm current collectors in PDMS singulation walls. By taking the advantage of low Young’s Modulus of PDMS and the “land-bridge” design, the bending stress within electrode layer is significantly reduced. In addition, we also develop a 5 um flexible SU8 layer between electrodes and current collectors to improve the adhesive strength. We prove that the hydrogen bond between SU8 layer and electrode forms hydrogen bonding enhances the electrode adhesive strength to flat current collector. Finally, to address the safety concerns of the Li-ion battery for wearables, an ionic liquid electrolyte (1M Lithium bis(fluorosulfonyl)imide (LiFSI) in 1-Butyl-1-methylpyrrolidinium bis(trifluoromethylsulfonyl)imide (Py_{14}TFSI)) is used in this work to provide non-flammability.

Artificial Mechanoreceptors from Hydrogels—Capacitive, Triboelectric and Piezoionic Sensors for Ionic Skin and as Interfaces with the Nervous System John D. Madden and Yuta Dobashi; Univ of British Columbia, Canada

Millivolt potentials and nanoampere ionic currents are the signals at the heart of our sensory system, and our nervous system in general. Can we make use of ionic signals in artificial sensors and neural interfaces? Here we discuss three versions of artificial ionic sensors.

In the first, the hydrogels are used as ionic conductors in capacitive or piezoresistive sensors. These are low power, soft sensors that build on the ionic skin concept developed almost a decade ago - combining mechanical toughness, transparency and compliance. Here there is no need for hard electronics or wires, except to deliver and record electronic signals. The interface between the ionic and electronic, and the wet nature of the hydrogels, are challenges - but there are solutions. The scalability of these approaches to create skins containing arrays of sensors is discussed, and compared with implementations using conductive elastomers.

In the second approach, change in surface contact between a hydrogel and a conductor or other charged interface, can lead to the generation of significant voltages. Hydrogel toughness and deformability, combined with mobile salt content, provide advantages for creating compliant sensors or even generators. Potentials at the level of volts or higher can be generated, making detection simple. Charge density and electromechanical coupling are relatively small, so generators will need to operate at high frequencies to run electronics. They rely on an electronically conductive interface, but can be self-powered (i.e. no input electrical energy is needed - the energy from the mechanical work done is sufficient).

A third sensing approach uses motion of ions induced by pressure gradients. This can include streaming, in which ions of one polarity are carried by moving solvent, producing currents and charging. In general, what can be called a piezoionic effect is involved - where there is an effect of pressure on the motion of ions. This is akin to piezoelectrics, except that it relies on a gradient, and charges are mobile rather than bound into a crystal. In hydrogels with both mobile anions and cations, such as Na+ and Cl-, the net current produced may be simply a result of anions being effectively larger than cations, experiencing more drag as they move through the hydrogel, and leading to a net current as the cations flow more freely. Voltages are small - typically millivolts. But charge can be large. And responses can be surprisingly fast - in the same range as our mechanoreceptors. The net effect can stimulate a nerve and lead to muscle contraction, fully self-powered. This transduction and transmission should be possible without the use of any metallic conductors, though this has yet to be shown, and our demonstration uses fine wires. Wires allow the signals to be transferred over larger distances, due to the much lower resistivity of metals than ionic conductors. As with any interface between electronics and tissue, there are electrical and mechanical impedance mismatches. These can be managed using conducting polymer coatings that absorb enormous concentrations of ions, or, perhaps, by avoiding the use of electronics completely. To expand the possibilities of ion only sensors, an active ionic system like that provided by our sodium/potassium ion pumps, is likely needed.

Rubbery Complementary Thermoelectric Generator Fabricated from Intrinsic Stretchable N-Type Semiconductor Yongcao Zhang, Diego Rosas Villalva and Derya Baran; King Abdullah University of Science and Technology, Saudi Arabia

Stretchable thermoelectric generators (TEGs) have proven to be promising candidates for wearable electronics and can harvest electrical energy from body heat. However, high-performance stretchable n-type TEGs lag the development of the organic thermoelectric (OTE). Here, we developed a novel n-type semiconducting nanofiber and an intrinsically stretchable n-type TEGs fabricated from percolated nanofiber network in the elastomeric materials. Taking advantage of nanofiber structure, extraordinary thermoelectric properties have been achieved by sequential doping. With increasing dopant concentration, a transition of the Seebeck coefficient from n-type to p-type was observed. Owing to the percolation network of n-type semiconducting nanofiber, the fabricated intrinsic stretchable TEGs retain their conductivity under high strains. The incorporation of stretchable p-type TEG material also allows to achieve the stretchable complementary TEG and harvest energy from different arbitrary surfaces. The demonstrated intrinsic stretchable n-type semiconductor will provide more insight toward complementary circuits and sensors

9:15 AM SB12.06.05
Hydrogels Based Triboelectric Nanogenerators (TENGs) for Energy Harvesting and Self-Powered Tactile Sensors Giuseppina Pace[1,2] and Marino Lavorgna[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Italian Institute of Technology, Italy

New low power technologies, as the one largely developed for the internet of Things (IoT), wearable and portable electronics, require only few tens of microwatts up to few mW of power supply to operate. This makes it possible their sustainable integration with energy harvesters that can scavenge the environmental wasted energy. In addition to provide the required electrical power to low power electronics, mechanical and thermal energy harvester can also be designed as self-powered sensors. This aspect hugely widens their potential impact in a variety of application fields including soft-robotics, artificial skin, and haptics.
Between mechanical energy harvesters, triboelectric nanogenerators (TENGs) have gained increasing attention as novel low-cost energy solution. Furthermore, they can be fabricated with low environmental impact materials and scalable printing processing. Recent developments in TENGs technology show that they can be used in different applications going from wearable and self-powered sensors to wind and sea wave energy harvesting (blue energy). [1] Differently from other mechanical energy harvesters, as piezoelectric and electromagnetic generators, TENGs can be fabricated from non-toxic, biodegradable and recyclable materials and can efficiently operate also in the low frequency range. [2]
TENGs energy conversion mechanism relies on the charge transfer which occur between two materials placed under friction forces and that own different electron affinities. Strategies to increase the charging of triboelectric materials (tribomaterials) through chemical modification or surface patterning have been proposed. We recently demonstrated that the electrode work function as well as electrode capacitance must be considered to improve TENGs power output, a main aspect which has been often disregarded in previous work. [3,4]
Here, we highlight the fundamental role played by the interface between the tribomaterial and the electrode in contributing to the increase of energy harvesting and tactile sensing of novel TENGs based on hydrogels. The specific role of composition, structure and electrolytic capacitance of hydrogel based on polyvinyl alchool derivatives, will be highlighted, and clarified. This work intends to provide useful guidelines for the future design of new materials and device structure design leading to improved TENGs performances, fostering their sooner integration into novel low power electronics.

Stretchable Redox-Active Semiconducting Polymers for High-Performance Organic Electrochemical Transistors Yahao Dai, Shilei Dai and Sihong

Wang; University of Chicago, United States

Wearable health monitoring technologies that can be integrated intimately with human bodies are of rapidly increasing interest in daily healthcare and self-diagnosis. Organic electrochemical transistor (OECT) is an emerging device platform for next-generation human-integrated bioelectronics owing to its high amplification and sensitivity to biological signals, and non-volatile signal retention for memory and computing applications. However, owing to the lack of stretchable redox-active semiconducting polymers, skin-like softness and stretchability have not yet been realized in high-performance OECTs for achieving seamless tissue-electronics interfaces. Here, we report two stretchable semiconductors for OECT devices, namely poly(2-(3,3′-bis(2-(2-(2-methoxyethoxy)ethoxy)ethoxy)-[2,2′-bithiophen]-5)yl thiophene) (p(g2T-T)) and poly-[3,3′-bis(2-(2-(2-methoxyethoxy)ethoxy)ethoxy)-2,2′-bithiophene] (p(gT2)), which give exceptional stretchability over 200% strain. In particular, the p(g2T-T) also shows great mechanical robustness for being able to sustain charge carrier mobility over 5000 stretching cycles, together with the OECT performance on par with the state of the art. Validated by the systematic structural characterization, sufficient chain alignment during stretching for stress dissipation is determined as the key enabler of high stretchability. By comparing the mechanical and electrical performance of different polymer semiconductors, the key design features for enabling the combination of high stretchability and high OECT performance are determined as non-linear backbone architecture, moderate side-chain density, and sufficiently high molecular weight. Using those highly stretchable polymer semiconductors, we fabricated an intrinsically stretchable OECT with the high normalized transconductance (~223 S cm^{-1}) and biaxial stretchability up to 100% strain. Furthermore, we demonstrated on-skin electrocardiogram (ECG) recording based on our stretchable OECT, and fabricated an intrinsically stretchable neuromorphic device with over 800 distinct memory states and good state retention capability (> 10^4 s) with the high stretchability of up to 100% strain over 100 repeated cycles.

10:15 AM SB12.06.07
Motion Artifact-Resilient Embedded Sensors by Mechanically Rendered Stable Zone Chanho Jeong[1,2] and Tae-il Kim[2]; [1]Carnegie Mellon University, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Recently, miniaturized and lightweight sensors have changed the conventional hard and bulk medical equipment to flexible form, allowing users to engage in daily activities while having sensors equipped or implanted. This simple change has provided continuous data acquisition of human conditions for the high yield of diagnosis. However, the continuously measured physiological/electrophysiological signals from a body-interfaced device are inevitably embedded into physical noise from body movement. This is because the body always moves by the skeletal system, which is controlled by muscle contraction and relaxation. Therefore, human-interactive devices that are closely placed to the body are also affected by skin and muscle movement. Consider that, in many cases, the transducer of the sensors is supposed to be deformed by the amount of the targeted physical quantity. However, unintended deformation of the sensor induces unexpected tensional or compressive force, generating errors. For these reasons, dynamic motion always diminishes the quality of the data, and reduces the signal-to-noise ratio. As an example, a tactile sensor aims to recognize touch. However, dynamic movement is also a factor that generates signal change without touch, and results in the user recognizing a virtual touch that does not really exist. The canceling of dynamic noises and extraction of the target signal are essential issues in body-interfaced devices.
The most common method is signal processing for noise canceling. However, this requires additional data processing, which potentially incurs signal loss of the original data. Alternatively, unconventional signal filtering using structures, materials, or designs of electrodes has been suggested. Representative examples are bending-insensitive devices using neutral planes, unidirectional sensors with precisely aligned patterns to have rather high sensitivity in one direction, and stretching insensitive sensors using wavy or origami forms that enable the sensors to change along with the deformation, while maintaining their performance. However, these methods concentrated on a single dynamic effect, and they also faced other problems. To resist dynamic movement, the sensor should be resilient to various deformations, like stretching, compression, and bending. The neutral plane method has high effectiveness for bending insensitivity, but no resistivity to stretching and compression. Unidirectional sensors are difficult to expand to various sensors, because they need to accompany processes that are of complicated structure, or difficult. In the case of origami and wavy 3D structures, some operating space over the whole device is required to properly work, and it is barely used for implantable devices.
Notably, motion-induced noise operates through the body surface direction, and the film shape sensor has varying sensitivity according to the orientation of the device. To eliminate dynamic motion artifacts more efficiently and universally, in this research, the film sensor is placed in a position where motion noises apply to a relatively insensitive direction, while letting the target stimuli apply to the sensitive area. The principles of the unidirectional sensors mentioned above are expanded from 2D body surface to 3D space, and the study is conducted on motion artifact-minimized sensors that do not require specifically aligned patterning to take a strict process and limit the variety of fabrication. The study aims to show sensors that focus on human-interactive devices while showing insensitivity to 75 % stretching, 25 % compression, and 5 mm radius of curvature bending, while maintaining the sensing ability of the sensor. As an demonstration, the pulse signal on a wrist is well measured while the hand is rotating, and artificial skin implanted on rat can distinguish external pressure from the effect of movement noise.

10:30 AM *SB12.06.08
Interfacing Imperceptible Electronics with the Human Body—New Solutions and Approaches Andrea Spanu; University of Cagliari, Italy

The advent of epidermal electronics, which can be traced back to the beginning of the 2010 decade, radically changed the idea of electronics/human body interfacing, blurring the boundaries between the system to be analyzed (the human body) and the tools that are necessary to effectively transduce its multifaceted biosignals. In particular, the newborn possibility of a seamless integration of electronic devices and the human skin quickly led to the rise of new perspectives and outlooks that ultimately lead to imperceptible electronics, a concept that literally break the obsolete dichotomy between the “soft” human body on one side and the “rigid” recording device on the other side.
Nowadays, two of the most interesting fields of applications of epidermal electronics are undoubtedly the development of sensing systems for robotic skin, and the engineering of bioelectrodes for the monitoring of biopotential, such as electrocardiography (ECG), electromyography (EMG) and electroencefalography (EEG) signals from the surface of the skin. Regarding the first application, we show here an approach based on Parylene C sub-micrometric substrates and the piezo(and piro) electric polymer PVDF coupled to an organic transistor called Organic Charge Modulated FET (OCMFET) for the development of tactile sensors for robotic skin applications. Thanks to the versatility of the OCMFET structure, the low-cost materials and the low-resolution fabrication processes, this method allows to easily obtain ultrasensitive temperature and force sensors on ultra-conformable substrates that can be easily transferred onto a target surface (including a robotic end effector or the human skin) without losing their characteristics. As pertains to the second application (which represents one of the most appealing example of the possible integration between this novel branch of electronics and the human body), despite the numerous different approaches that have been proposed so far, some of the intrinsic weaknesses of using ultrathin electrodes within the biomedical domain are still yet to be solved. The first issue is related to the breathability of these epidermal patches, an important aspect when on-body measurements are taken into consideration. With the intent of overcoming this issue and thus improving the comfort of the subject during the measurement, we developed a simple yet effective solution for the development of tattoo electrodes for biopotential recordings, which relies on biocompatible materials and low-resolution fabrication techniques. In particular, Parylene C-based submicrometer-thick electrodes have been rendered breathable through a large area, oxygen plasma-based perforation technique, surpassing the breathability of common textiles like jeans and approaching that of knitted clothing, thus making these electrodes suitable for long-term biopotential recordings. The second important aspect that we recently tackled is related to the methods of

connection of such imperceptible films to the external electronics, a problem that effectively voids some of the main advantages of having an ultra-thin and conformable device. The adopted solution relies on free-standing, ultra-thin PEDOT:PSS based functional films with conductive and ferrimagnetic properties, thanks to the integration of inexpensive ferrite powder layers within the film itself. The obtained electrodes can be transferred on the skin as temporary tattoos and directly contacted using magnetic connectors without compromising their conformability.
The proposed approaches, being at the edge between the fervent fields of epidermal and organic electronics, represent interesting examples of how it is possible to obtain high-performing and conformable tactile sensors, while at the same time overcoming some of the more important issues and limitations that stem from interfacing electronics and the human body.

11:00 AM SB12.06.09
Design of a Fully-Resorbable Soft Electronic Device for Neural Stimulation and Monitoring Simon Regal[1,1], Maxime Leprince[1,2], Pascal Mailley[1], Napoleon Torres-Martinez[1], Jenny Molet[1], Fabien Sauter-Starace[1], Isabelle Texier-Nogues[1] and Rachel Auzely-Velty[2]; [1]University Grenoble Alpes, CEA, Leti, France; [2]University Grenoble Alpes, CNRS, France

Currently, clinical electrocorticography (EcoG) electrode matrices are embedded in inelastic silicone rubber. For subchronic studies, neural implants need to be removed during a second surgery in order to limit immune system reactions or infectious risks. However, any surgery involves risks for the patients and can lead to complications. The development of transient electronic devices opens the way to new medical possibilities for mid-term post-surgical follow-up, such as electrophysiological monitoring, on-demand and controlled drug delivery, or electrical stimulation in tissue regeneration. Implants able to degrade harmlessly inside the body eliminate the need of removal surgery with associated risks. Compared to non-degradable devices, they potentially reduce inflammation responses and chronic adverse conditions that could decrease device functionality.
A bioelectronic device consisting of poly(lactic-co-glycolic acid) (PLGA) films as insulating substrates, sputtered molybdenum (Mo) as conductive tracks, and conductive polymer electrodes for tissue interface, has been fabricated using microfabrication techniques. With their mixed ionic/electronic conductivity and tunable mechanical, electrical, electrochemical, and biological properties, conductive polymers are materials of choice for the design of the conductive electrodes of such transient devices. Herein, resorbable materials based on sulfated hyaluronan modified with phenylboronic moieties (HAS-PBA) as dopants of poly(3,4-ethylenedioxy)thiophene (PEDOT) were specifically developed for this application.
The thickness of the entire device is 40 µm thick with Mo tracks of only 500 nm, whereas the length and width are respectively 9 mm and 4 mm. Electrical impedance spectroscopy showed that the PEDOT:HAS-PBA layer reduced the electrode impedance (580 Ω at 1 kHz), providing a better interface than Mo metal alone (3400 Ω at 1 kHz). The charge storage capacity of electrode material showed an increase from 5 mC/cm^2 to 26 mC/cm^2 for Mo and PEDOT:HAS-PBA, respectively. The device was developed for a working period between 1 and 2 months, and a complete resorption around 3 months. In vitro characterization of device stability for electrophysiological monitoring followed by device degradation was carried out over a 3-month period. The next step will be to implant the device subdurally in contact with rat brain cortex for electrical stimulation and recording, and to explore its bioresorbability properties *in vivo*.
In summary, we describe the development of a thin and flexible device that is suitable for different applications such as pre-surgical localization of epileptogenic foci or post-surgical monitoring of brain activity. The lifetime of our device is perfectly adapted to these applications.

11:15 AM SB12.06.10
Air-Stable Ultra-Flexible Organic Photonic System for Cardiovascular Monitoring Tomoyuki Yokota, Iwao Shirayama and Takao Someya; The University of Tokyo, Japan

Optical bioimaging techniques, such as imaging using fluorescent probes, photoacoustic imaging, and near-infrared spectroscopy, are noninvasive methods that is widely used in medical devices for measuring biological information from outside. In recent years, with the development of semiconductor technology, miniaturization of these imaging devices has become possible. In particular, organic optical devices have such features as high efficiency, flexibility, and low weight; hence, they are being increasingly applied to healthcare through integration into wearable devices. For example, a flexible device that integrates an organic light-emitting diode (OLED) and an organic photodetector (OPD) can be attached to a finger, and the pulse wave can be calculated by measuring the light reflected from the body. Measuring the blood oxygen ratio using two-color light sources, such as red and green, or red and near-infrared light-emitting diodes, is also possible. Other biometric data, such as veins and fingerprint images, can also be obtained using high-resolution imaging sensors. Improving the conformability of the device to the body is important to perform such *in vivo* imaging with high accuracy.
Soft optical devices should be developed to improve the conformability of devices to the skin. Previously, extremely soft organic optical devices have been realized by ensuring the elasticity of the substrate and required materials. Owing to the development of new materials and processes, soft organic optical devices can achieve the same electrical properties as devices fabricated on glass or thick plastic film substrates. Furthermore, the thickness of the film substrate can be reduced to realize ultrathin organic optical devices with improved skin conformability. An OLED that is formed on a 1.5 µm-thick plastic substrate and can be attached to the skin has been reported.
However, the integration of multiple types of organic optical device, such as OLEDs and OPDs, on the same thin substrate of less than 50 µm without using the lamination process has not been reported. This is because organic optical devices fabricated on a flexible substrate are not stable and require an encapsulating layer with high barrier properties, and making the film thinner while maintaining the barrier properties is difficult. Furthermore, to integrate different optical devices, it is necessary to fabricate the devices using a vacuum process, which results in insufficient characteristics of the organic photodiodes or organic photovoltaics. Therefore, it is necessary to form OPDs using a solution process and improve the stability of the organic optical devices to integrate high-performance organic optical devices on the same ultrathin substrates.
In this study, we developed an ultra-flexible optical sensor system wherein OLEDs and organic photodiodes are integrated on the same substrate by improving the air stability of ultra-flexible OLEDs and photodiodes. By applying an inverted structure, the ultra-flexible OLEDs were operated for more than 10 days, even without a high-barrier passivation layer. The ultra-flexible OLEDs exhibited high air stability, wherein the current density was maintained at more than 50% of the initial state. The organic photodiodes also demonstrated high air stability, with less than 1% change in photocurrent and less than 10 nA/cm^2 dark current after 10 days. The sensor system integrating these air-stable optical devices is extremely thin, with a total thickness of 5 µm. Therefore, it can be directly attached to the skin, and the pulse wave can be measured easily. Furthermore, we succeeded in measuring the pulse wave propagation time by combining an optical system with an electrocardiogram. When the blood pressure value was calculated from the measured pulse wave propagation time, a high correlation coefficient of 0.89 was achieved. This value was measured using a conventionally used cuff-type blood pressure-monitoring system.

11:30 AM SB12.06.11
Honeycomb Film Morphologies for High-Performance Stretchable Electrochemical Transistors Antonio Facchetti; Northwestern University/Flexterra Inc, United States

The realization of fully stretchable electronic materials is central to advancing new types of mechanically agile and skin-integrable optoelectronic device technologies. Here we demonstrate a materials design concept combining a porous organic semiconductor honeycomb film morphology with a biaxially pre-stretched platform that enables high-performance organic electrochemical transistors (OECTs) with charge transport stability up to 30-140% tensional strain, limited only by metal contact fatigue. The pre-stretched honeycomb channel semiconductor, donor-acceptor polymer DPP-g2T

(DPP=diketopyrrolopyrrole, 2T=dithiophene), exhibits high ion uptake with ultra-stable electrochemical and mechanical properties, > 1500 redox cycles with 10000 stretching cycles under 30% strain. Highly reliable electrocardiogram recording cycles and synapse responses under varying strains, along with mechanical finite element analysis, underscore that the present stretchable OECT design strategy is suitable for diverse applications requiring stable signal output under deformation with low power dissipation and robustness to mechanical deformation.

SESSION SB12.07: Applications III

1:30 PM *SB12.07.01
Soft Adaptive Robots Inspired by Nature Barbara Mazzolai and Emanuela Del Dottore; Istituto Italiano di Tecnologia, Italy

Natural organisms are adaptive, constantly learning and evolving. Since the dawn of life on Earth 3.8 billion years ago, natural species have evolved behaviors with characteristics suited to survive in their environment and to sustain life for generations. Perfection is not nature's goal. Nature focuses on evolution. Therefore, nature experiments, re-combines the existing and adapts according to results. Thus, why are roboticists looking at natural organisms for the robot revolution? By looking at natural organisms' life and evolution strategies, nature can provide engineers with the rules to design and develop functional embodiments and energy-efficient behaviors, which are the keys for artificial machines to better deal with unstructured and challenging environments.
With this vision, our approach is to take inspiration from plants and soft animals in order to design robots with high morphological adaptability, distributed sensory systems, as well as energy-saving mechanisms.
More specifically, in this talk, I will explain how soft animals and plants offer new insights to generate new multi-functional materials for morphological adaptation and computation, mechanisms for moving-by-growing, strategies for climbing and adhesion, multi-sensory information processing and distributed architecture of functionalities, as well as new forms of energy. Examples will include recent advances in artificial self-growing robots, technologies and mechanisms for adaptive anchoring, soft manipulators for adaptive grasping, and biodegradable robots.These eco-robots will find applications for environmental exploration, monitoring, precision agriculture, and for improving basic knowledge on natural phenomena.

2:00 PM SB12.07.02
Soft Actuators Made of Discrete Grains Sophia T. Eristoff[1], Sang Yup Kim[1,2], Lina Sanchez Botero[1], Trevor Buckner[1], Osman Dogan Yirmibesoglu[1] and Rebecca Kramer-Bottiglio[1]; [1]Yale University, United States; [2]Sogang University, Korea (the Republic of)

Soft actuators grant soft robots meaningful mechanical force while maintaining inherent compliance. Stimuli-responsive soft actuators respond to changes in the environment to initiate actuation, allowing for remote actuation and further enhancing the adaptability of soft robots. Recent advances have shown thermo-responsive phase-change actuators can produce high forces with significant volumetric expansions. These phase-change actuators rely on the thermally-driven liquid-to-gas phase-change of encapsulated low boiling point solvent within a soft bulk elastomer. Simultaneously, granular media has the opportunity to shift between critical states via jamming, exhibits bulk reconfigurability via different particle packings, and can provide viscosity enhancement to enable 3D printing of a variety of materials. In this work, we present soft granular actuators, where each grain consists of a hyperelastic silicone shell and multiple low boiling point solvent cores. When subject to temperatures past the boiling point of the encapsulated solvent, each individual grain undergoes rapid volumetric expansion of approximately 700%. The actuation force of a single grain is large enough to lift a mass 2000x its own weight in less than 2 milliseconds. Additionally, individual grains can be arranged in a soft silicone pouch and when subject to a change in ambient pressure, the grains collectively undergo jamming behavior and a stark increase in stiffness is observed. When grains are embedded in an uncured resin, they induce thixotropic behavior of the carrier resin, enabling 3D printing of freeform soft actuators with high shape retention. Furthermore, the granular composite can be printed onto a variety of inanimate objects to impart motion. In sum, distinct soft granular actuators enable scalable actuation from micro-scale individual grains to meso- or macro-scale granular agglomerates. When embedded in resin, grains enable freeform 3D printing of actuators with high resolution and large volumetric expansions. Combining the advantageous properties of phase-change soft actuation and granular media, this work presents the opportunity to realize soft actuators with tunable bulk properties, compatibility with self-assembly techniques, and on-demand reconfigurability.

Vine Growing Robots for Medical Applications—Design and Miniaturization Tania Morimoto; University of California, San Diego, United States

Soft growing robots, also known as vine robots or tip-everting robots, have recently emerged as a promising class of soft robot. They consist of an inflatable, thin-walled, hollow tube that is inverted inside itself. The inverted material everts, or extends, from the tip of the robot as it is pressurized with air or fluid, in a manner similar to how plants grow. This method of movement is fundamentally different from that of traditional soft, flexible robots and manual surgical tools, since they are not pushed from the base and therefore result in no relative movement between the robot body and the environment. These robots therefore have significant potential for improved safety and navigability through highly constrained and sensitive areas deep inside the human body. However, current vine robot designs are fundamentally limited in how small they can be scaled, therefore limiting their applicability in realistic clinical scenarios. This talk will focus on our approach to addressing this challenge of vine robot miniaturization. First, we analyze the impact of the vine robot design parameters on their miniaturization. Second, we propose several new vine robot architectures that overcome the current scaling limitations. Critically, there are several material dependent design parameters that significantly affect the scaling capabilities of a given robot architecture. Third, we investigate several approaches to integrating actuators that can enable steering of the vine robots, even at small scales. Finally, we highlight the potential impact of the proposed robot architectures and associated models through experimental validation of a robot designed for endovascular surgery.

3:45 PM SB12.07.05
Transparent and Highly Voltage-controllable Electro-tactile Actuator Kyeonghee Lim, Sumin Kim and Jang-ung Park; Yonsei University, Korea (the Republic of)

Tactile sensation plays key roles in the realization of senses of prosthetics, virtual reality (VR), augmented reality (AR), and display touch panels. In recent years, vibro-tactile technology was dominant in this field of research. However, until now, most vibro-tactile devices have critical limitations to provide a variety of sensations and stimulation in close intervals due to their bulky forms. Therefore, electro-tactile device is a promising candidate for a tactile

stimulation system. Herein, we demonstrate a transparent, voltage-controllable electro-tactile actuator capable of presenting a variety of senses and high-resolution tactile information of 2 mm. This electro-tactile actuator is advantageous to control the frequency, amplitude, and pulse width of applied electrical pulses to different mechanoreceptors. We exhibited the effectiveness of this actuator through cognitive experiments on human subjects and neuronal signals from the fingertips to the brain. Through the cognitive experiments, 10 subjects detected stimulation at a low voltage on the fingertip electro-tactile device (<10 V), and it was possible to cause a large range of senses such as vibration, tapping, hardness, and pain by varying stimulation frequency (10-300 Hz). Pulse signals transmitted into the skin through an actuator were also measured as neuronal signals. This electro-tactile actuator is expected to work in many fields, including transparent mobile displays, artificial prosthetics, or even VR and AR tactile displays due to its accuracy in local stimulation, and high transparency.

4:00 PM SB12.07.06
A Method to Measure and Optimize Full Cycle Efficiency of Soft Electrostatic Actuators Steven L. Zhang[1], Soo Jin Adrian Koh[1], Philipp Rothemund[1], Toshihiko Fukushima[1], Sophie Kirkman[1] and Christoph Keplinger[1,2,2]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]University of Colorado Boulder, United States

Energy efficiency of actuators is a critically important metric for untethered and mobile robotic systems. The field of soft electrostatic actuators is missing an universal, easy to use tool and a standard that allow measurement and analysis of actuator's intrinsic electrostatic-mechanical efficiency. Thus, in this work, a method to measure and optimize the efficiency of soft electrostatic actuators is developed, where the four work conjugate parameters: voltage, charge, force, and displacement, can be monitored in real time. The full cycle efficiency of electrostatic actuators can be calculated by dividing the area enclosed in the force-displacement plane and the area enclosed in the chargevoltage plane. We demonstrate our method using HASEL actuators as a model system, and the intrinsic electrical and mechanical losses were studied, and efficiency was calculated at different driving voltages and loads. It was found that there is an optimal load resulting in an efficiency of 58% for HASEL actuators. The method can be further used to study the impact of various parameters such as frequency, and the use of new materials systems and geometries on the efficiency.

4:15 PM SB12.07.07
Millimeter-Scale Soft Electrohydraulic Actuators for Locomotion in Aquatic Environments Florian Hartmann and Herbert R. Shea; École Polytechnique Fédérale de Lausanne, Switzerland

Undulating fin and tail propulsion—used by marine animals across many size scales—represents an efficient locomotion method, both on and under water. It is silent and enables a variety of maneuvers. Robotic swimmers can achieve such life-like locomotion using soft actuators but typically measure several tens of centimeters, preventing applications that benefit from smaller scales. Here we present the design, material approaches, and fabrication processes of soft mm-scale electrohydraulic actuators. Our actuators use zipping of metalized polymers films to displace a dielectric fluid, which generates bending of fins, creating a periodic undulation. We developed a fabrication strategy based on multilayer lamination to enable actuators which operate reliably when submerged in water at voltages from 500 V to 2 kV. The actuators are fast, capable of operation up to 20 Hz, and provide suitable amplitudes for swimming, with bending angles up to 15 degrees. With these actuators, we demonstrate flatworm-inspired robots, only a few tens of millimeters long, that locomote both on or under water.

4:30 PM SB12.07.08
Soft and Highly Integrated Electronic Fibers Fabien Sorin[1], Andreas Leber[1], Chaoqun Dong[2], Hritwick Banerjee[1] and Stella Laperroussaz[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland, Switzerland; [2]University of Cambridge, United Kingdom

Stretchable optical and electronic fibers constitute increasingly important building blocks for a myriad of emerging applications, such as in robotics, sensing, medical implants or e-textiles. They are particularly suitable for wearables and smart textiles as seamlessly integrated devices that can bring high added values for monitoring, energy harvesting, haptic and even actuation functionalities. Yet, it remains challenging to fabricate efficient and advanced soft fiber-base devices that can undergo significant mechanical deformation in a simple and scalable way. The preform-to-fiber thermal drawing technique is a powerful platform to fabricate multi-material fibers with complex architectures and functionalities. Until recently, this fabrication approach has been restricted to rigid thermoplastic or glass fibers, preventing their use for mechanical sensing or actuation, and rendering difficult their use in wearable approaches or within textiles.
In this contribution we will show how we could revisit the selection criteria for cladding materials compatible with the thermal drawing process, and fabricate super-elastic fibers with advanced electronic functionalities. We will demonstrate how, thanks to a deeper rheological characterization, we could identify thermoplastic elastomers that could be drawn from a solid preform at high viscosity (Advanced Materials, 2018, 201707251). Subsequently, we will demonstrate that thermoplastics, liquid metals, and conductive polymer composites could be co-drawn with prescribed architectures within thermoplastic elastomer cladding. This allowed us to successfully fabricate stretchable optical but also electronic fibers that are used as precise and robust pressure, strain or more generally deformation and haptic sensors. We will in particular show examples of electronic fibers for strain or pressure sensing, that can be integrated into textiles and fabrics for large area pressure mapping (Adv. Funct. Mat. 30, 1904274 (2019)), and for polymer composite part monitoring (Adv. Mat. Technologies 6, 2000957 (2021)). We will also introduce an original strategy based on fibers that integrate tens of liquid metal electrodes that can act as a soft transmission line for sensing multiple mechanical deformation events along the entire fiber length (Nature Electronics 3, 316 (2020)). Based on the same combination of micro-structured thermoplastic elastomers and liquid metal electrodes, we will present self-powered strategies via soft triboelectric fibers (Nature Communications. 11, 3537 (2020)). These examples of fibers enable to realize, with a few connections at fiber ends, robust large area sensing fabrics, paving the way towards novel opportunities for advanced yet scalable soft electronics, soft prosthesis, wearable devices and electronic textiles. We will conclude with a hint on recent developments (currently under review) of steerable multi-material soft fibers to realize highly integrated thin catheters with micro-channels, optical waveguides and electrodes, paving the way towards novel opportunities in soft robotics.

SESSION SB12.08: Poster Session II

Soft Actuators Based on Liquid Crystal Elastomer and Laser Induced Graphene Stella Drewes[1], Alexander Dallinger[1] and Francesco Greco[1,2]; [1]Graz

University of Technology, Austria; [2]Scuola Superiore Sant'Anna, Italy

Thermoresponsive Liquid Crystal Elastomers (LCEs) are widely studied for their use as soft actuators as they feature excellent actuation properties including large actuation strains and reversible actuation processes. To overcome the prevalent limitations of rigid heating elements hindering the actuation performance of soft actuators, composites of LCEs and a soft heating structure promise a great enhancement of the actuation behaviour. As compliant heating elements conductive tracks of Laser Induced Graphene (LIG) are used which are obtained from laser scribing with an IR CO_2 laser on a polymeric precursor substrate. The precursor is converted into a conductive porous carbon thanks to a photothermal pyrolysis process. By embedding these conductive LIG tracks in a thermoresponsive LCE matrix a temperature sensitive soft actuator was built in which the LIG served as a Joule heating element to resistively heat the LCE and trigger an actuation. The actuation performance of the LCE and the LCE/LIG composite were investigated regarding actuation strain and stress and a demonstrator was produced.

SB12.08.02
Development of High-Resolution Elastomeric Electrodes Using Gold Nanosheets and Its Applications Seongsik Jeong, Jiyun Lee, Hyeseon Jo, Seojun Heo and Haejin Kim; Gyeongsang National University, Korea (the Republic of)

Soft electronics necessitate the electronic devices that can communicate with various parts of the human body and acquire bio-signals with a sufficient quality, resolution, and stability. In that sense, the elastomeric electrodes with an appropriate form factor, the similar mechanical properties with a human-skin or an organic tissue, and a sufficient mechanical stretchability without compromising the electrical performances (e.g., electrical conductivity and interfacial resistance) need to be fulfilled. Also, elastomeric electrodes with high-resolution patterns need to be acquired to develop device applications with high integration density and improved performances. In addition to the successful demonstration of the gold nanosheets (AuNSs) based elastomeric electrodes with high mechanical durability and reliability, the development of high-resolution and elastomeric electrodes has been a big challenge due to lack of understandings in the fabrication parameters. In this work, the correlation between the AuNS structure and the patterning resolution were explored to carry out the elastomeric electrodes with a high-resolution pattern with several tens of micrometers. The optimized manufacturing process enabled the development of the AuNSs elastomeric electrodes with high-resolution, mechanical stretchability up to 100% and mechanical durability simultaneously. The developed AuNSs elastomeric electrodes showed the sheet resistance less than 10 Ω/sq under the 100% mechanical strain. In addition, the mechanical integrity of the AuNSs based elastomeric electrodes could be confirmed by examining the electrical performances even after 30% reciprocating 100,000 stretch-release cycles, which showed a marginal conductivity degradation after the tests. Based on the successful implementation of the elastomeric electrodes, elastomeric transistors were fabricated by using poly(3-hexylthiophene-2,5-diyl) (P3HT), poly(styrene-block-butadiene styrene) (SBS) nanocomposite semiconductors and 1-Ethyl-3-methylimidazolium bis(trifluoromethyl-sulfonyl)imide (EMIM-TFSI) based ion-gel dielectric. It is noted that the elastomeric transistor almost maintained their initial performances under 100% mechanical strain. Furthermore, the elastomeric inverter and logic circuits developed by connecting the number transistors with a proper design showed outstanding performances regardless of various mechanical strain. The overall experimental results are expected to contribute to the fast advancement of related industries such as wearable smart health monitoring devices, displays with different form-factors, and sensors by developing high-resolution elastomeric electrodes high mechanical durability.

SB12.08.03
Ion-Dipole-Mediated, Mechanosensitive Iontronic Skin with Ultrafast Self-Healing Both in Air and Underwater Zhengyang Kong[1], Joo S. Kim[1], Hanbin Choi[1], Elvis K. Boahen[1], Dong J. Kim[1], Wu B. Ying[2] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Ningbo Institute of Materials Technology and Engineering, Chinese Academy of Sciences, China

The properties of the human skin such as self-healing and mechano-sensation even in aquatic environments has inspired the design of various underwater self-healing based iontronic sensors that respond to strain, stress, and pressure. Stretchable iontronic sensors that emulate these functionalities as well as high sensitivity can be utilized in wide range of applications including water-resistant human-machine interface, and wearable sensors in high humidity environment (water, sweet, etc.). However, it is usually challenging to design iontronic sensors with stretchability, high sensitivity, and self-healable ability both in-air and underwater simultaneously. Conventionally, normal self-healing is attained via dynamic bonds, but these bonds will be saturated or coordinated with water molecules in high humidity conditions causing breakdown of the reversible process and subsequent loss of self-healing properties. Moreover, the sensitivity to water molecules can defunctionalize the electrical properties and mechanical property of the sensor limiting its sensing ability in aquatic environment. Hence, it is necessary to design and develop materials with underwater self-healing ability and outstanding waterproof properties for highly sensitive iontronic to ensure stability in humid conditions as well as prolong the lifespan of the device.
Here, we describe a highly deformable iontronic sensor from a novel designed polymer matrix with excellent waterproof property, high sensitivity and can autonomously self-heal in both dry and humid conditions. Our design strategy is the combination of fluorinated groups, glyceryl benzenediborate (GB) and hydroxyl-terminated polybutadiene (HTPB) in the design of a novel polyurethane (PU) structure together with compatible ionic species to create an iontronic sensor. First, the self-healing ability of the sensor originates from the dynamically reversible boronate bonds in the GB, which can undergo both bond exchange reaction in air and reversible hydrolysis underwater. The superb waterproof property was obtained due to the fluorinated groups within the hydrophobic soft segment of the PU that have stronger hydrophobic properties, which can ensure the stability of all performance in water. We also can maximize the underwater self-healing ability by adjusting the hydrophobicity to control the water intake. Moreover, the highly electronegative fluorine atoms interact with the cation of the ionic liquid via ion-dipole interaction establishing ion confinement effect. The ions are therefore trapped by the carbon-fluorine bonds generating ultra-low initial capacitance value. Under external stimuli such as stress or strain, the ion-dipole interactions are broken creating a high increase in capacitance change generating high sensitivity. As a result, the novel iontronic sensor can achieve excellent sensing performance and self-healing properties both in dry and wet conditions for the development of next-generation wearable sensors.

SB12.08.04
Development of High-Resolution Stretchable Electrodes and Its Applications Using Gold Nanosheets (AuNSs) Hyeseon Jo, Seongsik Jeong, Jiyun Lee, Seojun Heo and Haejin Kim; Gyeongsang National University, Korea (the Republic of)

With an increase of the interest in wearable devices and healthcare monitoring systems, research on the development of stretchable electrodes has been conducted to develop wearable applications with sufficient reliability and lifetime. To develop the stretchable devices with superior reliability, it is essential to acquire highly durable and high-performance stretchable electrodes that can sustain the mechanical strain without any electrical performance degradation. Furthermore, the stretchable electrodes necessitate high-resolution patterning capability to achieve a high degree of integration when designing the stretchable circuits or sensors. In this work, gold nanosheets (AuNSs) stretchable electrodes with high-resolution patterns were carried out by adjusting the structure of the AuNSs through the parameter analysis during the synthesizing process. Specifically, a polydimethylsiloxane (PDMS) elastomer was used as a matrix to embed the AuNSs and develop the stretchable electrodes in a nanocomposite format that can exhibit a high mechanical

durability and excellent electrical performances. Application of hot-pressing to the AuNSs facilitated a firm contact between the AuNSs and hence they remained intact when stretched. With optimized hot-pressing conditions, superior properties of the AuNSs stretchable electrodes, including lower surface roughness, high mechanical durability, excellent electrical conductivity, and high stretchability, can be achieved. Based on the manufactured stretchable electrodes, the electrical performances with respect to the mechanical strain of a high-resolution stretchable electrodes were examined by measuring the electrical conductivity of the electrodes under different levels of the mechanical strain up to 100%. The resulted AuNSs stretchable electrodes showed the sheet resistance lower than 10 Ω/sq. Regardless of the mechanical strain. Also, the stretchable electrodes maintained their electrical performances without any further degradation even after 100,000 of stretch-release cycles. In addition, the dynamic electrical performance of the elastomeric transistor was investigated by determining the drain current (−ID) in real-time corresponding to various types of mechanical stimuli, such as stretching, twisting, and poking. When continuous and sequential mechanical stimulation was received, the ON and OFF currents of the transistor measured for 60 seconds were confirmed. The overall experimental results is expected to contribute to accelerating the growth of wearable applications including displays with various form-factors, healthcare monitoring sensors, and soft robots.

SB12.08.05
High-Resolution Au Stretchable Electrodes toward Soft Integrated Circuits and Sensors Seojun Heo, Jiyun Lee, Seongsik Jeong, Hyeseon Jo and Haejin Kim; GyeongSang National University, Korea (the Republic of)

As interest in wearable devices has increased in recent decades, a considerable effort has been devoted to develop mechanically elastomeric devices including sensors, transistors, logic circuits, and integrated circuits. For an accomplishment of the true realization and commercialization of the wearable device applications necessitate the development of the elastomeric electrodes with high conductivity, environmental stability, low contact resistance, stable performance against various mechanical stimuli, and high integration, it is still difficult to achieve simultaneously. Development of gold based elastomeric electrodes by using 1D/2D gold particles have been proposed to meet the requirements as addressed above. As such, 2D gold nanosheets (AuNSs) were considered to be one of the great candidates in developing the elastomeric electrodes with high mechanical integrity, high electrical conductivity, low contact resistance. Nevertheless conventional AuNSs based elastomeric electrodes which were fabricated by using mechanical stamping or lift-off processes, limited in providing the high-resolution patterns.
In this work, we developed a stretchable device that meets all the aforementioned requirements using AuNSs on which a 2-D percolation network is formed. Specifically we investigated the effect of the AuNS structure on the resolution of the electrode pattern during the wet etching process. Through the wet etching process, the integration of AuNSs electrode patterns could be enhanced to achieve the resolution in tens of micrometers. Also, the ligand on the surface of the gold nanosheets was effectively removed by using the hot-pressing process with aim to lower the contact resistance between the AuNSs and to improve the electrode conductivity. Furthermore low resistance changes under 30% 1-million stretch-release cycle tests were conducted to ensure the durability of the elastomeric electrodes. The elastomeric transistors maintaining their performances regardless of the mechanical strain was manufactured by using an organic semiconductor nanocomposites and ion-gel. Finally, stretchable devices including inverters, logic gates and oscillators were developed to broaden the application scope in the soft electronics. Development of high-resolution AuNS stretchable electrodes is expected to aid in the rapid advancements the application scope in soft electronics.

We would like to acknowledge the financial support from the National Research Foundation of Korea (NRF) grant funded by the Korean government (NRF-2022R1C1C1011130).

SB12.08.06
Bio-Inspired Electronic Eyes for Artificial Vision System Min Su Kim and Dae-Hyeong Kim; Seoul National University, Korea (the Republic of)

Recent technological developments in mobile electronics and machine vision have required advanced imaging recognition systems. However, conventional imaging devices using a flat sensor array have several limitations such as complex lens optics, optical aberration and large module size. To solve this problem, bio-inspired image sensors mimicking the structural and functional advantages of the of nature eye have been extensively studied. A curved image sensor that mimics hemispherical structure of the animal retina can effectively overcome the limitations of conventional imaging systems. It has a simple configuration and miniaturized module size while maintaining high optical performance such as wide field of view (FoV) and low optical aberration.

In addition, curved image sensors applying unique properties of organisms that evolved to survive in specific environments have also been reported. For example, artificial imaging systems that mimic the compound eyes found in insects have infinite depth of field (DoF) and a wide FoV. Imaging systems that mimic telescopic vision of avian eye and the visual system of xenos peckii for recognizing image depth have been demonstrated. By using various optical filters, artificial vision inspired by mantis shrimp can enhance the color sensitivity.

Recently, our group mimics the unique vision of feline eye. Feline-eye-inspired vision system mimics the variable pupil and biological reflector. Blurring the background to distinguish the prey from the complex environment is essential for targeting the prey. In the dim environment, the feline pupil fully dilates to make narrow DoFs in the both vertical and horizontal direction. In the bright environment, the feline pupil contracts to become a vertically elongated shape, resulting in a narrow vertical DoF and a deep horizontal DoF. In both cases, the focus is made on the overlapped region of the DoFs, and the background environment is blurred. Therefore, felines can target the prey at both night and day. Tapetum lucidum is a multi-layered tissue located between the retina and choroid. It consists of periodically repetitive cells including arrays of parallel crystal rods. Each array of rods (n = 1.83) and each intervening layer (n = 1.33) are approximated as alternating layers with a high and low refractive index. The transmitted light is reflected back to the photoreceptor via tapetum lucidum, which enhances the sensitive scotopic vision.

The device, inspired by the unique vision of the feline, consists of a hemispherical silicon photodiode array integrated with an artificial tapetum lucidum and a variable aperture. The artificial tapetum lucidum made of a patterned inverse opal structure is located behind the ultrathin silicon photodiode. It enhances the photo-absorption by reflecting the light back to the photodiode, which increases the sensitivity under a low light condition. The variable aperture mimics the feline's pupillary movement, whose shape changes between the vertically-elongated slit-like shape and the fully-dilated circular shape. This variable aperture enables the targeted imaging with asymmetric depth-of-fields as well as the facile control of the incident light amount.

SB12.08.09
Reconfigurable and Reusable Soft Modular Blocks Assembly for Soft Robotic Skin Yoon Jaeyoung, Hayun Kim and Yongtaek Hong; Seoul National

University, Korea (the Republic of)

Soft electronics have been widely researched due to their applicability to arbitrarily curved surfaces where conventional electronic devices cannot be applied. Furthermore, the mechanical mismatch at the devices-soft body interfaces can be minimized due to their softness. Among the methods for imparting softness to electronics and devices, the most adopted technology is stretchable hybrid electronics (SHE); SHE is a methodology of manufacturing soft electronics or devices by electrically connecting rigid or soft circuits or sensors (islands) via stretchable interconnects (bridges). The soft devices based on this island-bridge structure can be attached to curvilinear surfaces. It is also applied to human skins or soft robotics and can perform its original function without significant degradation, even under deformations. Recently, body attachable soft devices attached to human skin to collect and transmit data such as vital signals and body movements have been manufactured. In addition, research to apply soft electronics to soft robotics is increasingly being studied. For soft robotics applications, soft circuits or electronics are required to retain their functionality even under dynamic deformation (e.g., bending, twisting, or inflating) of soft robotics. Furthermore, because soft robotics can be used in various environments, their body size and actuation motion can be programmed in multiple ways. Accordingly, a new manufacturing method is required to complete soft circuits for the robotic skin.
In this work, we demonstrate reconfigurable and reusable soft modular blocks assembly based on SHE for soft robotic skin. Our soft modular block assembly technology enables immediate electrical circuit creation when soft modular blocks are assembled; This can be achieved by a sticky and highly conductive contact pad. These contact pads are fabricated on the electrodes of the FPCB, and soft modular blocks with these contact pads are assembled onto curvilinear and deformable soft bodies. Finally, the assembled blocks are physically and electrically connected through stretchable interconnect blocks. Silver nanowires (AgNWs)-embedded PDMS are chosen for the interconnect block because AgNWs network has the advantage that conduction path is maintained even under stretching deformation of PDMS. The vertically-aligned Ni particles are introduced into the PEIE (Polyethyleneimine ethoxylate) and PDMS (polydimethylsiloxane) matrix for the high conductivity of the pad. An electrical conduction path is formed between Ni particles exposed on the surface of the contact pad and the AgNWs on the surface of the interconnect blocks. Furthermore, we demonstrated the assembly of soft modular LED blocks on a soft body. The LEDs on the blocks are immediately turned on when the LED blocks and interconnect blocks are assembled. In addition, the soft modular LED blocks can be disassembled to complete the other device with a new configuration. This immediate soft device creation and soft blocks reconfiguration of our technology can be utilized as soft robotic skin. We demonstrated the applicability of our technology as soft robotic skins through integration with soft modular blocks assembly and soft robots.
This research was supported by the Display Center of Samsung Display and Seoul National University.

SB12.08.10
Development of Elastic Synaptic Devices based on Mechanically Durable and Stretchable Electrodes Jiyun Lee, Seojun Heo, Seongsik Jeong, Hyeseon Jo and Haejin Kim; Gyeongsang National University, Korea (the Republic of)

The human brain is a complex neural network with more than 100 billion neurons and 100 trillion synapses, which act as bridges to connect the neurons for signal communications. Moreover, it is a biocomputing system that covers advanced computation and cognitive processes while using only 20W of power. The development of neuromorphic devices to mimic the functions of such an efficient information processing and storage capability is emerging as a key technology in digital environments, which necessitate complicated information processing and high-density information storage functions. In particular, there has been a surge in related research on neuromorphic systems that mimic the electronic synapses with the operation of transmitting and computing the information signals. The electrical properties (e.g., electrical post-synaptic current (EPSC), paired-pulse facilitation (PPF)) of the developed synapse are characterized when the synapses connecting neurons exchange spike signals to process the information. The early stage of the research on developing synaptic devices was mainly based on a CMOS-based integrated circuit that requires numerous transistors to realize synapse characteristics, resulting in a limitation in the system complexity and reduced integration. Memristors were first proposed to overcome the limits however, high-power consumption per unit device was considered to be one of the disadvantages compared to the bio-synapse. Recently, the three-terminal synaptic transistors mimicking the human brain function were considered to be one of the outstanding candidates that fulfill various requirements to mimic the bio-synaptic systems. Also, synaptic devices with mechanical stretchability were developed to meet the increasing demand and interest in wearable device applications.
In this work, elastomeric synaptic transistors were developed to perform various synaptic behaviors, including EPSC, PPF, long-term memory (LTM), and STM under various mechanical stimuli. Specifically, the elastomeric electrodes were manufactured by using the gold nanosheets (AuNSs) embedded within the elastomer polydimethylsiloxane (PDMS). Also, an organic semiconductor Poly(3-hexylthiophene-2,5-diyl) (P3HT) nanocomposites and ion-gel were utilized as elastomeric semiconductor and dielectric, respectively. Transfer characteristics of the devices were derived by applying a pulse-type voltage to the gate electrodes. Other synaptic characteristics, including EPSC, and PPF values were carried out under various levels of the mechanical strain, which resulted in stable performances regardless of the various level of the mechanical strain. Also, LTM was achieved by repeatedly learning for a short time while continually administering a pulse-type spike at 0.15s intervals. In addition, it was confirmed that the synapse characteristics were well maintained under the mechanical stimuli up to 100%. Overall, the developed elastomeric synaptic devices with advanced signal transmission and cognition functions while consuming less energy are expected to contribute to the advancement of soft robot engineering and the development of next-generation intelligent wearable devices.

SB12.08.12
3D Printing of Liquid Metal Embedded Elastomers for Soft Thermal and Electrical Materials Phillip Won[1], Conor S. Valentine[1], Mason Zadan[1], Chengfeng Pan[2], Michael Vinciguerra[1], Dinesh K. Patel[1], Seung Hwan Ko[3], Lynn S. Walker[1] and Carmel Majidi[1]; [1]Carnegie Mellon University, United States; [2]The Hong Kong University of Science and Technology, Hong Kong; [3]Seoul National University, Korea (the Republic of)

Liquid metal embedded elastomers (LMEEs) are composed of a soft polymer matrix embedded with droplets of metal alloys that are liquid at room temperature. These soft matter composites exhibit exceptional combinations of elastic, electrical, and thermal properties that make them uniquely suited for applications in flexible electronics, soft robotics, and thermal management. However, the fabrication of LMEE structures have primarily relied on rudimentary techniques that limit patterning to simple planar geometries. Here, we introduce an approach for direct ink write (DIW) printing of a printable LMEE ink to create three-dimensional shapes with various designs. We use eutectic gallium-indium (EGaIn) as the liquid metal, which reacts with oxygen to form an electrically insulating oxide skin that acts as a surfactant and stabilizes the droplets for 3D printing. To rupture the oxide skin and achieve electrical conductivity, we encase the LMEE in a viscoelastic polymer and apply acoustic shock. For printed composites with a 80% LM vol. fraction, this activation method allows for a volumetric electrical conductivity of 5×10^4 S cm^{-1} (80 % LM vol.) – significantly higher than what had been previously reported with mechanically sintered EGaIn-silicone composites. Moreover, we demonstrate the ability to print 3D LMEE interfaces that provide enhanced charge transfer for a triboelectric nanogenerator (TENG) and improved thermal conductivity within a thermoelectric device (TED). The 3D printed LMEE can be integrated with a highly soft TED that is wearable and capable of providing cooling/heating to the skin through electrical stimulation.

SB12.08.13
A Generalizable, Multimodal Wireless Chemical Sensing Scheme for Bio-Integrated Electronics Tzu-Li Liu and Jinghua Li; Ohio State University, United States

Monitor biomolecule in bodily fluid plays an important role of reflecting health status and medical treatment. However conventional approaches rely on in-lab equipment or complex wireless electronics, which typically need battery source or complex circuits, and limit the use of real-time monitoring and bio-integrated applications. We aimed to bridge the gap between biochemical sensing and wireless electronics.

We have developed a class of inductor-capacitor (LC) chemical sensors inspired by radio frequency (RF) tuning circuits. The wireless flexible circuit can seamlessly integrate with bio tissue/ personal accessories due to its flexible, concise, and battery-free circuit. Compared to the conventional LC circuit, in which the biochemical sensing interface needs to be within the transmitter, our design can modulate into two function parts: an antenna coupler, that separately encapsulates, and an extended biochemical sensing interface, that can be direct contact with the targeted region.

We have demonstrated its universal sensing capability by using common bio-sensitive elements (e.g., ion-selective membranes, aptamers, and enzymes) on the sensing interface. We also demonstrate its multifunctionality as a sensor metric, which allows the detection of multiple biomarkers simultaneously. The demonstration as “smart accessories” and “miniaturized probe” based on this methodology suggests its broad capability in advanced wireless scenarios.

SB12.08.14
Wearable Soft Robotics Gripper for Increased Access to Soft Robotics Education Abigail R. Lockhart-Calpito[1], Jonathan Chinana[2,1], Harrison Young[1], Lucas Gerez[1], Holly M. Golecki[3,1] and Conor J. Walsh[1]; [1]Harvard University, United States; [2]Navajo Technical University, United States; [3]University of Illinois at Urbana-Champaign, United States

In recent years, the field of soft robotics has gained a significant amount of attention due to its various applications and increase in research, such as wearable robots, assembly line machines, surgical robots and search and rescue devices. A Soft Robotics Toolkit (SRT) project was developed as an open access resource to support the effort to educate and expose users from K-12 to the field of soft robotics. The SRT aims to overcome the challenge of disseminating robotic-hardware resources and to spread soft robotics educational content, which is less prevalent than that of traditional robotics. The Soft Robotic Gripper (SRG) kit was developed to encourage users to explore design, fabrication, and application of soft robotic technologies. Our motivation is to develop a soft robotics kit which can help fill this gap in academics. The initial SRG kit allowed users to assemble a hand held gripper with two silicone fingers, controlled by a center hub of electronics to grip and release objects. The silicone fingers are cast with a user-assembled mold constructed from cardboard and glue provided in the kit. Channels through the mold are made with toothpicks in order to provide clearance for the tendon actuator. The gripper could be configured to be operated manually and automatically, with an ultrasonic sensor and motor. The previous SRG was evaluated and well received by K-12 students in the USA and India.
We converted the previous kit into a wearable device which could be attached to the user’s forearm and hand to better highlight the potential applications of soft robotics in assistive wearable devices. The electronics and hardware are fixed to a size-customizable sleeve which is attached to the user's forearm. The SRG extends from the wrist and is tendon driven. These modifications bolster the educational potential of the device by creating more avenues for exploration and encouragement in creative thinking in the field of assistive devices. We simplified the previous electronic design, allowing all electronics to be added to a breadboard. This will allow user interaction and engage with assembling a circuit.
Our secondary goal was to reduce the production cost of the device, increasing the accessibility of the kit. Manufacturing advantages include a reduced reliance on custom injection molded components and PCBs, which both increased production cost and limited creative freedom of users. A control has also been implemented in the wearable SRG in which the plantar flexion of one of the users fingers can be used to open and close the fingers. We replaced the custom electronics and hardware components with simpler, off the shelf alternatives. This allows users to gain an understanding of common electronics, allowing for translation of their learned skills to other future projects and existing K-12 curricula. These changes allowed for the only custom piece in the kit to be a wearable garment.
The effectiveness of the kit was decided by user testing and cost analysis. The revised SRG toolkit contains soft robotic components that are simple to assemble into the wearable SRG, in addition to a straightforward and educational guide on how to build your own wearable robot. The contents of the kit is sufficient for the baseline robot, but alterations can be made depending on the user’s desires. The previous electronics were successfully simplified on the current design of the wearable, tendon-actuated SRG. The improved SRG kits were beta tested with middle and high school students at an outreach event hosted by researchers. With this data, the researchers uncovered the successes and challenges resulting from the building process in order to inform design iterations. This project has increased access to soft robotics education. Furthermore, the transition from a hand held device to a wearable device will motivate students to learn about prosthetic and assistive devices inspiring future innovators in soft wearable robotics.

Development and Evaluation of an Accessible Soft Aquatic Robot Jaylynn Kim[1,2], Baran Mensah[3,2], Harrison Young[2], Lucas Gerez[2], Holly M. Golecki[1,2] and Conor J. Walsh[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Harvard University, United States; [3]Massachusetts Institute of Technology, United States

The field of soft robotics has garnered attention as a medium for education due to its hands-on fabrication methods, accessible materials, and applications in a wide range of STEM fields. With the potential for a more diverse set of disciplines and applications, a soft aquatic robot was developed for educational purposes as a project inspired by marine biologists’ use of underwater robots that mimic fish to explore underwater habitats. The soft aquatic robot is simple, easy to build, and functional, making it an ideal candidate for use as a manufacturable educational tool for K-12 students. The aquatic robot is composed of a hybrid rigid body and a soft tail that uses the Fin Ray® Effect, a model of fish fin deformation during swimming, and is oscillated by two electromagnets located in the watertight body. The robot uses an open-loop control system to simplify the system's electronics. The use of an off the shelf microcontroller and motor driver to alternate the polarity of the electromagnets allows students to learn widely used tools to control robotic platforms, including Arduino microcontrollers. The electronics are also designed to be simplistic and compact, allowing ease of setup and minimization of the robot's size. The soft tail was designed to be compatible with a single open-faced mold, facilitating the replication and manufacturing of the soft structure. The ease of replication allows for students to gain hands-on experience with the fabrication of soft robotics materials in a classroom setting. Functionality of the soft robotic swimmer was measured by measuring the thrust generated by the tail and the robot’s top speed in body lengths per second. The replicability was measured as a percentage of successful replications of the tail through user testing from the targeted demographic, K-12 school students, in an outreach program. The soft aquatic robot was tested with a group of students to validate an increase in familiarity and interest in engineering fields. The development of this low cost and accessible kit will allow young students to be exposed to new materials, robotics, and the field of engineering, which are less accessible due to high cost and equipment.

SB12.08.17
3D-Printed Triboelectric Nanogenerator Sensors for Soft Haptic Interfaces Hyeonseo Song, Jin Pyo Lee, Yeonwoo Jang and Jiyun Kim; UNIST, Korea (the Republic of)

Haptic interfaces allow us to interact with the virtual environment by sensing our realistic tactile information and delivering them to the computer system. However, rigid and cumbersome form factors of haptic interfaces limit the comfortable interfaces and various applications. Here we report triboelectric-based 3D-printed soft haptic interfaces with free-form factor. An elastic material 3D printing enables us to fabricate soft haptic interfaces with 3D sensors

as we desire. After printing some components of the 3D flexible sensors, we use the active materials to achieve surface modification of printed components and assemble those functionalized components into a single structure. When we apply the external force to the sensor structure with multiple components, those components are contacted or separated from each other. Due to their different surface electron affinities the triboelectric effect occurs, which derives the electron transfer and generates the electrical signal. This electrical signal is transmitted as realistic tactile information to the computer system for interacting with the virtual environmental system. We expect these soft haptic interfaces will contribute to expand the haptic technologies for various applications.

Biostable Neuromorphic Devices Enabled by Plasma Polymerized PTFE for Long-term Wearable Bioelectronics Dong Hyun Choi, Kyungho Park, Kyungmoon Kwak, Hyung Tae Kim, Jusung Chung and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

As the coronavirus disease 2019 pandemic has been prolonged, the limitation of the face-to-face medical system that mankind has built previously have been highlighted. This is because the bed occupancy rate increases as the number of newly confirmed cases and severe cases occurring around the elderly increases, which causes a shortage of beds and medical personnel. Accordingly, telehealth medical systems such as home treatment and telemedicine have attracted attention. Therefore, a new paradigm that can stably respond to changes in living biosignals anytime and anywhere is required to realize a telehealth medical system.

Long-term wearable bioelectronics has the potential to break the existing face-to-face medical system. By attaching a medical device onto the body, living biosignals can be continuously collected and processed anytime, anywhere. Furthermore, it can be spontaneously transmitted to the medical staff through medical applications. However, for long-term wearable bioelectronics, conventional electronic materials could not be applied due to their brittle nature and poor biostability. In addition, long-term wearable bioelectronics requires superior reliability and uniformity under the device level so that temporal and inter-device electrical characteristics are consistent.

In this research, we propose a plasma polymerized polytetrafluoroethylene (PTFE) as the active layer for flexible and biostable neuromorphic devices satisfying the strict requirements of long-term wearable bioelectronics. The neuromorphic computing system is inspired by the human brain, such that it can emulate biological synapses to concurrently perform cognition, learning, and memory. Therefore, it has advantages realizing a telehealth medical system that stably responds to changes in living biosignals anytime and anywhere. Also, PTFE is flexible and biostable material to be mainly used as a non-stick or chemical stable coating for cookware and scientific tools. Since its outstanding thermal stability, it has the advantage that plasma polymerization is enabled through the sputtering process, unlike other polymers or organic materials. With deposition by the sputtering process, PTFE could have superior film quality and large area uniformity than the conventional solution process, and secure superior reliability at the device level and inter-device uniformity.

To emulate this biological synapse, we fabricated an artificial synapse with a metal-insulator-metal structured neuromorphic device. To fabricate the PTFE-based neuromorphic device, the PTFE for the active layer was deposited by radio frequency magnetron sputtering on an indium-tin oxide coated polyethylene terephthalate substrate. After the deposition, the sample was annealed at 100°C for 1 h in ambient air. Then, Al top electrode was deposited by an electron beam evaporator via a shadow mask. To measure the current-voltage characteristics of the PTFE-based neuromorphic device, the positive and negative voltage sweeps applied to the top electrode. The set and reset voltages were 2.7 V and -2.1 V, respectively. And the device showed a stable resistive switching window over 10^3 at a 0.1 V of reading voltage for 100 consecutive cycles. For the excitatory post-synaptic current (EPSC) variation depending on the pike pulse width, the EPSC increased drastically and immediately returned to its initial value, but it took more time to return to its initial value as the spike pulse width increased. The potentiation-depression characteristics according to 10 repetitions of consecutive 10 positive pulses, followed by 10 negative pulses were measured. The EPSC of the PTFE-based neuromorphic device can be precisely controlled by multiple cyclical positive and negative spike pulses. Based on these results, PTFE-based neuromorphic devices may considerably contribute to the development of neuromorphic computing platforms and long-term wearable bioelectronics.

Development of an Accessible and Affordable Rehabilitation Glove David R. Medina[1,2] and Ayoub Ellouzi[3]; [1]University of Illinois Urbana Champaign, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]BunkerHill Community College, United States

Each year, approximately 12,500 individuals survive spinal cord injuries (SCI). As of 2016, the population with SCI was estimated to be 276,000. As a result, many are left with a drastic reduction of upper extremity function, specifically in the hands. This can impact the quality of life and independence of a person. While the recovery of the hand is function highly desired, limited treatments are available to aid in recovery, let alone affordable treatments. Along with SCIs, strokes can also lead to a reduction in extremity function. The limb that is most prone to paralysis is the hand, as a stroke causes loss of sensation and inability to move the hand. One of the most effective methods of restoring hand activity is physical therapy (PT). Physical therapists rely on repetitive hand exercises to slowly regain the function of the limbs of the patients. Oftentimes, this process can take years of constant physical therapy with the aid of a therapist. A rehabilitation device that can help the patient perform these exercises from home would help patients to perform regular exercises at home and in some cases save the patient from traveling and also reduce the cost of recovery. Several emerging technologies address hand rehabilitation. A glove termed the Soft Rehabilitation Device is a pneumatic glove that assists patients with grip control and makes grasping motions easier. Attached with a waist pack that controls the pneumatics and can program with exercises the patient can control. The “Music Glove” by Flint Rehab works by motivating users to perform hundreds of therapeutic hand and finger exercises while playing an engaging musical game, NEOFECT’s RAPAEL Smart Glove is a biofeedback system to help patients with neurological and musculoskeletal injuries regain their hand mobility. Based on this research, all the currently available rehabilitation gloves sit at a price range above the thousands when factoring in the subscription-based training software some brands lude. A more affordable and open-source solution is needed. In this project, we used accessible soft-robotics building techniques available on the Soft Robotics Toolkit and a 3D printer to build the mold or finger shape using silicon material. After determining the shape of the glove and choosing the appropriate type of fabric using design heuristics, the elements of the glove were identified. The final prototype includes flex sensors and accelerometers, off-the-shelf microcontrollers, and a fluidic control board. Using this prototype, two types of movement were successfully achieved which are flexion and extension motions. We aim to provide instructions for an open-source design of a rehabilitation glove to create an affordable and easy-to-implement device on the Soft-Robotics Toolkit. Creating an open-source device will lead to further developments and innovation with patients as end users and designers.

A 3D Printed Liquid Metal Emulsion for Low-Stress-Activated Stretchable Electronics Ramon E. Sanchez, Stephanie F. Zopf and John W. Boley; Boston University, United States

Integrating liquid metal (LM) into 3D stretchable devices remains a manufacturing challenge due to its intrinsically low viscosity and high surface tension. Current manufacturing methods require the use of complicated lithography and molding techniques which increase fabrication complexity and limit widespread adoption. Modifying the LM rheology by creating LM emulsions dispersed in a carrier liquid can create a stable 3D printed emulsion, which can be integrated with other printed materials in a single fabrication process, reducing manufacturing complexity. This work presents a 3D printable strain-induced electrically conductive liquid metal emulsion for the programmable assembly of soft conductive composites. This liquid metal emulsion exhibits shear yielding and shear thinning rheology that is compatible with direct ink writing (DIW). Examples of complex self-supported 3D printed structures with spanning features are presented to demonstrate the 3D printability of this emulsion. Stretchable liquid metal composites are fabricated by integrating this emulsion into a multi-material printing process along with a 3D printable elastomer, combined with manual pick and place of off-the-shelf electronics. The as-printed composites exhibit a low electrical conductivity but can be transformed into highly conductive composites by a single axial strain at stresses that are an order of magnitude smaller than previous stress-activated emulsions. The effects of axial strain and cyclic loading on the electrical conductivities and sensitivities of these composites are characterized. The electrical conductivity increases with activation strain, with a maximum observed conductivity of 2.32×10^5 Sm^{-1} at strains greater than or equal to 200%. The electrical conductivity of these composites reaches a steady state for each strain after one cycle and remains stable with low variation (< 7%) over 1,000 cycles. The strain sensitivities of these composites are constant and significantly lower than that of a bulk conductor, making them suitable as stretchable conductors. The utility of these composites is shown by employing them as wiring into a single fabrication process for a stretchable array of LEDs.

Facile Synthesis and 3D Printing of Soft Materials and Their Applications in Sensors Kumkum Ahmed; Shibaura Institute of Technology, Japan

Ion conductive polymers and elastomers have drawn worldwide attention for their multifuntional applicability in batteries, electroactive soft robotics, and sensors. In this work, facile synthesis of network polymers via thiol-ene reaction has been focused on to create 3D printable flexible and soft sensing materials. A variety of materials such as ionic gels, ionic porous polymers, elastomers, and composites have been synthesized and characterized. To develop ionic liquid-based gels and porous polymers, ionic liquid has been incorporated into the thiol–ene network of thiol-based multifunctional monomers and acrylate crosslinkers. By carefully selecting the polymerizing conditions and solvents, developing gel and/or porous polymers are designed. In addition to ionic liquid-based gels and porous polymers, PDMS-based polymers, gels, and elastomers are also synthesized using multi-functional vinyl sulfones and dual functional thiol containing PDMS crosslinkers initiated via thiol-ene reaction mechanism. The developed gels and elastomeric materials showed 3D printability with good resolution with tunable conductivity (ionic gels and porous polymers), mechanical flexibility, and high thermal stability and showed piezo-capacitive sensing characteristics. These 3D-printable, designable materials can find prospective scope in the fields of MEMS, microfluidics, and sensors.

Responsive Soft Polymers Fabricated via Light-Induced 3D Printing Ignazio Roppolo; Politecnico di Torino, Italy

In the last decade light-induced 3D printing experienced an explosion of interest, especially from the materials point of view. In fact, while in the past most of the attention was devoted just to obtain fast and precise printing, in the latest years the focus of academic and industrial research is moving toward the synthesis of materials with improved mechanical properties or with new functionalities.
This 3D printing technology is of particular interest for soft polymers. In fact, those materials have complex tooling and often are fabricated via casting, which requires multiple steps and involves many limitations. On the other hand, light-induced 3D printing can offer the possibility to build object with almost arbitrary shape with also high precision without tooling.
However, be limited to “material properties” + “design of the structure” archetype doesn’t allow to understand the full potentialities of 3D printing. In this talk, it will be showed how responsive soft polymers can be developed by an engineered study of the photocurable formulations, of the local properties of the materials and of the devices’ design.
Increasing step by step the level of complexity, different functional soft polymers will be showed: (i) PDMS-like 3D printable monomers, which can be used to replace standard silicone for complex structures(1); (ii) self-healing 3D printable hydrogels, which can be shaped almost arbitrarily and have the properties of self-recovery from damages(2) and (iii) 4D printable structures with programmed microstructure in which controlled movements or shapeshifting are induced by an external magnetic field(3-5).

Stretchable 3D Printed Thermoelectric Generators for Liquid Crystal Elastomer Actuation, Control and Energy Recovery Mason Zadan, Dinesh K. Patel and Carmel Majidi; Carnegie Mellon University, United States

Liquid crystal elastomers (LCE) are a class of shape memory polymers that exhibit muscle like work energy densities and contraction strains. By transitioning between a liquid and crystalline phase the mesogens, induced by thermal stimuli, reorient themselves inducing macroscopic contractions and expansions upwards of 40%. By precisely controlling heating and cooling, LCE responses can be tailored for actuation and locomotion in soft systems. Recently, this material architecture has been explored for soft robotic actuators and systems. The main limitations of LCE actuators are their slow response times, stemming from high transition temperatures and passive convective cooling. LCEs also suffer from poor energy efficiencies with energy partially lost through convective heat transfer. As a potential solution, in this talk, I focus on recent work in bendable and stretchable thermoelectric devices (TED) that convert temperature differentials across oppositely doped semiconductors into a potential difference through the Seebeck effect along with acting as

active heaters and coolers through the Peltier effect. Through the Seebeck effect, TEDs are introduced to address energy efficiency issues by introducing passive environmental energy harvesting along with internal regenerative energy recovery in soft robotic systems. Through the Peltier effect, TEDs are introduced to actively heat and cool LCE layers for actuation. This is enabled by developing 3D printed high density TEDs with semiconductors wired together with Eutectic Gallium Indium (EGaIn) liquid metal (LM) interconnects to actively heat and cool and recover energy from LCEs while staying mechanically compliant. These LCE-TED transducers, allow for single input multidirectional actuation enabling integration into a PI-controller with <0.5 degree error. As energy harvesters these LCE-TEDs are integrated into a robotic walker recycling environmental waste heat along with recovering small amounts of energy through regenerative energy harvesting. Energy harvesting and actuation characterization is given highlighting device power densities, deflection, blocking force, and robust mechanical characterization.

9:15 AM SB12.09.05
All-Printed Stretchable Integrated Electrochemical Sensing System with Digitized Electrochromic Display Lu Yin, Mengzhu Cao, Kyeong Nam Kim, Sheng Xu and Joseph Wang; University of California, San Diego, United States

The rapidly developing flexible wearable sensing systems commonly rely on wireless communication or colorimetric assays for data interfacing, which cannot operate independently and requires external electronics to obtain exact numerical data. In this work, we present a wearable sensing epidermal patch with dedicated batteries as the energy supply and an electrochromic display for data visualization, all integrated into a highly compact, stretchable form factor. The patch can operate with multiple types of sensing mechanisms for electrolyte and metabolite monitoring, rapidly displaying the sensing result within a second. Fabricated via layer-by-layer screen-printing of customized elastomeric composite inks, the device demonstrates high flexibility and stretchability enduring thousands of stretching deformation cycles without affecting its performance. Merging low-power consumption, autonomous operation, and superior mechanical performance, the device is of high practicality and convenience for various applications in professional sports, personalized wellness management, and beyond.

Directly-Printed Soft Three-Dimensional Electrodes for High-Density Electromyography Recording for Long Term Monitoring of Ischemia and Volumetric Muscle Loss in Murine Models Moohyun Kim, Sumin Kim and Jang-ung Park; Yonsei University, Korea (the Republic of)

In modern electromyography (EMG) recording, conventional surface electrodes are commonly used. These electrodes tend to be rigid and do not conformally attach with skin surfaces. Modern research focuses developing electrodes on flexible substrate that have good surface adhesion with biological interfaces. These devices are still limited as the sensing electrodes as they do not conformally contact with the body. Also, the flexible substrates tend to be bulky in size which limits seamless in-situ electrode deployment. The recording signal obtained by surface electrodes are weaker than needle-based electrode that penetrates the epidermis layer of the skin, removing signal resistance. That said, these needle-based electrodes are highly intrusive and cause inflammations when used for a prolong duration. For long-term EMG monitoring of patients with muscular disability, clinical approach favors using surface electrodes which are skin-compatible but lacks signal quality. Herein, we present a substrate-less device that is made of biocompatible soft electrodes for high-density EMG recording. These electrodes are directly printed to form three-dimensional (3D) structure on water-soluble thin film. These electrodes are injected into the skin to remove signal interfaces from epidermis layer, producing high-quality EMG signals that modern surface electrodes fail to capture. Furthermore, the simple and easily manipulatable printing technique allows printing of array of 3D soft electrodes for high-density EMG recording to monitor complex musculoskeletal movement. Furthermore, the soft electrodes have self-repairing property that provides mechanical durability for more advanced and intense movements. Due to its non-invasive property, we are able to detect and monitor the rehabilitative effect of muscle extracellular drugs in murine models of ischemia and volumetric muscle loss. The long-term recording of EMG signal shows the extensiveness of muscle-rehabilitative drugs to treat muscle trauma, providing new possibility for drug screening. The seamless method of device implementation and the significant quality of EMG signals provides interesting prospect for advanced clinical study or human-robot interfaces.

Multimaterial Printing of Artificial SA-II Mechanoreceptors Using Engineered Composites with Negative Piezoresistance Mina Lee, Michael Sotzing and Alex Chortos; Purdue University, United States

The peripheral nervous system collects and efficiently transmits large amounts of sensory information using parallel signaling. Afferent nerves encode tactile stimuli recognized by cutaneous mechanoreceptors into action potentials and transmit them from the periphery to the central nervous system. Creating an artificial peripheral nervous system could enable important applications in medical devices and robotics. Therefore, interest in neuromorphic systems has been increasing. Recently, there has been a proliferation of research into mimicking slowly adapting type 1 (SA-I) afferent nerve that measures pressure on the skin. Biological skin includes a multitude of receptors for different stimuli. Therefore, to mimic the capabilities of the biological somatosensory system, it is necessary to develop artificial afferent nerves that are sensitive to a range of stimuli such as stretching and vibration.
We developed a flexible artificial afferent nerve that emulates a slowly adapting type 2 (SA-II) mechanoreceptor that detects skin stretching. The artificial afferent nerve consists of a piezoresistive composite mimicking Ruffini endings and a ring oscillator that converts the strain information into a frequency-domain signal that mimics action potentials. The coupling between the sensor and oscillator requires two unique sensor properties: (1) the sensor resistance must decrease while being stretched to achieve increasing frequency output, and (2) the resistance must change by several orders of magnitude to match bio-inspired frequency ranges. To meet these requirements, we implemented a composite material exhibiting negative piezoresistance over several orders of magnitude. The piezoresistor consists of nickel particles as the conductor and a continuous phase consisting of elastomers and oil. Varying the ratios of these components allows for tuning the material's properties, including the elastic modulus, dynamic range, and range of resistance change. As the oil content increased, the range and rate of resistance variation increased. This wide range of tunability suggests that our artificial neurons could potentially be adapted to different applications. Our artificial SA2 receptors are fabricated using a single multi-material print that includes pick-and-placing of an integrated circuit chip, printing a stretchable conductor as interconnects, and printing the negative piezoresistive material as a sensing component. Our printed artificial afferent nerves will aid in advances in neural prosthetics, soft robotics, and wearable electronics.

10:30 AM *SB12.09.08
Printed Electronic Skin allowing Robots to Feel, Learn and Mimick the Mechanical and Thermal Pain Reflexes Joao Neto, Radu Chirila, Abhishek Singh Dahiya, Fengyuan Liu and Ravinder Dahiya; University of Glasgow, United Kingdom

Biological skin comprises thousands of distributed receptors (mechanoreceptors, nociceptors etc.) which allow us to detect a wide range of mechanical and thermal stimuli and react accordingly. This work presents a printed electronic-skin (e-Skin) with pressure and temperature sensors connected with a peripheral nervous system-like localised learning scheme, allowing robots to mimick the mechanical and thermal pain related reflexes. The “bio-like” learning with pressure sensors is achieved using printed array (12x14) of synaptic transistor-based neural system on flexible substrate. Likewise, the thermal pain reflexes were obtained with a nanowire based soft thermoreceptive e-Skin having miniaturized (~700μm^2) artificial thermoreceptors. Both

mechanical and thermal e-Skin prototypes were integrated on the fingertip of a robotic hand and biological system like reflexes are demonstrated in response to pernicious mechanical and temperature stimuli via localized learning at the hardware level. The localised learning could substantially reduce the data latency and decrease the cognitive load on the robotic platform.

11:00 AM SB12.09.09
Crawl, Climb, Perch and Fly—*Origami*, *Kirigami* and 3D Printing of Soft Robots for Versatile Locomotions Terry T. Ching[1,2], Joseph Zhi Wei Lee[1], Shane Kyi Hla Win[1], Luke Soe Thura Win[1], Danial Sufiyan[1], Charlotte Pei Xuan Lim[1], Nidhi Nagaraju[1], Yi-Chin Toh[3], Shaohui Foong[1] and Michinao Hashimoto[1]; [1]Singapore University of Technology and Design, Singapore; [2]National University of Singapore, Singapore; [3]Queensland University of Technology, Australia

Background. Untethering soft robotics from electrical or pneumatic power is one of the major challenges facing the field. Maintaining a sufficiently high power-to-weight ratio is the key problem of untethered operations. Untethered operations necessitate that the robot has sufficient mechanical power to carry its structural weight as well as additional payloads such as power sources (i.e. batteries), actuators (i.e. pneumatic pumps, valves), and microcontrollers. Existing demonstrations of untethered soft robots typically involve weighty slabs of pneumatic network actuators (PneuNets) made from silicone rubber, which further decreases the power-to-weight ratio. In addition, the fabrication of these PneuNets actuators heavily relies on replica molding, which renders them unsuitable for rapid prototyping.
Contribution. Combining 3D printing and kirigami-based thin-film polymers allowed the development of a novel method for the fabrication of pneumatically-driven actuators. Our technique effectively decreased the overall weight of the actuating units (20 g), which can be combined with lightweight pneumatic pumps and a control board. The developed actuating units are modular, allowing for rapid prototyping of soft actuators that are customizable and capable of complex locomotions (i.e., crawl, climb, perch and fly).
Techincal achievement. To realize the lightweight soft robots, the weight of the structure was reduced using PVC sheets (0.18-mm thick) with predesigned incisions by a cutting plotter. A single sheet of material is prone to twisting and bending. However, a rolled sheet with a curved surface gains anisotropic structural rigidity without adding extra weight. Selectively rolling sections of the PVC sheet aided in the reinforcement of the overall rigidity of the structure. The reduction of the overall weight of the actuators was further achieved by making lightweight pneumatic balloons. Direct ink writing (DIW) of silicone adhesive on silicone sheets (0.8-mm thick) allowed fabricating silicone balloons that served as standardized actuation modules for all the demonstrated locomotions. Next, to convert the expansion of the silicone balloons to bending motion, we took advantage of the mechanical properties of the curved surfaces; analogous to the cross-sectional curvature found in the blade of a tape measure (*i.e.,* spring return pocket tape measures). The slight cross-sectional curvature keeps the blade rigid when extended. Crucially, the cross-sectional curvature permitted anisotropic motions of the film actuator. By sandwiching a silicone balloon between two sheets of PVC in this curved configuration, we reproducibly demonstrated bending motion when the balloon was pneumatically expanded. Harnessing the bending motion and using the *kirigami*-patterned structural frame, we prototyped soft robots mimicking the locomotion of (1) crawling turtle, (2) climbing inchworm, (3) perching bat, and (4) flying and foldable wing of a ladybug. Importantly, the overall weight of the structure (*kirigami* of PVC sheets using a cutting plotter) and silicone balloons in both instances weighed < 20 g but could carry a payload of > 100 g, which is a substantial weight reduction compared to the existing soft robots system. As such, the soft robot was capable of carrying additional payloads (e.g., pneumatic pump (8 g), valves (5 g each), battery (~15 g), and microcontroller (~7 g)) to achieve untethered operation.
Significance. Overall, we designed a method of fabricating lightweight, untethered soft robots capable of mimicking locomotion such as crawling, climbing, perching and flying. Advantageously, our approach allows designing locomotions and prototyping new structures only using the PVC sheets and repositioning the modular actuators. Ultimately, we envisage potential applications of the developed actuators in rehabilitation, disaster relief, and space exploration.

11:15 AM SB12.09.10
High Precision Embedded 3D Printing of Soft Materials via the Solvent Exchange Method Wonsik Eom, Tanver Hossain, Vidush Parasramka, Randy H. Ewoldt and Sameh Tawfick; University of Illinois at Urbana-Champaign, United States

Embedded 3D printing enables the direct ink writing of ultrasoft materials which, due to gravity, cannot support their own weight in the air such as large aspect ratio 3D objects, thin closed shells, and hierarchically branched vessel networks. The support gel surrounding the extruded filaments prevents their sag or collapse. Gel-embedded printing resolution is currently on the order of 50 micrometers, limited by the interfacial tension ratios of the printing materials and support gel, the viscosity and the yield stress of the two materials, and the time required to post-cure by heat or UV light. Herein, we have significantly extended the library of printable materials and the achievable resolution and feature size by developing an embedded ink write exploiting the solvent exchange method. The printed material is initially dissolved in a solvent, which as soon as the filament is extruded from the nozzle solidifies due to the miscibility of the solvent in the gel. Hence, no post-curing is required, and the resolution is only limited by the nozzle size down to 3.2 micrometers. We applied this method to print intricate thread spools mimicking the skeins found in the hagfish slime, hair arrays, and complex fiber architecture similar to those found in biological tissue.

11:30 AM SB12.09.11
Ultrasensitive 3D Printed Self-Healing Ionic Hydrogels for Wearable Multifunctional Sensing Giorgio Mogli[1], Annalisa Chiappone[2], Ignazio Roppolo[1] and Stefano Stassi[1]; [1]Politecnico di Torino, Italy; [2]Università di Cagliari, Italy

The demand to connect the human and technology worlds has increased dramatically in recent years. Softness, multi-sensing capability, self-healing ability, and adaptability are all characteristics of living tissues. Robots and machines, on the other hand, are generally stiff and unable to self-repair. As a result, devices with intermediate qualities are required to connect the two worlds. Tactile or smart sensors, which are devices that can feel external stimuli such as deformations, temperature, wetness, and light, and are inspired by the human skin, which is the greatest sensor tissue of living humans, could be an ideal option. The key difference between standard sensors and these ones is that they are made of flexible materials to be more adaptable to the uneven surfaces of soft tissues and robots. Tactile sensors can be used in a variety of disciplines, including wearables [1], e-skin [2], prosthetics [3], and soft robotics [4], because to this capability. As a result of these advancements, the global market for soft tactile sensors has seen incredible growth in recent years. In particular, despite its relevance in biomedicine, reproducing haptic sensation remains a task that has yet to deliver consolidated results: flexible strain sensors are great candidates to overcome this difficulty.
Because of their softness and water-rich environment, hydrogels are attractive options for the production of sensing-active materials, as they may be able to overcome mechanical incompatibilities between humans and electronics. Hydrogels are water-based materials that can be easily manufactured and have great transparency and stretchability without losing conductivity.
Herein, an extremely flexible strain sensor based on a 3D printable self-healing hydrogel is presented. The photocurable ink was prepared by mixing an aqueous solution of Poly (vinyl alcohol) (PVA) with acrylic acid (AAc), Poly (ethylene glycol) diacrylate (PEGDA), a water-compatible photoinitiator and sodium chloride (NaCl) to endow ionic conductibility. The device were then printed with a commercial Digital Light Processing printer. The sensor, exploitable both as piezoresistor or piezocapacitor, presents high sensitivity to external stimuli, together with an extreme stretchability. The sensors show self-healing ability at room temperature without any stimuli and are able to restore both mechanical properties and strain sensitivity after the self-healing procedure and also after a drying and water restoring process. The very high strain sensitivity and the 3D printing capability enables the hydrogel to be

implemented into complex shape wearable strain sensors to monitor various human motion and physiological data, making it a viable solution for the creation of easily manufactured and conformable devices.

11:45 AM SB12.09.12
Stretchable Printed Circuit Board and Organic Circuit for Ultra-Flexible Biosignal Sensor Rei Kawabata[1,2], Teppei Araki[1,2], Mihoko Akiyama[1], Tianxu Wu[1], Yusuke Okabe[3], Hirotaka Koga[1], Takafumi Uemura[1], Masaya Nogi[1], Katsuaki Suganuma[1] and Tsuyoshi Sekitani[1,2]; [1]SANKEN (The Institute of Scientific and Industrial Research), Japan; [2]Department of Applied Physics, Graduate School of Engineering, Osaka University, Japan; [3]Cemedine Co., Ltd., Japan

Printable and stretchable electrodes are attracting considerable attention in the development of wearable devices for long-term health care monitoring. In this study, we developed stretchable electrodes using silver microparticles (AgP) and a small amount of silver nanowires (AgNWs). The developed electrodes enabled low-temperature curing at 100 °C with cyclic durability over 50% strain. An amplification device using a stretchable printed circuit board was fabricated using our stretchable electrode that successfully amplified pseudo biosignals and maintained its amplification factor over 50% strain. Electrodes in wearable devices can continuously probe bioelectrical signals and realize high signal-to-noise ratio with signal amplification at the probe [1, 2]. However, typical rigid electrodes are difficult to mechanically conform to the skin. Hence, composites of silver particles and polymer are a promising solution for the development of stretchable and printable electrodes [3, 4]; conventional Ag-based stretchable electrodes require complex chemical treatment and high-temperature annealing for the enhancement of their conductivity and durability. Improvement of the electrical properties of stretchable electrodes based on a simple, low-temperature printing process therefore remains challenging.
Our stretchable electrode contains AgP with a small amount of AgNWs, enabling it to maintain conductivity of over 5×10^3 S cm^{-1} and lower its fabrication temperature from 150 °C to 100 °C. Further, the durability strain of the stretchable electrode increased 7.5 times upon the addition of 1 wt% AgNWs. A stretchable printed circuit board based on our stretchable electrode was developed and implemented to fabricate an ECG amplification device. In this device, the organic thin film transistor and other components with mechanical properties different from those of a stretchable electrode were integrated to amplify the pseudo-ECG with an amplification factor of over 10 under strain. The stretchable printed circuit board is expected to promote the development of wearable devices with enhanced biocompatibility and contribute to the realization of long-term biosignal measurement, enabling the early detection of diseases.

1:30 PM *SB12.10.01
Towards Robust and Sustainable Soft Robots through Self-Healing Polymers Julie Legrand, Seppe Terryn, Ellen Roels, Seyedreza Kashef Tabrizian, Pasquale Ferrentino, Zhanwei Wang, Fatemeh Sahraeeazartamar, Joost Brancart and Bram Vanderborght; Vrije Universiteit Brussel, Belgium

Soft robots are flexible machines with numerous advantages. They provide safe human-machine interaction and are able to achieve complex motions with regard to their rigid counterparts. However, the softness of this type of robot makes them susceptible to cuts, shears, and punctures due to sharp objects. Moreover, those robots are often made of non-recyclable plastics, which forces the user to throw the robot away and replace it completely when damaged. The Brubotics and FYSC groups of the Vrije Universiteit Brussel work on an alternative to make soft robots more robust and sustainable. To do so we use Diels-Alder (DA) polymers, resulting from reactions between a diene (furan) and a dienophile (maleimide). Those reactions form thermoreversible cross-links in the polymer network. The reversible covalent bonds of this polymer allow recovering from macroscopic damage, like cuts and punctures, upon a heat-cool cycle (90°). Therefore, the polymer can be cut and healed back together to reform a single part with full recovery of the initial material properties [1]. By varying the network properties of the polymer, different mechanical properties, ranging from hyperelastic (100 kPa) to hard thermosets (10 GPa) can be obtained leading to multi-material parts with strong multi-material interfaces [1]. This material has been used to build complex, multi-material, soft actuators, grippers and prosthetics, but also modular and reconfigurable robots [1,2]. As the DA bonds are completely reversible, a soft robot can be robustly assembled, then disassembled, using its pieces for reassembling another robot. Sensing capabilities can be added to those robots by making the DA polymers conductive. To do so, (hybrid) carbon black and nanoclay fillers are added, creating a conductive DA polymer that can be molded or 3D printed. A conductivity ranging from 10µ to 100 S/m can be obtained depending on the proportion of carbon black and fillers added [3]. Using this technique, soft strain and capacitive self-healing sensors can be built and integrated in our soft, self-healing robots to provide feedback information to control them. Using the same sensors, damage detection of the self-healing robot can be performed by detecting reduced or absence of conductivity. In case of damage, the robot can be warmed up at ±90° for approximately 1h, which increases the mobility of the DA bounds, and then cooled down, let to heal, for 24h [1]. This healing process can either be performed by the operator or by the robot itself, by integrating either a heater [4] or shape memory alloy wires inside the robot's body. Shape memory alloy wires can be driven by an electrical current. The wire therefore heats up and shrinks, which allows to simultaneously close the wound and heat the damaged area up to heal it. Although the control of soft robots is challenging, relatively accurate results can be obtained by using finite element methods based on an experimental characterization of the materials to build the inverse kinematic controller [5]. Combining those above-mentioned techniques allows to create and control robust, sustainable soft robots for industrial and medical applications.

2:00 PM SB12.10.02
Self-Healing and Stretchable Ionically Conductive Materials for Electronics and Soft Robotics Yu Jun Tan; National University of Singapore, Singapore

Living matter self-heals when suffering from injuries. For instance, human skin heals from wounds of various degrees. On the contrary, synthetic materials degrade over time due to fatigue, corrosion, or damage. Meanwhile, living matter conducts electricity using ions, such as the neurons in the human body; in contrast, synthetic electronics conduct electricity using electrons. Therefore, inspired by the remarkable capability of nature, smart and self-healing ionotronics ans soft robotics are being intensively researched to mimic natural systems. A stretchable ionogel consists of ionic component(s) confined within a solid polymer network. Self-healing ionogels were developed based on (i) ions immobilized in self-healing polymers; and/or (ii) dynamic interactions between the ionic components with the polymer. A self-healing ionotronic device functions by using both the mobile ions and electrons, whilst they can self-repair damages inflicted on them. We developed self-healing and stretchable double network ionogels by integrating a covalently cross-linked acrylic acid network and a dynamic ionically cross-linked coordination between the acrylic acid chains and metal ions [1]. We also developed a self-healing ionogel composed of a fluorocarbon elastomer and a fluorine-rich ionic liquid, which offers fast and repeatable electro-mechanical self-healing in wet, acidic and alkali environments due to the ion-dipole interactions [2]. These self-healing ionogels can be 3D printed using extrusion-based methods. The inks exhibited thixotropic behavior that is favorable for extrusion-based 3D printing. We demonstrated that these materials can be used in pressure and strain sensing applications and serve as transparent electrodes in optoelectronics for soft robotics [3].

2:15 PM SB12.10.03
Self-Healing Effects of Small Molecule Acids on a Ultra-Conformable Stretchable Mixed Conducting Polymer Complex Colton Duprey[1], Hadi Rouhi[1], Katherine Webb[2] and Evan K. Wujcik[1]; [1]The University of Alabama, United States; [2]Vanderbilt University, United States

Polymeric piezoresistive sensors show great promise in movement monitoring, biosensing, and soft robotics. Their polymer composition provides flexibility and stretchability allowing for unique applications where traditional metallic materials are too brittle and rigid. A templated polymer complex composed of poly(2-acrylamido-2-methyl-1-propanesulfonic acid), polyaniline, and a small molecule dopant. The impacts the various dopants have on the material's conductivity, stretchability, mechanical and self-healing properties, and piezoresistive sensitivity are studied. Generally, small molecule dopants that increase conductivity decrease stretchability and mechanical stability, which stems from more acidic dopants being able to protonate and facilitate ion transport throughout the sensor. Conversely, functional groups with increased hydrogen bonding tend to increase mechanical and self-healing properties. By increasing our understanding of the impact these various dopants have on the properties of the polymer complex, the material can be tailored to specific applications, allowing for increased sensitivity when needed or increased stretchability when required. This will allow for the development of novel materials as we seek to manufacture better stretchable electronics.

2:30 PM BREAK

3:00 PM SB12.10.04
Towards Self-Healing Electronics—Hydrogen Bonded Conjugated Polymers via Ureidopyrimidinone Megan M. Westwood and Bob Schroeder; University College London, United Kingdom

As electronic devices become increasingly integrated in our lives, the progression from portable to wearable devices is inevitable and offers the possibility of advanced healthcare diagnostics for future generations.[1] Aiming to mimic human skin, these new materials must be stretchable and have the ability to heal in response to stress. Organic semiconductors, specifically conjugated polymers, are a promising candidate for realising electronic skin as they are intrinsically flexible and can be modified *via* chemical design to achieve both high performance and that allow energy dissipation under stress through introduction of supramolecular motifs.

Prior research has shown that incorporating pendant hydrogen bonding groups into a conjugated polymer can result in recovery of the mechanical properties after deformation.[2,3] However, the induced structural disorder reduces electronic performance which has to date only partially been recovered and the direct effect of non-covalent groups is not fully understood. Maximising the strength of dynamic bonds through use of a quadruple hydrogen bonded system, such as ureidopyrimidinone (UPy), offers a design pathway to more efficient healing semiconductors.[4]

We have synthesised a series of fluorene based polymers bearing UPy groups to investigate their directing effects within a conjugated polymer matrix. Here, the purpose was to decouple competitive interactions between hydrogen bonding within sidechains and the polymer backbone. Spectroscopic, thermal and mechanical analysis showed dramatic changes within the polymer structure upon installation of only 10% UPy with respect to other solubilising side chains. In this presentation we will discuss the structure-property relationships exhibited in these materials and the effect on self-healing efficiency in optical devices, offering a design paradigm for future biomimetic materials.

3:15 PM SB12.10.05
Water-Accelerated Autonomous Self-Healing Elastomer for Underwater Wearable Electronics. Fang-Cheng Liang and Chi-Ching Kuo; Institute of Organic and Polymeric Materials, Research and Development Center of Smart Textile Technology, National Taipei University of Technology, Taiwan

The conventional self-healing mechanism is a highly energy-consuming temperature-dependent inducing spontaneous reparation and thus impedes further integration in electronic (e-) skin. Herein, we present an innovative concept of a water-assisted room-temperature autonomous self-healing mechanism based on synergistically dynamic covalent Schiff-based imine bonds with weak hydrogen bonds. Significantly, the supramolecular water-assisted self-healing polymeric (WASHP) films possess rapid self-healing kinetic and high stretchability behavior through the reversible dissociation/association process. In comparison with the pristine room-temperature SHP, our WASHP demonstrates the remarkably mechanical performance for self-healing elastomers at room temperature so far, alongside accelerated the self-healing time up to 1hr and exhibits superior performance including tensile strain increased up to 9050%, self-healing efficiency up to 95%, and toughness up to 144.2 MJ/M3), respectively. As a proof-of-concept, we designed a versatile WASHP-based light-emitting touch-responsive device (WASHP-LETD) and perovskite quantum-dots-based (PeQDs) white LED backlight. The WASHP-LETD possesses remarkable mechanical deformation performance (pressure, bending, and strain), whereas WASHP-PeQDs exhibit outstanding long-term stability even under water environment beyond 1 year, highlighting its potential utilized in white LED with highly pure white color rendering. This work provides a mechanically robust approach for producing eco-friendly, economical, and waterproof e-skin device components.

3:30 PM SB12.10.06
Ultra-Stretchable Self-Healing Mixed Conductive Polymer Composite with Silver Nanowires Showing Increased Mechanical Performance Colton Duprey[1], Hadi Rouhi[1], Yang Lu[2] and Evan K. Wujcik[1]; [1]The University of Alabama, United States; [2]Georgia Institute of Technology, United States

Effective wearable sensors, stretchable electronics, and soft robotics materials must have a sufficiently high balance of conductivity, stretchability, and robustness. Intrinsically conductive polymers offer a critical step toward improving wearable sensor materials due to their tunable conductivity, soft/compliant nature, and ability to complex with other synergistic molecules (e.g., polyacids, small molecule dopants). The addition of nanofillers offers the potential to improve the properties of these polymer composite for soft robotics and wearable applications. While nanofillers typically increase conductivity at the expensive of mechanical properties, here we show an increase in mechanical properties, which the interface between the polymer matrix and the AgNW is hypothesized to be integral for the formation of an active network. These form a polymer nanocomposite with high electronic sensitivity, unprecedented mechanical properties (a maximum strain of 4693% at ambient humidity; ~52 RH%), and repeatable, autonomous self-healing efficiencies of greater than 98%. To illustrate the remarkable sensitivity, the material was employed as a biomedical sensor (pulse, voice recognition, motion), topographical sensor, and high sensitivity sensor.

3:45 PM SB12.10.07
Fabrication of a Flexible Electroadhesive Component by Additive Manufacturing for Wall-Climbing Robots Taekyu An, Sukeun Yoon and Jihoon Kim; Kongju National University, Korea (the Republic of)

Existing robots that are capable of climbing walls mostly rely on rigid actuators such as electric motors, but soft wall climbing robots based on electroadhesion (EA) have not yet been widely achieved. EA electrically generates an electrostatic force to activate the adhesion force. EA as compared to other adhesion solutions can possibly adhere without damage to the target surface with a relatively simple system, low weight, and low electric consumption. EA consists of two interdigitated electrodes, a dielectric layer, and an insulating layer. The dielectric layer must have high dielectric constant and high insulation resistance to increase its adhesion force. However, high insulation resistance and dielectric constant are conflicting parameters, and it is important to find a trade-off point. In this study, to implement EA through additive manufacturing, flexible-EA(F-EA) pad was manufactured by forming electrode patterns on flexible copper clad laminate(FCCL) using digital light processing (DLP). The photocurable resin patterned on FCCL by DLP was used as an etchant resistor. Portions of the Cu layer without the photocured resin was removed during wet chemical etching, leaving the electrode patterns on FCCL. To enhance electroadhesive force, ceramic composite layer was printed over the patterned FCCL. The electroadhesive force was simulated by a finite element method (COMSOL) according to various electrode patterns and compared to the experiments. The climbing robot was operated by rotating the track with wheels while having the F-EA embedded in the track. The size of the track was designed considering the adhesion force of the embedded F-EA and the weight of the climbing robot. Experimental results revealed that climbing robot has excellent climbing performance on a wide variety of surface.

4:00 PM DISCUSSION TIME

4:15 PM SB12.10.09
Soft Robotics for Reactive Skins, Haptics, and Biosensors in Smart Minimally Invasive Surgical Tools. Arincheyan Gerald and Sheila Russo; Boston University, United States

Robotic Minimally Invasive Surgery (R-MIS) provides significant advantages to both the surgeon and the patient, such as improved accuracy, automated surgical tasks, faster patient recovery times, and reduced patient trauma. However, many current R-MIS systems do not possess haptic feedback, relying instead on sensory substitution in the form of visual cues to the surgeon. The lack of direct tactile feedback can result in excessive application of forces onto the patient's tissue. This is particularly problematic in the case of flexible surgical instruments such as endoscopes, wherein frictional forces affect force transmission along the length of the device. Excessive forces in colonoscopy can lead to severe adverse events (SAEs) such as bleeding, perforation, and splenic injury. This highlights the necessity of a comprehensive haptic feedback system that can sense forces exerted by the colonoscope onto the tissue and directly relay haptic feedback to the surgeon.

In prior work, we developed a soft robotic reactive skin that can be mounted onto a colonoscope to detect incident force on colon tissue. In our current work, we augment the sensing capabilities of the soft robotic skin with a wearable pneumatic glove that provides haptic feedback to the surgeon. Incident force on the soft robotic skin triggers the pneumatic actuators on the glove, causing them to inflate and provide haptic feedback to the user's fingers. The glove consists of a main fabric piece and modular actuators that wrap around the base of the fingers. The glove is designed to be minimally intrusive and possesses a low vertical profile (1 mm), allowing the endoscopist to maintain finger dexterity and grasp the colonoscope. The actuators are controlled by enabling proportional inflation based on the magnitude of the incident forces on the sensors. The glove was validated using a series of experiments. First, the duty cycle of the glove control system was varied to assess the ability of the actuators to hold pressure at discrete values to enable the surgeon to distinguish between different magnitudes of force. The actuators inflate once the incident force crosses a predefined threshold value of 1 N and reaches max pressure at a force value of 2.2 N. The threshold value can be tuned depending on the nature of the procedure as forces experienced in colonoscopies are highly variable (i.e., up to 40 N). This test was further expanded to ascertain the force mapping capabilities of the haptic glove, i.e., to determine the output force of the actuators in response to the incident forces on the soft robotic skin. The force exerted by the actuators increased directly in proportion to the incident force with a max value of 20 N, which was 9 times larger than the incident force. The haptic feedback system was then subject to an in-vitro surgical evaluation. The haptic glove was worn by an endoscopist whilst performing a mock colonoscopy using an artificial colon. The soft robotic skin was mounted on the colonoscope to provide force sensing that was relayed as haptic feedback to the endoscopist via the wearable device. The endoscopist performed the procedure with and without haptic feedback and evaluated each case using a NASA task load index. The colonoscopy trial with haptic feedback had improved sub-scores compared to the case without haptic feedback, signifying an easier, less demanding workload for the endoscopist.

This soft robotic haptic feedback system can be expanded to mimic varied physical sensations encountered during MIS such as tissue palpation or bending of the flexible surgical tool. It can also be used to alert the surgeon to SAEs, such as bleeding when integrated with biosensors. The versatility and modular nature of the glove also makes it suitable to be adapted to other MIS procedures where haptic feedback is beneficial, such as bronchoscopy or neurosurgery.

4:30 PM SB12.10.10
Tunable Tissue-Like Conductive Hydrogel Scaffolds for Neural Cell Differentiation Christina M. Tringides, Marjolaine Boulingre and David Mooney; Harvard University, United States

Multielectrode arrays would benefit from intimate engagement with neural cells, but typical arrays do not present a physical environment that mimics that of neural tissues. We hypothesized that a porous, conductive hydrogel scaffold with appropriate mechanical and conductive properties could support neural cells in 3D, while tunable electrical and mechanical properties could modulate the growth and differentiation of the cellular networks. By incorporating carbon nanomaterials into an alginate hydrogel matrix, and then freeze-drying the formulations, scaffolds which mimic neural tissue properties were formed. Neural progenitor cells (NPCs) incorporated in the scaffolds formed neurite networks which spanned the material in 3D, and differentiated into astrocytes and myelinating oligodendrocytes. Viscoelastic and more conductive scaffolds produced more dense neurite networks, with an increased percentage of astrocytes and higher myelination. Application of exogenous electrical stimulation to the scaffolds increased the percentage of astrocytes and the supporting cells localized differently with the surrounding neurons. The tunable biomaterial scaffolds can support neural co-cultures for over 12 weeks, and enable a physiologically-mimicking *in vitro* platform to study the formation of neuronal networks. As these materials have sufficient electrical properties to be used as electrodes in implantable arrays, they may allow for the creation of biohybrid neural interfaces and living electrodes.

4:45 PM SB12.10.11
Silicone Materials with Tunable MRI Contrast for Applications in Soft Robotic Medical Phantoms Yasmine Osmani, Ben Dickie, James O'Connor, Brian Derby and Steve Edmondson; The University of Manchester, United Kingdom

The availability of soft robotic phantoms, with realistic motion, would be a significant advance in developing cancer treatments by magnetic resonance imaging (MRI) guided radiotherapy; but is currently limited by available silicone materials. A successful soft phantom must display the appropriate balance of mechanical properties, MRI contrast and manufacturability. Here, we present material development for 3D printable silicone materials that work towards overcoming this challenge.

Robotic phantoms must present MRI relaxation times that simulate biological tissues, typically assessed using time constants T_1 and T_2 for longitudinal and transverse relaxation. Human tissue relaxation times can range from 600 – 3000 ms for T_1 and 35-110 ms for T_2 , although the precise range depends on the magnetic field strength used during a particular scan. Therefore, appropriate phantom materials should allow for significant T_1 and T_2 tunability. For soft robot fabrication the challenge is to develop compositions that achieve the desired relaxation values, have optimum pre-cure viscoelasticity for printability, while also maintaining post-cure mechanical properties comparable to those human tissues; which typically range from <100 kPa – 1 MPa. This work aims to present material formulations to 3D print MRI compatible soft robots with tunable and values.

We have developed printable silicone blend composed of high viscosity and low viscosity PDMS materials, which was then blended with silicone oils of varying lengths, to allow for relaxation rate tuning. This simple approach has extended the T_1 relaxation range, of typical unmodified silicones, from 1159 - 1229 ms to 1140 – 2313 ms and the T_2 relaxation range from 14 – 23 ms to 13 - 34 ms. Ink printability has been assessed using rheological characterisation. At an angular frequency, ω, of 10 s^{-1}, the addition of 30% silicone oil decreased the storage modulus G' from 9.0 kPa to 7.4 kPa and the yield stress from 8.6 kPa to 1.3 kPa, confirming that the ink remained printable. Simplified brain phantoms were then produced via extrusion 3D printing. These were imaged in a clinical grade MRI scanner, and showed appropriate contrast under T_1 weighted imaging.

Our preliminary data on printable silicone formulations has demonstrated that it is possible to fabricate soft robotic structures via additive manufacturing with appropriate T_1 weighted imaging contrast. Further work is needed to access materials with appropriate T_2 contrast and optimise the post curing mechanical properties to be consistent with that of human tissue. This material blend presents a promising option not only for MRI applications but also surgical training phantoms, substrate and scaffold structures, soft facial prosthetics and electronic skin.

SESSION SB12.11: Materials III
Session Chairs: Francesco Greco and Andrea Spanu
Friday Morning, December 2, 2022
Hynes, Level 3, Room 309

9:15 AM SB12.11.02
Understanding the Mechanics of 3D Knitting for Additive Manufacturing of Textile-Based Soft Robots Vanessa Sanchez[1,2], Kausalya Mahadevan[1], Gabrielle Ohlson[1], Moritz A. Graule[1], Michelle C. Yuen[1], Clark B. Teeple[1], James C. Weaver[1], James McCann[3], Katia Bertoldi[1] and Robert J. Wood[1]; [1]Harvard University, United States; [2]Stanford University, United States; [3]Carnegie Mellon University, United States

Soft robots allow gentle, safe interactions between devices and people and can even account for a level of environmental and task-specific uncertainty due to their inherent material compliance. Challenges remain, however, in creating affordable, accessible, durable, and customized devices for where light weight, comfort against skin, and low-form factor are paramount, including personalized healthcare, thermoregulation, and assistive technology. The ability to additively manufacture textile-based soft robots on-demand would address these limitations, with V-bed weft knitting representing a promising approach due to its highly multi-dimensional design space. Specifically, knitting has the ability to tune material properties across four distinct length scales, from yarn-scale material incorporation, to local stitch geometries, to self-assembled architectures from collections of stitches, and finally at the scale of engineered global shaping. Yet as a consequence of the broad frontier in this emerging field, there is a lack of understanding of how these parameters (1) tune mechanical properties such as anisotropic stress-strain behavior and (2) affect system-level manufacturability, both of which must be established through physics-based guidelines in order for integrated devices to be created effectively.

In this work, we take a step toward establishing these guidelines by developing a library of knit structures and studying how local stitch geometry, self-folding structures, and constituent material properties tune the anisotropic stress-strain behavior of knits. We relate this knowledge to global shaping

strategies used in knitting to create monolithically 3D-knit soft robots. Resulting devices can perform a variety of application-specific tasks using complex and multi-degree-of-freedom motions. Furthermore, we highlight the ability to pair knit actuation with direct integration of deformation sensing.

9:30 AM BREAK

10:00 AM SB12.11.06
Stretchable and Lightweight Soft Conductive Composites Embedded with Liquid Metal Microfiber Networks Jiexian Ma, Pu Zhang and Zihan Liu; SUNY Binghamton, United States

Soft conductive composites are essential components of stretchable electronics, soft robotics, soft sensors and actuators. Liquid metals are ideal fillers of soft conductive composites because of their high conductivity and supreme compliance. Existing liquid metal composites usually require a relatively high filling ratio of liquid metals, which inevitably make the composites heavy and expensive. In this presentation, We report the design and fabrication of a new paradigm of liquid metal composites by embedding liquid metal microfiber networks into soft elastomers. Experimental results indicate that this new composite is highly conductive, lightweight, super-stretchable, and low cost. The mechanical and electrical properties of this new liquid metal composite are characterized. In addition, we will demonstrate a few potential applications in stretchable electronics and sensing.

10:15 AM SB12.11.07
Solvent-Assisted Filling and Selective Dewetting of Liquid Metal for Layer-Structured 3D Interconnect and VIA for Stretchable Electronics Woojin Jung and Tae-il Kim; Sungkyunkwan University, Korea (the Republic of)

As research on stretchable electronics is developing rapidly and becoming complex, the requirement for novel fabrication method for 3D interconnects owing to stable vertical interconnect access (VIA) for complex printed circuit boards (PCBs) is emerging. However, there are only a few attempts to resolve this issue. This is because the electrically conductive material filling VIAs must be intrinsically stretchable. Due to this, many researchers adopted Gallium-based liquid metal to fabricate VIAs. Its liquid nature allows it to adapt its shape to extreme mechanical stimulation, such as stretching or torsion. Using this advantage, researchers manually inject the liquid metal into VIAs, which is unsuitable for fine interconnects below the mm scale. Here, we demonstrate solvent-assisted liquid metal filling into various interconnect shapes, including VIAs and selective dewetting of liquid metal exposing PCB board. This process is spontaneous. Therefore, it takes advantage to fabricate small patterns, even sub-micrometer circuits. We provide the theoretical background of liquid solvent-assisted liquid metal filling and selective dewetting. Also, We suggest the design criteria for the geometry and dimension of liquid metal interconnects to obtain structural stability without dewetting based on theoretical and computational background. The experimental evidence agrees with the design criteria. We demonstrate a simple stretchable NFC device with this novel fabrication method and design criteria. We successfully transferred micrometer-size light-emitting diodes (LEDs) with only 230 micrometers to the stretchable liquid metal PCB without any soldering process. This is because the liquid metal makes conformal contact with the electrodes of LEDs and adheres firmly. The device operates stably under repetitive stretching and releasing due to the stable connection of VIA between the upper and lower layer.

10:30 AM SB12.11.08
Tracking High Voltage Capacitance Evolution as Indicator for Electrode Degradation in Dielectric Elastomer Actuators Haleh Shahsa, Jiahao Gu, Ang Li, Siyoung Lee and Mihai Duduta; University of Toronto, Canada

Dielectric elastomer actuators (DEAs) are soft, electrically driven devices that convert electrical energy to mechanical deformation. Despite their advantages, the widespread adoption of DEAs is limited by limited understanding of failure modes. Here we report a method to continuously monitor high voltage capacitance during DEA actuation as an indicator of device degradation. Our approach can track energy conversion efficiency, but also show changes in the device's properties in real-time. This unprecedented insight enables a novel way to study DEAs, evaluate degradation mechanisms, and correlate material structure to device performance.

Carbon nanotube (CNT)-based electrodes are a promising option for making DEAs as they are highly conductive and compliant. The long-term performance of CNT-based DEAs, however, is limited because of their structure degradation. The CNT concentration affects the performance of the DEA and the breakdown field. The high concentration will cause an early breakdown, while the low concentration will lead to poor electromechanical performance. With our high voltage capacitance tracking method, we optimize a specific set of carbon nanotube electrodes to demonstrate a DEA capable of withstanding 5 kV DC actuation (>100 V/μm) for over 3 hours continuously, with peak specific strain energy of >90 J/kg and peak electro-mechanical energy conversion rate of 7%.

Metal nanowires, such as Silver and Copper, provide high conductivity and are widely being used for transparent stretchable electronics. Moreover, they are significantly larger than CNTs, and maintain a high aspect ratio across scales. Mixing the CNTs with metal nanowires at different mixing ratios changes the decay rate of DEAs as compared to pure CNT electrodes. This work is a necessary step towards developing ultra-resilient DEAs and enabling a wide range of applications, from wearable devices to soft machines across different scales.

SESSION SB12.12: Applications IV
Session Chairs: Piero Cosseddu and Darren Lipomi
Friday Afternoon, December 2, 2022
Hynes, Level 3, Room 309

1:30 PM SB12.12.01
Light Driven Bio Hybrid Actuators Ilaria Venturino[1,2], Vito Vurro[1], Matteo Moschetta[1], Silvio Bonfadini[1], Valentina Sesti[1,2], Chiara Bertarelli[1,2], Luigino Criante[1] and Guglielmo Lanzani[1,2]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy

Bio hybrid actuation is a novel trend in soft robotics combining soft polymeric scaffold and biological active component (i.e. flagella, bacteria). A promising class of bio hybrid actuators are those based on muscle cells.[1] Muscular tissues are characterized by outstanding performance (i.e high efficient energy storage, high power/weight ratio, self-repair capability)[2] that are very promising in actuation field especially if compared with other type of actuators. These features can be reproduced *in vitro* mimicking the native muscle structure and organization and leading to the already mentioned bio hybrid actuators. Typically, these devices are controlled by an electrical pulses, applied by electrodes to the tissue.
An interesting alternative to the electrical stimulation can be given by the use of light. Photostimulation can be a competitive alternative to the classic one

due to its low damaging level and high spatial and temporal resolution[3]. Since muscle cells are not sensible to light several strategies have been found (i.e. optogenetics, IR stimulation, photo sensible materials).[4,5]
In this work we present the skeletal muscle cells photopacing mediate by a photochromic molecules, named Ziapin2.[6] This molecule is an azobenzene compound that is able to isomerize due to light interaction. This approach was tested on single skeletal muscle cells and on muscle tissue realized exploiting the same cell line and a micro-patterned Polydimethylsiloxane (PDMS) thin film.

1:45 PM SB12.12.02
Stacked Rigid and Compliant Dielectric Structures for Increasing Force Range in Soft Capacitive Sensors Kieran Morton[1], Ryusuke Ishizaki[2], Bertille Dupont[1], Austin Weir[1], Victor Mitchell[1], Han C. Nguyen[1] and John D. Madden[1]; [1]The University of British Columbia, Canada; [2]Honda R&D Co. Ltd., Japan

Soft force sensors have a myriad of applications including soft robotics, medical devices, and industrial environments. Compared to mechanoreceptors in the skin, emerging technologies are still poor in the combination of sensitivity, directional distinction, and dynamic range. In this work a capacitive sensing approach is presented that employs a mechanically structured dielectric to enable a combination of high sensitivity at low forces that correspond to light touch, and an ability to operate at high forces needed for tight gripping. The sensor uses the change in capacitance resulting from the movement of four electrodes on the top surface of the dielectric relative to a bottom electrode to determine normal and shear displacements, and corresponding forces. A soft silicone elastomer (Shore Hardness 00-30) is used to form the body and conductive elements of the sensor. Initial work using a dielectric with a pillar structure showed high sensitivity at pressures of up to 76 kPa, but signal saturation occurred at higher loading as pillars are flattened and contact one another at large strains. To increase force range while maintaining sensitivity, a two-stage dielectric architecture is used to create a structure which is highly compliant to normal and shear forces at small forces, while maintaining reasonable sensitivity at high normal forces. Several shapes are explored for the purposes of enhancing low-force response, combining a softer upper architecture such as pyramids with stiffer lower pillars. A molding and bonding process is used to fabricate these stacked sensors. Four primary designs are presented in this work with different combinations of pyramid and square structures. The selection of structures is informed by literature on pyramidal sensors, empirical design, and simulations. COMSOL is used to predict sensor response. These sensors are characterized in a three-axis characterization setup for low-force, and a single-axis characterization setup for high-force. The combination of inverted pyramids in the high sensitivity layer and square pillars in the high force layer achieves a balance of high sensitivity while maintaining a wide dynamic range and a relatively flat, skin-like upper surface. This sensor functions in a normal force range of 0.05 N - 50 N. At lower forces (0-20 N) shear displacements are measured, with a sensitivity of 265 fF/N (1.35 fF/Pa), enabling detection of a displacement of 23 mm, corresponding to a force of 60 mN, and a shear stress of 89 Pa. The normal force sensitivity is 54 fF/N (0.28 fF/kPa), down to a normal force of 13 mN. This resolution is similar to that of human mechanoreceptors at frequencies of less than 20 Hz. At large loads (25 N – 50 N), there is some hysteresis and loss of sensitivity, but a change of 15 fF/N (0.08 fF/kPa) enabling force discrimination. Multi-stage dielectric structures consisting of two different pillar shapes allow for capacitive sensors to have a large force range, and yet high sensitivity to light touch, by combining shapes of varying compliance in series. Force range and sensitivity have potential to adapt to higher levels by using stiffer elastomers. Lateral spatial resolution in these sensors is several millimeters – significantly lower than in skin – but is resolvable by making the sensing skin thinner to increase resolution.

2:00 PM SB12.12.03
A Soft Tensile Valve for Analog and Self-Sensing Control of Soft Actuators Junsoo Kim, Jun Kyu Choe, Hyeonseo Song, Jiyun Kim and Joonbum Bae; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Utilizing inflation of flexible materials, pneumatic soft robots have expanded unexplored fields previously inaccessible to hard robots. Soft robots are especially specialized for adaptation to complex environments and safe interaction with humans, via harnessing intrinsic compliance. However, pneumatic soft actuators have been generally controlled by hard electronics such as controllers and solenoid valves. When these hard electronics are located externally, the robot must be tethered by tubes and electrical cables, and when they are integrated within the robot, its entire softness is sacrificed.
To realize autonomous control of soft robots without electronic components while achieving untethered and fully softness, soft valves capable of controlling pressure using on/off switching mechanisms have been developed (octobot, soft check valve, soft bistable valve, buckling-sheet ring oscillator, etc.). However, these soft valves are challenging to be utilized in proportional applications where continuous and precise control is required because they only discontinuously control the pressure based on the on/off switching mechanisms. Additionally, they require additional sensors for analog sensing of human motion in human-robot interaction, making the system more complex and demanding the use of sensors and electronic controllers.
In this work, we developed a STV (soft tensile valve) for analog and self-sensing control of pneumatic soft actuators without any electronic devices. The developed STV continuously adjusts the pressure according to stretching deformation, making it easy to self-sense simple human movements due to its linear and stretchable form, like a soft stretching sensor.
The main part of the STV consists of concentrical inner and outer tubes, and yarns, helically wrapping the inner tube with a constant pitch, with two channels: 1) An inlet channel is a cavity between the inner and outer tubes 2) An outlet channel is a cavity inside the inner tube. Constant supply pressure is supplied to the inlet channel, while the outlet channel is exhausted to the atmosphere via the in/out connector on one end of the STV. A chamber connector at the other end of the STV has a chamber port that supplies pressure to the actuator, which is located in the middle of the inlet and outlet channels. Stretching the STV causes helical yarns to deform the shape of the inner tube, resulting in continuous change of chamber pressure due to the change of pneumatic resistance of the inlet and outlet channels. To accommodate task-dependent customizations, the profile of chamber pressure can be programmed by adjusting design parameters such as the number of helical yarns, pitch length, and in/out directions, etc.
By mechanically embedding abilities of self-sensing and continuous pressure control, STV can replace sensors, controllers, and solenoid valves in simple human-robot interaction. As applications, we demonstrate an untethered and electronic-free soft gripper with continuously adjustable gripping force and a soft exosuit that adaptively changes the elbow assist torque according to the elbow angle. We expect STV to pave the way for electronic free and fully soft robots in human-robot interaction.

2:15 PM SB12.12.04
Soft Artificial Electroreceptors for Noncontact Spatial Perception Won Jun Song, Younghoon Lee, Yeonsu Jung, Ho-Young Kim and Jeong-Yun Sun;

Seoul National University, Korea (the Republic of)

Elasmobranch fishes, such as sharks, skates and rays, use a network of electroreceptors distributed on their skin to locate adjacent prey. The receptors can detect the electric field generated by the biomechanical activity of the prey. By comparing the intensity of the electric fields sensed by each receptor in the network, the animals can perceive the relative positions of the prey without making physical contact. Inspired by this capacity for prey localization, we developed a soft artificial electroreceptor that can detect the relative positions of nearby objects in a noncontact manner by sensing the electric fields that originate from the objects. By wearing the artificial receptor, one can immediately receive spatial information of a nearby object via auditory signals. The soft artificial electroreceptor is expected to expand the ways we can perceive space by providing a new sensory modality that did not evolve naturally in human beings.

2:30 PM SB12.12.05
Evaluation of Mechanical Properties of Polycaprolactone (PCL) Staple Electrospun Nanoyarns Using Novel Fabrication Technique Mohamad Keblawi and Vince Beachley; Rowan University, United States

Biotextiles are biomaterials with textile structure designed for biomedical applications. Depending on their structural properties, biocompatibility, and biostability, biotextiles can be used for various tissue engineering applications such as scaffolds and implants. Electrospun nanofibers have been widely used in many biomedical applications ranging from tissue engineering to drug delivery. Electrospun nanoyarns are biotextiles fabricated using electrospun nanofibers. Currently, electrospun nanoyarns are produced using continuous fiber filaments. As opposed to continuous filament yarns, staple yarns are produced by spinning discrete fiber segments. Due to the difficulty in adapting textile manufacturing processes, staple nanoyarn production is yet to be explored. This study aims to introduce and create a high throughput device capable of collecting and fabricating staple nanoyarns of different materials utilizing the electrospinning technique. The device consists of a roving belt that is used to continuously collect discrete nanofiber segment, which are then spun to create the yarn. The purpose of the project is to fabricate nanoyarns that utilize the advantages of electrospun nanofibers such as high surface-to-volume ratio, and ease of surface functionalization while controlling nanofibers parameters such as fiber length and density, feed rate etc, which current methods do not allow. This will facilitate the systematic investigation of the properties of nanoyarns. Polycaprolactone (PCL) is one of the most widely used polymers for biomedical applications due to its biocompatibility and desirable biodegradation profile. PCL electrospun nanoyarns of various parameters will be fabricated using the proposed device, and their mechanical properties will be explored and compared.

Ion-Based Dynamic Tactility for Healthcare and Robotics Unyong Jeong and Taeyeong Kim; Pohang University of Science and Technology, Korea (the Republic of)

Human skin has different types of tactile receptors that allow distinguishing of mechanical stimuli and temperature. The receptors are composed of ion conductors and their operation is based on the dynamics of the ions. A large number of thermoreceptors and mechanoreceptors are spatially distributed in the dermis, hence the spatial profiles of strain and temperature on the skin can be perceived distinctively. The viscoelastic deformability of the ionic receptors maintains stable electrical signals under large shear strains. This talk presents artificial ionic receptor designs that can simultaneously detect thermal and mechanical information. Two variables are derived from the analysis of the ion relaxation dynamics; the charge relaxation time as a strain-insensitive intrinsic variable to measure absolute temperature, and the normalized capacitance as a temperature-insensitive extrinsic variable to measure the strain. In the fast transient somatosensory processing, the ensemble of the first spikes in the spike trains encodes the dynamic tactile information. This talk proposes artificial dynamic sensory systems based on a new concept, position-encoded spike spectrum (PESS).

8:30 AM *SB12.13.02
Wearable Sensors and Actuators for Mediated Social Touch Heather Culbertson; University of Southern California, United States

Social touch is a complex but crucial component of our daily interactions. Touch has been shown to be able to both convey and elicit emotions, even in the absence of other contextual cues. However, the sense of touch is almost universally removed from all digital interpersonal communication. We are limited in our attempts to express emotions to lines of text on a screen or simple emojis. Our lab is developing a method to allow individuals to send digital touch messages to their friends and partners through wearable haptic devices with the goal of conveying emotions.

Our work seeks to create a wearable haptic device that uses combinations of common social touch gestures (strokes, pats, pokes, squeezes, and massage) to convey emotions to a user through mediated social touch. This talk will discuss a set of wearable haptic sensors and actuators that have been designed to sense and display social touch to the user. These wearable systems use a variety of haptic modalities, including pressure, skin slip, vibration, and electrotactile to convey these social touch gestures with varying realism. I will also discuss our results on conveying emotion through mediated social touch and how the perceived emotion (valence and arousal) can be controlled using the touch's speed.

9:00 AM SB12.13.03
3D Electrically Conductive, *In Situ* Assembled VOC Sensor Incorporating $Ti_3C_2T_X$ MXene and Graphene Nanoribbon (GnR) Sara Mohseni Taromsari, Chul Park and Hani E. Naguib; University of Toronto, Canada

Detection of exhaled volatile organic compounds (VOCs) have long been critical in breathalyzing as a non-invasive diagnosis method. In this regard, development of wearable electrochemical sensors that can accurately monitor exhaled VOCS with various concentrations is essentially important for therapeutic applications. In this study, a novel flexible, highly sensitive, fast responding VOC sensors have been designed and fabricated that can be incorporated into breath analysis devices. Firstly, $Ti_3C_2T_X$ MXene was chosen and synthesized to utilize its high electrical conductivity (5000 S/m) and abundant -O, -OH and -F terminal groups inherently grafted on its surface area. Next, MXene was hybridized with graphene oxide nanoribbon (GOnR), synthesized by chemical unzipping of multi-walled carbon nanotubes (MWCNT). The hybridized compounds were then thermally annealed in an Ar atmosphere at 700 ºC, to reduce the GOnR to graphene nanoribbon (GnR) in presence of MXene and benefitting from its large aspect ratio (500), bridging effect and facile orientation. The redox reaction during the annealing process, transferred the oxygen groups from GOnR to MXene, further significantly

increasing MXene's reactive epoxy groups. Secondly, a novel fabrication technique was developed by combining coaxial electrospinning of styrene-butadiene-styrene (SBS)@cetrylammoniumbromide (CTAB) core@shell membranes and simultaneous electrospraying of MXene and GnR hybrids. The formation of electropositive CTAB shell of SBS membranes electrostatically attracted the electronegative nanohybrids, which enabled in-situ formation of a 3-D electroactive network. The manipulation of MXene's terminal groups and significant increase in the more active oxygen groups, resulted in up to 10-fold enhanced ammonia, acetone, ethanol and methanol response compared to the neat MXene and GnR sensors. The in-situ selective deposition of the fibers led to a 3-D active and conductive structure with enhanced specific surface area of 148% and 125% compared to the neat SBS and conventionally coated SBS and XYZ directions conductivity of 12.21 S/m, 11.75 S/m, 10 S/m, respectively. Thanks to these enhancements, the sensors demonstrated expanded working range of 40 ppb-6000 ppm attributed. The sensors also exhibited mechanical stability for up to 600 deformation cycles which is required for integration into wearable devices and environmental stability when exposed to 80% relative humidity (RH).

9:15 AM SB12.13.04
A Bio-Inspired Interactive Soft Machine Integrated with Embodied Highly Stretchable, Multifunctional Electronic Circuit Feiyang Yuan, Zhexin Xie, Jiaqi Liu, Lufeng Tian, Bohan Chen, Zhongqiang Fu, Sizhe Mao and Li Wen; Beihang University, China

The octopus's tentacles have unique sensing and locally computing capabilities, contributing to their extraordinary manipulation in complex environments. In this study, we imitate this unique feature of octopus tentacles and implement a bio-inspired soft tentacle robot that integrates highly deformable sensors and control circuits. In particular, we integrate IC chips, electronic components, and flexible sensing (suction, bending, and temperature sensing) through printing and transferring liquid metal circuits onto stretchable silicone substrate. Electronic intelligence was embedded into the tentacle. As a result, the tentacle can perceive and processes information, thus endow grasping decision and altering control parameters. Then, we realize the interactive control of the prototype with one human finger. We designed a liquid metal sensing circuit and embedded three vacuum suction cups for haptic feedback. The results show that the tentacle prototype with an integrated sensing-control circuit can reconstruct its bending curve. The robot system can complete the tasks of identifying and avoiding obstacles, detecting and closed-loop grasping objects in an unstructured environment. Through the suction haptic feedback, one can operate the bio-inspired prototype to search, grasp and fetch the target object without visual information. This paper provides a new method for soft robots that operate in unstructured environments and interact safely with humans.

9:30 AM SB12.13.05
Delivering Multi-Sensory and Multi-Scale Haptic Cues through Wearables Marcia K. O'Malley; William Marsh Rice University, United States

Vibrotactile haptic feedback is ubiquitous for notifications and alerts in portable devices such as phones, smart watches, and fitness trackers, but the set of possible notifications is limited by the nature of the eccentric motors so often used to deliver such cues. Wearable haptics refers to systems worn on the body or integrated into clothing that can provide haptic feedback to the wearer in a wide range of forms, such as vibrotactile, cutaneous, skin stretch, pressure, and kinesthetic feedback. The potential for wearable haptics is supported by technological advancements in sensing and actuation that allow for the design and deployment of flexible materials, fabrics, and small-footprint actuators that can augment and enhance human performance. While rigid and grounded haptic feedback devices have been explored as a means to train new motor skills, rehabilitate movement coordination after neurological injury, and even augment human force output capabilities in tasks such as lifting or running, the application space is limited due to the weight and scale of such devices. Wearable haptic devices seek to overcome the limitations of rigid and grounded haptic devices.

In recent years, my group has been designing novel wearable haptic systems that provide multiple haptic modalities of feedback to the user, including vibration, skin stretch, pressure, and kinesthetic feedback, all packaged in bands that can be worn on the arm. We are also exploring how to encode high-fidelity haptic cues that can be actively explored by the fingers within low-fidelity haptic cues that are displayed on the arm. We are particularly interested in applications where the provision of such feedback has a measurable impact on human performance. In this talk, I will present some of our wearable haptic systems, describe our target applications, and highlight the distinguishing features our hardware while identifying opportunities for improvement.

9:45 AM SB12.13.06
PRESENTED ON-DEMAND ONLY: Functional Polymer Gels Based on Oligomer Fluids Zhenwu Wang; Karlsruhe Institute of Technology, Germany

Polymer gels, such as hydrogels, have been widely used in biomedical applications, flexible electronics, and soft machines. Polymer network design and its contribution to the performance of gels have been extensively studied. In this study, the critical influence of the solvent nature on the mechanical properties and performance of soft polymer gels is demonstrated. A polymer gel platform based on poly(ethylene glycol) (PEG) as solvent is presented. Compared to the corresponding gels based on water and ethylene glycol, the PEGgel with physically cross-linked poly(hydroxyethyl methacrylate-*co*-acrylic acid) demonstrates high stretchability and toughness, rapid self-healing, and long-term stability. Depending on the molecular weight and fraction of PEG, the tensile strength of the PEGgels varies from 0.22 to 41.3 MPa, fracture strain from 12% to 4336%, modulus from 0.08 to 352 MPa, and toughness from 2.89 to 56.23 MJ m^{-3}. Finally, rapid self-healing of the PEGgel is demonstrated and a self-healing pneumatic actuator is fabricated by 3D printing. The enhanced mechanical properties of the PEGgel system may be extended to other polymer networks (both chemically and physically cross-linked). Such a simple 3D-printable, self-healing, and tough soft material hold promise for broad applications in wearable electronics, soft actuators, and robotics.

10:00 AM SB12.13.07
PRESENTED ON-DEMAND ONLY: Understanding Continues Force/Energy-Displacement Path of Multistable Metamaterials to Program Their Functionalities Hossein Mofatteh, Benyamin Shahryari, Armin Mirabolghasemi and Hamid Akbarzadeh; McGill, Canada

Mechanical metamaterials are designed to show properties that do not exist in conventional materials. Bistability and multistability as unconventional properties have recently been realized in alternative architectures, such as an inclined beam, curved beam, shallow shells, Origami, and shellulars. Using multistable mechanical metamaterials to develop deployable structures, electrical devices, and mechanical memories raises two unanswered questions. First, can mechanical instability be programmed to design sensors and memory devices? Second, how can we tune mechanical properties at the post-fabrication stage via loading/unloading? Answering these questions requires a thorough understanding of the snapping sequences and variations of the elastic energy in multistable metamaterials. Herein, we model multistable metamaterials as a chain to be transformed into the desired shape by applying deformation on one point. We develop an algorithm based on the snapping sequences for modeling a chain composed of bistable cells. Its solution provides a continuous path with all possible configurations and snap-back released energy. Furthermore, by investigating a 1D chain, we found instability forces are deriving factors of snapping sequence. It has been shown that the order of instability forces determines how many configurations are achievable. We comprehensively unveil the mechanics of deformation sequences and continuous force/energy-displacement curves. This method offers an insight into the programmability of multistable chains, which is exploited here to fabricate a mechanical sensor/memory with sampling and data reconstruction functionalities.

1:00 PM *SB12.14.01
Toward the Design of High-Realism Texture Displays James E. Colgate; Northwestern University, United States

An unsolved problem in haptics is the realistic display of texture. In other words, it is generally not possible to measure a real-world texture such as a wooden surface, and then based on that measurement, display a virtual texture that, when explored by the bare fingertip, feels convincingly like the original. In this talk, I'll discuss recent experiments that have shed light on the requirements for texture display, as well as progress in developing effective displays.

In a first set of experiments, the skin vibrations caused by sliding over a texture were recorded and then precisely replayed as subjects' index fingers moved over an electroadhesion-based variable friction device. Although an excellent match was achieved in the vibrations, the subjective experience of the replay was little like that of the original texture. Replays were much weaker and qualitatively different. We speculated that the difference was due to the nature of the variable friction technology, which produces stimuli that are synchronous across the contact area of the fingerpad. Physical textures, in contrast, produce distributed stimuli reflecting the spatial inhomogeneity of both the texture and the skin.

In a second set of experiments, we explored the role of asynchronous, inhomogeneous stimuli by using a 14 pin, high-bandwidth pin array to create various vibratory indentation patterns on the index finger. We found that inhomogeneity did, in fact, play a significant role in the subjective experience: greater inhomogeneity led to greater subjective intensity. Surprisingly, it proved difficult to explain these results based on a standard elastic half-space model of skin mechanics, but easy to explain them based on a simple model of surface strain.

Taken together, these studies underscore the importance of distributed actuation, but fall short of providing a prescription for displays capable of high realism. The necessary spatial density and temporal bandwidth are not fully known, and significantly, the relative importance of normal versus lateral surface tractions is not well-understood. We explored this latter topic in a third set of experiments performed with a soft, wearable array of ferromagnetic "pucks". Subjects wore this array on their index fingers while exploring surfaces with various shapes and configurations of magnets hidden underneath. The array provided principally lateral tractions, yet proved quite capable of reveal spatial details such as the locations of edges and vertices. In ongoing work, the ferromagnetic pucks are being replaced by individually addressable electroadhesive pucks (still in a soft, wearable device) so that dynamic, texture-like stimuli may be created. Progress in achieving realism will be discussed.

1:30 PM SB12.14.02
Silver Nanowire Based Transparent and Flexible Force Sensors Nagasarvari Garikapati, Sreekeerthi Pamula and Parasuraman Swaminathan; Indian Institute of Technology Madras, India

Flexible electronics has permeated diverse fields owing to its ease of fabrication, robustness, lightweight, and cost-effectiveness. Touch sensors are used in various areas such as biometric authentication and display devices. Among the plethora of touch sensing techniques adopted, capacitive sensing is popular owing to its high sensitivity, simple structure, thermal stability, and low power consumption [1].
Silver nanowires (AgNWs) have excellent electrical, optical, and mechanical properties and can withstand small bending radii and high strain without affecting the optoelectronic properties. They are thus a viable candidate for transparent, flexible, and foldable devices [1]. Herein, we report flexible force sensors based on capacitive touch sensing, printed using AgNW ink on polyethylene terephthalate (PET) and polydimethylsiloxane (PDMS) substrates, which are both transparent and flexible. The patterns were printed using a custom-built extrusion-based direct writer. PDMS is used to encapsulate the device to provide it with mechanical stability as well as environmental protection. It also acts as the sensing dielectric. PDMS has a low surface energy and is well known for its flexibility, thermal stability, biocompatibility, transparency in the visible region, hydrophobicity, and chemical resistance [2, 3]. Moreover, PDMS can be spin-coated directly on the device and cured below 150 °C, which is compatible with many flexible substrates. The capacitance of the printed network varies with the thickness of the PDMS layer, which can be adjusted using the spin coating parameters.
When metal oxide nanoparticles such as zinc oxide (ZnO) are added to the PDMS matrix, porosity in the polymer matrix tends to reduce and the barrier protection is increased. Moreover, ZnO possesses high hardness, low refractive index, and hydrophobicity [4]. Therefore, PDMS-ZnO is also used as an encapsulant cum dielectric in this work and the force response of the sensors with PDMS and PDMS-ZnO coatings is compared. The change in intrinsic capacitance on touch is sensed by an LCR meter and the applied force is measured as a function of the change in capacitance to calibrate the touch sensor as a force sensor.
Experimentally obtained results have been validated computationally by designing and modelling these capacitance-based planar force sensors using COMSOL simulation software. To incorporate the property of flexibility, the capacitive behaviour of these devices in both flat and bent configurations is compared. The direction of bending and the force applied play a crucial role in the net change in capacitance.

Multistimuli Responsive Sensors at High Resolution Anna Maria Coclite; Graz University of Technology, Austria

Embedding sensors in smart architectures that record the response from the environment and transform it in a measurable signal is the objective of artificial skins. In this talk, an artificial skin based on a hybrid multi-stimuli responsive material, combining force, temperature and humidity sensing will be presented. The new sensor concept is realized by combining a hydrogel and a piezoelectric material in an array of core-shell structures. This architecture is achieved thanks to the use of vapor-based technologies for material processing, i.e. initiated chemical vapor deposition, atomic layer deposition and nanoimprint lithography. We demonstrate that the skin can detect the stimuli with lateral resolution below the one of human skin. Possible applications

stem from robotics to smart prostheses.

2:00 PM SB12.14.04
Ultraflexible Ferroelectric Transducers and Organic Circuits for Energy-Efficient Wireless Health Patches Andreas Petritz[1,2], Esther Karner-Petritz[1,2], Takafumi Uemura[2], Philipp Schäffner[1], Teppei Araki[2], Barbara Stadlober[1] and Tsuyoshi Sekitani[2]; [1]Joanneum Research Forschungsgesellschaft mbH, Austria; [2]Osaka University, Japan

Health is a very precious commodity, as we experience every day and especially in these times shaken by a pandemic. Continuous recording of health status through diagnostic techniques that combine high wearing comfort with high reliability, accuracy and cost-effectiveness is therefore very desirable. In this context, we present an ultraflexible solution for the power supply of wireless medical patches for monitoring of heart rate and blood pressure. The ultraflexibility is due to the very low overall thickness (only 2.5 µm in total) of the ferroelectric polymer transducers, organic rectifiers and capacitor components manufactured on a substrate only 1 µm thick, and it guarantees high sensitivity (15 nC N^{-1}), superior component reliability (over 6000 cyclic loading) and a very high peak power density (1 mW cm^{-3} at 2 Hz excitation). Our health patch solution not only includes this radically reduced layer thickness, but also new material combinations (ferroelectric polymers on parylene), novel device concepts (organic thin-film transistor-based diodes) and new integration principles (multi-stack transducers on 3D curved surfaces).[1]

[1]Petritz, A., Karner-Petritz, E., Uemura, T. et al. Imperceptible energy harvesting device and biomedical sensor based on ultraflexible ferroelectric transducers and organic diodes. Nat Commun 12, 2399 (2021). https://doi.org/10.1038/s41467-021-22663-6

2:15 PM SB12.14.05
PRESENTED ON-DEMAND ONLY Skin-Conformable Stretchable Sensor for Highly Anisotropic Piezoelectric Signals to Detect Convoluted Multiaxial Motions Asad Nauman, Jun-Chan Choi, Jae-Won Lee, Dong Yeol Hyeon, Kwi-Il park and Hak-Rin Kim; Kyungpook National University, Korea (the Republic of)

Stretchable and multidimensional strain sensors are of great interest for their applications in, health monitoring, soft robots, and detection of human joint motion. Human joints involving ranges of complex motion and joint forces, need to be monitored in real-time with high precision and conformability of wearable strain sensors. For various complex motions, involving different strain ranges, require specific sensitivity for each motion to be introduced, due to the trade-off between sensor sensitivity and stretchability. Traditional stretchable and flexible strain sensors fabricated based on uniform sensing substrate, lack the tunability and anisotropic sensitivity. Many of the existing monitoring systems to continuously monitor the complex joint motion of the human body, that is, wrist, finger, neck, and shoulder, suffer from severe limitations due to their rigid structures and lack of complex motion detection. These sensors fail to give multidirectional deformation information and are sufficiently inadequate for data processing.
In the recent era, stretchable sensors have given new dimensions of research to facilitate the applications of wearable healthcare sensors in monitoring human motions and vital signs. Stretchable piezoelectric sensors due to their quick response to mechanical deformation and adequate sensitivity are one of the suitable candidates for human body motion monitoring. However, the lack of multifunctional ability and adequate stretchability simultaneously in a single unit, makes it difficult for these sensors to detect the complex joint motion of human joints with large strains and multiaxial motions. To achieve the desired anisotropic sensitivity and stretchability, besides the adaptation of intrinsic material stretchability, structural engineering is of high importance. Here, we proposed a mechanically architectured heterogeneous structure with intrinsically stretchable active piezoelectric and passive elastomer gratings to tune the sensor's sensitivity depending on the deformation direction. Strain redistribution over the heterogeneous structure is optimized by the mechanical and structural parameter optimization to realize the tunable sensitivity. The local vertical stress distribution over the active piezoelectric material is enhanced when the deformation strain is applied parallel to the alignment direction of gratings, which results in higher sensitivity of output voltage while lower stretchability. The finite element analysis shows an interestingly high concentration of localized stresses inside the piezoelectric layer compared to the passive layer which gives the proof of higher output signals in parallel deformation. The stress distribution and as a result the sensitivity is tuned to the minimum value as the deformation strain angle is perpendicular. The fabricated sensor can monitor and distinguish complex joints motion such as stretching ratio, bending direction, radius, and motion mode simultaneously within one sensor unit. The final device is highly stretchable, lead-free, and skin conformable due to the PDMS matrix and soft Ecoflex. Further, we have used a single electrode piezoelectric configuration for the first time as a sensing unit to increase conformability and portability. A successful demonstration of each motion mode and direction detection and monitoring has been performed experimentally and validated through simulations.
This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean government (MSIT) (No 2019R1A2C1005531).

10:30 AM *SF01.01.01
Shape Memory in Self-Adapting Colloidal Crystals Chad A. Mirkin; Northwestern University, United States

Reconfigurable, mechanically responsive crystalline materials are central components in many sensing, soft robotic, and energy conversion and storage devices. Crystalline materials can readily deform under various stimuli, and the extent of recoverable deformation is highly dependent upon bond type. Indeed, for structures held together via simple electrostatic interactions, minimal deformations are tolerated. In contrast, structures held together by molecular bonds, in principle, can sustain much larger deformations and more easily recover their original configurations. Herein, we study the deformation properties of well-faceted colloidal crystals engineered with DNA. These crystals are large in size (> 100 μm) and have a body-centered cubic (BCC) structure with a high viscoelastic volume fraction (> 97%). Therefore, they can be compressed into irregular shapes with wrinkles and creases, and remarkably, these deformed crystals, upon rehydration, assume their initial well-formed crystalline morphology and internal nanoscale order within seconds. For most crystals, such compression and deformation would lead to permanent, irreversible damage. The significant structural changes to the colloidal crystals are accompanied by dramatic and reversible optical property changes. For example, while the original and structurally recovered crystals exhibit near-perfect (> 98%) broadband absorption in the UV-vis region, the deformed crystals exhibit significantly increased reflection (up to 50% of incident light at certain wavelengths), mainly due to increases in their refractive index and inhomogeneity. This work shows that preparing crystals held together with macromolecular bonds are a viable strategy for creating shape memory materials that can be deliberately engineered to exhibit a wide range of reversible structural and property changes simply not accessible with conventional crystalline architectures held together by other types of bonds.

Encoding Assembly, Transformations and Functions of Nanoscale Architectures Oleg Gang; Columbia University/Brookhaven National Laboratory, United States

The ability to organize diverse types of functional nanocomponents into the targeted architectures promises to enable a broad range of nanotechnological applications, from new classes of engineered biomaterials to photonic devices and materials for energy applications. However, current methods are limited in their ability to create 3D nanostructures with prescribed architecture and integration of different types of nanocomponents. The talk will present our progress in establishing a self-assembly platform for the encoded fabrication of designed large-scale and finite-size nano-architectures from diverse inorganic and biomolecular nanocomponents through the DNA-programmable assembly. The recent advances in creating periodic and hierarchical organizations from inorganic nanoparticles and proteins will be presented. The formed nanostructures can be farther transformed into fully inorganic 3D replica via nano-templating. The use of the developed assembly approaches for generating functional nanomaterials with nano-optical, mechanical, and biochemical functions will be demonstrated. Finally, the progress in creating nanomaterials with switchable states will be discussed.

11:30 AM *SF01.01.03
Reactions, Materials and Assemblies Under Rotation Bartosz A. Grzybowski[1,2]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Polish Academy of Sciences, Poland

The uses of rotary systems, e.g., centrifuges or evaporators, are commonplace in separations, but much less explored as the means of controlling the outcomes of chemical reactions or molecular-scale self-assembly or separation processes. Nevertheless, the idea of setting a reaction vessel on spinning is appealing because rotation can generate centripetal and shear forces that could be hard to maintain in a stationary frame of reference. In my talk, I will discuss how this concept can be used to couple macroscopic rotation to events taking place at much smaller scales, down to the molecular. I will illustrate how rotation can mediate self-organization of complex fluidic reactors (driving multistep reaction sequences), affect molecular conformations and enhance crystallization processes, help purify complex mixtures, or set up microgravity conditions for levitating reaction units.

Sheraton, 5th Floor, The Fens

1:30 PM *SF01.02.00
Logical Breakdown: Encoding Boolean-based Responsiveness into Hydrogel Biomaterials Cole A. DeForest; Univ of Washington, United States

The successful transport of drug- and cell-based therapeutics to diseased sites represents a major barrier in the development of clinical therapies. Targeted delivery can be mediated through degradable biomaterial vehicles that utilize disease biomarkers to trigger payload release. Here, we report a modular chemical framework for imparting hydrogels with precise degradative responsiveness by using multiple environmental cues to trigger reactions that operate

user-programmable Boolean logic. By specifying the molecular architecture and connectivity of orthogonal stimuli-labile moieties within material crosslinkers, we show selective control over gel dissolution and therapeutic delivery. To illustrate the versatility of this methodology, we synthesized seventeen distinct stimuli-responsive materials that collectively yielded all possible YES/OR/AND logical outputs from input combinations involving enzyme, reductant, and light. Using these hydrogels we demonstrate the first sequential and environmentally stimulated release of multiple cell lines in well-defined combinations from a material. We expect these platforms will find utility in several diverse fields including drug delivery, diagnostics, and regenerative medicine.

2:00 PM *SF01.02.01
Artificial Molecular Machines That Work at All Scales Nicolas Giuseppone; University of Strasbourg, France

Making molecular machines that can be useful in our macroscopic world is a challenging long-term goal of nanoscience. Inspired by the protein machinery found in biological systems, and based on the theoretical understanding of the physics of motion at the nanoscale, organic chemists have developed a number of molecules that can produce work when triggered by various external chemical or physical stimuli. In particular, basic molecular switches that commute between (meta)stable states, and more advanced molecular motors that produce unidirectional cyclic motions out-of-equilibrium when fueled with external energy, have been reported. However, the integration of individual molecular motors in a continuous mechanical process that can have measurable effects at various length scales and up to the macroscale remains an important objective. We will discuss advances developed by our group on artificial molecular machines, which involve their mechanical coupling with polymer systems. We will show how it becomes possible to integrate them and to make use of their mechanical work going from individual molecular devices to macroscopic materials.

2:30 PM *SF01.02.02
Reversibly Photocontrolled Polymer Networks Through Photoswitchable Dynamic Covalent Bonds Julia Kalow; Northwestern University, United States

In polymer networks based on dynamic covalent bonds, changes in reactivity can be translated into macroscopic responses. Light offers precise, tunable, and noninvasive spatiotemporal control over molecular reactivity. The Kalow lab has designed crosslinks that allow us to tune the thermodynamics and kinetics of dynamic covalent bonds with light, including visible light, based on the conformation of an adjacent photoswitch. When incorporated into polymer networks, the stability or lifetime of these dynamic covalent bonds can be tuned with light. I will discuss the molecular mechanisms underlying these macroscopic changes, as well as rational optimization of photoswitches to enable applications in 3D cell culture.

3:00 PM BREAK

Photoswitchable Polymers for Gated Protonic Conductivity Rachael Hannah[1], Ryan C. Chiechi[2] and Ben L. Feringa[1]; [1]University of Groningen, Netherlands; [2]North Carolina State University, United States

Biological systems rely on ionic gradients to function, therefore materials that can conduct protons or larger ions have the potential to interface with living organisms, and have useful applications in medical technology. Incorporating photoswitches into these materials could enable gating of ionic conductivity, given a particular stimulus. Photoswitches are a class of molecular machines wherein the molecule undergoes a conformational change in response to light stimulation. Photoswitches have already incorporated into a variety of polymers, either into the backbone or as pendant groups, to provide novel functional materials. Spiropyrans are a type of photoswitch that undergo a ring-opening reaction upon irradiation with ultraviolet light to form a highly conjugated, zwitterionic merocyanine form. Incorporation of spiropyrans into various hard and soft materials is a well-studied field, and they have been shown to be able to switch protonic conductivity on and off in metal organic frameworks (MOFs). We have synthesised styrene-based polymers with spiropyran pendant groups anchored through methacrylate moieties (SP-MA) via RAFT polymerisation methods, to be able to control the ionic conductivity of the material with ultraviolet light. The synthesised polymers exhibit photoswitching behaviour in solution and in thin films with high on/off ratio and good fatigue resistance. We then investigated the protonic conductivity of the polymers, by first swelling with ethanol and doping the polymers with sulphuric acid. Acid doping induces the ring-opening reaction, giving the protonated merocyanine, and trapping the proton. Irradiation with visible light induces the ring-closing reaction, giving a free proton, which can then move through the material. The polymer's ability to gate protonic conductivity in thin film devices was measured with impedance spectroscopy.

3:45 PM SF01.02.06
Nanocrystal Superparticles with Whispering-Gallery Modes Tunable Through Chemical and Optical Triggers Emanuele Marino, Harshit Bharti, Jun Xu, Cherie R. Kagan and Christopher B. Murray; University of Pennsylvania, United States

Whispering-gallery microresonators have the potential to become the building blocks for optical circuits. However, encoding information in an optical signal requires on-demand tuning of optical resonances. Tuning is achieved by modifying the cavity length or the refractive index of the microresonator. Due to their solid, nondeformable structure, conventional microresonators based on bulk materials are inherently difficult to tune. In this work, we fabricate irreversibly tunable optical microresonators by using semiconductor nanocrystals. These nanocrystals are first assembled into colloidal spherical superparticles featuring whispering-gallery modes. Exposing the superparticles to shorter ligands changes the nanocrystal surface chemistry, decreasing the cavity length of the microresonator by 20% and increasing the refractive index by 8.2%. Illuminating the superparticles with ultraviolet light initiates nanocrystal photo-oxidation, providing an orthogonal channel to decrease the refractive index of the microresonator in a continuous fashion. Through these approaches, we demonstrate optical microresonators tunable by several times their free spectral range.

4:00 PM SF01.02.07
Design and Application of Dynamic Polypyrrole Core-Shell Particles Weize Yuan and Timothy Swager; Massachusetts Institute of Technology, United States

Conducting polymer fabricated oil-in-water (o/w) colloidal particles had been developed via a single step of in situ interfacial polymerization of an emulsion phase. A unique core-shell structure of these particles was exhibited where the shell was governed by a thin layer of polypyrrole (pPy) film at the o/w interface. These core-shell particles demonstrated unique actuation configurations when pPy is chemically oxidized into the charged state or alternatively reduced into the non-charged state. Notably, these particles showed their ability to expand up to 400% in dimension while retaining their structure and were able to shrink back to their original sizes when reduced. The forces generated from their particles' interface during expansion can be calculated by measuring the size of the triggered inflation of pPy particles inside the different polyethylene glycol (PEG) gels. In addition, post functionalization of pPy particles via a thiol-Michael reaction was able to modify the hydrophobicity of pPy particles' interface. The particles hence showed remarkable conformal coating behavior onto hydrophilic membranes with the attached carboxylates functional groups on the particle surfaces. The

capability of post-functionalize pPy core-shell particles' surface provides the chance for them to be further bio-conjugated as well. Organic dyes compatible with the core-shell particles could be trapped within the interior of the core structure, indicating the prospects of pPy particle as a platform for loading small molecules. The dynamic structures and unique properties of these pPy particles have been demonstrated to be applicable in actuation, coating, and biosensing.

4:15 PM SF01.02.08
Optimal Design Methodology for Maximum Electro-Momentum Coupling in Piezoelectric Metamaterial Scatterers Jeong-Ho Lee, Zhizhou Zhang and Grace Gu; University of California, Berkeley, United States

As an elastodynamic bianisotropy, Willis coupling has been widely employed for acoustic metamaterials in which the linear momentum is additionally coupled to strain at the macroscale while it is coupled only to velocity by mass density at the microscale. Recently, a novel coupling, called electro-momentum coupling, is discovered for piezoelectric materials responding to electric fields such that the macroscopic momentum can also be coupled with electric stimuli. This electromechanical bianisotropy implies the possibility of programmable functionality in piezoelectric metamaterial devices as electro-momentum coupling can be smartly controlled by modulation of external stimuli, *i.e.,* active wave manipulation by stimulus modulation. However, the theory of how the electro-momentum coupling coefficient depends on external stimuli has not been developed in the previous literature. At the same time, how to rationally design microstructures with consideration for their sensitivity to the coupling coefficient has not been widely studied for two-dimensional cases. In this work, we aim to propose a general, optimal design methodology to design microstructures of piezoelectric metamaterials with external stimuli that can reach the theoretical maximum bianisotropic performance of scattering proposed in our previous work for piezoelectric metamaterial scatterers. Additionally, machine learning algorithms will be used to efficiently complement computational approaches in the design framework as well as to overcome the intrinsic nonlinearities of coupling.

4:30 PM SF01.02.09
Multifunctional Photoresponsive Organic Molecule for Electric Field Sensing and Modulation Patrick J. Saris, Shakthi Srinivasan and Andrea M. Armani; University of Southern California, United States

Bioelectricity is crucial to the normal function of organisms. It is also likely to be an indicator of damage or disease and can drive wound healing. We have engineered a molecular tool to study nanoscale electrical environments that can both “read” and “write” the surrounding bioelectric field. The “read” module is a voltage sensitive fluorescent dye which exhibits aggregation induced emission and two photon absorption. The “write” module consists of a pair of photoconductive organic molecules inspired by xerography, which can be activated with ultraviolet light to modify the local electric field. The rational and computational design of each module, as well as the reduction in crosstalk between the modules, will be discussed. Our all-optically-controlled molecular device is compatible with imaging techniques already widely used by researchers in the field, while adding co-localized multifunctional control.

SESSION SF01.03: Smart Functions of Stimuli-Responsive Materials III
Session Chairs: Po-Yen Chen and Siowling Soh
Tuesday Morning, November 29, 2022
Sheraton, 5th Floor, The Fens

8:30 AM *SF01.03.01
Responsive Soft Matter via Multi-Material 3D Printing Jennifer A. Lewis; Harvard University, United States

Soft responsive materials are of great interest for applications ranging from soft robotics to frequency shifting antennae. By combining inverse design and multi-material 3D printing, we have created soft materials that actuate in response to external stimuli. We have developed multiple printable inks composed of different elastomeric matrices, whose mechanical properties and shape-morphing behavior are programmed on demand. Several examples will be highlighted, including planar and 3D architectures with controlled local composition and structure.

9:00 AM *SF01.03.02
Soft Medical Robots Xuanhe Zhao; Massachusetts Institute of Technology, United States

This talk will discuss the smart materials, fabrication, and clinical translations of soft medical robots. We will use a magnetically-steerable soft guidewire robot capable of teleoperated robotic neurointervention as an example. We will first discuss the theory of magnetically-responsive soft materials that enables predictive models for the large deformation and actuation of the soft robot. Then we will discuss how to use the massive simulation data of the models to guide the design, 3D printing, and control of the soft robot. Thereafter, we will demonstrate the soft guidewire robots’ applications in remotely treating hemorrhagic and ischemic strokes by robotic aneurysm coiling and clot retrieval, respectively. We will validate the safety and efficacy of the soft guidewire robot in both phantom models and live pig models, and compare its performances with experienced neurointerventionalists carrying out manual operations. I will conclude the talk with a vision for the future development and impacts of soft medical robots – aided by and synergized with technologies such as mechanics-based AI, VR, and precision medicine.

9:30 AM *SF01.03.03
Programmable Shape-Change and Crawling Gels David H. Gracias; Johns Hopkins University, United States

The living world is composed of materials with a large water content and understanding how to create smart hydrogel materials and structures is critical to enable human-collaborative robots, biomedical and adaptive devices. In this talk, I will describe results on temperature and DNA stimuli responsive gels that illustrate the use of molecular design, micro/mesoscale patterning, and segmentation and swelling/deswelling to drive complex shape change, programmability, and even unidirectional locomotion. Importantly, these functions are driven by temperature or chemical signals without the need for any wires, tethers, or external power sources. They illustrate the ability to control and manipulate shape, curvature, and displacement by environmental cues offering the potential for smart materials and devices with a wide range of applicability in engineering and medicine.

10:00 AM BREAK

10:30 AM *SF01.03.04
Stimuli-Responsive Polymer-Ligated Nanoparticles and Nanorods—From Self-Assembly to Tailored Optical and Catalytic Properties Zhiqun Lin;

National University of Singapore, Singapore

In this talk, I will discuss a unique amphiphilic-nonlinear-block-copolymer-nanoreactor strategy for crafting stable hairy nanocrystals (nanoparticles (NPs) and nanorods (NRs)) with light- as well as thermal-promoted reversible and reliable self-assembly and tunable optical and catalytic properties. The size and shape of hairy nanocrystals can be precisely tailored by modulating the length of inner hydrophilic block of nonlinear block copolymers. The permanent anchoring of stimuli-responsive polymers on the nanocrystal surface renders the attractive feature of self-assembly and disassembly of nanocrystals on demand using stimuli of different wavelengths of light or temperature. In the first study, photo-responsive polymer-ligated noble metal NPs and NRs display tunable surface-plasmon resonance absorption and the reversible transformation of NPs and NRs between their dispersed and aggregated states. In the second study, thermo-responsive polymer-ligated noble metal NPs manifest controllable catalytic activity in nonmonotontic (i.e., non-Arrhenius-type dependence on temperature) or on/off (i.e., effectively switched "on" and "off" catalysis over temperature) manner over a broad region of temperature. By extension, this strategy enables the crafting of a family of stable stimuli-responsive nanocrystals and their assemblies for fundamental research in self-assembly and crystallization kinetics of nanocrystals as well as potential applications in optics, optoelectronics, magnetic technologies, sensory materials and devices, catalysis, nanotechnology, and biotechnology.

11:00 AM *SF01.03.05
Electrostatic Self-Assembly of Nanoparticles into Static and Out-of-Equilibrium Materials Rafal Klajn; Weizmann Institute of Science, Israel

Self-assembly of inorganic nanoparticles into ordered structures (superlattices) has led to a wide range of nanomaterials with unique optical, magnetic, electronic, and catalytic properties. Various interactions have been employed to direct the crystallization of NPs, including van der Waals forces, hydrogen bonding, as well as electric and magnetic dipolar interactions. Among them, Coulombic interactions have remained largely underexplored, owing to the rapid charge exchange between nanoparticles bearing high densities of opposite charges (superionic nanoparticles). In this talk, I will describe a new method to assemble superionic nanoparticles under conditions (room temperature, concentrated salt solutions) that preserves their native surface charge density. Under these conditions, the Coulombic interactions between superionic nanoparticles are reminiscent of short-range intermolecular interactions. Our methodology was used to assemble oppositely charged NPs into high-quality superlattices exhibiting Catalan shapes. This methodology can be applied to a wide range of charged nanoparticles of various sizes, shapes, and compositions. I will also discuss how electrostatic interactions can be used to assemble nanoparticles into transient assemblies, whose lifetime depends on and can be controlled by the availability of a small-molecule ionic "fuel".

11:30 AM *SF01.03.06
Active Matter Swarms for Cargo Capture, Transport, and Delivery Ayusman Sen; The Pennsylvania State University, United States

Autonomous nano/microparticles are of great current interest due to their potential applications in cargo delivery, nanoscale assembly, robotics, fluidics, and chemical/biochemical sensing. Light provides a particularly useful means of manipulating motility since the stimulus can be applied remotely, patterned with a photomask, and readily translated to irradiate specified locations. A single particle generates a relatively small propulsive force and cannot be employed to transport a largo payload. As with social insects, such as ants, the solution lies in designing swarms of particles that can act cooperatively. Accordingly, the three outstanding challenges in the expanding field of autonomous nano/microparticle systems are: 1) to design fuel-free systems in which directed motion of nano/microparticle swarms can be powered solely by light, 2) to demonstrate function that can only be carried out by swarms, rather than by individual particles, and 3) to repeatedly pickup, transport, and deliver multiple cargo types. We will simultaneously showcase all three capabilities using titanium dioxide microparticle swarms. The swarms can be moved directionally using light. The swarms can collect and release a variety of inert cargo particles on demand. Moreover, the cargo particles of different sizes can be sorted and released sequentially.

SESSION SF01.04: Smart Functions of Stimuli-Responsive Materials IV
Session Chairs: Noemie-Manuelle Dorval Courchesne and Olga Kuksenok
Tuesday Afternoon, November 29, 2022
Sheraton, 5th Floor, The Fens

1:30 PM *SF01.04.01
Actuation of 3D Printed Nanocolloidal Hydrogel with Structural Anisotropy Eugenia Kumacheva; Univ of Toronto, Canada

Polymer hydrogels exhibit actuation properties that result in stimulus responsive reversible shape transformations and have promising applications in soft robotics, drug delivery systems, sensors, and microfluidic devices. Actuation occurs due to differential hydrogel swelling and is achieved by modulating site-specific composition of hydrogel sheets, either laterally (in-plane), or via a bilayer approach.
We proposed a different strategy for hydrogel actuation that originates solely from its structural anisotropy. For 3D-printed single-layer hydrogels formed by cellulose nanocrystals (CNCs) and gelatin methacryloyl we showed that shear-induced orientation of CNCs results in anisotropic mechanical and swelling properties of the hydrogel. Upon swelling in water, planar hydrogels acquired multiple complex 3D shapes that are achieved by (i) varying CNC orientation with respect to the shape on the hydrogel sheet and (ii) patterning the hydrogel with the regions of shear-mediated and random CNC orientation. This study shows the capability to generate multiple shapes from the same hydrogel actuator based on the degree of its structural anisotropy. Furthermore, it introduces a biocompatible nanocolloidal ink with shear-thinning and self-healing properties for additive manufacturing of hydrogel actuators.

2:00 PM *SF01.04.02
3D Fabrication of Biohybrid Networks Using Protein Mechanophores Alshakim Nelson; University of Washington, United States

Bio-sourced and biodegradable polymers for additive manufacturing could enable the rapid fabrication of parts for a broad spectrum of applications ranging from healthcare to aerospace. However, a limited number of these materials are suitable for vat photopolymerization processes. Herein, we report a process to fabricate protein-based constructs using commercially available vat photopolymerization printers. Bovine serum albumin (BSA) is a single-chain nanoparticle that can be chemically derivatized with acrylate and methacrylate functionalities. Aqueous resins were formulated from these materials to produce complex 3D geometrical constructs with a resolution comparable to commercial resins. While BSA is often used in cell culture protocols and diagnostic assays, we demonstrate that BSA can serve as junctions within polymer networks to afford stiff hydrogels and bioplastics with unique physical properties. Protein-based shape-memory objects that utilize BSA as mechanophores will be highlighted as opportunities for future applications.

2:30 PM *SF01.04.03
Self-Healing Hydrogels—From Soft Robots to Self-Repairing Biomaterials Shyni Varghese; Duke University, United States

Polymer networks are widely used in biomedical and environmental applications. Hydrogels with “living” functions such as self-healing and stimuli-responsiveness are particularly attractive because of their ability to repair structural damages and adapt to the environmental changes. Furthermore, self-healing hydrogels with shear-thinning properties can be potentially used to deliver biomolecules or as building blocks towards in situ curing scaffolds. Herein, I will briefly discuss our efforts in creating self-healing hydrogels and harnessing their properties for applications in soft robotics and tissue repair.

3:00 PM BREAK

3:30 PM SF01.04.04
Modeling Hydrogels with Host-Guest Interactions—Focus on Pattern Formation and Restructuring Olga Kuksenok and Yao Xiong; Clemson University, United States

Pattern formation and reconstruction under external stresses plays an important role in defining functionality of a broad range of soft confined systems. Herein we focus on dynamic control of pattern formation and restructuring in hydrogels with host-guest interactions. We extend the three-dimensional gel Lattice Spring Model (gLSM) to capture the dynamics of the PNIPAAm hydrogels with pendant azobenzene moieties immersed into alpha-cyclodextrins (alpha-CD) solutions under the UV and visual light. While planar *trans*-azobenzene moieties can be recognized and efficiently accommodated by the alpha-CD cavities to form inclusion complexes, an exposure to UV irradiation drives the *trans*-to-*cis* photoisomerization and dissociation of the complexes. We first demonstrate that the proposed model accurately reproduces volume phase transitions in azobenzene-functionalized hydrogels with host-guest interactions reported in recent experiments. We then uze spaciotemporal variations in UV irradiation to control pattern formation in thin hydrogel films under the rigid and soft confinements and to control hysteresis loops. The soft confinement is introduced via illuminating the ridges of the thin hydrogel samples with UV light and thereby introducing localized regions with higher rigidity. We show that controllable feedback mechanisms can be introduced into the networks with host-guest interactions via well-defined illumination patterns.

3:45 PM SF01.04.06
Biotemplating of Functional Nanomaterials into Magnetically Driven Microrobots for Biomedical Applications Carlos Franco Pujante[1], Salvador Pane i Vidal[1] and Josep Puigmartí-Luis[2]; [1]ETH Zurich, Switzerland; [2]Universitat de Barcelona, Spain

In micro and nanorobotics research, while a significant body of small-scale device investigation has been dedicated to building artificial versions of nature, other studies have exploited biological structures as templates or scaffolds to engineer robotic devices or machinery. This approach, known as Biotemplating, offers a robust methodology for manufacturing small-scale devices (i.e., micro and nanorobots) with potential applications in different fields like biomedicine.

Herein, we present a universal biotemplating approach that uses naturally occurring helical architectures to obtain controlled 3D assemblies of nanocrystalline of various functional materials like metal-organic frameworks (MOFs), piezoelectric nanoparticles, and 2D materials. Our process exploits Spirulina platensis, filamentous cyanobacteria with a helical body, which provides the shape of the final composite microstructure. Next, we create a magnetic helical chassis on top of the Spirulina platensis, which is subsequently coated with various functional nanocrystals. The resulting composite helical structure is a highly integrated, magnetically driven functional material-based microrobot.

In particular, taking advantage of these highly tunable materials, we demonstrated outstanding localizing drug delivery when biocompatible porous materials like Mil-100 nanoparticles are integrated with our magnetic biotemplates.
Additionally, the inclusion of piezoelectric nanoparticles like Barium Tinante (BTO) allows us to fabricate magnetically driven microrobots with the capacity to degrade fibril proteins, such as Aβ-42 amyloid aggregates, involved in Alzheimer's disease. Our studies demonstrated that, under low-power ultrasound stimulation, the piezoelectric microbots generate reactive oxygen species (ROS) that can disintegrate the protein aggregates into smaller amyloids in less than one hour.
Finally, the unique physicochemical properties of 2D-Materials like Molybdenum Difsufice (MoS2) grats the microrobots with the ability to locally increase the temperature. Our microrobots offer exceptional capabilities for photothermal ablation, inducing cancer cell killing with similar efficiency as state-of-the-art chemotherapeutic drugs.
Moreover, the chemistry of the MoS2 can be easily modified in order to achieve additional functionalities. For example, we show that the microrobots can also serve as on-the-fly biorecognition platforms by decorating their surface with streptavidin-functionalized gold nanoparticles, which can selectively capture and transport biotin-coated microbeads.

In summary, we have created a universal biotemplating-based methodology to fabricate 3D helical assemblies with functional nanocrystals. Taking advantage of the specific chemistry associated with each kind of functional material, we are able to tune the microrobots to the application of interest. The countless possibilities of our newly introduced biotemplated methodology are only matched by the amount of different functional systems and their specific properties, opening the door to a vast number of application in micro and nanorobotics.

4:00 PM SF01.04.07
One-Step, Rapid 3D Printing of Multi-Stimuli-Responsive Bilayer Structures for Microscale Actuators and Sensors Xiao Huan and Ji Tae Kim; The University of Hong Kong, China

Microscale stimuli-responsive structures play an important role in micromechanical systems as they can serve as sensors or actuators [1-5]. However, the development of simple and rapid methods for their fabrication remains an unsolved challenge[6-8]. Here, we present a one-step, bi-material 3D printing method for fabricating multi-stimuli-responsive microactuators[9]. A two-phase femtoliter meniscus formed on a theta micropipette is used to print a freestanding bilayer microstructure with programmed shape and composition, which undergoes an asymmetric volume change upon the adsorption or desorption of water. The printed bilayer structures exhibit reversible, preprogrammed actuation under time-varying humidity and infrared (IR) light stimuli. Furthermore, the method provides unprecedented process simplicity in multi-segmented structuring, configuring useful microscale moves such as gripping micro-objects. In this talk, I will also discuss the potential of our method to afford a diverse class of smart-bilayer devices such as actuators, sensors, and energy harvesters, by diversifying printing materials.

IR-Responsive Plasmonic Indium Tin Oxide/Polyketone Nanocomposites with Fast Self-Healing Features Andrea Pucci[1], Alessio Gabbani[1], Francesco Pineider[1], Virgilio Mattoli[2], Valentina Cappello[2], Mauro Gemmi[2], Arianna Mazzotta[2], Esteban Araya Hermosilla[2], Marina Ruggeri[1], Francesco Picchioni[3], Ranjita Bose[3] and Felipe Orozco[3]; [1]University of Pisa, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]University of Groningen, Netherlands

Materials endowed with (very) fast self-healing are highly demanded to get rid of polymer pollution and enhance the materials service life. On this account, in this contribution, nanocomposites with rapid self-healing thermo-responsive characteristics were proposed and based on the homogeneously dispersed indium tin oxide (ITO) nanocrystals (NCs). ITO NCs were used as an infrared photothermal source due to to their remarkable near-infrared (NIR) plasmonic properties and visible transparency. A furan grafted polyketone (PKFU) was utilized as supporting polymer matrix and obtained by the Paal-knorr functionalization of PK and crosslinked via the Diels-Alder (DA) reaction of an aromatic bismaleimide. Nanocomposites containing the 0.4−1.5 wt% of ITO NCs showed strong NIR absorption and, once exposed to IR irradiation, displayed fast heating (30 seconds) up to temperatures higher than 160 °C and superior to 60 °C gathered by the bare PKFU. The addition of ITO NCs did not affect the thermal behaviour of the matrix with the retro-Diels-Alder onset at 95 °C and the softening point at 50 °C that triggered the healing process. It was worth noting that the nanocomposite containing the 0.9 wt% of ITO NCs displayed the fastest healing rate that occurred after 1 second of IR irradiation, i.e. significantly faster than 50 seconds required for the bare crosslinked PKFU.

SESSION SF01.05: Smart Functions of Stimuli-Responsive Materials V

Stimuli Responsive Covalent Nanogels—A Chemically Versatile Drug Delivery Platform Nazila Kamaly; Imperial College London, United Kingdom

Nanogels are hydrogels within the nanometer range consisting of crosslinked porous polymer networks with the ability to retain high volumes of water or biological fluids whilst maintaining their structure. They have a wide range of chemical flexibility in their design, allowing their characteristics such as size, charge, degree of porosity and degradability to be easily tuned by the choice of monomeric building blocks. Since nanogels can retain a high volume of water, they are extremely biocompatible. This excellent and unique property makes them an ideal nanoplatform for the delivery of biological drugs such as enzymes and proteins. Nanogels are prepared via polymerization of monomers or precursors by chemical crosslinking or via physical crosslinking of preformed polymers via amphiphilic or electrostatic interactions. In particular, covalently crosslinked and co-polymerized nanogels (Figure 1) have superior properties as they offer: 1) encapsulation stability for biologically sensitive payloads, 2) they have low immunogenicity and toxicity, and can be designed to be fully biodegradable, 3) multiple biological payloads can be delivered in a single nanogel, facilitating combination therapies, 4) their synthesis can be aqueous based and easily scaled, and 5) they are soft nanoparticles that can easily squeeze through restricted sites under hemodynamic shear flow. In this manner, nanogels are the ideal delivery platform for biological drugs especially since biological therapeutics can be encapsulated into nanogels using mild aqueous reaction conditions. In this talk I will present some of our work on stimuli-responsive nanogels.

Multiresponsive Hydrogels as Smart Materials for Actuator and Sensor Functions in Microfluidic Application Brigitte Voit[1,2]; [1]Leibniz Institute of Polymer Research Dresden, Germany; [2]Technische Universität Dresden, Germany

Responsive polymeric materials are becoming a highly studied field especially with regard to their use in technical applications, e.g. as sensors and actuators in microsystems and microfluidic applications, since they are able as volume gels to carry out mechanical work reacting on e.g. chemical stimuli. In addition, compartimentalization becomes an issue for being able to localize specific actions and reactions e.g. by patterning specific hydrogel compartments. We will report on the preparation and integration of responsive and biocompatible hydrogel dots and hydrogel dot arrays of high flow and shear stability in microfluidic channel and chamber reactors. For that, multiresponsive hydrogels are developed making use of interpenetrating network approach and the concept of graft copolymer networks for retaining responsivity for up to four different stimuli in one hydrogel.[1] The hydrogels have been adapted for integration into microfluidic devices as volume-changing gels, adjusting degree of swelling as well as mechanical stability and allowing their use as effective sensors and actuators as needed for a chemical valve function. First examples of their use as chemical transistors and the development of logical modules for achieving basic logic gate functions through a microfluidic setup are shown.[2] Further optimization has been achieved by combining in double-crosslinked systems permanent and dynamic and reversible crosslinking points introducing redox functions and host-guest interactions.[3,4,5] The dynamic responsive behavior could be translated into micrometer hydrogel dots in microsystems combining actuator function with specific bioresponse. First results are presented to use reversible redox bonding in hydrogels for triggered peptides capturing.[6]

9:15 AM *SF01.05.03
Rational Molecular Design of Stimuli-Responsive Conjugated Functional Materials for Optical Biosensors Jinsang Kim; Univ of Michigan, United States

Conjugated polymers (CPs) and organic molecules have become emerging materials for many modern technologies due to their readily tunable properties by variation of chemical structure and easy fabrication. Particularly the stimuli-responsive properties have gained much interest in sensor application of conjugated organic and polymeric materials. Our self-signaling optical sensors are designed to achieve high sensitivity by means of the external stress-responsive optical property of conjugated polymers. Receptors are rationally designed to provide specificity toward a target analyte to realize high selectivity. DNA aptamer design, specific chemical reaction, secondary bonding, lipid molecule, and antibody-antigen interaction have been utilized in the receptor design. The concept, design principles, and applications of polydiacetylene-based optical sensory systems for the detection of DNA, proteins, metal ions, influenza virus, antibiotics, prostate specific antigen, nerve agents, platelet activation, and melamine will be discussed.
Novel sensory systems based on emissive super-cooled liquids and metal-free purely organic phosphors (POPs) will also be briefly presented. In our recent development of highly emissive and metal-free purely organic phosphorescence materials for the last decade, directed intermolecular heavy atom effects were rationally implemented in aromatic carbonyl molecules to promote spin-orbit coupling and suppress vibrational dissipation. Due to rather slow electron spin flipping of POPs, the slow phosphorescence feature renders highly sensitive oxygen quenching via energy transfer from POP's triplet state to surrounding oxygen molecules in the ground state. This unique phenomenon has been utilized in a newly devised lipid-polymer hybrid POP turn-on nanoprobe for chorioretinal hypoxia detection *in vivo* using rabbit retinal vein occlusion and choroidal vascular occlusion models.

Non-Viral Nanocarriers for the Delivery of Nucleic Acids and Genome Editors Sarah Gong; University of Wisconsin–Madison, United States

The CRISPR/Cas9 system is a revolutionary and versatile genome editing technique with wide-ranging utility. It can target and edit disease-causing mutations in a sequence-dependent manner, resulting in a permanent genetic change and thus offering the promise to cure genetic diseases. *In vivo* somatic genome editing using CRISPR/Cas9 is anticipated to be the next wave of therapeutics for many major health threats. However, one major hurdle to clinical translation of the CRISPR-based gene therapy is the lack of safe and efficient delivery systems for the CRISPR genome editors. We sought to develop customizable, safe and efficient nanoplatforms to deliver a wide range of biologics *in vitro* and *in vivo*. Our design criteria include (1) good biocompatibility, (2) high loading content and loading efficiency, (3) excellent stability before reaching the target cell, (4) high specificity to target tissue/cell, (5) high cellular uptake, (6) efficient endosomal escape capability, (7) rapid release of the cargo inside the cytosol via a stimuli-responsive release mechanism, (8) efficient transport to the nucleus, and (9) ease of production, storage, and transport.

Following this set of design criteria, we have engineered several types of multifunctional nanocarriers for safe and efficient delivery of biologics during the past few years, including polymeric Cas9/sgRNA ribonucleoprotein (RNP) nanocapsules [1], GSH-responsive silica nanocapsules [2], and self-assembled polymeric RNP or RNP-ssODN nanoparticles [3]. Our judiciously designed nanocarriers can encapsulate various types of payloads (i.e., DNA, mRNA, Cas9/sgRNA RNP, Cas9 mRNA/sgRNA, base editor, etc.) with high loading contents and high loading efficiencies. The versatile surface chemistry allows for surface PEGylation and/or targeting ligand conjugation that improves the pharmacokinetics and cell/tissue-specific delivery efficiency. These nanocarriers can induce high transfection efficiency/genome editing efficiencies *in vitro* and *in vivo* in different cells/tissues without apparent toxicity. Specifically, through local or systemic administrations, our nanocarriers were proved to be effective in transfection or genome editing in neurons and astrocytes in the brain (via both local and systemic delivery), retinal pigment epithelium (RPE) cells in the retina (via subretinal injection), myofibers and satellite cells in the muscle (via intramuscular injection), epithelial cells in the lung (via intratracheal administration), and hepatocytes in the liver (via intravenous injection). Moreover, the in vivo biocompatibility and immunogenicity of these nanocarriers after systemic or local administrations were demonstrated by systematic investigation of the blood biochemical parameters, inflammatory cytokines and organ/tissue histology. Thus, we anticipate that these multifunctional nanocarriers can be further tailored to enable gene therapy for many different types of diseases including Alzheimer's disease, Duchenne muscular dystrophy, and cystic fibrosis.

10:45 AM SF01.05.06
Active Molecular Junctions with Sub-Nanometer Tunability for Reconfigurable Nanosystems Farnaz Niroui; Massachusetts Institute of Technology, United States

Controlled and reversible mechanical reconfiguration is core to embedding intelligent and adaptive performance within devices. Achieving such tunability at the nanoscale is a fundamental challenge. As dimensions are reduced to the few nanometers, surface adhesive forces become dominant causing instability and irreversible collapse in mechanically mobile structures. We present a platform in which mechanically reconfigurable molecular layers with engineered mechanical properties are used as tunable interconnects between neighboring surfaces. In this design, molecular layers serve as nanoscale springs to balance out the surface adhesive forces, enabling a controlled and reversible reconfiguration. Utilizing this hybrid organic-inorganic platform, which can be stimulated electrostatically or thermally, we demonstrate sub-10 nm active structures with < 1 nm precision in tuning. With these tunable building blocks, we achieve active modulation of optical and electrical responses which we further use to demonstrate applications in reconfigurable nanoscale devices and active surfaces.

11:00 AM SF01.05.09
Morphing and Color-Changing Liquid Crystal Elastomer Structures for Soft Robotics Xueju Wang and Yi Li; University of Connecticut, United States

The large, reversible shape-changing behaviors of liquid crystal elastomers (LCEs), resulting from liquid crystal-polymer network couplings, are promising for many applications. Despite intensive studies, harnessing molecular-material-structure interactions of LCEs for the design of locally controlled shape-morphing structures remains a challenge. In this talk, I will present our recent effort on a facile and versatile strategy to tailor the stiffness and the morphing behavior of reconfigurable LCE structures via locally controlled mesogen alignment and crosslinking densities. Selective photopolymerization of

spatially aligned LCE structures yields well-controlled lightly and highly crosslinked domains of distinct stiffness and selective permanent mesogen programming, which enables various previously inaccessible stiffness-heterogeneous geometries, as demonstrated in diverse morphing LCE structures via integrated experimental and finite element analysis. Furthermore, reprogramming of the non-photopolymerized regions allows for reshaping, as shown in a sequentially shape-morphing LCE rod and "face". The heterogenous morphing LCE structures have the potential for many applications including in artificial muscles, soft robotics, and many others. In addition, I will introduce a simple strategy for creating 3D thermocromic LCE structures with synchronous shape-morphing and color-changing capabilities for biomimetic robotics.

1:45 PM SF01.06.03
Mesoscale Photomechanical Coupling in Photoactive Liquid Crystal Elastomers Ruobing Bai and Zhengxuan Wei; Northeastern University, United States

Some molecules can absorb light of a certain wavelength and change their shape, dissociate, or combine to form new molecules. Embedding these molecules into a rubbery liquid crystalline polymer network enables photoactive liquid crystal elastomers (LCEs) that generate large deformation and decent amount of mechanical work upon light illumination. Photomechanical actuation of photoactive LCEs has attracted increasing attention in recent years due to its wireless and fast energy transmission, rich tunability, capability of micromachines, and delivery of high energy density. New applications include photo-responsive robots, metamaterials, motors, optical waveguides, fibers, and other light-modulated devices. However, compared to an individual photoactive molecule, most existing macroscopic photoactive LCEs perform much poorer in their actuation performance (e.g., work output, thermodynamic efficiency, deformation) by orders of magnitude, severely limiting their application in real working scenarios. This contrast highlights an urgent research need for mechanistic understanding of photomechanics in these materials at the mesoscale (e.g., micrometer) that bridges a nanoscale molecule and a macroscale material. This talk will present our recent progress in such fundamental understanding of mesoscale photomechanical coupling. Incorporating the single molecule photoreaction and the long-range directional molecular interaction into a continuum theoretical framework, we investigate multiple interesting phenomena including tunable molecular alignment, photomechanical phase transformation and material instability, formation of microstructure, temperature-modulated photo-actuation, and their consequences in macroscopic applications.

3:00 PM SF01.06.05
Stimuli-Responsive Liposomal Drug Delivery Platforms for Controlled Release Jinchao Lou and Michael D. Best; University of Tennessee-Knoxville, United States

Liposomes are effective drug delivery nanocarriers due to their unique bilayer structure and versatile nature in encapsulating both hydrophilic and hydrophobic drugs within the hydrophobic bilayer and aqueous core, respectively. To control the time and location of cargo release, different triggered release strategies have been developed to minimize off-target effect as well as increase the drug potency. Commonly explored stimuli include internal stimuli (i.e. pH) or external stimuli (i.e. light). To expand the toolbox, here, we present novel strategies for targeting a variety of stimuli, all of which are proven to be upregulated in certain diseased cells and are closely related to numerous pathological conditions. To do so, lipids are designed to undergo chemical or conformational changes upon coming in contact with target stimuli. Such structural changes are expected to disrupt the membrane integrity and cause the release of encapsulated cargo when these lipids are incorporated within the membrane bilayer. For each case, the design and synthesis of the desired responsive lipids will be discussed. Fluorescence-based release assays to evaluate release properties utilizing both hydrophilic and hydrophobic dyes, as well as dynamic light scattering (DLS) analysis and scanning transition electron microscopy (STEM) techniques to probe the membrane property change before and after triggered release will also be presented.

2:15 PM BREAK

3:15 PM SF01.06.07
Metamaterial Sensing and Memory via Multistability and Viscoelastic Effects Katherine Riley and Andres F. Arrieta; Purdue University, United States

The concept of intelligence in materials is gaining increasing attention as a means to enhance the inherent responsiveness and adaptability of engineered systems. Basic changes in material properties, such as stiffness or density, or even larger scale reactions, such as shape memory, are well-established material responses to environmental stimuli, including shifts in temperature, pH, or humidity. Engineered metamaterials may incorporate these fundamental material responses in combination with multiscale structural architectures and carefully designed unit cells to achieve advanced functionalities, including programmable morphing, sensing, and memory.

In this research, we examine a polymer metamaterial composed of dome-shaped unit cells connected by a base membrane. The spatially distributed domes have varying geometries and corresponding stability properties. These metamaterials are cast or 3D printed using viscoelastic, polymeric materials, with embedded piezoelectric sensing strips composed of a polymer-based filament with conductive additives. The interaction of the material viscoelasticity with the structural mono, meta, or bistability of the unit cells allows for the metamaterial to have unique, time-dependent behaviors which may be used for distributed mechanical sensing and memory. These include the critical mechanosensing capabilities of nonlinear signal amplification and filtering and thresholding. Inspired by mechanosensors found in nature, the metamaterial amplifies mechanical signals above a predetermined threshold, corresponding to the minimum snap-through force of the domes, while filtering out those below this threshold. This amplification is due to the highly nonlinear strains experienced by the unit cell during snap-through. Furthermore, the viscoelastic behaviors of stress relaxation, creep, and creep recovery may be used to sense the time elapsed in a local stable state or since a snap-through event triggered by an environmental stimulus, such as a mechanical load or change in temperature. The phenomenon of pseudo-bistability, in which a unit cell structure exhibits bistability for only a limited amount of time due to viscoelastic

material relaxation, is particularly interesting as it allows the metamaterial to sense, react, and self-reset after a programmed delay. The pseudo-bistability may be further manipulated by exploiting thermal properties of the polymer material. These combined material and structural capabilities ultimately enable the metamaterial to sense and remember spatiotemporal patterns that convey information about the metamaterial's environmental history. This class of intelligent metamaterials that can sense and respond to distributed external stimuli over large areas have potential applications in a wide range of industries, including soft robotics, advanced packaging, and smart buildings.

3:30 PM SF01.06.09
Shell-Mediated Deformation and Fracture Behavior of Liquid Metal Particles for Mechanoresponsive Electronics Wilson Kong[1], Nicholas Morris[2,3], Zachary Farrell[2,1] and Christopher E. Tabor[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States; [3]Nextflex, United States

Responsive materials utilizing room-temperature liquid metals (LM) are gaining strong interest in flexible electronics, 3D printing, and biomedical therapeutics. The facile production of LM core-shell particles is enabled through the rapid formation of a passivating surface oxide that prevent LM droplets from coalescing. Rupturing these oxides can facilitate mechanically-responsive switching from electrically insulating to conducting states. While the relative ease of gallium oxide deformation is attractive for intrinsically stretchable electronics, the oxide shell dominates much of the LM mechanical behavior. Previous works show that this oxide matures over time under ambient conditions, which can increase the stiffness of the LM particles.[1] Chemical functionalization of LM particles have demonstrated ways to disrupt the oxide formation or hinder its growth.[2] However, the lack of complete control over the LM oxidation may introduce mechanical hysteresis into these materials systems. Furthermore, environmental conditions and dynamics of particle strain also play a large role in influencing this hysteresis. Therefore, having an improved understanding on the influencing factors towards LM particle rupture can potentially improve efforts in controlling its mechanical response. In this work, we demonstrate the deformation and fracture behavior for single-particles of eutectic Ga-In (eGaIn) alloy under variable conditions. Through in situ compression testing, this investigation focuses on the effects of 1) oxygen content, 2) compression rate, and 3) particle coatings that influences the eGaIn mechanical behavior. By coating eGaIn with materials having well-known mechanical properties (i.e., silica), we can supersede the properties of the gallium oxide and develop LM particles with predictable and tunable mechanical behavior under ambient conditions. Compared to oxide-coated eGaIn, SiO_2-eGaIn particles fracture in an abrupt and brittle manner. The silica shell thickness can be modified to change the mechanical properties of eGaIn particles as desired. With controllable stiffness and fracture behavior that is not dependent on the environmental conditions, these modified eGaIn particles can be explored for a variety of mechanoresponsive applications including pressure-sensitive solders or sensing devices.

Sensitive Determination of SARS-COV-2 and the Anti-Hepatitis C Virus Agent Velpatasvir Enabled by Novel Metal-Organic Frameworks Nageh K. Allam; American University in Cairo, Egypt

Herein, we report on the electrochemical determination of velpatasvir (VLP) as the main constituent of Epclusa, a SARS-COV-2 and anti-hepatitis C virus (HCV) agent, using a novel metal–organic framework (MOF). The NH_2-MIL-53(Al) MOF was successfully modified with 5-bromo-salicylaldehyde to synthesize 5-BSA=N-MIL-53(Al) MOF. The synthesized MOF has been characterized using Fourier transform infrared spectroscopy, X-ray powder diffraction, scanning electron microscopy, cyclic voltammetry, square wave voltammetry, and electrochemical impedance spectroscopy. The modified MOF showed higher electrochemical activity and response than the bare NH_2-MIL-53(Al) MOF. Compared to the bare carbon paste electrode (CPE), the 5-BSA=N-MIL-53(Al)/CPE platform was shown to enhance the electrochemical oxidation and detection of the anti-SARS-COV-2 and anti-HCV agent. Under optimized conditions, the 5-BSA=N-MIL-53(Al)/CPE platform showed a linear range of 1.11×10^{-6} to 1.11×10^{-7} and 1.11×10^{-7} to 25.97×10^{-6} M Britton–Robinson buffer (pH 7) with a detection limit and limit of quantification of 8.776×10^{-9} and 2.924×10^{-8} M, respectively. Repeatability, storage stability, and reproducibility in addition to selectivity studies and interference studies were conducted to illustrate the superiority of the electrode material. The study also included a highly accurate platform for the determination of VLP concentrations in both urine and plasma samples with reasonable recovery.

SF01.07.02
Probing Macromolecular Complexes with a Reconfigurable Nanoscale DNA Force Spectrometer Yuchen Wang, Michael Darcy, Ralf Bundschuh, Michael Poirier and Carlos Castro; The Ohio State University, United States

Single molecule force spectroscopy is a powerful approach to studying the structure of biological materials and their kinetic properties. Nevertheless, the probes limit integration into complex systems, and the cost and complexity of the equipment and assays limit broader use. DNA-based nanodevices are a promising alternative that allows for probing the force response of biomolecules such as nucleosome. Here, we build on these prior works to develop a nanoscale DNA force spectrometer (nDFS). Specifically, the nDFS allow for enhanced control over forces and especially the application of compression forces. Moreover, the readout from electron microscopy can provide the unique chance to observe the detailed sample structure conformation under force instead of end-to-end distance.
The hinge structure nDFS is fabricated by scaffold DNA origami, and it consists of two arms connected by several single-stranded DNA scaffold linkers. The device behaves like a torsional spring where the arms are stiff, and the mechanical properties are determined by the design of the hinge vertex. We demonstrated the ability to control both the equilibrium angle and stiffness by modifying the detailed vertex architecture. Specifically, the mean angle can be tuned over a range of 35 deg to 87 deg, which provides a passive approach to modulating forces applied by the nDFS. We also developed an active approach to the nDFS open or closed by forming or disrupting a DNA duplex strut between the arms, controlled via strand displacement. The toggling strategy is used to 1) apply compressive forces to a 249 bp double-stranded DNA (dsDNA) 2) and apply tensile forces to mon-nucleosome or tetra-nucleosome array, as proved experimentally. For future work, we seek to expand the applicability of nDFS to a broader experimental environment by enhancing the structural stability in low ionic conditions and increasing the force measurement range.

SF01.07.03
Soft-Robotic Actuations of Collectively Assembled Soft-Electronics Based on MXene/Liquid Crystal Elastomer Bilayer Woongbi Cho[1] and Jeong Jae Wie[2,1]; [1]Inha university, Korea (the Republic of); [2]Inha University, Korea (the Republic of)

To achieve remotely controlled shape-reconfiguration in miniaturized soft-electronics, liquid crystalline polymer with alignment programming is a great candidate to replace the passive deformation of stretchable electronics under mechanical tension. In this presentation, we introduce programmable and shape-reconfigurable and locomotive soft-electronics by preparing the MXene/liquid crystalline elastomer bilayer (MLB) with a concept of collective assembly. The high light-to-heat conversion efficiency and high electrical conductivity (~5,100 S cm^{-1}) of MXene layer enables MLB to perform photo-/electro-thermally driven reversible in-plane bending and torsional twisting according to offset angle of molecular alignment by near-infrared (NIR) light irradiation and voltage application. Importantly, the introduction of collective assembly enhances the diversity and functionality in shape-reconfiguration of MLB via attaching the ends of MLBs by utilizing the conductive paste. To demonstrate applicability as a soft-robotic system, we engineer the both geometries and alignment nature of applied MLBs blocks for assembly to achieve various remotely controllable dynamic motions including crawling, continuous rotation, as well as jumping and slingshot inspired actions via snap-through buckling.

SF01.07.04
Covalent Adaptable-Conjugated Polymer Network for Self-healing Electronics Laine Taussig[1], Cedric Plesse[2], Fabrice Goubard[2] and Aram Amassian[1]; [1]North Carolina State University, United States; [2]CY Cergy Paris Universite, France

Covalent adaptable networks (CAN's) have emerged as an innovative class of materials as they possess advantageous properties of both thermoplastics and thermosets enabling dimensional stability and dynamic response to external stimuli. With the addition of conducting nanoparticles, CAN's have been used to successfully fabricate electronically conducting composites that are mechanically and chemically robust and can self-repair, therefore extending the lifetime and application of soft electronics. In this work, an electronically conducting CAN is demonstrated by employing vinylogous urethane vitrimer and conjugated polymer poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS). To our knowledge, this system is the first fully organic electronically conducting vitrimer. Due to the nature of the covalent network, the material is chemically resistant to solvents, as it maintains a constant crosslink density, and is soft and bendable at room temperature. At elevated temperatures, the transamination exchange reaction is activated and accelerated in the presence of acidic PSS, therefore exhibiting fast reorganization and stress relaxation. We demonstrate temperature activated self-healing and shape memory functions of this material while maintaining conductivity above 100 S/cm. The findings shown here have promising potential for use in self-healing organic electronics such as sensors and wearable devices.

SF01.07.05
One-Step Droplet Fluidic Production of Multi-Component Conjugated Polymer Janus Microspheres with Integrated Photonic, Magnetic and Catalytic Microswimmer Functionality Chenxi Hao, Liam Jowett and Gareth Redmond; University College Dublin, Ireland

Conjugated polymers have been extensively investigated with respect to potential applications in diverse areas ranging from opto-electronics to energy conversion to life sciences. Technological embodiments usually involve thin polymer films or, for applications in aqueous or biological media, the covalent modification of polymer molecules by incorporation of polar or ionic functionalities. In this study, we explored simple conjugated polymer microspheres where manipulation of microsphere morphology, composition, surface functionality, and sphere-environment interactions, respectively, permit investigation and demonstration of stimulus-responsive behaviors.

Specifically, we applied digital droplet fluidics to the production of size monodisperse conjugated polymer-based microspheres. To this end, using real-time *in situ* (on-chip) optical imaging methods, we developed a T-junction microfluidic droplet generation technology for the production of aqueous suspensions of surfactant-stabilised micro-droplets that contain fluorescent conjugated polymer and associated organic solvent. Collection of droplets followed by gradual solvent extraction results in the formation of 'hardened' spherical polymer micro-particles whose morphological, compositional and optical properties can be studied using appropriate methods. We selected poly[2-methoxy-5-(2'-ethylhexyloxy)-1,4-phenylene vinylene] (MEH-PPV) as a reference conjugated polymer as the ethyl-hexyl side chains provide for good solubility in many common organic solvents. We studied MEH-PPV/$CHCl_3$ droplet formation in surfactant/water flows and systematically varied parameters, such as, relative flow rates of the phases, surfactant concentration, polymer concentration, and polymer molecular weight to identify effects on MEH-PPV microsphere morphological and spectroscopic properties. In addition, a range of other solvents and co-solvents, e.g., toluene, DCM, EtOAc, MeCN, porogens, e.g., 2-methyl-pentane, and surfactants, e.g., oleic acid, were also screened. Imaging studies were extensively employed for morphology characterisation and data were combined with spectroscopy data to build a comprehensive process-property map for this system. In addition, real-time *in situ* optical imaging of the progress of solvent extraction permitted elucidation of the mechanism of surface 'dimpling' during the formation of morphologically textured emissive MEH-PPV microspheres.

By including additional components in the organic phase, the microfluidic approach was extended to the single-step formation of biphasic 'Janus' or 'snowman' microparticles composed of emissive MEH-PPV and biocompatible, biodegradable poly(D,L-lactide-*co*-glycolide) (PLGA) as well as triphasic, 'multi-lobed' PLGA-MEH-PPV-PLGA micro-particles characterised by correlative confocal fluorescence-SEM. Further incorporation of superparamagnetic oleic-acid stabilised Fe_3O_4 nanoparticles permitted the formation of magnetic field-responsive fluorescent MEH-PPV-PLGA Janus particles that behaved as a type of active matter that exhibited magnetic field-induced liquid-solid extraction and other dynamic phenomena, such as, field-assisted single-particle lateral translocation and dipole-mediated multi-particle chaining both of which were monitored during real-time *in situ* imaging studies. In addition, these particles exhibited a well-defined fluorescence quenching response in the presence of electron deficient model organic compounds that permitted demonstration of low threshold detection of volatile nitroaromatics. Finally, asymmetric photoinduced deposition of Pt islands on Janus microparticles of PCBM/MEH-PPV-PLGA with embedded oleic-acid stabilised Fe_3O_4 nanoparticles permitted the fabrication and demonstration of novel magnetic field responsive catalytic microswimmers.

SF01.07.06
Enzyme Responsive Rigid-Rod Aromatics Target "Undruggable" Phosphatases to Kill Cancer Cells in Mimetic Bone Microenvironment Meihui Yi[1], Fengbin Wang[2], Weiyi Tan[1], Jer-Tsong Hsieh[3], Edward H. Egelman[2] and Bing Xu[1]; [1]Brandeis University, United States; [2]University of Virginia, United States; [3]University of Texas, United States

Bone metastasis remains a challenge in cancer treatment. Here we show that enzymatic responsive rigid-rod aromatics, acting as the substrates of "undruggable" phosphatases, to kill cancer cells in mimetic bone microenvironment. By phosphorylating the hydroxyl and conjugating nitrobenzoxadiazole (NBD) to the carboxylate of hydroxybiphenylcarboxylate (BP), we obtained pBP-NBD (**1P**) as a substrate of both acid and alkaline phosphatases. **1P** effectively kill both metastatic castration-resistant prostate cancer cells (mCRPCs) (e.g., VCaP or PC3) and osteoblast mimic cells (Saos2) in their co-culture. Fluorescent imaging reveals that **1P** enter Saos2 almost instantly to target the endoplasmic reticulum (ER) of the cells and that co-culturing with Saos2 cells boosts the cellular uptake of **1P** by mCRPCs. Using cryo-EM, we determined the nanotube structures of both enzyme substrate **1P** (2.4 Å

resolution, pH 5.6) and enzymatic processed compound **1** (2.2 Å resolution, pH 7.4). The helical packing of both nanotubes is identical, held together by strong pi-stackings interactions. Besides reporting the atomistic structure of nanotubes formed by the assembly of rigid-rod aromatics, this work expands the pool of molecules for designing EISA substrates that selectively target TME.

SF01.07.07
Fast and Large Motion of Self-Oscillating Gels Based on High Diffusivity Induced by Phase-Separated Structures Jaewon Choi[1], Taehun Chung[1], Ryo Yoshida[2] and Younsoo Kim[1]; [1]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [2]The University of Tokyo, Japan

Unlike conventional stimuli-responsive gels, self-oscillating gels can spontaneously repeat swelling/de-swelling without on-off switching of external stimuli such as temperature, pH, etc. This mechanical oscillation is achieved by inducing the Belousov-Zhabotinsky (BZ) reaction. [1] Due to these characteristics, they have been attracting attention, as they can be utilized as biomimetic and living materials showing heartbeat-like motions. However, the degree of swelling/de-swelling change that causes mechanical oscillation of the gel was usually small and slow. In addition, for the overall mechanical oscillation of the gel, the size of the gel must be smaller than a chemical wave of several hundred micrometers, so the entire swelling/de-swelling oscillation has not yet been shown in the bulk-scale gel of centimeters or more. Furthermore, the BZ reaction required strong acidic conditions, and the duration of this reaction was short. These problems could be overcome by using specific hydrated protic ionic liquids (PILs) as an alternative medium for the BZ reaction. [2] However, no oscillation was observed in conventional self-oscillating gels because of the low diffusivity of the BZ substrates into the gels in the highly viscous solution, such as hydrated PILs. [3]
Herein, we designed novel self-oscillating gels showing fast and large deformation by tuning the internal structure of the gels. Using the collapsed form of poly(*N*-isopropylacrylamide) in a salt solution, it is possible to synthesize the phase-separated structures showing fast and large shrinkage of the gels. [4] We prepared the poly(NIPAAm-*co*-Ru(bpy)$_3$) gel with the phase-separated structures, and it was immersed in a catalyst-free BZ solution containing the substrates (malonic acid, sodium bromate, and nitric acid or hydrated PILs). Interestingly, our phase-separated gels can oscillate even in a highly viscous solution owing to its high diffusivity. Furthermore, our gel exhibited a fast propagation rate and long wavelength of the chemical wave. As a result, even in centimeter-scale bulk gels, overall swelling/de-swelling oscillations could be exhibited, an unprecedented oscillation that significantly improved the dimension of oscillations. This presentation will discuss the synthetic strategy of self-oscillating gels and their improved performance on oscillation period, amplitude, and diffusivity.

Tuning Chiro-Optoelectrical Signals Enabled Precise Patterning for Encryption Application Moon Jong Han, Minkyu Kim and Vladimir Tsukruk; Gerogia Institute of Technology, United States

Multifunctional biomolecules for organic field-effect transistors (OFETs) based on chiral photonics have received much attention for next-generation optoelectronics including quantum information and encryption as well as integrated logic circuits. Despite recent advances, OFETs for encryption applications responding to both humidity and light, exhibiting reconfigurable and multivalued logic systems, are not reported. Herein, a simple and promising approach for highly secure optoelectronic encryption by facilitating humidity-sensitive chiral pitch of cellulose nanocrystals (CNCs) dielectric layer is suggested. By the addition of salt into the photonically-active chiral nematic CNCs network, the remarkable photonic band gap is shifted, converting into distinguishable and quantized electric signals directly depending on repetitive change and humidity, and incident wavelength of light. The interdisciplinary convergence between CNC nanotechnology and the multivalued logic system can provide optoelectronic counterfeiting, imaging, and information processing with logic nodes triggered by the polarization of light, humidity, and salt concentration. As a proof-of-concept, the integrated circuits sensing circularly polarized light and humidity are demonstrated as a physically unclonable functional device.

Accelerated DNA Hydrogel Self-Assembly via Single Base-Pair Mismatch for Enzyme-Free Picomolar MicroRNA Detection Hyebin Na, Jae Chul Park and Yoon Sung Nam; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Over decades the demand for point-of-care testing (POCT) has increased due to the outbreak of global pandemics caused by infectious diseases. There are substantial developments in the POCT systems targeting microRNAs (miRNA) which regulate the expression of various target genes. To make POCT possible, the enzymatic amplification should be replaced because of the difficulties rising from enzyme storage and handling. We use a target-catalyzed toehold-mediated strand displacement (TMSD) cascade with three hairpin DNAs for the enzyme-free isothermal amplification technique. Furthermore, we assembled Y-shaped DNA products formed by TMSD cascade reaction into a hydrogel using biotin-streptavidin interaction, following a closely-packed three-dimensional network of Förster resonance energy transfer (FRET) donor and acceptor. The signal amplification was 4.8 times higher than that without hydrogel assembly. However, the hydrogel-based miRNA detection system shows a limit of detection (LOD) of 1.5 nM, which is similar to that of the system without amplification. The low sensitivity is caused by the low TMSD reaction affinity between RNA and DNA, which has around 35 times lower reaction rate constant than that of DNA and DNA. Herein, we present a new system using a single mismatch to the stem of the hairpin DNA. The mismatch lowers the local stability of hairpin DNA and accelerates the cascade TMSD reaction. For empirical verification, we introduced a mismatch in each of the three hairpin DNAs for the TMSD cascade system. The mismatch-induced accelerating only works with the first hairpin DNA, which supports our theory that the RNA-DNA TMSD is the rate-limiting reaction, not the DNA-DNA TMSD. We also investigated the effect of the mismatch position by comparing the first hairpin DNAs with a mismatch at the 5 th, 9 th, and 13 th nt from the toehold. The system with 5 th nt mismatch was the one with the most rapid and efficient reaction. The results suggest that the mismatch near the toehold efficiently facilitates the opening of the hairpin DNA by miRNA. The mismatch-induced thermodynamic driving method dramatically improves the LOD sensitivity from 1.5 nM to 60 pM. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (2020R1A2C2004168).

Electro-Mechanical Leak Detection System Utilizing Conductive Fluids Morgan A. Payne, J Tayler Quinn, Eric Balle and Allyson Causey; Texas A&M University, United States

Due to the chemical recovery process employed within Black Liquor Recovery Boilers, the Pulp and Paper industry experiences a unique problem when a leak or fault occurs in a bottom floor composite tube. Water leaking from these tubes into a surrounding smelt bed poses the potential for catastrophic losses as it reacts violently and instantaneously with the smelt bed's high sodium and sulfur content. The acoustic sensing techniques and methodologies currently utilized for the detection of leaks within these systems, despite being universally accepted, are unreliable and erroneous. The acoustic detection system relies on the propagation of minute vibrations along these boiler tubes and throughout the smelt bed. The dampening effect of the smelt bed on these vibrations presents a significant problem for this system, often resulting in undetected leaks. An electro-mechanical leak detection system, utilizing conductive fluid coating, was designed, and operated to enhance detection response time, based on the necessity for the improvement of the current leak detection systems employed within Black Liquor Recovery Boilers. This detection system provided continuous identification via live resistance measurements of a conductive fluid layer applied to the surface of the boiler tubes. When a leak or fault occurred, the disruption of the coating's surface area resulted in a detectable resistance change. To demonstrate the system's improved accuracy and real time performance in the recognition of leaks and faults compared to the current acoustic detection, the system was implemented and evaluated with various scenarios. The results proved this prototype system can alert an operator to a leak in 20 seconds. This research into the utilization of conductive coatings, specifically within an electric leak detection system for Black Liquor Recovery Boilers, provides a starting point for continued research on the industrial applications of conductive fluids.

SF01.07.11
***Diphylleia grayi*-Inspired Hydrochromic Adhesive PDMS Film Using Nano Sphere Lithography** SeungJe Lee[1], Minji Ko[1], Gang Yeol Yoo[2], Keyong Nam Lee[1], Yun Jae Eo[1] and Young Rag Do[1]; [1]Kookmin University, Korea (the Republic of); [2]KOREA ELECTRONICS TECHNOLOGY INSTITUTE, Korea (the Republic of)

Many living things in nature have the ability to change their colors, and this has inspired the development of bio mimetic technology, such as flexible information display devices, color control applications, and energy-free applications. Inspired by the ability of *Diphylleia grayi* to become transparent on rainy days, we developed a hypochromic adhesive PDMS film. We produced a *Diphiylleia grayi*-inspired PDMS film by forming a nanocavity structure on the surface of a PDMS (Polydimethylsiloxane) film based on Mie theory. The formation of nanocavities on the PDMS surface induced scattering, reducing the surface transmittance, and leading to transparency in wet state. Nanocavity structures were fabricated using polystyrene (PS)-based nanosphere lithography (NSL) and PDMS transfer methods. Nanosphere lithography using polystyrene beads is suitable for forming various cavities because the process makes it easy to adjust the diameter via reactive-ion etching (RIE). Scattering-induced PDMS films were optimized using polystyrene beads of various sizes (0.2, 0.4, 0.6, 1.0, and 2.0 μm). The greatest contrast between wet and dry states was shown in the 1.0 μm cavity structured PDMS film (44.93% (ΔTD) T = 59.11-14.18%) and 54.88% (ΔH = 69.42-14.54%)). The optimized film with 1.0 μm nano-pores suggests the possibility of application to various water-changing applications that require color change, such as smart windows, camouflage, and transparent umbrellas for rainy weather. To improve the wettability of the PDMS surface, polyvinyl alcohol (PVA) was used to modify the surface. The PDMS film surface was measured with a scanning electron microscope (SEM). The scattering effect of the nano-cavity structure was measured by UV-visible spectroscopy, and the haze value was measured using a hazemeter.

SF01.07.12
Fabrication of Graphene-Incorporated Thermoresponsive Nanocomposite Hydrogels with Precision Control of Programmable Actuation Jisu Hong, Jiseok Han and Chaenyung Cha; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Hydrogels capable of stimuli-responsive deformation are widely explored as intelligent actuators for diverse applications. It is still a significant challenge, however, to "program" these hydrogels to undergo highly specific and extensive shape changes with precision, because the mechanical properties and deformation mechanism of the hydrogels are inherently coupled. Herein, two engineering strategies are simultaneously employed to develop thermoresponsive poly(N-isopropyl acrylamide) (PNIPAm)-based hydrogels capable of programmable actuation. First, PNIPAm is copolymerized with poly(ethylene glycol) diacrylate (PEGDA) with varying molecular weights and concentrations. In addition, graphene oxide (GO) or reduced graphene oxide (rGO) is incorporated to generate nanocomposite hydrogels. These strategies combine to allow the refined control of mechanical and diffusional properties of hydrogels over a broad range, which also directly influences variable thermoresponsive actuation. It is expected that this comprehensive design principle can be applied to a wide range of hydrogels for programmable actuation.

SF01.07.13
A Reprogrammable Pixelated Metamaterial with Rich Mechanical and Shape-Shifting Reconfigurability Jun Kyu Choe, Jiyoon Lee, Hajun Lee, Yeonwoo Jang, Hyeonseo Song and Jiyun Kim; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Mechanical metamaterials refer to collectively structured forms of unique micro-architectures that can exhibit previously unattainable properties, such as negative Poisson's ratio, programmable shape transformation, negative or tunable coefficients of thermal expansion, and high stiffness-to-weight ratio structures. Traditional mechanical metamaterials were fabricated with simple designs using rigid bodies connected with mechanical hinges, but recent efforts to exploit soft materials with instabilities and stimuli-responsive materials have opened the avenues for mechanical metamaterials which can demonstrate dramatic shape and mechanical reconfigurability. These reconfigurable soft architectures that respond to their environment have various potential applications, such as soft robotics, flexible electronics, and human-machine interfaces (HMI). However, most shape-shifting mechanical metamaterials presented to date focused on increasingly complex structures with predetermined mechanical properties that cannot be altered post-fabrication, while stimuli-responsive metamaterials produced only simple, homogeneous changes in mechanical properties.
We introduce a real-time reprogrammable shape- and rigidity-morphing metamaterial, where the stiffness of each unit micro-architecture of a pixelated structure is independently controlled on-demand, producing rich shape reconfigurability and tailoring capability of local or global mechanical properties. This concept is realized through harnessing solid-liquid phase transition of low-melting-point-alloy (LMPA) layers, discretely embedded inside each unit cell of an elastomeric endoskeleton, originally designed to show buckling-induced auxetic behavior. The selective stiffness control of each pixel releases a tremendous number of hidden states driven by different deformation mechanisms and patterns. The morphed shape can be further permanently maintained without requiring external stimuli or energy inputs for the load-bearing applications especially when the materials need to actively transform to adjust to circumstances. Finally, we show that local stiffness tuning can be leveraged for the global mechanical characteristics, enabling multi-state analog control of the stress-strain characteristics and Poisson's ratio of the material between two extreme states.

SF01.07.14
Transparent Liquid-Solid Interface Triboelectric Nanogenerators with Silver Nanowires Onuralp Cakir[1], Doga Doganay[1], Melih O. Cicek[1], Sahin Coskun[2] and Husnu E. Unalan[1]; [1]Middle East Technical University, Turkey; [2]Eskisehir Osmangazi University, Turkey

Triboelectric nanogenerators (TENGs) have been of great interest since they were proposed. Power is generated by static electricity caused by the contact of two separate surfaces. Therefore, any place where there is motion can be an effective work place for smart TENGs to be used as both self-powered sensors and energy harvesting units. In this study, the use of optimized Ag NW network in a liquid-solid interface triboelectric nanogenerator system as the current collector layer is explored. A thin PDMS layer is spin coated onto the Ag NW network to fabricate transparent TENG electrodes. The triboelectric

response between the water droplets and the PDMS layer is investigated. The TENG device is found to produce up to 1.8 V and 40 nA per water droplet. The resulting transparent self-powered sensor with optimized Ag NW network is suitable for many sensing applications such as chemical concentration measurement and heater activation under rainy weather.
This work was supported by The Scientific and Technological Research Council of Turkey (TUBITAK) under Grants No: 121N708 and 119N413.

SF01.07.15
Floating Buoy as a Triboelectric Nanogenerator for Blue Energy Harvesting Onur Demircioglu, Melih O. Cicek, Doga Doganay, Gunay Gazaloglu, Ahmet C. Yalciner, Simge Cinar and Husnu E. Unalan; Middle East Technical University, Turkey

Triboelectric nanogenerators (TENGs) can be used as both self-powered sensors and energy harvesting units anywhere there are stimuli from both the environment and human activities. Given situations like these, water waves are one of the best sources of environmental stimuli for TENGs to harness waste energy. In this study, a low-cost adaptation of a TENG was made by modifying a commercial buoy used by sailors and marine workers. A pendulum mechanism was used for the fabrication of the TENGs. While the inside of the buoy was coated with polyurethane (PU) foam, the counter triboelectric layer was prepared by coating an aluminum ball with poly (dimethyl siloxane) connected to a spring inside the buoy. As a result of contact-separation caused by wave stimulus on the buoy, triboelectrification was provided even in low frequency regime. An open-circuit voltage (Voc) of 141 V and a short-circuit current (Isc) of 8.89 μA were obtained from measurements made in a coastal port laboratory to simulate the actual state of sea waves. In addition, a power of 1.07 W/m^2 was obtained at an impedance match of 300 MΩ under a wave frequency of 1 Hz and a wave height of 11.8 cm, which is characteristic of Turkey's typical coastal waves. This study demonstrates that blue energy harvesting by TENGs can be an effective solution for low power electronics in the marine environment.

SF01.07.16
Elastic Photonic Microbeads Containing Non-Close-Packed Colloidal Crystals for Photonic Inks Jong Hyun Kim, Jong Bin Kim, Yehun Choi, Sanghyuk Park and Shin-Hyun Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Crystalline colloidal arrays exhibit vivid structural colors through wavelength-selective diffraction, which shows high color purity and brightness. The resonant wavelength of structural color is easily tuned by adjusting the lattice constant between crystal planes or refractive index. Moreover, the structural colors are non-fading and non-toxic, unlike chemical pigments. These novel properties of colloidal crystals have the potential to be applied to coloration fields such as displays, aesthetics, and color pigments. In particular, the colloidal arrays can be formed in microbeads format using emulsion droplets, which can be used as a new material of photonic inks for cosmetics, printings, and paintings, as an alternative to chemical pigments. For example, the colloidal particles can be self-assembled in the droplets by solvent evaporation, which enables the structural coloration by forming close-packed colloidal arrays. However, the evaporation-induced assembly method requires a long time for the crystallization of colloidal particles. Moreover, the microbeads with close-packed arrays have low mechanical stability as the colloidal particles are simply in contact with each other without a medium. To overcome the time-consuming process and ameliorate the mechanical property, the colloidal particles form non-close-packed arrays in the photocurable medium due to the interparticle repulsion, which is emulsified in water to form oil-in-water (O/W) emulsion droplets. The repulsive interparticle interaction induces the spontaneous crystallization of colloidal particles without the evaporation process, which can enable the production of the microbead with high mechanical stability by photopolymerizing resin of emulsion droplets. Nevertheless, the low color saturation and brightness of photonic microbeads due to the low colloidal crystallinity and incoherent scattering is still a problem for the practical application of photonic inks.
Here, we suggest a novel strategy to produce elastic photonic microbeads with enhanced color brightness and saturation through oil-in-oil (O/O) emulsion templates. The elastic microbeads are produced by emulsifying a photocurable dispersion in the mineral oil using a microfluidic device. As the photocurable dispersion, the silica particles are dispersed in poly(ethylene glycol) phenyl ether acrylate (PEGPEA). The silica particles form non-close-packed colloidal arrays due to the interparticle repulsion by the solvation layer. The emulsion droplets of silica-PEGPEA dispersions are collected and irradiated by ultraviolet to photopolymerize of PEGPEA and form photonic microbeads. The photonic microbeads show brilliant structural color with color bright enhancement because the crystallinity of colloidal arrays is higher than those prepared by the O/W emulsion template. The high crystallinity is attributed to the reduced influence on the repulsive interparticle interaction by the continuous phase. When the continuous phase of water or oil diffuses into the emulsion droplets, water molecules disturb the interparticle repulsion of silica particles by hydrogen bonding with silica particles whereas oil molecules do not interact with silica particles, which can enhance the crystallinity of silica particles. Moreover, the color saturation of microbeads can be further enhanced by transferring the microbeads into the mixture of the mineral oil and silicone oil When the microbeads are suspended in the oil mixture where the refractive index between microbeads and oil mixture is matched, the incoherent scattering can be suppressed at the surface of microbeads, which can enhance the color performance. Furthermore, the microbeads with enhanced color brightness and saturation are highly deformable, which can improve the fluidity of the oil mixture. Therefore, the elastic photonic microbeads can be used as colorants in photonic inks for printings of structural colors.

Multifunctional Highly Porous PolyHIPE Materials for Sorption, Filtration and Wound Dressing Applications Matthew D. Thum, Nickolaus weise, Maryssa Beasley, Grant Daniels, Spencer Giles, Kenan Fears, Chris So and Jeffrey Lundin; US Naval Research Laboratory, United States

Multifunctional porous polymers can serve as the basis for numerous applications and using high internal phase emulsion (HIPE) templating has proven a facile method of producing a tunable porous polymer scaffold. In this study, novel therapeutics were incorporated into an absorbent, mechanically robust, and hemostatic high surface area polymer foam through HIPE synthesis. Specifically, we demonstrate the use of HIPEs composed of hydrophilic acrylates, and polyethylene glycol (PEG) monomers as the basis for a multifunctional microporous polymer scaffolds and show compatibility with either enzymatic peptide decontaminants, or quaternary ammonium salts for added functionality. Furthermore, we discuss using 3D printing as a means to control the spatial loading of additives and fabricate structures with individually specific morphologies. The robustness of HIPE templating and 3D printing is examined by evaluating the effect of additive incorporation, and polymerization technique, on the activity of the dopant. Materials characterization included ATR-IR, gel fraction, DSC, TGA, and SEM analysis to evaluate effects of therapeutic loading on polymerization and the micro-structure of the polymer foams. Chemical decontamination capabilities were determined via simulant (2-CEES, and Demeton-S) challenges monitored via GCMS and antimicrobial assays were performed against *S. Aureus*. We demonstrate HIPE templating as a highly versatile approach to the design of porous polymer materials for sorption, filtration, and wound dressing applications. The relatively inexpensive fabrication and simple detoxification chemistry paired with the porous foam form factor presents an interesting approach to the development of a broad spectrum self-decontaminating material.

SF01.07.18
Microscale Photothermal Actuation Examined in Stiff/Soft Composites Jorge Jimenez[1], Georgia Kaufman[2], Michael Gallegos[2], Emily Huntley[2], Holly M. Golecki[1] and Bryan Kaehr[2,3]; [1]University of Illinois at Urbana-Champaign, United States; [2]Sandia National Laboratories, United States; [3]Center for Integrated Nanotechnologies, United States

The development of micro-scale tools employing smart, autonomous materials can enable widespread applications—from microsurgery and diagnostics, to the assembly of complex microdevices. With continuing development of smart and environmentally responsive materials compatible with 3D printing, cue-

driven tools such as micro-grippers with high spatial and temporal precision can give rise to biocompatible devices. In this work, we investigate additive manufacturing of microgrippers based on bioinspired heuristic designs coupled with environmentally actuated hydrogels to form hybrid microsurgical tools. The aim of this work is to develop robust micro-grippers integrated into imaging/optogenetic devices at the scale of single fiber optics and individual biological cells to enable single cell extraction or localized drug delivery. Using multiphoton lithography, we fabricate resin grippers and scissors that incorporate inert skeletal components. Hydrogels that respond to changes in temperature, pH and light are used to control device movements, and are fabricated in situ from the light output of the tip of the fiber. We evaluate the response time, accuracy and cyclability of grippers. By leveraging gripper geometry, surface treatments, and hydrogel chemistry, we iterate on designs to optimize for response time. Following this optimization, we designed microgrippers that incorporate a photothermal transducer within a thermally responsive gel actuator fabricated on the tip of a 200-micron diameter core fiber and demonstrate capture and release of microscale objects. Overall, this work provides a foundation to integrate stimuli responsive mechanical functions with micro-scale optical devices.

SF01.07.20
Unsupervised Machine Learning for Accelerated Density-Dependent Liquid Crystal Simulations Haritosh Patel, Baptiste Lemaire and Haichao Wu; Harvard University, United States

Material science, including rational design and discovery, has been motivated by the needs of today and tomorrow. Within the Aizenberg lab, a class of materials known as adaptive materials are currently being developed for their applications in soft robotics, energy harvesting, and more. Adaptive materials are classified by their ability to show a spectrum of complex behaviours under various stimuli. For example, the use of molecules that exhibit crystal-like properties in a liquid state, referred to as liquid crystals (LCs), have been used to recreate polymeric skins with capabilities of real-time drug delivery. These materials can be polymerized into liquid crystal elastomers (LCEs); they are able to produce anisotropic soft actuation with elastic behaviour. As the materials being designed become increasingly complex, complete understanding of their behaviour is difficult from just experimental and theoretical approaches. Hence, the use of accurate and fast simulation methods can play a critical role in providing material behavioural insight and ultimately into rational material design.

Conventional simulation methods that model the behaviour of individual molecules and groups of atoms are molecular dynamic (MD) and Monte Carlo (MC) methods. The methods, although differing in approach, both take an all-atom approach. MD simulations slowly evolve a system of molecules based on their position and trajectories determined by Newtonian physics, whereas MC simulations holistically perturb the system with small random steps, only accepting the changes that lower the energy of the system. As both approaches require calculating the force or energy exerted on or by each atom, the time required to complete one simulation can take hours if not days on dedicated research clusters. This provides motivation for designing a new approach to simulation that can provide similar accuracy while drastically reducing execution times. This research consists in using neural networks to slash computation times while maintaining a high level of accuracy. The conventional approach and paradigm that simulations are segmented in time and dimensional scales can be broken by use of machine learning to investigate properties to high degree of precision even at large scales.

In this research, we developed a neural network that can be used for predicting phase transitions of monomeric LCs, referred to as mesogens. Efforts were made to optimize neural network architecture, cost functions, and learning hyperparameters. In this work we prove the hypothesis that the fundamental method in which neural networks learn is in part synonymous to MC methods. MC iterations are accepted or declined based on a probabilistic distribution of the overall system to minimize free energy. Every iteration of the system is provided a small perturbed state. This state is accepted in general if the energy of the system is reduced and declined otherwise. Similarly, to this, each learning iteration of the neural network, instead tunes its neuron weights and biases in such a manner that the cost function is minimized. We take inspiratation from the Onsagar model as the free energy analog for the form of the cost function. In contrast to MC methods, the learning of a neural network system was accomplished within few hundred iterations (a small fraction compared to MC methods). Additionally, once a network has reached convergence, it can provide insight of various systems of similar environmental parameters without the need of re-learning, whereas MC methods must iterate through a simulation for every unique initial condition. Hence by leveraging the energy minimization aspect from MC methods, but implementing the ideology behind neural networks, we can maintain high accuracy while reducing simulation time. The proposed research outline indicates exploration of an innovative method for understanding material properties which has the potential of accelerating rational material design.

SF01.07.21
Light-Induced High Frequency Oscillation of Aligned Azobenzene Liquid Crystalline Polymers Kyung Min Lee, Ecklin Crenshaw and Nicholas P. Godman; Air Force Research Laboratory, United States

Photoactuators are attractive systems in which light energy is converted into motion. Previously, we reported the oscillatory behavior of cantilevers composed of glassy, azobenzene-functionalized liquid crystalline polymer networks (azo-LCNs). The azo-LCN cantilever containing 20% azobenene oscillates at high frequencies (50-120 Hz) and large amplitudes when exposed to light from a 442 nm coherent wave (CW) laser. The frequency of photoinduced oscillations was strongly affected by the aspect ratio of the cantilever, whereas the amplitude of the oscillation was affected by temperature. An azobenzene functionalized LC elastomer (azo-LCE) was prepared and the photoresponsive behavior is compared with the glassy azo-LCN. The glass transition temperature of azo-LCE is lower than room temperature. The fundamental photoresponses of these glassy and elastomeric azobenzene liquid crystal polymers (azo-LCN and azo-LCE) are further compared by examining the cantilever aspect ratio, laser intensity, and temperature. This photoinduced large bending and oscillation response of azo-LC polymers can be used for soft robotics and flow control.

SF01.07.22
Enhanced Stability and Solubility of Photoacids in Binary Solvent Mixtures for Light-Driven Reversible CO_2 Capture-Release Anna de Vries[1], Manuel Reiter[1], Kateryna Goloviznina[2], Evgeniya Vorobyeva[1], Yayuan Liu[3], T. Alan Hatton[4], Mathieu Salanne[2] and Maria Lukatskaya[1]; [1]ETH Zurich, Switzerland; [2]Sorbonne Université, France; [3]Johns Hopkins University, United States; [4]Massachusetts Institute of Technology, United States

Rapid rise of atmospheric CO_2 levels urgently requires more affordable carbon capture technologies with innovations beyond present-day energy intensive regeneration processes such as temperature or pressure swing [1]. Recently, pH-swing was proposed as a promising low energy alternative approach for CO_2 release. A pH-swing - i.e. cycling between CO_2 absorption at high pH, forming HCO_3^-, and CO_2 desorption at low pH - omits the need to increase temperature or decrease pressure during desorption for sorbent regeneration [2]. Controlled and reversible acidification of a solution can be achieved by the excitation of photoacids. Metastable photoacids are organic molecules that can reversibly lower pH of a solution under UV-visible light. Merocyanine-type photoacids can decrease the pH by up to 3.5 units in less than 30 seconds (pH-jump), and then reverse to the original pH in darkness within 15 minutes through thermal relaxation [3, 4]. The non-invasive nature of these light switchable proton emitters renders highly relevant applications in functionalized surfaces, such as membranes [5] and sensors [6], or pH-driven reactions such as hydrogel formation [7] or CO_2 absorption/release [8]. Merocyanine-type photoacids are generally limited by their low chemical stability due to hydrolysis (half-life is 16 hours) and low solubility in water (0.19 mM) [5]. In aprotic organic solvents such as dimethyl sulfoxide (DMSO), photoacids display higher chemical stability and solubility, however pH-jump in such solvents is not reversible [3].

Herein we propose to dissolve photoacids in water-DMSO solvent mixtures to achieve the 'best of both worlds': high reversibility of pH-jump as well as high chemical stability and solubility. By combining pH-jump, solubility and stability studies, we demonstrate that solubility can be enhanced by 2 orders of magnitude, and half-life increased by 1 order of magnitude in DMSO-water mixtures. UV-Vis absorption, Nuclear Magnetic Resonance spectroscopy, Small-Angle X-ray Scattering and Polarisable Molecular Dynamics simulations were used to reveal the role of H-bonding networks and modified solvent structure to enable these enhancements. Besides optimizing for specific properties, binary solvent mixtures provide an additional degree of freedom to tune photoacid properties such as pK_a and relaxation kinetics that can also be applied to other types of photoacids. Finally, the photoacid in an optimal solvent mixture of 15% DMSO in water enables a highly reversible, stable and controlled CO_2 capture-release system. With higher stability and solubility, photoinduced pH-swing has the potential to drastically reduce energy demand, material degradation and infrastructure of mature carbon capture technologies by ambient CO_2 desorption that is controlled by visible light.

Microfluidics-Assisted Production of Dual Responsive Microcapsule for Urolithiasis Therapy Byung Kwon K. Kang and Dong-Pyo k. Kim; Pohang University of Science and Technology, Korea (the Republic of)

Stimuli-responsive drug delivery systems are receiving great attention in drug delivery research because they have promising potential as a controlled drug delivery method. Recently, various drug delivery systems have been developed that can respond to extrinsic (ultrasound, light, temperature, magnetic and electric fields) and intrinsic stimuli (pH, enzymes, and oxidation). Among these stimuli, the ultrasonically stimulated drug delivery system has been shown to be applicable as a practical drug delivery system due to its non-invasiveness and deep permeability.
Urolithiasis is a hard crystal stone of accumulated minerals and salts in the ureter, ureteropelvic junction, and kidney due to dietary habits and genetic calcium metabolism. Kidney stones can cause kidney pain, obstruction of urinary flow, and urinary tract infections. Surgical treatment methods (ureteroscopy, percutaneous nephrolithiasis, and extracorporeal shock wave lithotripsy) were required to treat the kidney stone. However, traditional surgery treatments lead to secondary diseases such as infections and bleeding during the treatment process. This work disclosed a chelator encapsulated microcapsule with ultrasound/magnetic responsive systems for urolithiasis treatment application. PLGA-based microcapsules loaded with chelating solutions and magnetic nanoparticles were produced in a microfluidics double-droplet generator with a uniform size (393 ±14 μm). The microcapsules (MNP-HMP/PLGA) exhibited magnetic mobility by the external magnetic field and controlled release by ultrasound. In addition, the therapeutic microcapsules were proven to have excellent chelator delivery efficacy, cell viability, and superior urolithiasis removal efficacy than conventional oral administration (citrate ingestion) in the kidney mimic chip. To the best of our knowledge, ultrasound/magnetic responsive microcapsule for urolithiasis therapy has not been reported. Finally, this novel drug delivery system with non-invasive/targeted/externally-stimulated drug release properties overcomes the limitations of traditional stone treatment methods and suggests a new approach to stone treatment.

SF01.07.24
Wireless Stimuli-Responsive Trimodal Display Enabled by Direct Capacitive Coupling Jihye Jang, Jin Woo Oh, Hyeokjung Lee, Hyowon Han and Cheolmin Park; Yonsei University, Korea (the Republic of)

With recent advances in stimuli-interactive displays, the development of a stand-alone stimuli-interactive display with no electrical interconnection is of great interest. Here, we present a stimuli-responsive polymer-based wireless display powered by direct capacitive coupling. A wireless stimuli-responsive display (WiSD), which is capable of sensing and visualizing various stimuli such as pressure, temperature, and humidity, consists of three layers: 1) two in-plane metal electrodes with a separated gap, 2) a ferroelectric polymer composite layer for field-induced electroluminescence (EL) and inverse piezoelectric sound, and 3) a stimuli-responsive polymer-based layer, respectively from bottom to top. Alternative current (AC) power supplied between the two in-plane electrodes of a power unit separated from the WiSD is wirelessly transferred to the WiSD via capacitive coupling. The stimulus applied on the stimuli-responsive layer is displayed by AC field-induced EL and inverse piezoelectric sound, which are dependent on the impedance of the stimuli-responsive layer. The AC-to-AC direct capacitive coupling, which does not require resonant frequency matching or current rectification, allows for efficient sensing and visualizing of a variety of stimuli with a broad range of AC frequency, including built-in house power (220 V/60 Hz). Furthermore, our WiSD does not require electrical interconnection, making it suitable for the wireless dynamic monitoring of the delivery of diverse medical fluids to patients in a timely and accurate manner. Moreover, a haptic wireless trimodal interactive display mounted on a human finger broadens the applicability of the WiSD, whereby finger touch is displayed through various outputs of AC EL, inverse piezoelectric sound, and tactile vibration, allowing for developing a wireless three-mode braille smart display.

SF01.07.25
Visible-Light Active Flexible and Durable Photocatalytic Antibacterial Ethylene-co-vinyl Acetate—Ag/AgCl/α-Fe_2O_3 Composite Coating Svetlana Vihodceva[1], Andris Šutka[1], Anna Kahru[2], Maarja Otsus[2] and Kaja Kasemets[2]; [1]Riga Technical University, Latvia; [2]National Institute of Chemical Physics and Biophysics, Estonia

When particles are mixed in polymer, particle surfaces become passivated by polymer matrix, leading to significantly reduced photocatalytic and, thus, also reduced antibacterial activity, as the catalytic particles become isolated from the outer environment and microorganisms reaching the surface. Herein, we demonstrate a facile and rapid approach for coating preparation at room temperature, yielding good adhesion of particles in combination with the particles' interface location. Flexible ethylene-co-vinyl acetate Ag/AgCl/α-Fe_2O_3 composite coatings were prepared by the spin-coating method. The synthesized photocatalytically active coating surface exhibited a distinct and rapid inhibition of bacterial growth, with at least a 7-log reduction of gram-positive bacteria Staphylococcus aureus viability after 30 min of visible-light illumination. We also analyzed the shedding of the Ag-ions and reactive oxygen species production from the composite coating and showed that reactive oxygen species played the main role in the photocatalytic bacterial inactivation, destroying the bacteria cell as proven by the Confocal Laser Scanning Microscopy.

SF01.07.27
Dynamic, Multi-Stimuli-Responsive, Core Cross-Linked Polymeric Nanocarriers Synthesized by PhotoATRP-Induced Self-Assembly Shayesteh Tafazoli and James F. Reuther; Umass Lowell, United States

Smart, multi-stimuli-responsive polymers that possess dynamic covalent bonds exhibit reversibility under equilibrium conditions. These are covalent bonds capable of exchanging or switching between several molecules in different environments. They have innumerable applications in areas including sensors, actuators, switchable wettability, and biomedical and environmental applications. In this project by utilizing one-pot, photo-controlled atom transfer radical polymerization induced self-assembly (PhotoATR-PISA) mediated by UV light (λ = 365 nm) using parts per million (ppm) levels (ca. <20 ppm) of a copper catalyst, varied polymeric nanostructures morphologies, ranging from nanospheres to worm-like micelles, were obtained at ambient temperature. Polymeric nanocarriers cross-linked efficiently via a clean, efficient, and controllable coumarin photodimerization improving the stability of nanocarriers for targeted delivery. At the same time, cross-linking of nanocarriers with N,N-cystamine bismethacrylamide (CBMA) could be cleaved via the responsiveness of the disulfide cross-link when exposed to the redox environment. In addition, kinetics of release could be tailored by the pH of the surrounding medium. Thus, the system also showed pH-responsive, redox-responsive, and photo-responsive controlled release behavior with a full release of cargo only observed in the right sequence of stimuli. The multi-stimuli-responsive nature of polymeric nanocarrier was used successfully for the controlled encapsulation and on-demand release of the hydrophobic molecule (Nile Red) as a drug simulant.

SESSION SF01.08: Smart Functions of Stimuli-Responsive Materials VII
Session Chairs: Yunteng Cao and Torsten John

Soft On-Demand—Electrochemical Modulation of Polythiophene Mechanical Properties for Smart Actuators Ilaria Abdel Aziz[1], Johannes Gladisch[1], Sophie Griggs[2], Maximilian Moser[2], Magnus Berggren[1], Iain McCulloch[2] and Eleni Stavrinidou[1]; [1]Linköping University, Sweden; [2]University of Oxford, United Kingdom

Interfacing electronics and biology opens the need for materials having suitable electrical and mechanical properties, as mixed ionic/electronic conductivity and softness. Among all materials, polythiophene conjugates emerged for their high biocompatibility, ionic as well as electronic conduction, and optical properties in the visible range. Remarkable results have been obtained interfacing polythiophenes-based transistors and actuators with mammalian cells, as well as plants, to a lower extent. However, the phenomena occurring at the interface between the material and the aqueous environment, as water intercalation and oxygen reduction reactions, are raising interest for their impact on the device performances and stability. In particular, volumetric changes driven by water intake during electrochemical doping/de-doping emerged as a limitation for transistor performances, since the irreversible water intake results in lamellar order disruption and consequently reduced hole mobility.
While this volumetric change represents a limitation for transistor devices, it opens to a new class of electrically addressable actuators, where both mechanical stimulation and mixed conduction play together. Since the electrochemical doping/de-doping is accompanied by water intake in the thin film structure, we expect the mechanical properties to change accordingly. Here, we investigate the volumetric changes and their correlation with the mechanical properties of a new group of polythiophene based materials, conjugated to ethylene glycol (EG) side chain of different lengths. The EG-side chains account for a better stabilization of the water. According to previous publications, our findings show that the electrochemical doping drives volumetric changes in aqueous environment up to 250% vs initial volume. Additionally, we demonstrate that the amount of volume change depends on the ionic strength of the solvent and the side chain length. Moreover, the water intake determines changes in the mechanical properties, in particular softening the material upon volumetric expansion.
Our findings deterministically correlate the mechanical properties, the volume changes and the doping state of the material, laying the basis for the development of low-voltage electrically addressable devices. This class of material and devices has a great potential interest for bioelectronic applications, as it accounts for ionic/electronic conduction and on-demand modification of stiffness, emerging as a smart platform for mammalian and plant cell stimulation and monitoring.

9:00 AM SF01.08.03
Helical-Shaped Self-Oscillating Gels Showing Autonomous and Magnified Mechanical Oscillation Taehun Chung[1], Hyein Kim[1], Young-Ki Kim[1], Ryo Yoshida[2] and Younsoo Kim[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]The University of Tokyo, Japan

Helical structures exist across multiple length scales, from DNA, collagen fibrils, and bacterial flagella to plant tendrils. They are important in living organisms in a biological context because of their unique properties, such as traveling and sensing. From an engineering point of view, these helical structures can be used in microscale soft robots.
"Self-oscillating" gels have become a distinguished class of smart soft materials because they undergo spontaneous and cyclic swelling-deswelling changes without on-off switching of external stimuli.[1] However, the practical applications of self-oscillating gel are still limited due to a small change in the degree of swelling (deswelling) and non-directional actuation by isotropic deformation.
Herein, to improve the degree of deformation of gels, we report an unprecedented method to convert an isotropic deformation into anisotropic and unidirectional deformation of gel. As a result of introducing a three-dimensional periodic gradient structure by photopolymerization into the gel network, a helical-shaped gel could be synthesized. The helical-shaped gels exhibited amplified uniaxial winding and unwinding during the Belousov–Zhabotinsky (BZ) reaction. In addition, the helical-shaped gels showed a significant change in length according to self-oscillation compared to the conventional rod-shaped gel. When one end of the gel is fixed, the helical-shaped gel repeatedly performs winding and unwinding movements without fatigue with a large amplitude (~14%), even at a constant temperature and without applying external stimuli. When the gel is floated on the water surface, and a BZ reaction occurs spontaneously inside the gel, it reciprocates at a constant speed. This presentation will discuss synthetic strategy, structure analysis, and improved self-oscillation of helical-shaped gels.

Light-Controlled Neurotransmitter Delivery in Solid State Nanopores for Retinal Prosthetics Angela F. De Fazio[1], Pascal Welzen[2], Jan Van Hest[2], Elisabetta Colombo[1,3], Fabio Benfenati[1,3], Francesco De Angelis[1] and Marzia Iarossi[4]; [1]Istituto Italiano di Tecnologia, Italy; [2]Eindhoven University of Technology, Netherlands; [3]IRCCS Ospedale Policlinico San Martino, Italy; [4]Italian Institute of Technology, Italy

Achieving precise control on the regulation of a flow is of outmost importance to obtain a reliable valve for the selective delivery of material from one side

to the other of the valve itself, in the attempt to mimic the selectivity and properties of cell membranes. In the literature numerous efforts of externally controlled gating have been reported; however, many of these strategies lack of scalability, fast responsiveness of the gating, efficient external control.
In this work, we aim to achieve controllable delivery of a neurotransmitter, glutamate, using light-gated solid-state channels. The channels were obtained by milling conical nanopores in a 500 nm thick Si_3N_4 membrane; then they were functionalized with an azobenzene-based polymer. The presence of numerous azobenzene molecules generates a polymeric structure able to switch between an expanded *trans* structure and a collapsed *cis* configuration. This conformational switch results into a gating behaviour inside the channels, between a closed (*trans* isomer) and an open (*cis* isomer) configuration. The polymer functionalisation was examined by AFM, while the amount of loaded polymer was quantified using a quartz microbalance. The *cis-trans* isomerisation within the channels was monitored by ellipsometry.
To test the light responsiveness and the gating efficiency, the nanopatterned membrane was encased in a home-made microfluidic device consisting of a chamber on top of the membrane and a bottom reservoir, located underneath the membrane. This was used to flow glutamate molecules through the channels. The gating capability was monitored by Current-Voltage (IV) measurements, while the amount of translocated neurotransmitter was quantified by fluorescence spectroscopy.
This light-gated microfluidic device may represent a viable option for any application requiring precise and controlled delivery of specific molecules in specific locations. For example, we envision the use of this technology in the field of retinal prosthetics, where it could be employed to restore the light-evoked glutamate outflow on the denervated inner retinal neurons upon photoreceptors degeneration.

9:30 AM SF01.08.05
3D Printed Hydrogels as Photothermal Actuators Melanie M. Ghelardini[1], Martin Geisler[2], Niclas Weigel[2], Jameson P. Hankwitz[1], Nicolas Hauck[2], Jonas Schubert[2], Andreas Fery[2,3], Joseph B. Tracy[1] and Julian Thiele[2,4]; [1]North Carolina State University, United States; [2]Leibniz Institute for Polymer Research, Germany; [3]Institute of Physical Chemistry and Polymer Physics, Technische Universität Dresden, Germany; [4]Dresden Center for Intelligent Materials, Technische Universität Dresden, Germany

Thermoresponsive hydrogels are 3D printed with embedded gold nanorods (GNRs) with average dimensions of 81 × 23 nm, which enable shape change through photothermal heating. GNRs are chosen for their tunable and intense extinction, which results in high photothermal heating efficiencies. The GNRs are functionalized with bovine serum albumin (BSA) and mixed with a photoinitiator and poly(*N*-isopropylacrylamide) (PNIPAAm) macromer to form an ink for 3D printing by direct ink writing. Use of a PNIPAAm macromer increases the homogeneity and optical transparency of the resulting gel in its swollen state in comparison with free-radical polymerization. The ink is printed into a gelatinous support structure to provide mechanical stability during printing and concurrent photo-crosslinking, preventing the spreading of the deposited ink prior to complete crosslinking. Use of a support structure is vital for maintaining the integrity of the print, as it compensates for the low viscosity of PNIPAAm, which restricts its use in extrusion-based printing. After crosslinking, the support structure is removed through heating in a water bath at 28 °C, which allows completion of 3D printing well below the transition temperature of the PNIPAAm. The 3D-printed composite exhibits a lower critical solution temperature of ~34 °C, whereupon it transitions from a transparent, swollen state to a shrunken, phase-separated state. Upon exposure to a near-infrared LED, the GNRs transduce light into heat, thus raising the temperature and driving the phase transition and shrinkage of the hydrogel-GNR composite. Reversible shrinkage is observed over multiple cycles of photothermal heating, demonstrating the promise of 3D-printed, photoresponsive structures as hydrogel actuators.

9:45 AM SF01.08.06
A Flexible Shape Memory Polymer Adhesive with Dual Adaptations ChangHee Son[1], Placid Ferreira[1] and Seok Kim[2,1,3]; [1]University of Illinois, United States; [2]Pohang University of Science and Technology, Korea (the Republic of); [3]Yonsei University, Korea (the Republic of)

A shape memory polymer (SMP) makes conformal and hermetic contact with a target surface at its soft, rubbery state, while it produces a high-strength dry adhesion at the rigid, glassy state. Recent SMP adhesive investigations demonstrate that SMP can stick to a variety of rough surfaces as well as rigid surfaces underwater. However, it is somehow challenging to achieve and maintain a strong adhesion on a flexible adherends such as common fabrics due to a modulus mismatch where the flexible adherends would easily be peeled off from SMP adhesives which are too rigid to adapt to the target surface flexing. Here, we present the dual adaptation of an SMP adhesive consisting of a thin SMP layer and a backing fabric, which involves the shape adaptation to produce a strong adhesive contact and the flexure adaptation to tolerate a flexing target surface. In order to determine the criteria for optimizing both shape and flexure adaptations, we present a theoretical justification and computational and experimental research. On the basis of these results, we demonstrate a dry and underwater adhesion performance of a thin SMP adhesive on common clothing to highlight its potential applications.

Actively-Triggerable Metals via Liquid Metal Embrittlement for Biomedical Applications Vivian R. Feig[1,2], Eva Remlova[2], Robert Langer[1] and Giovanni Traverso[1,2]; [1]Massachusetts Institute of Technology, United States; [2]Brigham and Women's Hospital, United States

Actively-triggerable materials, which break down upon introduction of an exogenous bio-orthogonal stimulus, enable precise control over the lifetime of biomedical technologies as well as adaptation to unforeseen circumstances, such as changes to an established treatment plan. Yet most actively-triggerable materials are low-strength polymers and hydrogels with limited long-term durability. By contrast, metals possess advantageous functional properties, including high mechanical strength and conductivity, that are desirable across several applications within biomedicine. To realize actively-triggerable metals, we leveraged a mechanism called liquid metal embrittlement, in which certain liquid metals penetrate the grain boundaries of certain solid metals and cause them to dramatically weaken or dissolve. In this work, we demonstrate that eutectic gallium indium (EGaIn), a biocompatible alloy of gallium, can be formulated to reproducibly trigger the breakdown of aluminum within different physiologically-relevant environments. The breakdown behavior of aluminum after triggering can further be readily controlled by manipulating its grain structure. Finally, we demonstrate three possible use cases of biomedical devices constructed from actively-triggerable metals.

10:45 AM SF01.08.08
Self-Healing Elastomers for Information Storage and UV-Sensing Tiwa Yimyai[1,1,2], Daniel Crespy[1] and Abdon Pena-Francesch[2]; [1]Vidyasirimedhi Institute of Science and Technology (VISTEC), Thailand; [2]University of Michigan–Ann Arbor, United States

Most electronic devices are composed of rigid and brittle components, which are typically not compliant and limit their applications. In contrast, flexible electronic devices are developed using compliant polymers to overcome the fracture problems of rigid devices, as well as to adapt to multiple conformations in a wide range of applications such as electronic skins, flexible displays, and tactile sensors. However, soft electronic polymer materials are typically vulnerable to mechanical damage caused by repeated use and accidental puncture with sharp objects, leading to functional failure. Therefore, self-healing materials provide an opportunity for repairing the damage and extending life-time. Herein, a self-healing polyurethane elastomer that is flexible, stretchable, and transparent was prepared. The self-healing elastomer relies on dynamic exchange reactions of disulfide bonds in its molecular structure upon activation with temperature. Inspired by the process of tattooing on human skin, a soft stretchable platform for reversible and irreversible information

encryption was developed by microstructuring the polymer matrix with a functional dye solution. Upon the healing of the polymer, the dye was embedded in the polymer matrix, protected from abrasion and extraction with solvents. By storing a UV-sensing dye in the polymer matrix, we successfully produced a photochromic self-healing polymer elastomer, which exhibited a great potential for wearable technologies in harsh environments that require resiliency, protection, and in-situ repair.

11:00 AM SF01.08.09
The Use of Phase Change Materials to Create Variable Stiffness Linkage-Fabrics Christian Partik, Elze Porte, Martyna Michalska and Mark Miodownik; University College London, United Kingdom

Animate materials that can respond to the input from their environment and dynamically change shape have seen increasing applications in recent years in the fields of soft robotics and assistive technology [1,2]. Their ability to morph from a flexible to a rigid state is one of their key attributes. However, current shape-changing structures that utilise actuators often require a constant energy supply to retain their rigid shape, while they return to the original structure when the energy is removed [3,4]. This limits the utility of the materials for applications such as assistive technology and deployable structures where energy use needs to be minimised to meet design requirements. This research aims to address this problem by developing a stiffness-changing structure that does not require constant energy input to maintain either the low or high stiffness state.

Phase change materials(PCMs) have traditionally been used as energy storage materials due to their high latent heat [5], but little attention has been paid to their potential for mechanical applications using the cyclic liquid to solid phase change of these materials. Phase change materials can be cooled below their solidification temperature and stay in their supercooled liquid phase for an indefinite period. Solidification can be triggered through the introduction of nucleation sites such as crystals by using electrical or mechanical triggers. By heating the material above its solidification temperature the phase change can be reversed.

In this work, we show that the mechanical properties of linkage-fabric structures can be controlled by the use of a phase change material incorporated into the fabric. We use sodium acetate trihydrate (CH3COONa×3H2O) as the phase change material with the nucleation from the liquid to the solid-state controlled by an electric impulse [6]. The linkage-fabric structures were designed using CAD software to create a flexible interlocking structure that when actuated modulates the stiffness of the fabric. The structures were 3D printed in nylon using Selective Laser Sintering (SLS). For each sample, supercooled sodium acetate and the conducting paths for the electrical signals were manually incorporated. The phase change response of the sodium acetate was triggered by silver electrodes with microcrystals embedded onto their surface, through which a DC voltage has been supplied. We present data on the effect of sodium acetate solution composition on the mechanical stiffness of the actuated fabrics, the reversibility of this change and the impact of fabric design on its property. The work shows that phase change materials can be used for the construction of linkage-fabrics with variable stiffness without requiring constant energy input. The work opens up myriad opportunities to exploit these structures in applications for deployable structures and assistive technology.

4D Printing of Dicyclopentadiene/$BaTiO_3$ Polymer Composites Hyoseop Kang and Woong-Ryeol Yu; Seoul National University, Korea (the Republic of)

Dicyclopentadiene (DCPD) is a thermosetting polymer capable of spontaneous frontal ring-opening metathesis polymerization (FROMP) by the thermal initiation of local sites. As such, DCPD can be printed into a free-standing structure without supports, which is not possible with a conventional fused deposition moulding printer. In addition, cyclooctane can be incorporated into DCPD during FROMP to develop new smart materials with shape memory performance. In the meantime, $BaTiO_3$ is one of piezoelectric ceramics with excellent dielectric and piezoelectric properties, being a promising material for piezoceramic devices. Due to its poor formability and brittles, $BaTiO_3$ is used as a filler for polymer composites. In this research, a piezoceramic composite was prepared using DCPD and $BaTiO_3$ and printed into a free-standing structure without supports. For this, $BaTiO_3$ nanoparticles were dispersed uniformly in DCPD solution, which was confirmed using SEM and EDS analysis. Then, optimal 3D printing condition of the composite solution was explored. Lastly, the shape memory performance and the dielectric constant of the printed composite were measured to investigate the possibility of a piezoelectric ceramic device.

11:30 AM SF01.08.11
Stimuli Responsive Molecular-Conductor Composites Raphael Pfattner[1,2], Elena Laukhina[2], Marta Mas-Torrent[1,2], Vladimir Laukhin[1], Jaume Veciana[1,2] and Sergi Riera-Galindo[1]; [1]Materials Science Institute of Barcelona (ICMAB-CSIC), Spain; [2]Networking Research Center on Bioengineering, Biomaterials and Nanomedicine (CIBER-BBN), Spain

Developing smart materials that can respond to an external stimulus is of major interest in artificial sensing devices able to read information about the physical, chemical and/or biological changes produced in our environment. Additionally, if these materials can be deposited or integrated on flexible, transparent substrates, their appeal is greatly increased. The BEDT-TTF=bis(ethylenedithio)-tetrathiafulvalene based quasi-twodimensional organic superconductor β-$(BEDT\text{-}TTF)_2I_3$ was first reported back in 1984.[1] Soon it became clear that ion radical salts derived from BEDT-TTF exhibit tunable electronic band structures. Therefore, such molecules are excellent building blocks for engineering a rich and diverse family of organic crystalline metals and semiconductors. When processed in composites, the high electrical performance of single crystals can be combined with the processing properties of polymers where at the percolation threshold, fascinating novel optoelectronic properties emerge.[2] Such systems can be further tuned by choosing the nature of the conductor enabling high sensitivity towards strain, pressure, temperature, humidity or even con-tactless radiation sensing *i.e.* bolometers.[3-5] This rich class of materials ranges from metals to semi-metals and semiconductors and is highly sensitive to a variety of external stimuli. Mechanisms of responses are discussed and correlated with fundamental properties of charge transport in these systems. Such materials allow for selective sensing enabled due to molecular design and structural control of the active components. These findings are highly promising for multidimensional selective sensing made possible by tuning molecular composition to maximize and, importantly, to decouple responses to strain, pressure, temperature, radiation, and recently also

humidity as an external stimulus. An attractive field of application in this context is human health care targeting environmental conditions relevant for human physiology.

Bioprinting Osmotically Actuated Tissue-Like Materials McKayla L. Torbett[1], Aida Fica[2], Manish Kumar[2], Berkin Dortdivanlioglu[2] and Stephen A. Sarles[1]; [1]The University of Tennessee, Knoxville, United States; [2]The University of Texas at Austin, United States

Hierarchal biomimetic materials that operate at the same, or greater, level of sophistication as biological tissues are yet to be fully realized, in part, because artificial materials fail to recreate the intricate network of compartmentalized cells as found in natural tissues. Compartmentalization is key in recreating the inherent physiochemical phenomena responsible for maintaining homeostasis in living organisms, such as tunable mechanical properties, selective permeability, stimuli responsiveness, and cellular communication. The Droplet Interface Bilayer (DIB) is a phospholipid model membrane consisting of a lipid bilayer formed at the interface of two monolayer-coated aqueous droplets in oil and is promising for realizing soft intelligent materials, as each droplet naturally forms a cellular compartment and can join with others to form a tissue-level hierarchy with customizable cells. This study aims to construct and characterize the collective and stimuli-responsive behaviors of multilayered, tissue-like compartmentalized materials built from lipid-stabilized aqueous compartments. To demonstrate the benefit of compartmentalized materials and to yield prototypes that will help us better understand their emergent properties, we chose to design an osmotically actuated material. Utilizing a commercially available, pneumatic bioprinter, nanoliter-sized aqueous volumes suspended in oil have been successfully printed in 2D and 3D arrangements to form networks of sophisticated, compartmentalized constructs. A change in conformation is induced as programmed osmolarity gradients, present within the printed structure, drive water towards cells of a higher solute concentration, thereby swelling or shrinking adjoining droplets accordingly. Permeability measurements obtained for single lipid bilayers, coupled with discrete printing parameters allow for the prediction and fine-tuned control of osmotic actuation and stimuli-responsiveness. Ongoing efforts seek to incorporate integral membrane proteins and pore-forming channels into the intercompartment membranes to accelerate water transport and, thus, osmotic actuation. Overall, the involuntary folding of printed networks results in a synthetic tissue-like material more closely resembling the collective functionalities and sophisticated behavior of biological tissues and unlocks many other stimuli-responsive functions capable through the use of biomolecules.

SESSION SF01.09: Smart Functions of Stimuli-Responsive Materials VIII

Rapid and Reversible Shape Memory Effect in Colloidal Crystals Engineered with DNA Heather Calcaterra[1], Seungkyu Lee[1], Sangmin Lee[2], Wisnu Hadibrata[1], Byeongdu Lee[3], EunBi Oh[1], Koray Aydin[1], Sharon Glotzer[2] and Chad Mirkin[1]; [1]Northwestern University, United States; [2]University of Michigan–Ann Arbor, United States; [3]Argonne National Laboratory, United States

Mechanically responsive crystals, which exhibit reversible, rapid, and complex dynamics, are essential to the development of flexible electronics, artificial muscles, and various dynamic components in soft robotics. However, due to the limited flexibility of atomic bonds, only a small number of reversible deformation modes have been realized for these materials. Colloidal crystals engineered with DNA represent an ideal platform for the development of mechanically responsive crystals, owing to the stimuli-responsiveness and high fidelity of the DNA bonds that define the crystal. Herein, we report the reversible mechanical responsiveness of colloidal crystals engineered with DNA to deformations typically considered irrecoverable in conventional molecular and atomic crystals. These advances were obtained through the synthesis of large (>100 μm) single crystals, which enable previously unrealizable characterization techniques including in-situ optical microscopy and single-crystal x-ray diffraction. These techniques shed light into both the unprecedented nature of the macroscale deformation and recovery as well as the resilient and flexible internal structure of the single crystals. Since single crystals are the basis for many optical and electronic device components, the synthetic methods and crystal deformation capabilities described in this work lay the foundation for the realization of advanced structural materials for applications such as optics, chemical sensing, and many others which require the properties of both soft and crystalline materials.

1:45 PM SF01.09.02
Enhanced Atmospheric Water Uptake of Hydrogels at Elevated Temperatures Xinyue Liu, Lenan Zhang, Shaoting Lin and Evelyn N. Wang; Massachusetts Institute of Technology, United States

To prevent the dehydration of living organisms, it is crucial to obtain and retain water, especially in hot weather. However, most materials, including plants, biological tissues, and inorganic sorbents, can lose more water at a high temperature and capture more water at a low temperature, because of the exothermic water vapor adsorption. Here, we discover a class of hydrogels that exhibit enhanced atmospheric water uptake when the temperature is elevated. For example, the adsorbed water in hydrogels is doubled when we increase the temperature from 25°C to 75°C and maintain 20% relative humidity. This abnormous temperature dependence of water vapor adsorption can be attributed to the first-order phase transition of polymer networks. We also developed a thermodynamic theory to analyze and predict the equilibrium water vapor adsorption at different temperatures and relative humidity. Our finding has profound implications for thermal energy management and atmospheric water harvesting.

2:00 PM SF01.09.03
Bio-Inspired and Stimuli-Responsive Adhesive Hydrogel Structure Fabricated by Single-Exposure Photolithography Jinsik Yoon and Wook Park; Kyung Hee University, Korea (the Republic of)

[Introduction] Since adhesive structures that can be attached by specific morphology do not require special chemical properties, diverse materials can be

adopted, and numerous researchers have applied bio-inspired frames in nature. Mainly, the mimicked adhesive structures consist of complex three-dimensional (3D) shapes rather than simple 2D shapes, and, in order to fabricate these structures, a series of rather complex processes are involved. Herein, we present the 3D bio-inspired (male diving beetle foot) adhesive structure fabrication utilizing a simple single-exposure photolithography system. The adhesive structure made of photocurable hydrogel cannot be attached in a contracted environment such as dried and ethanol, but the structures will be deformed into a concave adhesive shape by local expansion in an underwater environment. In addition, it is confirmed that adhesion can be controlled by stimuli according to changes in the surrounding environment.

[Materials and Methods] A photolithography system, based on a mercury−xenon lamp ultraviolet (UV) light source (365 nm, Hamamatsu) with a fiber-based light guide to solidify photocurable polymers, a digital micromirror device (DMD, Texas Instruments) to reflect desired UV light patterns, and objective lens (Olympus) to adjust the pattern size, was utilized in order to create 3D adhesive hydrogel structures. The photocurable hydrogel material was prepared by mixing Poly(ethylene glycol) diacrylate (Mn 700, Sigma-Aldrich) and Irgacure 1173 (photoinitiator, BASF) by a vortex mixer (Scientific Industries).

[Results and Discussion] The 3D hydrogel structure fabricated through the single-exposure photolithography process was expected to maintain different polymeric network densities locally, and through Raman spectroscopy analysis, the local carbon double bonding (1635 cm^{-1}) intensity was demonstrated to be different. The hydrogel structures exposed to dry or ethanol solution were not able to adhere due to the convex surface based on shrinkage. But, the hydrogels soaked in water environment were transformed into a concave shape due to local expansion based on difference of polymeric densities, enabling adhesion. The expanded and adhesive hydrogel structure immersed in water was saturated with pull-off force under the pre-loading condition of about 70 kPa, and the force was about 130 mN. Additionally, the change of hydrogel structures according to temperature change was analyzed. The hydrogel structures could not be adhered due to shrinkage on the basis of water temperature increase around 50 degrees Celsius. Contrary to the previous case, the hydrogel structures could be adhered in accordance with expansion based on ethanol temperature increase nearly 40 degrees Celsius.

[Conclusion] We have shown bio-inspired and stimuli-responsive adhesive hydrogel structures fabricated by utilizing a single-exposure photolithography process. The created hydrogel structures are transformed into an adhesible form by local expansion in water, and in addition, the frame is transformed according to the change of the surrounding thermal environment. Thus, the adhesion states can be controlled. We believe that the manufactured adhesive hydrogel structure will contribute to soft actuation and robotics fields.

2:15 PM SF01.09.04
Physically Crosslinked Thermoresponsive Polymer Hydrogels for Cooling-Triggered Drug Release Romario Lobban and Leon Bellan; Vanderbilt University, United States

Physically crosslinked thermoresponsive polymer hydrogels undergo a well-known gel-to-sol transition upon being cooled below their LCST. Accompanying this transition is a massive increase in the release rate of sequestered payloads. We explore the possibility of using such a system for cooling-triggered, local release of pain relief therapeutics. Currently, opioid addiction and abuse result in over 115 deaths per day in the US alone. A safer, non-systemic, local mechanism for relief from acute (e.g. perioperative pain) and chronic pain is therefore needed. Ideally, patients and caregivers should be able to trigger this mechanism, non-invasively and on demand, via an external stimulus. As icepacks are already widely applied to temporarily ease local pain, introducing a drug delivery mechanism switched “ON” by cooling would enable long duration, enhanced pain relief triggered by a method with which patients are already familiar. Herein, we describe how cooling-triggered drug release can be achieved using a drug-loaded physically crosslinked thermoresponsive polymer hydrogel encapsulated in a rate-limiting nanoporous membrane.
We formulated a Soluplus (a polyvinyl caprolactam copolymer from BASF) solution (10%-30% w/v, with 3% $CaCl_2$) and loaded 0.5%-1%w/w_{gel} Nile Red (NR, as a model molecule for bupivacaine, a common anesthetic) into it. We then heated this solution above its LCST within a mold to form 0.2 ml hydrogel pellets. Finally, we dipped these pellets in an alginate bath for 4 minutes to encapsulate them in ~500-micron-thick, calcium-crosslinked alginate shells. We placed these pellets in a 40°C PBS well for 3 hours to account for any initial burst release. Next, we alternated each pellet between warm (40°C) and cool (~23°C) separate wells, allowing the pellets to spend 24 hours at each temperature. The amount of NR released into the wells at the different temperatures was then determined using a plate reader. Additionally, to ensure that the NR is released in a form accessible to cells, we exposed HUVEC cells to solution drawn from the wells containing the pellets and observed their fluorescence (NR fluoresces minimally in water but becomes very fluorescent in nonpolar environments such as lipid membranes).
We observed that pellets released ~100 times more NR into the surrounding PBS when kept at ~23°C compared to when kept at 40°C. As the LCST of our Soluplus formulation is ~30°C, this indicates that its gel-to-sol transition results in a huge increase in the rate of release of NR. When HUVEC cells were exposed to the PBS into which a hydrogel device had released NR, they showed clear signs of NR uptake, indicating availability to cells. NR release from the pellets described above can therefore be switched ON by cooling below the LCST of the constituent hydrogel and OFF again by heating above said LCST. The payload released is shown to be available to cells. These results demonstrate that physically crosslinkled thermoresponsive polymer hydrogels can be used for cooling-activated drug release, a promising new approach for patient triggered, on-demand delivery of therapeutics.

2:30 PM SF01.09.05
Tricolor Visible Wavelength-Selective Hydrogels for Cell Encapsulation and Release Teresa Rapp and Cole A. DeForest; University of Washington, United States

Over the past decade, photoresponsive biomaterials have birthed a surge of innovation in targeted drug delivery and 4D cell culture. Compared to other material-modifying stimuli (e.g., pH, enzymes, heat etc.), light is a particularly powerful stimulus for targeted drug delivery, uniquely affording spatiotemporal control in an orthogonally specified manner with different wavelengths. Despite its established promise in laboratory settings, significant challenges remain in pushing these technologies to the clinic. Current photosensitive materials are constrained by their reliance on high-energy UV light which is poorly penetrant through human tissue, limiting the depths to which they may be used for *in vivo* treatment. Additionally, photoresponsive materials developed thus far most typically respond to one or potentially two distinct wavelengths, thereby missing significant opportunities for reaction multiplexing by taking advantage of the entire spectrum of visible and IR light. In this work, I will discuss our recent results in designing and synthesizing a series of visible light-responsive cytocompatible polymer crosslinkers for next-generation hydrogel photodegradation. Translating well-established photochemistries of ruthenium polypyridyl complexes and *ortho*-nitrobenzyl moieties into the biomaterials space, we have created a series of crosslinkers that selectively respond to either red, green, or blue light. When incorporated within step-growth polymeric hydrogel networks, stable gels are formed that are highly sensitive to low-intensity visible light irradiation, reversing gelation within seconds through up to 2 cm of tissue. Reaction cytocompatibility ensures that cells in gels exhibit excellent viability throughout encapsulation, long-term culture, and photorecovery for downstream single-cell analysis. Permitting for the first time sequential photodegradation events deep within living tissue, we anticipate that these user-programmable biomaterial systems will pave a new and sustainable route to clinical drug delivery.

Self-regulated Mixing Leads to Hierarchical Composites with Design Flexibility Ting Xu[1], Le Ma[1], Hejing Huang[2] and Alfredo Alexander-Katz[2]; [1]University of California, Berkeley, United States; [2]Massachusetts Institute of Technology, United States

The modernization toward nanocomposites has been stalled due to the inability to modulate their structures over all length scales albeit of surging developments in colloidal synthesis and self-assembly. Realization of large scale assembles requires long-range diffusivity, a fundamental challenge in nanoscopically ordered systems. This is due to the competition between the enthalpic forces to form assemblies and the kinetic barriers to diffuse through ordered domains. We hypothesize that forming nanostructures in dilute, miscible solution will overcome these fundamental challenges and experimentally realized this by leveraging entropy-driven phase behavior upon increasing composition diversity, akin to that seen in high entropy alloys. The complex blends, composed of nanoparticles/block copolymers/small molecules, self-regulate the spatial distribution of each component to enhance miscibility and, thus, minimize the enthalpic effects. The resultant entropy-driven phase behavior enables NP ordering unachievable before, even in dilute solutions, with unparalleled design flexibility. This makes it kinetically feasible to realize nanoscopic ordering-induced macrophase separation with tunable microstructures. In addition to opening all-new pathways to modulate nanocomposites, these energetic insights may be applicable to understand behavior in other complex blends such as liquid-liquid phase separation.

1:30 PM SF01.10.02
Fluorescent Polymer Particles of Nanometer and Micrometer Lengthscales Towards Labeling Applications—Synthesis and Properties Nikunjkumar Visaveliya; The City College of New York, United States

Various types of fluorescent organic dyes of diverse characteristics are routinely utilized for labeling purposes due to their easy use, low cost, and availability of full emission wavelength range. However, organic dyes are very sensitive to their surrounding in which they rapidly degrade either via chemical degradation or photodegradation. To avoid the concern of degradability, inorganic nanoparticles, in particular, quantum dots are highly versatile and photostable. However, quantum dots are relatively toxic to biological systems, and hence their widespread and safe uses are a concern. Alternatively, dye-doped polymer particles are promising for labeling and imaging due to their properties that overcome limitations of photodegradation as well as toxicity. Fluorescent polymer particles can be prepared simply by incorporating fluorescent dyes in the polymer nanoparticle matrix. In this work, various experimental strategies for the nanoscale fluorescent polymer particles have been developed to bind the fluorophores inside the matrix covalently or non-covalently, as well as at the surface through direct adsorption or based on bio-conjugation. Besides, Hydrophilic and hydrophobic microscale fluorescent polymer particles were prepared via photopolymerization by droplet microfluidics. Highly controlled color compositions were inserted inside the fluorescent polymer microparticles, and a color combination library of the multi-colored fluorescent polymer microparticles was synthesized. Furthermore, soft and bright particulate assemblies were enabled through interfacial interactions at the intermediate scale between the nanometer and micrometer length scale. Overall in this work, various techniques for the synthesis of nanoscale fluorescent polymer particles, as well as microscale fluorescent polymer particles with hydrophobic and hydrophilic characteristics, and assembly of the fluorescent polymer particles at the multiscale level are presented.

1:45 PM SF01.10.03
Self-Orienting and Self-Actuating Materials Based on Anomalous Ultrasonic Scattering Matthew Stein, Sam Keller, Yujie Luo and Ognjen Ilic; University of Minnesota, United States

Contactless manipulation by waves is broadly applicable in systems ranging from assembly and imaging to holography and haptics. However, conventional laws of wave scattering intrinsically limit the actuation force based on the shape and the size of the object: for example, common manipulation mechanisms work for objects with a dimension smaller than the wavelength or a shape that is highly symmetric and often rely on complex feedback control and object tracking. Here, we introduce the concept of a stimuli-responsive acoustic material whereby the dynamics and motion become controllable by a deliberately engineered metamaterial surface.

We present theory, simulations, and experiments to show how the embedding of momentum-shaping surface scatterers can steer and bend ultrasonic waves and lead to programmable self-actuation. To demonstrate the versatility of this concept, we present several examples of advanced actuation functionalities, including autonomous path following and contactless tractor beaming, that are uniquely enabled by anomalous ultrasonic scattering and are beyond the limits of traditional wave-matter interactions. Our work shows how deliberate patterning of a material surface can open new frontiers in contactless actuation and enable unprecedented control of self-actuating dynamics with subwavelength resolution.

2:00 PM SF01.10.04
Polybutadiene Elastomers with Degradation Profiles Programmed by Microencapsulation and Controlled Release of Metathesis Catalysts Brad H. Jones, Samuel C. Leguizamon, Hannah Narcross and Koushik Ghosh; Sandia National Laboratories, United States

The principles of microencapsulation and controlled, *in situ* release of functional compounds have been exploited extensively in the development of stimuli-responsive materials, such as self-healing composites and coatings with sensing capabilities. In contrast, there are comparatively few examples by which the same principles have been utilized for stimuli-responsive polymer degradation, despite recent evidence that *in situ* transformations may present new and improved opportunities for remediation of plastic waste. With this context in mind, we illustrate that microencapsulation of alkene metathesis catalysts provides a powerful method to create polybutadiene (PB) elastomers with programmable degradation profiles. Such catalysts, highly active towards depolymerization of PB via ring-closing metathesis, are rendered effectively latent by microencapsulation within a glassy polymer. The micron-sized polymer/catalyst particles are easily compounded into PB resin which is subsequently crosslinked by radical chemistry, yielding particle-loaded elastomers with similar mechanical properties to particle-free controls. Relying on judicious selection and design of the encapsulant or encapsulating system, the catalyst can be released *in situ* through temperature, time, or light exposure, among other phenomena, thereby initiating rapid depolymerization of the elastomer to soluble products. We anticipate that this approach can be expanded to deliver existing and emerging functional compounds for chemical transformation of polymers with reduced resource requirements, as well as precise control over the conditions under which such transformations are effected.

2:15 PM SF01.10.05
Data-Driven Pathway to Predict Stimuli-Responses of Hollow Polymers Kazi Zihan Hossain and M. Rashed Khan; University of Nevada, Reno, United States

Melt-extruded hollow thermoplastic polymers are a new class of materials for stimuli-responsive applications, i.e., shape reconfigurable robotic clothes, ultra-stretchable touch and twist sensors, and programmable knitted textiles. Under large deformation (stimuli), such materials exhibit hyperelasticity. However, the stimuli-responsive functional behavior of such materials remains a crucial knowledge gap that persists in literature due to time and strain of energy-dependent property variations. This talk will introduce a data-driven pathway harnessing integrated computational materials engineering (ICME) to study, predict, and optimize hyperelastic hollow polymer fibers' behavior. To do so, we calibrated properties utilizing a constitutive materials model, extracted the parametric values using TN (three networks) model, and emulated experimental stress-strain behavior in a finite-element-based multiphysics environment with 99.99% confidence. We also tested and verified our model's accuracy for different compositions of thermoplastics and fabrics. Optimizing the stimuli-responsive functional behavior from hollow thermoplastic fibers requires numerous cost-incurring melt-extrusion runs to characterize strain-dependent behavior. However, from our proposed finite element analysis, we can not only predict strain-dependent behavior but also change shape and geometries for new understandings without running additional melt-extrusions or experiments. Additionally, our ICME approach can be extended to other stimuli (e.g., temperature, humidity, and chemical exposure) for the next generation of pre-programmed functional device fabrication from hyperelastic hollow fibers that may not even exist to date (i.e., body-worn programmable digital clothes).

2:30 PM SF01.06.08
Aptamer-Actuated Two-Dimensional Photonic Crystal Hydrogel Sensors James Westbay, Kyeongwoo Jang and Sanford Asher; University of Pittsburgh, United States

We previously pioneered photonic crystal (PC) hydrogel materials for sensing applications. Here we report novel stimuli-responsive, two-dimensional PC hydrogels that utilize DNA aptamers as molecular recognition agents. The PC hydrogel consists of a PC array embedded into a DNA-functionalized hydrogel. Hybridized strands of DNA attached to the hydrogel polymer network form reversible hydrogel crosslinks. One of the strands contains an aptamer sequence that sensitively and specifically binds a chemical target. On addition of the aptamer's binding target, competitive aptamer-target binding breaks hydrogel crosslinks, actuating swelling. This in turn increases the lattice spacing of the embedded PC array, shifting PC Bragg diffraction. Thus, the concentration of the chemical target can be monitored through PC Bragg diffraction shifts. As proof-of-concept, we fabricated aptamer-actuated PC hydrogels using a well-studied adenosine-binding aptamer. Our PC hydrogels specifically respond to adenosine in both pure-buffer and serum solutions with <30 μM limits of detection. We are currently investigating the generalizability of these materials by fabricating PC hydrogels that respond to proteins.

Autonomous and Life-Like "Self-Oscillating" Polymer Gels as Novel Functional Softmaterials Ryo Yoshida; The University of Tokyo, Japan

Several types of stimuli-responsive polymer gels that reversibly swell and deswell in response to environmental changes have been developed by many researchers. By using these gels as "intelligent" or "smart" gels, many applications in soft actuators as artificial muscles, drug delivery systems, cell culture systems in tissue engineering, purification or separation systems, biosensors, shape memory materials, and molecular recognition systems, etc. have been explored.
On the other hand, in 1996, the author reported "self-oscillating" polymer gels that spontaneously repeat swelling–deswelling changes in a closed solution without any on–off switching by external stimuli, such as heart muscle. They have attracted considerable attention as a new type of gel with an autonomous function that is clearly different from conventional stimuli-responsive gels. The autonomy in the gel is provided by the design, which creates a dissipative structure in the material. The gel has an energy-conversion system involving an oscillatory chemical reaction (called the Belousov–Zhabotinsky (BZ) reaction) which allows periodic mechanical motion of the polymer chain. Since the first report, the author has systematically developed self-oscillating polymer gels from fundamental behavior to construction and demonstration of material systems for potential applications in biomimetic materials, such as autonomous soft actuators, automatic transport systems, and functional fluids exhibiting autonomous sol–gel oscillations similar to those of the ameba. Recently, BZ gels with similar properties have sometimes been called "Yoshida gels". In this presentation, the research developments and recent progress on self-oscillating polymer gels from the author's group are summarized.

8:30 AM SF01.11.03
Exercise-Mediated Biochemical Secretion Guides Maturation and Repair of Neuromuscular Actuators Ritu Raman, Naomi Lynch and Angel Bu; Massachusetts Institute of Technology, United States

Introduction: Stimuli-responsive actuators that match the flexibility and adaptability of skeletal muscle are of significant interest in powering the next-generation of responsive machines. However, abiotic actuators have yet to match muscle's energy efficiency or its ability to dynamically adapt to gain-of-function cues, such as exercise, and loss-of-function cues, such as damage. We have engineered bioactuators, powered by skeletal muscle and controlled by motor neurons, and deployed them as functional actuators in soft robots. Deeper understanding of the stimuli-responsive nature of these bioactuators requires studying how damage that disrupts intercellular signaling between motor neurons and skeletal muscle can impact mobility.
Measuring and modulating intercellular signaling requires tools for longitudinal tracking of biochemicals exchanged between cells within tissues. We leveraged a custom-built micro-invasive interstitial fluid sampling tool to measure biochemical signaling in space and time within our bioactuators. We used this tool to identify muscle-secreted cytokines that are upregulated in response to exercise, driving hierarchical tissue assembly. Moreover, we show that exercise-mediated biochemical secretion enhances repair after injury and accelerates functional integration of bioactuators implanted in animals. We anticipate that this will advance understanding of how to design bioactuators that are robustly responsive to injury when deployed in real-world applications.
Methods: We use our established protocols to engineer neuromuscular bioactuators using mouse and human skeletal muscle and motor neuron lines. Briefly, bioactuators are formed by embedding optogenetic skeletal muscle myoblasts and motor neurons within separate layers of a fibrin/Matrigel hydrogel and growing them around a flexible skeleton. Neuromuscular junctions are formed within 3 days and muscle contraction can be controlled via light stimulation of the muscle or upstream chemical stimulation of the neurons. We have developed a tool, composed of a nanofluidic pump coupled to a micro-scale probe, that enables minimally-invasive sampling of interstitial fluid from tissues. We use mass spectrometry to quantify secretion of hundreds

of peptides and proteins in parallel.
Results & Discussion: Our bioactuator and sampling tool enabled investigating the impact of exercise-mediated biochemical secretion on tissue maturation and response to injury. Sampling interstitial fluid in engineered tissues showed significant proteomic differences between control and exercised groups. Specifically, light-stimulated exercise of optogenetic muscle upregulates the secretion of cytokines that enhance nerve growth including axon guidance pathways mediated by netrin and nicotinic acetylcholine receptor signaling pathways. When bioactuators were implanted in a volumetric muscle loss model *in vivo*, targeted exercise upregulated secretion of cytokines that promoted innervation and angiogenesis, enhanced functional recovery after injury. These results indicate: 1) our sampling tool can be used to monitor intercellular signaling in stimuli-responsive living materials; 2) exercise-mediated cytokine secretion can be used to guide assembly of such materials; 3) stimuli-responsive living materials can modulate intercellular signaling *in vivo* and enhance integration of implanted tissues.
Conclusion: There is a critical need to develop bioactuators for functional applications, and to monitor and modulate intercellular communication within such stimuli-responsive living materials. We have developed a bioactuator and sampling tool that enables monitoring intercellular signaling, and established how exercise-mediated biochemical secretion guides tissue maturation. This platform is being used to advance mechanistic understanding of neuromuscular tissues and develop stimuli-responsive bioactuators for engineered living machines.

8:45 AM SF01.11.04
Enhanced Mechanoluminescence Intensity of PDMS-ZnS—Cu by Variating ZnS Particle Volumetric Content and Kirigami Structure Incorporation Michael A. Listyawan[1], Geon-Tae Hwang[2] and Jungho Ryu[1]; [1]Yeungnam University, Korea (the Republic of); [2]Pukyong National University, Korea (the Republic of)

Mechanoluminescence (ML) material has an innate characteristic to exert luminescence as a response to mechanical stimuli such as tensile, compression, friction, etc. Its unique characteristic of exerting light without any electrical energy is enabling this material for a wide range of applications such as wind-driven displays, stress sensors, strain sensors, etc. One of which is a ubiquitous lighting device, where commonly lighting applications require electricity that involves components to support the circuitry. Bypassing the need for electricity will not only improve efficiency but even reduce cost substantially and improve the durability of the device since numerous components might fail and break at any given time. However, the ML material faces many challenges to be adopted as a practical and functional application which mainly is the intensity. With this study, we can enhance the luminescence intensity from the elastomer composite of PDMS-ZnS: Cu significantly by increasing the powder volumetric content up to 30% without any significant decrease in stretchability. Nevertheless, with higher than 30% volumetric content, has a lesser luminescence output but it has higher intensity if applied with lower displacement. Additional finite elements analysis (FEA) simulation is also done to observe the mechanisms. We also detect a lower load-luminescence activation when incorporated with kirigami structures. The luminescence intensity of different kirigami shapes is compared, and the stress-strain relation is mapped using FEA simulation. Overall, the kirigami shape incorporation improves the overall stretchability range and has a better sensitivity according to the simulation. However, each shape has a different stretching range, and some shapes are more sensitive to load as the edges act as a stress concentrator. The T-shaped kirigami cuts possess the widest range out of all compared kirigami shapes.

9:00 AM SF01.11.05
PRESENTED ON-DEMAND ONLY: Supramolecular Hybrid Hydrogels as Rapidly On-Demand Dissoluble, Self-Healing and Biocompatible Burn Dressings Aslihan Gokaltun[1], Letao Fan[1], Luca Mazzaferro[2], Delaney Bryne[1], Martin L. Yarmush[1], Tianhong Dai[1], Ayse Asatekin[2] and Berk Usta[1]; [1]Harvard Medical School, United States; [2]Tufts University, United States

Supramolecular hydrogels (SHs), a novel class of PCHs, are held together by non-covalent crosslinks such as host-guest chemistry, electrostatic interactions, and hydrogen bonding. These hydrogels can respond to environmental stimuli such as light, pH, and electric field. Unlike most synthetic hydrogels with permanent chemical crosslinks, SHs can undergo dissolution in response to various environmental stimuli and self-heal when damaged. Despite decades of efforts, state-of-the-art synthetic burn dressings to treat partial-thickness burns are still far from ideal. Current dressings adhere to the wound and necessitate debridement. This work describes the first “supramolecular hybrid hydrogel (SHH)” burn dressing that is biocompatible, self-healable, and stimuli-responsive (on-demand dissoluble) for easy and trauma-free removal, prepared by a simple, fast, and scalable method. These SHHs leverage the interactions of a custom-designed cationic copolymer via host-guest chemistry with cucurbit[7]uril and electrostatic interactions with clay nanosheets coated with an anionic polymer to achieve enhanced mechanical properties and fast, on-demand dissolution. The SHHs show high mechanical strength (> 50 kPa), self-heal rapidly in ~1 min, and dissolve quickly (4-6 min) using amantadine hydrochloride (AH) solution that breaks the supramolecular interactions in the SHHs. Neither the SHHs nor the AH solution have any adverse effects on human dermal fibroblasts or epidermal keratinocytes *in vitro*. The SHHs also do not elicit any significant immune response *in vitro*. Furthermore, *in vivo* murine experiments show no immune or inflammatory cell infiltration in the subcutaneous tissue and no change in circulatory cytokines compared to sham controls. Thus, these SHHs present excellent burn dressing candidates to drastically decrease pain and time associated with dressing changes.
Due to the ease of their fabrication, which only involves two steps of mixing, we expect these novel SHHs will enable large-scale yet low-cost fabrication, addressing a critical bottleneck for translation to clinical applications. Further, due to this ease and the speed (15 seconds) of SHH formation, we envision that the dressings could even be formed at the bedside and on-field synthesis of the patients with customizations as necessary. Such novel and on-demand dissoluble SHHs have great potential as second-degree burn dressings. They will i) provide easy burn care, ii) eliminate mechanical and surgical debridement, iii) promote wound healing and enhance the healing process to treat second-degree burns. To this end, we will follow up this study with investigations on the *in vivo* efficacy of SHHs in burn wound healing progress. We expect our invention to remove the challenges and shortcomings associated with current burn dressings and bear pain-free (or reduced pain), easy to apply, and removable burn dressings.

9:15 AM SF01.11.06
Collective Behavior Triggers Chemomechanical Oscillations in Active Hydrogels Baptiste Blanc[1,2], Johnson Agyapong[3,2], Ian Hunter[2], Ali Aghvami[2] and Seth Fraden[2]; [1]Massachusetts Institute of Technology, United States; [2]Brandeis University, United States; [3]Syracuse University, United States

Quorum sensing refers to the ability of yeast and other unicellular organisms to switch behavior in response to increasing numbers or density, inducing responses such as oscillating production of chemicals and biofilm formation. There has been much interest in obtaining a quorum sensing behavior in synthetic analogues, employing, for example the enzyme urease or the Belousov Zhabotinsky (BZ) reaction, for novel bioinspired smart material. In this work, we demonstrate that the quorum sensing response of an assembly of soft small BZ hydrogels (smaller than their critical size to oscillate on their own) can trigger their chemomechanical oscillations. We first report that a single spherical BZ gel smaller than a critical size of 350 micrometers in diameter does not chemically oscillate when left alone. In contrast, a 2D layer made of the same spherical BZ gels present chemical oscillations that last for days. To understand the physicochemical cause of this critical size, we experimentally engineer the coupling of single BZ gels to their environment by imposing a flow of reactants around them. By comparing the oscillation patterns obtained in a convective flow set up with those obtained when only diffusion takes place, we establish experimentally that the passive transport of the inhibitor outside the bead produced by the BZ reaction solely controls the pattern of oscillations. We finally discuss why this discovery paves the way to the design of optimized BZ chemomechanical machines.

9:30 AM SF01.11.07

Tunable Rigidochromism of Copper-Pyrazolate Complexes Yuichiro Watanabe[1], Benjamin Washer[2], Matthias Zeller[2], Sergei Savikhin[2], Lyudmila V. Slipchenko[2] and Alexander Wei[2]; [1]Kyoto University, Japan; [2]Purdue University, United States

Copper(I) ions and pyrazoles can self-assemble into macrocyclic clusters with intense solid-state phosphorescence at ambient temperatures. We are investigating a series of tetranuclear Cu–pyrazolate (Cu_4pz_4) complexes whose luminescence relies on a cluster-centered triplet state (^3CC), and whose energies are influenced by substituents far from the Cu_4 core. These remote substituent effects are steric in nature and support a tunable rigidochromism with emissions ranging from yellow to deep blue, confirmed by TD-DFT calculations. As pyrazole ligands increase in structural complexity, polymorphs with different luminescent wavelengths emerge that allow rigidochromic behavior to be tuned by extrinsic physical and chemical stimuli (i.e. heat, and hydrocarbon vapor treatment).

9:45 AM SF01.11.08
Thermo-Responsive Modulus Tuning of 3D Printed Hydrogels Kusuma Betha Cahaya Imani and Jinhwan Yoon; Pusan National University, Korea (the Republic of)

Materials with a controllable mechanical property are highly studied in recent years, because of their many possible applications. One of the popular materials to be studied is hydrogel, because of its ability to contain a high amount of water, allowing for mechanical properties control through external stimuli. In this study, a combination of micelles, ionic bonding, and hydrophobic association was used to prepare hydrogel. A fine mechanical tuning by temperature control was achieved through the hydrophobic association. In addition, there is a sharp stiffness change from rubbery to glassy material, induced by phase separation at high temperature. This ability is attractive for the development of biomimetic materials, and safety equipment which requires both elastic and stiff property at room and high temperature.

PRESENTED ON-DEMAND ONLY: Tuning Multiferroic $La_xSr_{1-x}Fe_{12}O_{19}$ from Ferroelectrics to Antiferroelectrics Guolong Tan; Wuhan University of Technology, China

The appearance of antiferroelectrics (AFE) in ferromagnetism (FM) system would give birth to a new type of multiferroic candidate, which is significant to the development of novel devices for energy storage. Here we demonstrate the realization of full antiferroelectrics in magnetic $La_{0.5}Sr_{0.5}Fe_{12}O_{19}$ system (AFE+FM), which also presents strong magnetodielectric response (MD) and giant magnetoresistance (GMR) effect. The combination of antiferroelectricity and ferromagnetism in one structure would create new types of multiferroic candidates. Here we propose a novel type of multiferroic candidate $La_xSr_{1-x}Fe_{12}O_{19}$, whose room temperature state could be tuned from ferroelectrics to antiferroelectrics by changing x from 0 to 0.5. The antiferroelectric phase was achieved at room temperature by replacing 0.5 Sr^{2+} ions with 0.5 La^{2+} ions in $SrFe_{12}O_{19}$, whose phase transition temperature of ferroelectrics (FE) to antiferroelectrics was brought down from 174°C to -141°C, while the temperature of antiferroelectrics converting to paraelectrics (PE) shifts from 490°C to 234°C after the substitution, generating a wide space between -141°C~234°C to accommodate the antiferroelectric state in $La_{0.5}Sr_{0.5}Fe_{12}O_{19}$ system. The fully separated double P-E hysteresis loops reveal the antiferroelectrics in $La_{0.5}Sr_{0.5}Fe_{12}O_{19}$ ceramics. $La_{0.2}Sr_{0.7}Fe_{12}O_{19}$, however, exhibits a hybrid ferroelectric/antiferroelectric state. Both compounds exhibit strong ferrimagnetism. In addition, the $La_{0.5}Sr_{0.5}Fe_{12}O_{19}$ ceramic demonstrates strong magnetoelectric coupling and giant magnetoresistance effect. A 1.1T magnetic field generates electronic polarization of 0.95mC/cm^2, reduces the resistance by 117% (GMR), enhances dielectric constants by 540% and right shifts the maximum dielectric loss peak by 208 kHz, showing giant magnetodielectric effect (GMD). The combined functional responses provide an opportunity to develop novel multiferroic memories and energy storage devices.

Analysis of Multichannel GaN/AlGaN Superlattice Device Conduction at Cryogenic Temperatures Annaliese Drechsler[1,2], Patrick Shea[2], Robert Howell[2] and Aristos Christou[1]; [1]University of Maryland, United States; [2]Northrop Grumman Corporation, United States

GaN/AlGaN and related heterostructures are key device structures to create the next generation of high electron mobility transistors, high power switches, and high frequency FETs. Typically, these devices are operated at room temperature or above, and high temperature operation, physics, and degradation have been widely studied. Recently, new applications have emerged for these materials including integration with superconductors for amplifier loads, photon detection, superconducting magnets, or other energy storage applications. To ensure that selected GaN/AlGaN devices are compatible with cryogenic operation, their behavior must be studied down to 4K. In this work, we investigate the parametric changes associated with cryogenic operation for the Superlattice Castellated Field Effect Transistor (SLCFET) and demonstrate operation of a SLCFET switch with exceptionally high performance at 4K.
Typical GaN/AlGaN devices are fabricated into HEMTs where charge is conducted by the interfacial piezoelectric strain between the GaN and AlGaN. This device structure maintains conductivity at low temperatures since the charge originates from strain instead of dopants. The SLCFET device similarly utilizes GaN and AlGaN, but to form a multichannel superlattice. The topmost channel is undoped, generating charge carriers like the GaN HEMT, but the lower channels don't experience this strain and require dopants to conduct charge, which may demonstrate freeze out due to insufficient carrier activation energy at low temperatures. Due to the combined nature of the structure, the cryogenic performance of the device was unknown.
To characterize this performance, a 4-point Van der Pauw structure for epitaxial resistance was measured using a non-magnetic Quantum Design PPMS system cooled from 300K to 3.5K. The resistivity decreased from the typical 300K value of 70 Ω/sq to 26 Ω/sq. This result is critical as it provides the first indication that the SLCFET device is not experiencing dopant freeze-out, despite having doped channels. If this was occurring, the resistance would decrease initially due to reduced scattering and then increase sharply once the thermal energy is insufficient to overcome the charge carrier formation activation energy barrier. Instead, the resistance shows a linear decrease from 300 to 150K and then begins to plateau. This suggests that the observed initial decrease is due to carrier mobility increase, likely from reduced electron-phonon scattering, which is then limited by defect scattering once the resistance starts to plateau.
To further understand this behavior, Hall Effect structures were tested using a 14T Quantum Design PPMS System. The samples were cooled to 4K and the magnetic field was swept from -4 to 4T. From the Hall coefficient, the average carrier density across the tested samples was calculated to be 5.69×10^{17} carriers/cm^3, within the typical range reported from room temperature characterization. This similarly indicates that the resistance decrease is not a result of increased charge carrier density. The resistance decrease then must be attributed to an increasing mobility, which has been calculated to increase from a typical average of 1500 cm^2/Vs to an exceptionally high 4151.5 cm^2/Vs. SLCFET switch was then analyzed using gate voltage-drain current characterization in a liquid-He Dewar. The on-state current shows a ~3x increase from the reduced resistance, while off-state leakage is reduced. Interestingly, the pinch-off voltage is nearly constant. The parametric changes can similarly be attributed to the mobility increase from reduced phonon scattering enabled by cryogenic conditions.
In conclusion, we studied the behavior of the multichannel SLCFET GaN/AlGaN device at cryogenic conditions. The epitaxial structure was observed to decrease in resistance which is attributed to a mobility increase due to reduced phonon scattering. The SLCFET switch structure was demonstrated with improved performance at 4K.

11:00 AM SF02.01.05
Architectural Cellular Structure via Freeze-Drying Method for High Strength and High Resilience Jongbeom Kim and Seung Min J. Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

3D architectural cellular structures that are fabricated via additive manufacturing methods are currently receiving much interest due to the tunable properties that can be realized by simply tuning the architecture of structures. However, the most of additive manufacturing methods do not meet the resolution to the nanoscale. Multiphoton lithography raises its resolution to the nanoscale, but there is a scalability issue that takes over several days to weeks to fabricate a centimeter-sized structure, making it difficult to use in bulk material applications. In this study, the freeze-drying method was used as a 3D structure manufacturing method. In the freeze-drying method, the solution is sublimed after frozen, leaving a solute in the inverse structure of the ice crystal inside to form a 3D structure. Due to this fabrication method, a 3D structure can be fabricated in a one-step process regardless of the material, and a centimeter-scale bulk structure can be easily produced depending on the size of the frozen template. As materials constituting a 3D structure, silver nanowire was added to a polymer solution containing cellulose nanofiber (CNF) or polyvinylalcohol (PVA) to fabricate a structure that has a high strength-to-mass ratio. In addition, controlling the cooling direction, the directionality of the ice crystals generated can be aligned to the same direction, so that the pores of the 3D structure grow in a frozen direction. This is called the directional freeze-drying method. Using the directional freeze-drying method, the structure with high strength as well as excellent resilience according to the directionality of the structures was fabricated. Structures were fabricated using various materials as well as polymers by freeze-drying. A 3D structure was fabricated using pollen, which can be commonly collected in the environment, and showed the possibility of using a pollen 3D structure for oil absorption.

SESSION SF02.02: Materials for Space and Insulation
Session Chairs: Alexander Goncharov and Nathan Mara
Monday Afternoon, November 28, 2022
Sheraton, 3rd Floor, Commonwealth

1:30 PM SF02.02.01
Carbon Nanotube Arrays as Adhesives Under Harsh Conditions as in Space Technology Christian Lutz and Hendrik Hoelscher; Karlsruhe Institute of Technology, Germany

For their potential use as dry adhesives under harsh conditions, we discuss the potential use of carbon nanotube (CNT) and nanofiber (CNF) arrays. The basic idea is to mimic the fine fibril structure of gecko toes by CNTs and CNFs. For that, we investigated the temperature dependence of the adhesion of carbon nanotube arrays by atomic force microscopy (AFM) in a temperature range from − 20 °C to + 240 °C. In order to mimic the specific conditions for space application as close as possible, we glued tiny meteoritic particles to AFM cantilevers as probes. The measurements revealed that the adhesion forces are practically constant in the investigated temperature range. Long-term measurements confirm the expected durability of carbonic arrays. The overall properties did not change after exposing the sample to simulated space condition. Additionally, we measured the adhesion between ice and carbon nanotubes at − 20 °C and obtained similar results. For these measurements, we used a bundle of CNTs as probe and grow a closed ice layer as sample

surface.

1:45 PM SF02.02.02
Improvement of Calcium–Magnesium–Alumino-Silicate (CMAS) and Hot Corrosion Resistance of Functionally Graded Al_2O_3/CYSZ Thermal Barrier Coatings (TBCs) Fatih Kirbiyik[1], Mustafa G. Gok[2], Dermot Brabazon[3] and Gultekin Goller[1]; [1]Istanbul Technical University, Turkey; [2]Gaziantep University, Turkey; [3]Dublin City University, Ireland

CMAS dusts and hot corrosion salts are one of the most serious threats to gas turbine blades. Both of these, at high temperatures, penetrate into the thermal barrier coating (TBC) on the turbine blade surface and/or degrade the chemical structure of the coating. Therefore, it usually causes stress-induced damage. In this study, a laser surface modification process was performed to increase the CMAS and hot corrosion resistance of functionally graded alumina/ceria-yttria stabilized zirconia (Al_2O_3/CYSZ) TBCs. Single layered CYSZ was chosen as the comparison to the developed and tested TBC material because it has high corrosion stability. Thermal cycling and thermal gradient tests were performed to understand the simultaneous effect of CMAS and hot corrosion, on CYSZ TBC and the laser surface modified Al_2O_3/CYSZ TBC. For thermal cycling and thermal gradient tests, TBCs with a mixture of CMAS powder and hot corrosion salt on their surfaces were heated to 1200°C by using a laser beam. The thermal cycle test was performed as heating from the surface of the TBC and then followed by air cooling, while the thermal gradient test was performed as heating from the surface of TBC and simultaneous water cooling from the back surface of the substrate. Damages in both coatings and their mechanisms were characterized using detailed macroscopic, microscopic (SEM) and phase (XRD) analyses.

2:00 PM SF02.02.03
Broadband Highly Reflective Materials as Multilayer Insulation Shields Xuanjie Wang, Chieloka D. Ibekwe and Shankar Narayan; Rensselaer Polytechnic Institute, United States

Critical for the functioning of many cryogenic systems, multilayer insulation (MLI) systems are used when lower heat leakage rates are required, including storage, transfer, thermal protection, and low-temperature processer. Three major modes of heat transfer in MLI are radiation, solid conduction and gas conduction. Among them, the radiation heat from the outer space is decisive, which strikes on the first reflective layer and heats up the inner layers. In order to shield from the harsh environment of space and harmful radiation from sun and earth, MLI systems have to provide several attributes, including being lightweight, highly reflective, thermally insulating, mechanically robust and electrically conductive. In our study, a broadband high reflection is achieved through geometry control of nanostructure by cost-effective manufacture method. Specifically, the hierarchical nanostructure with more than 90% reflectance shows excellent insulation ability under the illuminance of one sun, achieving 40% less heat gain compared to the conventional aluminum reflector in the calorimetric measurement. The optical simulation guides the geometry control in the fabrication process with tuned structures. The reflector is stable under long time UV exposure environment. The simple manufacturing techniques presented in this study to generate nanoengineered surfaces can lead to further advancements in solar reflectors with well-controlled optical properties for different conditions.

2:15 PM SF02.02.04
Developing Spacecraft Reliability for Lunar Missions—Radiation Shielding Ronald H. Freeman; Journal of Space Operations & Communicator, United States

Radiation exposure from SPEs presents a significant hazardous concern for exploration missions outside the protection of the Earth's magnetic field, which could impair their performance and result in possible mission failure.The impracticability of Earth-Moon transits for repairs, replacements affords a need for greater self-reliability of lunar spacecraft. Radiation environment consists mainly of solar wind (including electrons and protons) to cosmic protons and ions as primary space environment. And, radiation secondary space environment of electrons and neutrons influences spacecraft as well as spacecraft electronic devices; results in spacecraft single event effect; causes displacement damage dose.The objective is to show distinct radiation-mitigating strategies and how they may be designed into different hierarchical levels of a system with the greater functional reliability as well as quicker resilient-like post-fault recoverability.The following radiation-mitigating strategies will be discussed and compared.
1. The satellite structure is the first radiation shield layer. A novel material known as boron nitride nanotubes (BNNTs) per their mechanical properties, suggest replacement of aluminum alloys as structural components for spacecraft, while also providing radiation shielding. More enhanced BNNT performance may be achieved when loaded with hydrogen. A comparison may be made with another shielding material under review, polyethylene composites. Moreover, technologies under review enable greater hydrogen storing capacity in BNNTs. 2. Radiation flux to dose conversions from OLTARIS and HZETRN afford efficacycomparative analyses for different novel radiation-mitigating strategies. 3. Electronic equipment used in the satellite missions is another layer of vulnerability with ionizing particle encounters, causing problems in normal operations. So, the combination of high-density shielding materials such as tantalum and tungsten and low-density ones such as polyethylene can be considered as an ideal strategy.4. Space computers suffer from the unwanted effects of cosmic energy. A single-event upset (SEU) occurs when high-energy particles or heavy ions strike a complementary metal oxide semiconductor (CMOS) device and cause unintended, logic-level transition. 5. In partial reconfiguration (PR), a partial bitstream is loaded into a select section of configuration memory to drive a change in logic. When a fault occurs in either the foreground circuitry of the FPGA or in the configuration memory region corresponding to the foreground circuitry, PR will restore that region to its original state. Detection and repair of SEU-induced faults are accomplished through a comprehensive strategy including partial reconfiguration (PR) of impacted cores, error correction codes (ECC) for memory that cannot be partially reconfigured, and soft error mitigation monitoring for the configuration memory of the FPGA.
6. As radiation-based faults are a great concern to spaceflight hardware, the concept of shielding, in which some sort of material serves as a boundary between cosmic radiation and the hardware at risk. Alternatively, radiation-hardened semiconductor manufacturing modifications are another method of mitigating radiation-induced faults in system hardware and have shown effectiveness. Radiation hardened by design (RHBD) methods will be discussed and comparatively analyzed.
7. Other approaches include fault-mitigation strategies based on a Redundant Multiprocessor System implemented within the FPGA fabric; improved characterizations of the radiation environments to which RadPC would be exposed, and a numerical modeling tool known as the Cosmic Ray Effects on MicroElectronics (CREME96) would be used to model the radiation environment. RadPC contributes to the field of space computing by providing a cost-effective, radiation-tolerant design using a commercial-off-theshelf FPGA to actively respond to radiation-induced faults in the device.

SESSION SF02.03: High Temperature on Materials
Session Chairs: Alexander Goncharov and Nathan Mara
Monday Afternoon, November 28, 2022
Sheraton, 3rd Floor, Commonwealth

3:00 PM *SF02.03.01
Elevated Temperature Thermomechanical Stability of Metallic Interfaces Containing 3D Character Nathan Mara[1], Justin Cheng[1], Zezhou Li[1], Shuozhi Xu[2], Youxing Chen[3], Mauricio De Leo[1], Jonathan Poplawsky[4], Nan Li[5], John K. Baldwin[5] and Irene J. Beyerlein[2]; [1]University of Minnesota, United States; [2]University of California, Santa Barbara, United States; [3]University of North Carolina at Charlotte, United States; [4]Oak Ridge National Laboratory, United States; [5]Los Alamos National Laboratory, United States

2-dimensional (2-D) sharp interfaces with distinct boundaries demarcating an abrupt discontinuity in material properties in nanolayered composites have been studied for almost twenty years and are responsible for enhanced behaviors such as strength, radiation damage tolerance, and deformability. However, 2-D interfaces have their limitations with respect to deformability and toughness. 3-D interfaces are defined as heterophase interfaces that extend out of plane into the two crystals on either side and are chemically, crystallographically, and/or topologically divergent, in three dimensions, from both crystals they join. Here, we focus on the thermal stability (up to 500° C) and mechanical behavior of nanolayered Cu/Nb containing interfaces with 3-D character. By co-sputtering the bimaterial interfaces between the constituent pure phases, the resulting compositional gradient gives rise to new interphase boundary structures, which have been analyzed and quantified via S/TEM and Atom Probe Tomography. Micropillar compression results show that the strength of Cu/Nb nanocomposites containing 3-D interfaces is significantly greater than those containing 2-D interfaces. Mechanical anisotropy, as well as shear banding is observed during pillar compression with retention of continuous layers across the shear band. We will present our recent results on deformation of such 3-D interfaces and structures, and describe their structural evolution mechanistically through the use of atomistic and Phase Field Dislocation Dynamics simulations.

3:30 PM SF02.03.02
Design of a Multiscale Porous High-temperature Ceramic Heat Exchanger Xiangyu Li[1,2], Chad Wilson[1], Lenan Zhang[1] and Evelyn N. Wang[1]; [1]Massachusetts Institute of Technology, United States; [2]The University of Tennessee, Knoxville, United States

The efficiency of a heat engine can be significantly improved by operating in a high-temperature and high-pressure environment. However, such extreme operating condition poses a severe challenge to the heat exchanger design. Although recently developed super alloys and ceramics can survive high temperatures and high-pressure loads, using these materials in a traditional heat exchanger design requires high cost and yields low power density. In this work, we propose a high power density ceramic heat exchanger for high-temperature applications enabled by a multiscale porous design. By optimizing the design of centimeter-scale macrochannels and micrometer-scale microchannels, significant improvement to both the heat transfer and structural strength are predicted, with a negligible pressure drop penalty, compared to current state-of-the-art solutions. An optimized design is expected to achieve high power density, light weight, low cost along with less than 4% pressure drop penalty. Furthermore, the heat exchanger design is customizable for different applications in hybrid and electric aerospace applications, as well as terrestrial power generation such as nuclear power generation and concentrated solar power generation, promising more than 2.5x thermal performance compared to state-of-the-art solutions utilizing commercially available superalloy and ceramic materials, while providing the benefits of low cost, scalable fabrication, low pressure drop and high structural strength.

3:45 PM SF02.03.03
Morphological Instabilities of Nanorods at Elevated Temperature. Omar Hussein[1], Keith Coffman[2], Khalid Hattar[3], Eric Lang[3], Shen Dillon[4] and Fadi Abdeljawad[1]; [1]Clemson University, United States; [2]University of Illinois Urbana-Champaign, United States; [3]Sandia National Laboratories, United States; [4]University of California, Irvine, United States

Recent advances in high-precision manufacturing and self-assembly techniques have enabled the fabrication of materials architectures with intricate nanoscale features. Notable examples include nanolattices, nanoscale rods, nanoporous materials, and stochastic nanostructures. Integrating complex designs with nanoscale induced materials properties enables a myriad of applications, including electronics, energy and microfluidic devices, structural, and photonics. While such materials enable enticing combinations of properties, the microstructural stability of nanoscale morphologies under high-temperature environments remains poorly understood. Owing to the increased interfacial contribution to the total free energy in nanoscale geometries, these structures are at highly non-equilibrium states and evolve by a wide range of mechanisms. Recent experiments demonstrate a morphological instability in which a polycrystalline micro- or nanoscale rod breaks up into single-crystal domains, a phenomenon reminiscent of the Plateau-Rayleigh instability in liquid jets. Our high temperature in situ annealing studies of a model alumina rod with a bamboo grain structure demonstrated the pinch-off instability initiated at a GB. Here, we develop a theoretical model to investigate the impact of grain boundaries (GBs) on the morphological instabilities of polycrystalline nanoscale rods. A neutral stability surface is obtained, which demarcates stable and unstable perturbations with respect to the breakup. Our analysis shows that GBs play a destabilizing role in which the critical wavelength for the instability decreases with increasing the GB energy. Further, it is shown that perturbation amplitudes introduced through grain size differences influence the magnitude of the critical wavelength for the instability. We complement our thermodynamic treatment with phase-field simulations that capture the kinetics of morphological instability. The study reveals that increasing the GB energy leads to accelerated pinch-off kinetics. Moreover, it is shown that variations in grain size could provide a pathway for the morphological instability, in which GB migration and shrinkage of small grains result in the development of free surface perturbations whose wavelengths exceed the critical value for the instability. In broad terms, our approach provides avenues to investigate the microstructural stability of nanolattices and nanoporous materials.

4:00 PM SF02.03.04
Refractory Alloys with Ru-Based B2 Precipitation-Strengthened Microstructures Sebastian A. Kube[1,2], Carolina Frey[1], Kaitlyn Mullin[1], Chiyo McMullin[1] and Tresa M. Pollock[1]; [1]University of California, Santa Barbara, United States; [2]Yale University, United States

To strengthen Refractory Multi Principal Element Alloys at 1200°C and beyond, one strategy aims to design stable microstructures of B2 precipitates embedded within a BCC matrix, which emulates the γ-γ' structure found in Superalloys. Here, we focus on Ru-based B2 intermetallics as one promising group of precipitates with a high thermal stability. We comprehensively explore the resulting space of alloy systems. We arc-melt a wide range of compositions and determine phase stability and mechanical performance under various thermal processing conditions.

4:15 PM SF02.03.05
Impact of Grain Boundary Pinning Using Silicon Refractory Inclusions in Screen Printed Silver Flake Inks for High Temperature Printed Electronics Applications Arjun Wadhwa[1], Jaime Benavides Guerrero[1], Mohammad Saadati[1], Martin Bolduc[2,1] and Sylvain G. Cloutier[1]; [1]Ecole

Technology Superiure, Canada; [2]Université du Québec à Trois-Rivières, Canada

The world of printed electronics is a fast-growing dynamic field employing the process of printing a functional material onto a low-cost substrate to form a device. Screen printing is one of the premier methods used to fabricate high-volume, low-cost devices typically with silver conductive pastes. These materials are limited to relatively low operational temperatures up to approximately 150 ^{0}C [1]. In this work, we demonstrate the ability to improve the thermal stability of commercially available silver screen printable ink[2] to fabricate a temperature sensing printed device capable to operate at high temperatures up to 700 ^{0}C. This is achieved by impregnating the silver ink with controlled quantities of silicon micro particles. First, we present the modification procedure of the ink and the mechanism employed to achieve enhanced thermal stability and its advantages compared to the traditional unadulterated silver ink [3,4]. Next, we outline the characterization procedure to quantify the grain growth and electrical conductivity of the modified ink processed at incremental temperature ranges over time. Further, we benchmark the enhanced stability of the modified ink versus the virgin ink and the state of the art[5] illustrating how the modification potentially allows low-cost silver inks to be utilized in high temperature environments in aerospace, chemical production, automotive industries. Finally, we validate the performance of the modified ink under elevated temperature conditions as a all silver resistance temperature detector (RTD).

***In Situ* Explorations of Serrated Plastic Flow in a CoCrFeNiW-C Alloy at Elevated Temperatures** Shaolou Wei and Cem Tasan; Massachusetts Institute of Technology, United States

Multi-component Co-alloys are a class of promising metallic materials for high-temperature applications. Provided the appreciable screening of their yield strength preservation trends depending on different alloy design strategies, systematic understandings of their plastic deformation response are still in lack. The present work is focused on the plastic deformation mechanisms of a CoCrFeNiW-C alloy in the 650-750 ºC temperature range, with emphases on dislocation slip intermittency and the resultant serrated plastic flow. By integrating high-temperature *in situ* SEM-based tests, statistical analyses, and theoretical calculations, the following mechanistic insights will be discussed: (1) What causes the serrated plastic flow response and thereby the transition in its module? (2) What are the latent dynamic features amongst the serration incidents? (3) What kinds of deformation substructures are associated with the serrated plastic flow? Quantitative analysis of the dislocation slip mechanisms as well as their impacts on damage initiation will also be revealed in greater depth.

4:45 PM SF02.03.07
LPBF of SiC-Reinforced In718 and CoCrFeNi for Improved High-Temperature Strength Alexander D. O'Brien, Emre Tekoglu and Ju Li; MIT, United States

With the ongoing development of advanced nuclear energy systems, there is an ever increasing need to design materials capable of achieving long lifetimes in high-temperature, high-irradiation, corrosive environments. Among those materials currently under consideration for the next generation of reactors, nickel superalloys are considered to be a staple due to their excellent high-temperature creep and oxidation resistances, and high entropy alloys are seen as promising candidates due to their considerable high-temperature strength and radiation resistances. Either category of material could be considered an excellent starting point for the development of critical components for new reactor systems. However, the upper ceiling on the capabilities of both could still be expected to be limiting factors in reactor operating conditions, making further improvement in their high-temperature capabilities highly desirable. We report on the fabrication of two new high-temperature metal matrix composites based on an Inconel 718 nickel superalloy and a CoCrFeNi high entropy alloy reinforced with SiC nanowires for improved strength. Composite powders of each material were prepared by high-speed blender declustering of as-received nanowires and the base alloy powders, followed by mechanical alloying via ball mill to produce a homogenous distribution of SiC on the surfaces of the metal particles. Additive manufacturing of composite powders was performed via laser powder bed fusion, which would provide a scalable method of producing these especially difficult to manufacture materials in any number of complex geometries. Analysis of the as-printed specimens revealed dissolution of the nanowires during laser melting, which was found to result primarily in the in-situ formation of Nb and Ti-based silicide and carbide nanoparticles in the Inconel composite, while silicon oxide nanoparticles were observed in the CoCrFeNi matrix. In both cases, the nanowire dissolution process and resulting nanoparticles appear to contribute to the formation of more desirable microstructures during printing, reducing the formation of cracks and pores and decreasing the average grain sizes compared to unreinforced samples prepared under the same conditions. Mechanical characterizations also revealed notable increases in hardness and tensile strengths of both composites, confirming the benefits of reinforcement. We believe that this work presents a simple and effective method for improving the strength and usability of high temperature materials prepared by additive manufacturing that may prove important in the face of ever-harshening environments in the energy sector.

SESSION SF02.04: Poster Session I: Materials for Extreme Conditions

Facile Li^+ Transport in NMC811||Graphite Lithium-Ion Batteries at Low Temperatures Enabled by Using Low-Polarity Solvents Bo Nan[1], Long Chen[1], Nuwanthi D. Rodrigo[2], Oleg Borodin[3] and Nan Piao[1]; [1]University of Maryland, College Park, United States; [2]University of Rhode Island, United States; [3]US Army Research Laboratory, United States

Li-ion batteries (LIBs) using graphite anode and high voltage nickel-rich cathodes ($LiNi_xCo_yMn_zO_2$ (x+y+z=1)) are the most promising energy storage technology in the foreseeable future. However, charging these LIBs at low temperatures (≤ -20 °C) remains challenging because the excessive resistances

encountered by lithium-ion in and across the bulk electrolytes and the interphases induce lithium plating on graphite anodes and electrolytes decomposition on the cathodes, which accelerate the capacity decay of the batteries. In particular, the significant increase of the charge-transfer resistance is the most problematic one and has barely been studied and well-regulated. Herein, we introduce a strategy of using low-polarity-solvents electrolytes that can reduce the resistance and activation energy in the charge transfer process effectively, allowing facile lithium-ion transport at subzero temperatures. The exemplary electrolyte enables the $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ ||graphite (NMC811||Gr) LIBs to deliver 81% of its room-temperature capacity at 1/3C at -20 °C and keep 84% and 78% of its room-temperature capacity at -30 °C and -40 °C, respectively, while maintaining decent energy density, fast-charging capability, and stability at room temperature and high temperature of 50 °C. The effective electrolyte engineering approach demonstrated in this work together with molecular simulations provides new insight and a general guideline for designing practical low-temperature electrolytes for LIBs.

SF02.04.02
Nanofibrous Polymeric Coatings as High-Performing Broadband Reflectors—Application in Multilayer Insulation Systems for Extreme Environments Chieloka D. Ibekwe, Xuanjie Wang, Brandon Bolzani and Shankar Narayan; Rensselaer Polytechnic Institute, United States

Multilayer insulation (MLI), also referred to as superinsulation, are thermal insulation materials used to prevent heat loss by radiation in spacecraft and cryogenic systems. They usually consist of multiple layers of reflectors (metallic reflectors or thin polymer films with vapor-deposited aluminum on one or both sides of each film), and spacers arranged hierarchically. These stacked layers have a cumulative effect of reflecting nearly all incident radiation. With an improved reflectance of each individual layer of reflector material, the overall performance of the MLI system goes up.
In this work, composite polymeric nanofibrous coatings of desired thicknesses were deposited on aluminum foil substrate by a controlled electrospinning nanofiber production method. Ultra-high broadband optical reflectance was achieved in the UV-NIR wavelength range of the solar spectrum, which is an improvement on the reflectance of the bare aluminum foil substrate. The coatings were exposed to UV radiation to investigate the UV resistance and durability. The thermal insulation performance of the electrospun coating was then quantified by calorimetric tests under vacuum conditions.
Our results show the feasibility of using electrospun nanofibrous coatings with tailored properties as high performing broadband reflectors in multilayer insulation systems for space applications.

Thermal Imaging to Characterize Performance of Space Grade Ablative Silicones Daria Monaenkova[1], Cody Schoener[1], Christopher Windiate[1] and Curt Johnson[2]; [1]Dow, United States; [2]Alloy Construction Company, United States

For decades Dow Silicones has been developing silicone solutions for aerospace, defense, and avionics. Silicone ablative coatings are a part of DOWSIL™ materials family and have been designed to prevent direct flame contact with underlying surfaces and protect rocket launch infrastructure and deployment devices, as well as aircraft engines, from extreme temperatures and oxygen attack. During launch, the rocket exterior is subjected to extreme temperatures over 1500 ºC in seconds, chemical exposure to fuel and intense vibration during takeoff. Silicone ablatives are easy to apply and offer superior performance under high shear, high heat flux environments, toughness, low thermal conductivity, and extended operation temperature range. The ablative coatings dissipate heat through thermochemical degradation. Slow release of pyrolysis gases creates a cooling effect within the material. The goal of this work was to demonstrate the performance of these formulations at close-to-reality thermal conditions. A custom imaging solution was designed to record heating and cooling behavior of a subset of application-tailored ablative coatings. In the experiments the coatings were applied to ceramic tiles and subjected to extreme temperatures for up to 30 seconds. The heating and cooling events were recorded with a high-resolution scientific long-wave infrared camera coupled with a machine vision camera. The details of the experimental set up, time-temperature profiles of the coated substrates, and thermal and digital images of the ablatives will be reported.

Coupling Characterization Techniques to Uncover New Understanding of Electrical Treeing Mechanisms and Physiochemical Properties Kerry L. Davis, Mohamadreza Arab Baferani, Yang Cao, Bryan D. Huey, Yara Suleiman and Sina Shahbazmohamadi; University of Connecticut, United States

Electrical treeing is a precursor to electrical breakdown in insulation systems. Unfortunately, every insulation system is prone to this defect-driven aging and degradation process, with profound implications for power systems, electronics, manufacturing, and lately the rapid rise in vehicle electrification. Prior characterization studies were mostly limited to visible light microscopy, during and after testing. Some researchers have used SEM, TEM, NMR, FTIR, laser, and ultrasound as well, but none of these techniques have gained popularity since not much additional data can be extracted compared to what is already available from visible light microscopy. Here, we implement much less commonly employed approaches in order to further investigate the underlying mechanisms in electrical treeing. This includes X-Ray Computed Tomography (xCT), which can uniquely resolve full tree structures in 3-dimensions including measuring tree channel diameters. Additionally, few researchers have taken advantage of Atomic Force Microscopy (AFM), especially Conductive Atomic Force Microscopy (C-AFM) or the recently developed Tomographic AFM which can map conductivity networks in 3D. This work thus couples visible light microscopy, xCT, C-AFM, AFM milling, and SEM, revealing not only the complex morphology of the electrical treeing, but also the physiochemical properties of its microstructures. While the first electrical treeing was already discovered on the surface of an “electrophore” by G C Lichtenburg in 1777, modern materials characterization of electrical tree features during and post-test are insightful for all stages of the treeing phenomenon: pre-treeing, tree initiation, tree growth, and runaway breakdown. Increased electrification in society can help to mitigate global warming, underlining the importance of optimizing future materials microsctructures, device designs, and manufacturing approaches for power systems.

SF02.04.06
***In-Situ* Mechanics of Steel, Superalloys and Bond Coating at -130ºC to 1000ºC** Sanjit Bhowmick and Eric Hintsala; Bruker, United States

High-strength structural materials such as Steel, Ni-based superalloys and diffusion bond coats are widely used in challenging environments with exposure to mechanical fatigue, particle impact, and erosion at elevated temperatures. Diffusion aluminide bond coats are an example of compositionally and microstructurally graded coatings with significant variation in engineered mechanical properties across the cross-section. Nanoindentation, pillar compression and cantilever bending, particularly *in situ,* can be considered as a well-suited technique for measuring the properties of such complex microstructural materials as the deformation volume can be carefully controlled to probe different precipitates and microstructural zones. In this study, an SEM nanomechanical instrument with integrated high-temperature and cryogenic stages was used to conduct pillar compression and cantilever bending experiments at -130ºC and up to 1000ºC.

8:30 AM *SF02.05.01
Pressure-Induced Phase Transformation, Optical Coupling and Coalescence of Nanoparticle Hongyou Fan; Sandia National Laboratories, United States

Naturally occurring system responses such as folding and unfolding in self-assembled DNA bundles show that natural designs are hierarchical, with structures and property on multiple scales arising through interactions of subunits or building blocks. Mimicking these designs in the fabrication of active materials requires a clear picture of the energy landscape that governs local interactions such as hydrogen bonding, van der Waals interactions, dipole-dipole interactions, and capillary forces, which will provide correct thermodynamic end points as well as facile kinetics for precise control of hierarchical structure leading to responsive functions. To date, fabrication of active and responsive nanostructures has been conducted at ambient pressure and largely relied on these specific chemical or physical interactions. Using pressure-induced assembly (PIA) that we recently demonstrated as an artificial actuator, we can emulate the natural folding and unfolding processes to: explore the energy landscapes that govern local interactions; design new classes of active materials with structures and functions that are not attainable for current nanomaterials; and investigate new properties resulting from folding and unfolding processes. We show that under a hydrostatic pressure field, the unit cell dimension of ordered 3D nanoparticle arrays can be manipulated to reversibly shrink and swell during compression and release of pressure. This allows for precise tuning of interparticle symmetry and spacing - ideal for controlled investigation of distance-dependent energy couplings and collective chemical and physical properties such as surface plasmon resonances. Moreover, beyond a threshold pressure, nanoparticles are forced into contact and sinter, forming new classes of chemically and mechanically stable 1-3D nanostructures that cannot be manufactured by current top-down or bottom-up methods. Depending on the orientation of the initial nanoparticle arrays, 1–3D ordered nanostructures (Au, Ag, CdSe, etc.) including nanorods, nanowires, nanosheets, and nanoporous networks can be fabricated. The PIA method mimics embossing and imprinting manufacturing processes and opens exciting new avenues for the study of responsive behaviors of active materials during compression (folding) and pressure release (unfolding). Stress-dependent control over the structure of nanoparticle or building block arrays provides a unique and robust system for the understanding of collective chemical and physical characteristics of nanocrystal superlattices.

High Pressure Study of UTe_2 in Pulsed Magnetic Field Daniel Braithwaite; Univ Grenobles Alpes, Grenoble INP, CEA, IRIG/PHELIQS, France

The unconventional superconductivity in the heavy-fermion paramagnet UTe_2 has recently attracted a lot of attention [1], particularly due to the reinforcement of superconductivity with magnetic field [2], and the probable spin-triplet and possibly topological nature of the superconducting order parameter. Pressure is a powerful tuning parameter in this system inducing multiple superconducting phases, changes of the magnetic anisotropy, and long range magnetic order [3]. A challenge is now to characterize the effects of combined pressure and magnetic fields applied along variable directions in this strongly anisotropic paramagnet. Several studies under pressure in high static magnetic field have been published, but a full investigation of this system requires magnetic field higher than the maximum available static magnetic fields. Here, we present an investigation of the electrical resistivity of UTe_2 under pressure up to 3 GPa and pulsed magnetic fields up to 58T applied along the hard magnetic directions b and c. We show that, near the critical pressure, a field-enhancement of superconductivity coincides with a boost of the effective mass related to the collapse of metamagnetic and critical fields[4]. These new elements improve our understanding of the interplay between magnetism and superconductivity, and the nature of these phases.

Geomimicry—Synthetic Diamond Inclusion as a Functional Materials Device That Retains Extremely Favorable High-Pressure Properties Ho-kwang Mao[1], Zhidan Zeng[1], Qiaoshi Zeng[1], Qingyang Hu[1] and Wendy L. Mao[2]; [1]Center for High Pressure Science & Technology Advanced Research, China; [2]Stanford University, United States

High pressures induce changes of properties and structures that could greatly impact materials science if such changes were preserved for ambient applications. Mimicking the geological process of diamond formation that the pressures and high-pressure phases in diamond inclusions can be preserved by the strong diamond envelope, we demonstrate that such process opens a great potential for creation of functional materials with extremely favorable properties.

10:30 AM *SF02.05.05
Melts and Disordered Structures Under Extreme Conditions Toshimori Sekine[1,2]; [1]Center for High Pressure Science and Technology Advanced Research, China; [2]Osaka University, Japan

Extreme conditions provide creation of new chemical bonding in materials. Pressure densifies materials and temperature enhances reactivity. Although we are exploring new fields using various techniques of static and dynamic compressions, recent progress in dynamic compression is challenging to provide high-resolution measurements temporally and spatially in a limited volume. Shock compression is a unique technique to generate multi extreme conditions in materials for a short time (nanoseconds to microseconds) because shock wave propagates as fast as tens micrometers per nanosecond and because pressures exceeding the material strength can be generated. The shock compressed state is determined through the Rankine-Hugoniot relations when we measure two parameters such as shock velocity and particle velocity. Strain rate at the shock front is 10^6 s^{-1} to 10^9 s^{-1}, depending upon how we generate shock waves. Temperature induced by shock compression depends upon the pressure and compressibility of material. Thanks to the recent laser technology development, application of high power laser becomes popular to reach unique high-pressure region of TPa (1000 GPa) high pressures in small volumes by the inertia.
I will present recent experimental results on silicate and carbonate and discuss the melts and disordered structures at extreme conditions. The state is called warm dense matter where the density is a few times of the solid and temperature is typically around and above 10000 K.

Nitrogen-Hydrogen, Carbon Monoxide, Phosphorus and iron Extended Solids Under Pressure—Beyond Pentazole, Chain and Molecular Structures Iskander G. Batyrev; DEVCOM U.S. Army Research Laboratory, United States

Structures of extended solids H-N, CO-N, P-N, and Fe-N under pressure are predicted using evolutionary algorithms based on DFT calculations. The found structures complement results of the previous, never ultimate because of evolutionary nature structure searches. We focus on the structures with three dimensional covalent bonds. The HN4 structure found at 50 GPa has Pbam symmetry group. Lowering the pressure down to 10 GPa changes the symmetry to Pmc21. Both structures are found to be metallic according to hybrid functional calculations. The structure of CON2 crystal at 40 GPa is made of eight-membered rings of singly bonded CON2 molecules in a three-dimensional framework structure in the space group of P43. It has high mass density comparable with that of cubic gauche nitrogen and high content of nitrogen atoms forming a spiral perpendicular to the eight member rings. PN4 has the highest concentration of nitrogen out of all known structures of P-N solids. The predicted structure of PN4 at 50 GPa has a P2/m symmetry group, and the crystal is metallic according to hybrid functional DFT calculations. The structure of the found iron-nitrogen compound FeN4 with symmetry group P21/c has high mass density and contains layers of Fe-N pentagons plane network and nitrogen dimers connecting the planes. Calculated phonon dispersions indicate dynamical stability of the systems, calculated Raman active frequencies of the compounds are compared with available experiments.

11:15 AM SF02.05.07
Pressure-Dependent Behavior and Low and High Temperature Photoluminescence (Pl) of Isotope Free Boron Arsenide Mahendra Subedi[1,2], Jose Perez[1], Bibhudutta Rout[1], Pawan Koirala[2], Tengteng Lyu[1], Hao Yan[1], Evan Hathaway[1] and Jingbiao Cui[1]; [1]University of North Texas, United States; [2]The University of Texas at Dallas, United States

We report high-pressure and low and high temperature photoluminescence (PL) and Raman measurements of isotope free boron arsenide (BAs). The Raman spectrum at ambient pressure shows two peaks at 715 cm^{-1} and 696.5 cm^{-1} that corresponds to the vibrational modes of ^{10}B and ^{11}B isotopes respectively. We observed that ^{10}B and ^{11}B peaks blueshift with increase in pressure that is due to phonon hardening. We also observed LO/TO phonon splitting with the increase in pressure from 10 GPa to 20 GPa, that occurs due to different rates of phonon hardening between two phonons (LO/TO) in both ^{10}B and ^{11}B isotope samples. High-pressure Raman spectra also suggest that as pressure increases, the conduction band minimum corresponding to the donor level decreases affecting the discharge of free carriers from defect states (1).The PL measurements reveal an indirect bandgap of about 1.72eV. BAs is investigated as a power electronic device because of its ultrahigh thermal conductivity greater than 1300 $W\ m^{-1}\ K^{-1}$, second to diamond, as predicted by First-principles calculations and reported experimentally (2). In heat management, BAs opens a whole new potential as a novel optoelectrical material due to its predicted high electron (~1400 $cm^2V^{-1}s^{-1}$) and hole mobilities (~2100 $cm^2V^{-1}s^{-1}$) (3). BAs has a comparable lattice constant and thermal expansion coefficient to Si, making it feasible to integrate in electronic devices (4,5). Our work establishes a foundation for strain engineering to regulate strain in the transistor channel that enhances transport properties of BAs which ultimately improves device performance.

Thermal Conductivity of Perovskites Under Pressure Songrui Hou, Richard Wilson and Chen Li; University of California, Riverside, United States

$SrTiO_3$ has soft optic phonons whose frequencies decrease upon cooling. The soft phonon mode at the *R* point is known to be related to the cubic-tetragonal phase transition in $SrTiO_3$ at ~105 K. This soft mode related phase transition introduces extra phonon scattering and results in a weak temperature dependence of the thermal conductivity of $SrTiO_3$ at high temperature, i.e., weaker than the typical $1/T$ dependence. Previous research reveals that pressure can also drive the soft mode related phase transition in $SrTiO_3$. In this work we aim to study the pressure dependence of the thermal conductivity of $SrTiO_3$ under pressure, $\Lambda(P)$. We measure the pressure dependent Raman spectrum of $SrTiO_3$ to confirm there is a phase transition around 9 GPa. We carry out time-domain thermoreflectance measurements in diamond anvil cells to obtain the thermal conductivity of $SrTiO_3$ up to 30 GPa. The results are compared with the control sample $KTaO_3$. The Raman spectrum of $KTaO_3$ suggests $KTaO_3$ does not experience phase transition up to 20 GPa. The second-order Raman peak shifts of $SrTiO_3$ and $KTaO_3$ display similar pressure dependence. We find $SrTiO_3$ has a much weaker pressure dependence in $\Lambda(P)$ than $KTaO_3$. We simulate our $\Lambda(P)$ data of $SrTiO_3$ and $KTaO_3$ by Leibfried-Schlömann equation. The equation fits the $\Lambda(P)$ of $KTaO_3$ well but overestimate the pressure dependence of $SrTiO_3$. We attribute the suppression on $\Lambda(P)$ of $SrTiO_3$ to extra phonon scattering introduced by soft mode related phase transition.

Evidence for Pressure Induced Unconventional Quantum Criticality in the Coupled Spin Ladder Antiferromagnet $C_9H_{18}N_2CuBr_4$ Tao Hong; Oak Ridge National Laboratory, United States

Quantum spin-1/2 ladders with two legs have been severing as a model low-dimensional spin system for discovery and understanding new phenomena. Here we present a comprehensive study of the effect of hydrostatic pressure on the magnetic structure and spin dynamics in a spin-1/2 coupled ladder antiferromagnet $C_9H_{18}N_2CuBr_4$ (DLCB for short). In DLCB, the inter-ladder coupling is sufficiently strong to drive the system to the long-range antiferromagnetic ordering phase below T_N=2.0 K. Analysis of the spin Hamiltonian suggests that DLCB is close to the quantum critical point in two dimensions at ambient pressure and zero field [1, 2]. The single-crystal heat capacity and neutron diffraction measurements suggets that the magnetic order breaks down above a critical pressure P_c ~1.0 GPa [3]. Estimates of the critical exponents suggest that this transition may fall outside the traditional Landau paradigm. By contrasting with quantum Monte Carlo calculations of the dynamic structure factor, the follow-up inelastic neutron scattering at 1.3 GPa further indicates an exotic quantum-disordered phase above P_c[3], characterized by two well-separated gapped modes, including one continuum-like and another resolution-limited excitation in distinct scattering channels.

Ultrastable Amorphous Sb_2Se_3 and Its Density-Driven Superconductivity Wenge Yang; Center for High Pressure Science & Technology Advanced Research, China

Chalcogenide glasses have been considered as a promising semiconductor in photovoltaic applications. The metastable nature limits its application condition, thus searching for ultrastable glass formation condition has attracted much effort. Here we report an enhancement in thermal stability by 17K comparing to ordinary formation condition in Sb2Se3 by optimizing the substrate temperature during the thermal evaporation process. Ultrastable amorphous Sb2Se3 showed the smallest surface roughness and highest refractive index. By in situ high temperature-high energy synchrotron X-ray diffraction, the difference in structure relaxation between ordinary and ultrastable amorphous Sb2Se3 was manifested by local structure evolution. Upon compression, amorphous Sb_2Se_3 undergoes a LDA to HAD transition at 24 GPa, defined as the amorphous density surpassing the crystal counterpart, and the superconductivity emerges. The superconducting critical temperature is enhanced when pressure induced crystallization at 51 GPa. HDA phase, featured by metavalent bonding, plays a pivotal role in the delocalization of electrons and the occurrence of superconductivity in the amorphous state. The results presented here provide a structural basis for the incipient structure of pressure-induced superconductivity in amorphous solids.

Investigating Ferroelastic and Multiferroic Behavior of Rutile-Like Frameworks Muzi Chen and Andrew Cairns; Imperial College London, United Kingdom

The prototypical rutile structure (TiO_2, TeO_2, etc.) has been shown to undergo a ferroelastic transformation from a tetragonal structure to the orthorhombic structure on compression or cooling. Following the ferroelastic transition, the structure shows negative linear compressibility (NLC) in one of the orthogonal directions. Negative linear compression (NLC) is the property of a material that refers to the phenomenon that when a system is uniformly compressed, it expands in at least one linear direction.[1] Material with negative compression properties has many promising applications in engineering, such as sensitive pressure sensing, actuators, and the development of artificial muscle—critically depends on the intrinsic NLC response. Therefore, we are interested in investigating whether this phenomenon occurs in its structural analogues.

In our work, we investigated the structural analogues to rutile, which are transition metal dicyanamide and tricyanomethanide systems, abbreviated as $M(dca)_2$ and $M(tcm)_2$ (M = Mn, Cu, Fe, Co, Ni, and Zn). Both variable-temperature diffraction and high-pressure diffraction were employed. Our results show significant negative thermal expansion (NTE) and negative linear compressibility (NLC) in a series of $M(dca)_2$ and $M(tcm)_2$ materials. The magnitude of thermal and pressure-induced structural changes in each case was proved to be affected by the transition metal size and Jahn Teller distortions.

3:30 PM SF02.07.01
Oxygen-Tailored Grain Growth Mechanism on Pt Films Thermistors—Deposition, Annealing and Application on Carbon Nanotubes-Based Microbolometers Erica Freire Antunes, Atasi Dan, Christopher Yung, Nathan A. Tomlim, John H. Lehman and Michelle S. Stephens; National Institute of Standards and Technology, United States

Uncooled microbolometers with vertically aligned carbon nanotubes (VACNTs) as an absorber and electrical substitution calibration have been developed by the NIST for broadband sensing of Earth outgoing radiation [1,2]. The current fabrication challenge is coupling a thin film thermistor to the devices. The key requirement for the thin film thermistor, besides a high temperature coefficient of resistance (TCR) [3] and low 1/*f* noise, is surviving to the harsh carbon nanotube growth environment [4]. In the present work, Pt thin film thermistors were microfabricated on Si wafers coated by $SiO_2/SiN_x/AlO_x$ films, similar to a microbolometer membrane. The Pt film were deposited by DC magnetron sputtering, and the deposition parameters, such as power, pressure, Ar/O_2 ratio, and film thickness were investigated. The samples were also submitted to a post-annealing to maximize their electrical conductivity and, consequently, the TCR [5]. Microstructural and morphological analysis of Pt film suggest that the TCR values can be tailored by the grain growth type mechanism defined during annealing step. The control of the grain size distribution through a normal grain growth with a preferential orientation Pt (111) has been achieved for samples with deposition environment free-of-oxygen [5]. Adding O_2 at the Pt sputtering atmosphere can lead to a Pt film with O_2 trapped on the Pt face-centered cubic crystalline structure, a misorientation of the grains, an oxide formation, and even an amorphization [6]. As platinum

oxides are not stable in high temperatures, the loss of oxygen can induce different grain growth mechanisms during annealing. Abnormal growth with bi-modal distribution of grains can occurs in high annealing temperatures for Pt films. Depending on the O_2/Ar ratio at the deposition, the distribution of grains sizes after annealing can become unimodal as in normal growth, but with grains much larger than the Pt film thickness. It implies that in an anisotropic grain boundary mobility leads to giant grains growth [7-9]. Finally, Pt thermistors were submitted to the VACNT growth environment to assess any change in the TCR values, resulting from their exposure to the hydrogen/hydrocarbon plasma at high temperatures.

Funding for this work was supplied by NIST, the NASA Instrument Incubator Program (IIP), and the NASA Earth Venture Continuity Program (EV-C).

Molecular Dynamics Estimations of Transport Properties of Pure Water and Methane Hydrate Systems at Pre-Nucleation Conditions Andre Guerra, Samuel Mathews, Alejandro Rey, Milan Maric and Phillip Servio; McGill University, Canada

Gas hydrates are inclusion compounds, in which gas molecules are trapped inside the solid phase of water. In the transition from liquid to the solid phase, water molecules form a lattice structure that arises from hydrogen bonds between adjacent molecules. If the phase transition occurs at severe enough pressures and in the presence of dissolved gas species in liquid water, the gas molecules can become trapped in "cages" as the solid lattice structure forms. Gas hydrates have been an active research topic due to their occurrence in the oil and gas industry. As a result, much of the body of knowledge focuses on water-in-oil emulsion gas hydrate systems. Recently, however, new green technologies that utilize gas hydrate formation phenomena in non-oil systems such as pre- and post-combustion carbon capture from flue gas, natural gas transport, and storage, or the desalination of seawater have been proposed. Most of these technologies require continuous or semi-continuous flow systems maintained near and at hydrate nucleation conditions. These technologies would benefit from improved prediction capabilities of transport properties at pre-nucleation conditions in their process design and control.
This work intended to extend the current understanding of water and gas hydrate systems by developing improved molecular simulations to estimate the viscosity, diffusivity, and thermal conductivity of pure water and methane hydrate systems at various conditions. LAMMPS molecular dynamics package was used to explore the performance of the TIP4P/2005 and TIP4P-ice water force fields in the context of transport property estimations of subcooled water systems. Various estimation methods were tested including the Green-Kubo and Einstein formulations for viscosity, diffusivity, and thermal conductivity. A new Stokes-Einstein formulation for viscosity was also tested in this work. This work implemented systems consisting of approximately 7,600 atoms that were methodically equilibrated with the primary intent to develop stable and physically representative systems adequate for the estimation of bulk phase transport properties via the methods above. Finally, the data generated in this study were compared to experimental data to validate their accuracy. This includes experimental viscosity measurements of methane hydrates systems collected by our research group in previous experimental work. The present study showed that the TIP4P-ice force field for water resulted in improved estimation of viscosity for pure water systems when compared to the TIP4P/2005 force field results. However, discrepancies in the estimations for the viscosity of methane hydrate systems indicate the necessity for re-parametrization of the TIP4P-ice force field taking new viscosity experimental data into consideration for gas hydrate applications.

4:00 PM SF02.07.03
Tunable Magnetic Structure and Topological Electronic States in Square-Net Materials Ratnadwip Singha[1], Tyger H. Salters[1], Samuel M. Teicher[2] and Leslie Schoop[1]; [1]Princeton University, United States; [2]University of California Santa Barbara, United States

Though numerous topological semimetals have been discovered in recent years, their band structures are rarely ideal. The linear band crossings are often obscured by trivial parabolic bands near the Fermi energy. Materials with square-net motif in their crystal structure proved to be an exception as they host clean Dirac cones over large energy range in the band structure [1-3]. *Ln*SbTe (*Ln*=lanthanides) family of materials with antimony square-net is one such example which also introduces magnetism in topological electronic states [4-6]. We show that in this group of compounds, a high degree of tunability can be achieved by changing the electron count at the square-net. Increased electron filling results in structural distortion and formation of charge density waves (CDWs). Moreover, the CDW modulation vector can be tuned continuously. These structural changes also lead to rich magnetic phase diagrams. As a specific example, we discuss CeSbTe, where a complex "devil's staircase" magnetic structure is observed within a certain electron filling [7]. We also show that the CDW creates idealized non-symmorphic Dirac semimetal, where all the trivial bands are gapped out near Fermi energy. Thus, we present a unique template material, where the topological band structure can be controlled by electron filling (tuning chemical potential), CDWs (gapping out non-essential band crossings), or magnetic field (changing the magnetic ordering).

A Novel Design of a High-Efficient Adsorption-Based Atmospheric Water Extractor for Extreme Conditions Bachir El Fil, Xiangyu Li, Gustav Graeber, Emily Lin, Chad Wilson, Chenyang Li, Yang Zhong and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Portable water supply has always been a critical part of any expeditionary tasks, especially in situations where portable or even ground water is scarce. Atmospheric water extraction is a system that is capable to obtain portable water, providing more mobile, flexible and self-sufficient operations. Unfortunately, state-of-the-art fog-harvesting and dew systems are limited to high humidity. For extreme conditions where portable water is scarce, adsorption-based atmospheric water extractor promises to supply drinking water regardless of the weather conditions. In this work, we leverage the adsorption properties of adsorbents including MOFs (e.g., MIL-101, UiO-66) and silicas to design a biomass-driven high performance atmospheric water extractor that is capable of producing abundant amount of water at extreme dry conditions (< 15% relative humidity). We first model and experimentally demonstrate the performance under a wide range of operating conditions. The innovative design of compact, mobile, and highly efficient atmospheric water extractor can provide a guideline for future water extractors.

SESSION SF02.08: Poster Session II: Materials for Extreme Conditions

SF02.08.01
Design and Modeling of Hydrogel-Based Adsorbent Bed for Energy Storage Liliosa Eyang Cole, Bachir El Fil, Xiangyu Li, Xinyue Liu, Carlos D. Diaz, Gustav Graeber, Leon C. Gaugler and Evelyn N. Wang; Massachusetts Institue of Technology, United States

Waste heat generation is ubiquitous in power systems operating in residential and industrial settings. While reuse of waste heat is common practice in industrial systems, an increase in the energy density of a waste heat collector is crucial for the improvement of system efficiency and feasibility. The hydrophilic nature of hydrogels creates a compelling prospect for thermal energy storage (TES), in the form of a chemical potential. In this work, we take advantage of the sorption capabilities of hydrogels, combined with waste heat collection from existing power systems such as HVAC, to design and engineer a hydrogel/salt composite. This composite is to be integrated into a compact TES device, to deliver an energy density greater than 200 $kWh/m^3/day$.
The hydrogel/salt synthesis requires paramount characterization and testing of polymer/salt combinations, to yield an effective, durable, and mechanically robust, high water uptake material, that will enable the required high-energy capacity. The composite's kinetics and low-temperature desorption capabilities play a critical role in surpassing the device design requirements. A novel technique is used to adhere the hydrogel onto the device, while maintaining good mechanical and thermal stability. This novel technique allows for an effective thermal conductivity greater than 1 W/m K. We developed a numerical model to simulate and predict the heat and mass transfer of the hydrogel within the device. The critical component where the hydrogel is mounted is a tube-fin heat exchange. The thickness and kinetics of the hydrogel composite layer is optimized to maximize the energy density of the TES. We characterize the hydrogel experimentally to validate the developed numerical models.

SF02.08.02
Core-Shell Structured Ultrahyperbranched Polymer Based Hydraulic Fracturing Fluid Crosslinker Wengang Li[1], Harbi Harbi[1], Majad Khan[2] and Muhammad Tahir[2]; [1]Saudi Aramco, Saudi Arabia; [2]King Fahd University of Petroleum and Minerals, Saudi Arabia

Hydraulic fracturing operation has been widely used in oil and gas industry production applications. Fracturing fluid plays a key role in transiting pressure, transporting proppant and minimizing possible leaking during the job, with thickeners and crosslinkers together to enhance fluid viscosity. Commercial crosslinkers are mostly borates or inorganic salts. Some polymeric crosslinker have also been used for guar gum and polyacrylamide (PAM) thickeners. When compared with linear and branched polymers, hyperbranched polymers have attracted significant attention due to their extraordinary properties, such as a lower viscosity, higher solubility, smaller size and higher surface functional group concentrations. Such properties make hyperbranched polymers potential candidates for downhole applications with low formation damage.
This paper demonstrated the A to Z for a novel core-shell structured ultrahyperbranched polymer (UHP) for applications of hydraulic fracturing fluid crosslinker. The UHP was designed and synthesized by growing a hyperbranched polymer shell structure from the surface of a pre-existing hyperbranched polymer core that acts as a macroinitiator. Characterizations for UHPs have been performed, such as FT-IR, NMR and GC-MS. Gelation properties with fracturing fluids were tested with rheometer following ISO 13503-1 method. Multiple functional groups were tested for different conditions. The synthesized UHPs have been approved potential crosslinkers for polymer based fracturing fluids.
The UHP crosslinkers will be further investigated for compatibility with current fracturing fluid package and tested in the field for future fracturing operations.

SF02.08.03
Development of Ion-Selective Electrodes for Detection of Nitrogen-Based Ions Among Soil Nutrients Seonghyun Hong, Seongjun Hong and Yang-Rae Kim; Kwangwoon University, Korea (the Republic of)

Recently, analyzing soil nutrients has been vastly emphasized in developing next-generation agriculture based on smart-farm. Remarkably, there is much attention to the on-site and real-time analysis of nutrients inside the soil. As a result, some attempts have been made to achieve this purpose. If it is realized, it enables minimal use of fertilizers and finally reduces overall analysis cost.
Conventional methods for analyzing soil nutrients include colorimetry, spectrophotometry, flame photometry, and atomic spectrometry. However, some of them require pre-processing steps and expensive equipment. Some methods are also challenging because of selectivity, on-site detection, and multiple analysis.
Ion-selective electrode (ISE)-based potentiometry has several advantages compared to the conventional methods. First, it allows minimal pre-treatment steps, especially for the soil sample. Second, it enables cost-effective analysis because it does not require expensive equipment. Third, it has superior selectivity compared to other methods. Fourth, on-site, real-time, and multiple monitoring of soil nutrients effectively works through miniaturization of the measurement part.
Nitrogen (N), phosphorus (P), and potassium (K) are estimated to be essential elements among several soil nutrients. In particular, nitrogen-based ions (ammonium, nitrate, and nitrite) are critical for efficient crop growth. Therefore, developing sensors for accurate and fast analysis of nitrogen-based nutrients is necessary. In this study, several ISEs have been prepared to detect nitrogen-based ions. The membranes of ISEs were optimized by changing the components (matrix, ionophore, plasticizer, and lipophilic additive) and their amounts. The experiments were carried out in a buffer solution, similar to the soil environment. The sensitivity and selectivity of ISEs were intensively investigated and compared with commercial ISEs. Finally, preliminary

experiments were performed inside the soil to monitor nitrogen-based ions directly and simultaneously.
This work was carried out with the support of Cooperative Research Program for Agriculture Science and Technology Development (Project No. PJ015725032021) Rural Development Administration, Republic of Korea.

SF02.08.04
Super Hydrophobic Polymeric Film for CMP Conditioner by Initiated Chemical Vapor Deposition (iCVD) Taeyoon Kim, Chulwoo Bae and Taesung Kim; Sungkyunkwan University, Korea (the Republic of)

Chemical mechanical polishing (CMP) has been widely used in semiconductor manufacturing. The CMP process is essential for the planarization of semiconductor wafers and highly integrated devices, which is a process that mechanically removes the chemical reaction layer created on the wafer surface. At the same time, the slurry liquid is supplied onto the polishing pad with asperity. For this purpose, a slurry solution containing abrasive particles and chemical compounds to perform a polishing role, a polishing pad providing adequate pressure and asperity with the surface of a wafer, and a diamond conditioner for maintaining the surface roughness of the polishing pad are required.
In the CMP process, shot asperity and glazing pores are produced due to friction and load applied between the CMP wafer and the CMP pad. In addition, the pores of the CMP pad are clogged by the slurry, thereby reducing the efficiency of the CMP process. In order to prevent this phenomenon, a diamond conditioner has been used to regenerate the pad surface and remove the slurry particles from the surface of the CMP Pad. The CMP pad conditioner has a stainless body with diamond edges fixed on Ni metal and an alloy coating. The diamond is shaken by physical force during the CMP process, which causes a crack. As acid or base solution penetrates this gap and corrodes the metal, diamonds fall out, or metal contamination occurs, damaging the wafer. The PTFE spray coating method has been applied to the CMP conditioner to prevent corrosive solutions such as acid and base. However, due to the poor bonding strength between PTFE and metal, the PTFE coating was easily peeled off from the load received during the CMP process, and it was not easy to coat uniformly.
In this study, h hydrophobic polymer coating through ICVD method on the CMP conditioner and their hydrophobicity improvement were evaluated to prevent acid or base solution penetration. First, the surface of the CMP conditioner was modified using plasma and a silane coupling agent to increase the bonding force between the polymer coating and the metal. 1,3,5,7-tetravinyl-1,3,5,7-tetramethylcyclotetrasiloxane was coated through the iCVD method, a technology that directly forms a polymer coating on the surface in the vapor phase. 1H,1H,2H,2H-Perfluorodecyl acrylate, which plays a role in hydrophobicity, was coated thereon. Characteristics of the surface of the CMP pad conditioner coated with the hydrophobic polymer were analyzed. FT-IR and XPS confirmed that organic materials were successfully formed on the surface, and the hydrophobicity of the surface was observed by the water droplet formed a high contact angle. In addition, the chemical stability of these CMP pad conditioners against corrosion from strong acid and the degree of peeling was tested in the CMP conditioning process.

SESSION SF02.09: Corrosion
Session Chairs: Nathan Mara and Dierk Raabe

Phase Transformations Under Redox Conditions: Example of Hydrogen-Based Direction Reduction of Iron Oxide Dierk R. Raabe, Yan Ma and Isnaldi Souza Filho; Max Planck Institute for Iron Research, Germany

The lecture presents recent progress in understanding the nucleation, transport and redox mechanisms of the phase transformations occurring during hydrogen-based direct reduction of iron oxides. The kinetics of the transformation and reactions strongly depend on mass transport kinetics, nucleation during the multiple phase transformations, the oxide's chemistry, microstructure, and on damage and fracture associated with the phase transformation and mass transport phenomena occurring during reduction. Understanding these effects is key to make hydrogen-based reduction of iron ores commercially viable, enabling massive CO_2 reductions in the metallurgical sector.

9:00 AM SF02.09.03
Structure-Modified Fluorescent Carbon-Dots with Improved Colloidal Stability in Porous Media at High Salinity and Temperature for Reservoir Tracer Application Wei Wang, Haofeng Song and Ayrat Gizzatov; Aramco Americas: Aramco Research Center-Boston, United States

Tracer technology has been increasingly used in inter-well tests to investigate reservoir performance, reservoir connectivity and residual oil saturation for providing useful information to improve decision making in reservoir management. Stable nanoparticle tracers with high-sensitive real-time detectability are highly desired, and as one of the nanoparticles tracers, carbon dots (C-dots) have been studied and tested as nano-agent tracer in field trial for reservoir monitoring in. In this research, we report a modified method to synthesize fluorescent C-dots with enhanced colloidal stability at ultra-high salinity and lowered retention in reservoir rocks for tracer application.

With a modified synthesis procedure, fluorinated and sulfonated functional groups were incorporated into the C-dots. The synthesis reaction occurs at hydrothermal condition with inexpensive starting materials and is readily to scale up for industrial application. Optical properties of the synthesized colloidal C-dots were studied by UV-visible and fluorescence spectroscopies. Retention and transport the C-dots in carbonate rocks were evaluated by core flooding experiments. The synthesized C-dots were readily dispersible in brines with extremely high salinity (TSD >120,000ppm) at high temperature (95°C), and still exhibit high quantum yield for fluorescence, enabling sensitive detectability by optical spectroscopic or imaging techniques. Coreflooding experiments revealed neglectable adsorption of the C-dots on reservoir rocks.

The synthesized C-dots exhibit improved stability at simulated oil reservoir conditions and lowered retention in reservoir rocks, while remained high fluorescence property, enabling their use as optically detectable nano-agent tracer in oil field application.

Soft, Pressure-Tolerant, Flexible Electronic Sensors for Sensing Under Harsh Environments Xueju Wang and Yi Li; University of Connecticut, United States

Energy-efficient, miniaturized electronic ocean sensors for monitoring and recording various environmental parameters remain a challenge because conventional ocean sensors require high-pressure chambers and seals to survive the large hydrostatic pressure and hash ocean environment, which usually entail a high-power supply and large size of the sensor system. In this talk, I will introduce soft, pressure-tolerant, flexible electronic sensors that can operate under large hydrostatic pressure and salinity environments, thereby eliminating the need for pressure chambers and reducing the power consumption and sensor size. By using resistive temperature and conductivity (salinity) sensors as an example for demonstration, the soft sensors are made of lithographically patterned metal thin films (100 nm) encapsulated with soft oil-infused elastomers and tested in a customized pressure vessel with well-controlled pressure and temperature conditions. The resistance of the temperature and pressure sensors increases linearly with a temperature range of 5 °C-38 °C and salinity levels of 30-40 Practical Salinity Unit (PSU), respectively, relevant for this application. Pressure (up to 15 MPa) has shown a negligible effect on the performance of the temperature and salinity sensors, demonstrating their large pressure-tolerance capability. In addition, both temperature and salinity sensors have exhibited excellent cyclic loading behaviors with negligible hysteresis. Encapsulated with our developed soft oil-infused rough polydimethylsiloxane (PDMS), the sensor has shown excellent performance under 35 PSU salinity water environment for more than 7 months. The soft, pressure-tolerant, and non-invasive electronic sensors reported here are suitable for integration with many platforms including animal tags, profiling floats, diving equipment, and physiological monitoring.

10:00 AM SF02.09.07
Studying the Effect of Silicon and Oxygen on the Structure and Performance of Titanium Nitride Coatings Gilad Zorn, Patrick Shower, Anteneh Kebbede, Scott Weaver, Rachel Rose, Jae-Hyuk Her and Josh Salisbury; General Electric Research Center, United States

Titanium nitride (TiN) coatings have a wide range of applications due to their practical properties such as high hardness, good corrosion resistance, heat resistance and excellent wear resistance. They have been widely used in various industries including decorative coatings, diffusion barriers and hard coatings. The properties of TiN can be greatly enhanced by addition other elements, such as Si [1-3]. Incorporation of Si in the TiN cubic structure leads to formation of TiSiN coatings characterized by high hardness and high oxidation resistance up to 800 °C. This enables synthesizing coatings and designing materials with a broad range of applications, especially as materials that should perform under harsh environments. The ternary TiSiN system is formed due to the total miscibility of Si, which creates a solid solution while preserving the crystalline structure B1 of TiN. Si is also believed to create nanocomposite structure of TiSiN coatings consisting of nanocrystalline TiN grains encapsulated by an amorphous silicon nitride (Si_3N_4) matrix. To achieve high hardness TiN films, significant bonding strength between Ti and N must be achieved. If the bonding is too weak, the surface of the coating can oxidize, forming titanium oxynitride and eventually TiO_2 even at room temperature conditions [4]. The oxynitride and oxide forms are known to exhibit a lower hardness than TiN and experience oxidation propagation.

This study is focused on the effect of Si and oxygen level on the TiN film's characteristics. X-ray Photoelectron Spectroscopy (XPS) was used to study the compositions and high resolution XPS was used to determine the surface oxide to nitride ratios. Mechanical tests were performed with nano indenter to determine the hardness of these coatings. The study shows the correlation between the hardness of the films and the percentage of the XPS titanium oxide component. X-ray diffraction confirmed the formation of titanium nitride cubic phase and different crystallographic orientations were observed depending on the composition of each film. The results of this study show that adding Si and reducing the oxygen level improved the performance of the TiN films as hard coatings.

10:15 AM SF02.09.08
Kinetics of High-Temperature Corrosion in Austenitic Steel Alloys from First Principles Seaton Ullberg[1], Iman Abdallah[2], Xueyang Wu[1], Adrien Couet[2], John H. Perepezko[2], Michael R. Tonks[1] and Simon Phillpot[1]; [1]University of Florida, United States; [2]University of Wisconsin–Madison, United States

Manufacturers of internal combustion engines seeking to optimize performance and efficiency design their components to operate at temperatures upwards of 700 °C. Under these extreme conditions, corrosive gases resulting from incomplete combustion reactions can drive the formation of a multilayered oxide film atop austenitic steel alloys which would be resistant at lower operating temperatures. In this work, we use density functional theory (DFT) calculations to evaluate the migration energy barrier of point defects in each phase of the oxide film to understand the atomistic mechanisms by which the corrosion process progresses. Particular attention is directed towards the $MnCr_2O_4$ spinel layer which has been observed experimentally to form rapidly and in direct contact with the alloy - mediating the flow of cations and oxidizing agents between the alloy and oxide film. These DFT results are extended to conditions representative of the application environment through the use of an ab-initio thermodynamics framework which translates the effects of finite temperature and pressure into adjustments of chemical potential.

This work was supported by the US Department of Energy Office of Energy Efficiency and Renewable Energy Project Number 1919-1744.

10:30 AM SF02.09.09
On the Enhanced Corrosion Resistance of PVDF-HFP/Nylon Composite Coatings Karen Y. Patino Jaimes[1,2,3], Eugene Caldona[1,4,3], Ellis Kim[1,2,3], Evelyn Winn[2,3], James Lambert[2,3], Erick L. Ribeiro[1,2,3] and Rigoberto C. Advincula[2,3,5]; [1]University of Tennessee Knoxville, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States; [4]North Dakota State University, United States; [5]Case Western Reserve University, United States

Organic polymeric coatings are widely employed for minimizing the effects of corrosion on metallic surfaces owing to their intrinsic ability to provide interfacial passivation while exhibiting outstanding mechanical integrity, thermal stability, and chemical resistance. Polymers with strongly-bonded electronegative atoms on their backbones are ideal coating matrices as they typically exhibit exceptional corrosion resistance. The inclusion of micro-and nanostructured additives, which can further delay the diffusion of aggressive electrolyte species through the coating layer, yields polymer composites with improved barrier properties and corrosion protection. Herein, we used Nylon 12 particles as fillers for poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) matrix, a highly thermally stable semi-fluorinated copolymer with low surface energy, and investigated the ability of the resulting composite coatings to protect mild steel substrates from corrosion. Results from electrochemical measurements indicate that small amounts of Nylon 12 (less than 2 wt.%) are needed to optimize the overall protection performance of the PVDF-HFP composite coatings. The corrosion resistance is mainly evaluated by Impedance analysis and Potentiodynamic chemistry in a 3.5 wt% NaCl test solution, supported by microscopy, spectroscopy, contact angle tests, and dielectric measurements.

SESSION SF02.10: Infrared and Laser Beam
Session Chairs: Alexander Goncharov and Nathan Mara
Wednesday Afternoon, November 30, 2022
Sheraton, 3rd Floor, Commonwealth

1:30 PM SF02.10.01
Selective Infrared Phonon Stimulation to Tune Thermal Transport Gaurav Kumar[1] and Peter W. Chung[2]; [1]Purdue University, United States; [2]University of Maryland, United States

The recent developments in high power optical sources at far-to-mid infrared (IR) frequencies (0.1 to 100 THz) have provided the means to investigate and control material properties in solid-state and condensed matter systems under nonequilibrium conditions[1]. In particular, in energetic materials where phonons are the primary carriers of heat, optical heating, and ultrafast spectroscopy have enabled the investigation of shock-induced chemistry[2], and ignition modulation[3]. In this work[4], we determine the degree to which material properties such as thermal diffusivity and conductivity can be modulated via a selective nonequilibrium infrared stimulation of phonons. Using the molecular crystal RDX, we use detailed momentum-dependent coupling information across the entire Brillouin zone and the phonon gas model to show that selective stimulation of certain low and mid frequency phonons can have a substantial positive/negative effect on the overall thermal transport properties. Specifically in the case of RDX, stimulating modes at ~22.74 cm^{-1} over a linewidth of 1 cm^{-1} can lead to enhanced scattering rates that reduce the overall thermal diffusivity and conductivity by 15.58% and 12.46%, respectively, from their equilibrium values. In contrast, stimulating the modes near ~1140.67 cm^{-1} over a similar bandwidth can produce an increase in the thermal diffusivity and conductivity by 55.73% and 144.07%, respectively. The large changes suggest a mechanism to evoke substantially modulated thermal transport properties through light matter interaction.

1:45 PM SF02.10.02
Laser Damage to Liquid Crystal Alignment Materials in Ordinary and Extraordinary Modes Zoey Davidson[1], Jason Wallace[2,3], Yasaman Sargolzaeiaval[1], Nathaniel Urban[2], Stavros G. Demos[2], Kenneth L. Marshall[2] and Selim Elhadj[1]; [1]Seurat Technologies, United States; [2]University of Rochester, United States; [3]D'Youville College, United States

We report on the laser-damage threshold of common liquid crystal alignment materials, including rubbed polyimides, rubbed nylon, and a photoaligned azobenzene. The photoaligned azobenzene is, in principle, more laser-damage resistant because of the no-touch processing in the clear aperture[1] with the added benefit of ease of scaling and processing. We further compare the polarization dependence of the damage threshold with respect to the alignment direction in ordinary and extraordinary modes at a near-infrared wavelength. Studies on polarization dependence on laser damage of liquid crystals with alignment layers have been very limited,[2] and none include photoalignment. Laser-damage thresholds depend substantially on the presence of aligned liquid crystal materials. We also compare laser-damage–threshold dependence on the electrical actuation state of the nematic liquid crystal material. These data inform design of high-power beam-shaping devices for applications in fusion, 3-D printing, and defense systems.

This material is based upon work supported by the Department of Energy National Nuclear Security Administration under Award Number DE-NA0003856, the University of Rochester, and the New York State Energy Research and Development Authority.

2:00 PM SF02.10.03
Optimized Liquid Crystals for High-Power Laser Beam Manipulation—An Evaluation and Feasibility Study Yasaman Sargolzaeiaval[1], Jason Wallace[2,3], Zoey Davidson[1], Nathaniel Urban[2], Stavros G. Demos[2], Kenneth L. Marshall[2] and Selim Elhadj[1]; [1]Seurat Technologies, Inc, United States; [2]University of Rochester Laboratory for Laser Energetics (LLE), United States; [3]D'Youville College, United States

Nematic liquid crystals (LC's), ubiquitous in high resolution displays, are typically composed of rod-shaped molecules that exhibit large dielectric anisotropy, high birefringence and excellent transparency in many regions of the electromagnetic spectrum. These properties make them well suited for use in various lasers and optical components, as well as in hybridized metamaterials as alternatives to existing semiconductor and phase change materials. Recently, the single shot laser damage threshold of both saturated and unsaturated nematic LC's revealed an intrinsic relationship between the degree of chemical bond saturation within LC molecules and laser damage[1]. These results suggest that rational molecular design routes exist for improving both the laser damage threshold and operational threshold of electrically switchable LC's. In this study we investigated one such optimized LC and characterized its laser damage threshold and switching behavior in the near-IR region. We also studied the lifetime of LC's upon exposure to a train of 1053 nm laser pulses with an average power density in the kW/cm2 regime and pulse repetition rates of 10 to 40 Hz. The thermal accumulation and spatial temperature profile during high power laser exposure was modeled using 3D simulations to estimate the LC lifetime and operation.

Surface Fatigue Behavior of Laser Peened Single Crystalline Turbine Blades—A Multicycle Nanoindentation Study Noah Holtham and Keivan Davami; University of Alabama, United States

Turbine blades are one of the most critical components in a modern gas turbine engine as they convert high energy combustion products into mechanical

work and drive the main turbine shaft. Although they are remarkably resilient, the blades are prone to damage initiated at the surface from mechanisms such as stress corrosion cracking, fatigue, and foreign object damage. Additionally, the growing need for higher-efficiency combustion engines requires higher operating temperatures which only accelerates the kinetics of crack growth and other deleterious effects. Fortunately, methods of fortifying the surface through localized cold working techniques show promise at significantly delaying crack growth, creep rate, and corrosion; thereby enabling longer service lives. In this work, one such method known as laser peening (LP) was applied to single crystal Nickel-based superalloy turbine blades. Sections of the turbine blades were cut into flat plates and LPed on a face approximately parallel to the [001] plane. The peening was conducted over 4 consecutive layers with an irradiance of 7 GW/cm^2 to maximize the depth of plastic deformation without causing reverse plastic straining and consequently degrading the mechanical properties. Following LP, one set of samples was placed in a furnace at 700 °C for 300 hours to gauge the retention of LP-induced microstructural modifications under thermal exposures similar to those experienced in gas turbine engines. Cyclic nanoindentation fatigue tests were then conducted to provide insight into the surface-level energy absorption of CMSX-4 and how that behavior changes after LP and thermal exposure. Indentation tests were performed with a load of 500 mN at 300 cycles using a Berkovich tip within dendrite core regions of each sample to reduce error associated with anisotropic mechanical properties. The LPed specimen showed a dramatic reduction in indentation depth in comparison to baseline sample which is likely due to the compressive residual stresses and work hardened microstructure impeding dislocation motion and limiting the depth to which the indenter can induce plastic deformation. Interestingly, the thermally-exposed samples presented an increase in indentation depth compared to the LPed specimen but did not regress all the way to the baseline depth, which is a testament to the thermal stability of LP-induced dislocation structures under high-temperature loads. Additionally, optical profilometry was used in tandem with indentation data to gauge the indent topography following the fatigue test. It was observed that significant pile-up occurred on the LPed samples following thermal exposure which could stem from the reconfiguration of dislocation into subgrains and a consequently change in dislocation mobility to promote pile-up, though this mechanism is not well understood. Overall, the surface fatigue tests performed in this work show the promise of LP as a post-processing treatment for the extension of single crystal Ni-based superalloy turbine blades lives which can be of great use in the creation more sustainable air travel and power generation.

SESSION SF02.11: Additive Manufacture for Extreme Environments
Session Chairs: Nathan Mara and Rongmei Niu
Wednesday Afternoon, November 30, 2022
Sheraton, 3rd Floor, Commonwealth

3:30 PM SF02.11.01
Additive Manufacturing of Superhydrophobic/Superoleophilic Fluoropolymer Composite Membranes for Oil/Water Separation and Anti-Icing Applications Eugene Caldona[1,2,3], Lucas Kilpatrick[2,3], Xiang Cheng[4,3], Li-Han Rong[4,3], Erick L. Ribeiro[2,3], David Dabkowski[2,3,2] and Rigoberto C. Advincula[2,3,4]; [1]North Dakota State University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States; [4]Case Western Reserve University, United States

Superhydrophobic materials repel water by combining the effects of low surface energy and hierarchical surface roughness. Although membranes made of such materials find applications in high-efficiency oil and water separation and deicing, traditional manufacturing techniques and materials limit the size and geometry of such membrane constructions. This study focuses on the design and fabrication of porous superhydrophobic membranes for oil/water separation applications. The membranes, composed of poly(vinylidene fluoride-co-hexafluoropropylene) (PVDF-HFP) matrix with varying amounts of silica particles, were 3D printed via direct ink writing. The printed PVDF-HFP membrane with 30 wt% silica displayed the best anti-wettability with a contact angle of ~161°, anti-icing with capability to delay frost formation, and superoleophilicity, allowing oil to pass, but rejecting water, through its openings. Such surface characteristics are mainly attributed to the synergistic effect of surface roughness brought by the presence of silica particles and low surface energy due to PVDF-HFP. Spectroscopic, microscopic, thermal, dynamic mechanical, and dielectric analyses are employed to characterize the printed membranes. Combined with mechanical robustness and high thermal stability, the silica-filled fluoropolymer membrane is practically useful in solving industrial problems concerning water contamination, oil spill, and ice formation.

3:45 PM SF02.11.02
Hydrogel Infusion Additive Manufacturing of High Entropy Alloys Max Saccone[1], Seneca Velling[1], Rebecca A. Gallivan[1], Kai Narita[1], Daryl W. Yee[2] and Julia R. Greer[1]; [1]California Institute of Technology, United States; [2]Massachusetts Institute of Technology, United States

Additive manufacturing (AM) of metal components has emerged as a uniquely powerful tool for creating parts with complex geometries, with applications from the aerospace to the biomedical industries. High entropy alloys (HEAs), which are alloys composed of four or more principal components, are known to be strong, heat-resistant, and corrosion-resistant. However, the compositional space occupied by HEAs is immense, so AM pathfinding requires high-throughput fabrication methods.

We developed a vat photopolymerization AM technique called hydrogel infusion additive manufacturing (HIAM), which enables fabrication of a wide variety of metals and alloys with complex shapes, microscale resolution, and overall cm-scale dimensions. HIAM makes use of a single resin composition and a single set of processing conditions during the vat photopolymerization process, followed by infusion of appropriate metal precursors into a 3D hydrogel structure. Heat treatment in oxidizing followed by reducing atmospheres converts the polymer/precursor matrix into the target metal. Unlike previous vat photopolymerization strategies which have target materials or precursors incorporated into the resin during the printing process, HIAM does not require re-optimization of resins and resin curing parameters when the target material is changed; relevant process control parameters are shifted to the hydrogel infusion and heat treatment steps.

We have previously demonstrated the fabrication of Cu metal and CuNi alloys with nanoindentation hardness ~50% greater than predicted by the Hall-Petch relationship. We have also used HIAM to fabricate octet microlattice architectures with beam diameters on the order of 50 μm from several materials including copper, nickel, silver, cobalt, cupronickel alloys, and tungsten. Here, we expand the scope of the HIAM technique by demonstrating the fabrication of CuNiCoFe microlattices with ~50 μm beam diameters.

We use x-ray diffraction, thermogravimetric analysis, and differential calorimetry to characterize the microstructural evolution of CuNiCoFe from hydrogel to oxide to alloy and show that despite thermodynamic predictions of a single face-centered cubic phase, certain processing conditions lead to non-equilibrium two-phase behavior. We further investigate the binding affinity of each metal precursor for the gel network via isothermal titration calorimetry experiments, and construct and validate a model to predict the partitioning of precursors in the infusion solution and in the hydrogel structure.

The ability to create high entropy alloys with arbitrary composition via a facile polymer-based AM process will enable researchers to further development of specialty HEAs for extreme conditions. This work sheds light on the non-equilibrium characteristics of high entropy alloys, which can and paves the path to fabricating arbitrarily complex alloys via the streamlined HIAM process.

3D-Printed PDMS-Based Membranes for CO_2 Separation Applications Dianne Gutierrez[1,2], Eugene Caldona[3,2,4], Zhenzhen Yang[2,4], Xian Suo[2,4], Xiang Cheng[5,4], Sheng Dai[2,4], Richard Espiritu[1] and Rigoberto C. Advincula[2,4,5]; [1]University of the Philippines, Philippines; [2]The University of Tennessee, Knoxville, United States; [3]North Dakota State University, United States; [4]Oak Ridge National Laboratory, United States; [5]Case Western Reserve University, United States

In this study, polydimethylsiloxane (PDMS)-based membranes containing silica for CO_2/N_2 gas separation were developed and fabricated via direct ink writing. Silica particles, with an optimum loading of 10 wt%, were used as fillers and thixotropic agent to enable 3D-printability of the PDMS ink. The printability of the inks was assessed by rheology, while the membranes were characterized by spectroscopy, microscopy, thermal analyses, and mechanical measurements to evaluate their suitability and practicality for carbon capture applications. Results showed that the printed membranes were nonporous, with thermal stability up to 400 °C, stretchability up to 163% of its initial length, and possessing an elastic modulus of 2.95 MPa. In terms of gas separation performance, the PDMS-based membranes showed high permeability for CO_2 gas, but with slightly low selectivity for CO_2/N_2 gas pair. The inclusion of silica particles resulted in an increased gas permeability without significant effect on the membrane selectivity. The performance and properties of the PDMS-silica membrane demonstrated the potential of 3D printing as an economical and sustainable fabrication method in developing materials for carbon capture applications.

4:15 PM SF02.11.04
Additive Manufacturing Beyond the Gaussian Beam—Insights from Microstructure-Based Modelling Robert D. Moore[1], Theron Rodgers[2], Sergio Turteltaub[3], Daniel Moser[2], Heather Murdoch[4] and Fadi Abdeljawad[1,1]; [1]Clemson University, United States; [2]Sandia National Laboratories, United States; [3]Delft University of Technology, Netherlands; [4]DEVCOM U.S. Army Research Laboratory, United States

Laser-powder-bed-fusion (LPBF) additive manufacturing (AM) has redefined design and manufacturing due to its ability to produce complex geometries with lower processing times and reduction in overhead costs. In traditional LPBF, a Gaussian laser beam is used as the energy input source. Existing experimental and computational studies mainly focus on establishing design maps relating Gaussian beam LPBF process parameters to resultant microstructures. Recent experimental findings revealed that the use of laser beams with complex profiles, such as Bessel or ring beams, opens a new design space by which AM microstructures can be tailored. However, an understanding of the thermal fields produced by these alternative laser beams and their impact on resultant microstructures remains poorly understood. Using a recently developed mesoscale model coupling thermal transport and microstructural evolution during metal AM, we explore the development of temperature fields and grain microstructures during LPBF using Ring and Bessel-like beams. Parametric studies are performed to reveal the influence of beam parameters and to quantify their effects by establishing solidification and temperature gradient spatial maps. Comparisons between the different beam profiles have shown that under specific beam parameters, both Bessel-like and Ring beams elicit a more equiaxed microstructure than a Gaussian beam of equivalent power, affecting the resultant mechanical properties of the printed components. Herein, we discuss expanding the AM parameter space to include laser beam profiles, while connections to multiscale modeling will be used to establish structure-property linkages with a primary focus on the mechanical properties of AM materials.

4:30 PM SF02.11.05
Shape-Dependence on the Deformation Mechanism of Small Platinum Nanoparticles at High Temperature Ingrid M. Padilla Espinosa[1], Tevis D. Jacobs[2] and Ashlie Martini[1]; [1]University of California Merced, United States; [2]University of Pittsburgh, United States

In addition to traditional displacive plasticity mechanisms where the atoms move in a collective fashion, deformation in small nanoparticles can also occur via surface diffusion. At the macroscale, diffusion often occurs at high temperatures and can be correlated to the melting point. For nanoparticles, the contribution of diffusive plasticity also depends strongly on particle size, resulting in nanoscale creep. As the nanoparticle size reduces, there are more atoms at the surface compared to the bulk which have fewer neighboring atoms, thus reducing the diffusion activation energy and reducing the melting point. While the effects of temperature, size, and strain rate on nanoparticle deformation have been previously investigated, the role of particle shape remains largely undefined.
We used molecular dynamics models to study the effects of surface energy and shape on the deformation mechanism of platinum nanoparticles under compression at temperatures ranging between 300 K and 800 K for three different shapes and three different sizes. A transition from displacive to diffusive deformation mechanism was observed for all nanoparticles with the increase in temperature. The results also demonstrate significant differences in deformation mechanisms between differently shaped particles, even for the same diameter, temperature, and strain rate. These differences are linked to the surface energy and diffusivity of the different facets and edges. Our findings provide a new understanding of the previously unexplored role of surface energy in the deformation of small metal nanoparticles, enabling the calculation of size-, shape-, and temperature-dependent nanoparticle properties and deformation mechanisms. Such understanding is crucial for designing nanoparticle-based systems where changes in properties occur from nanoparticle structural changes due to plastic deformation.

SESSION SF02.12: Poster Session III: Materials for Extreme Conditions

SF02.12.01
3D Printing via Direct Ink Writing (DIW) of Self-Healing Elastomers Erick L. Ribeiro[1,2,3], Emily Buckner[1,2,3], Eugene Caldona[2,2,3] and Rigoberto C. Advincula[2,2,3]; [1]The University of Tennessee,Knoxville, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Autonomous self-healing elastomers have attracted much attention owing to their capacity to enhance the lifespan, stability, and safety of products. The ability to utilize such materials to manufacture complex structures via three-dimensional (3D) printing techniques is highly desired and has the potential to

impact several fields, ranging from medicine to aerospace, and the electronics industry. Nonetheless, the complexity arising from the self-healing elastomers intrinsic polymeric structure and rheological properties have restricted their 3D printing applications to manufacturing only at lab-scale operation. Herein, we present our findings on the addition of poly(BCOE), a well-known autonomous self-healing polymer (SHP), to a commercially available silicone rubber (Dow DOWSIL™ 795). More specifically, we investigated the dispersion of poly(BCOE) in the commercial adhesive matrix in different mass ratios (0, 10, 30, and 50 wt%), and their corresponding effects during the production of tensile bars via Direct Ink Writing (DIW). FTIR spectra of SHP samples confirm the presence of urethane group hydrogen bonds, which are associated with its autonomous self-healing properties. DSC reveals that the crystallization temperatures of Dow795 and 10 wt%-SHP/Dow795 are both -45 °C. In addition to that, TGA curves demonstrate the thermal degradation temperature range, where an increase in the mass ratio of the SHP with respect to the adhesive matrix resulted in a lower degradation temperature. Such findings confirm the successful dispersion of poly(BCOE) in the Dow795 matrix. Incomplete degradation indicates that constituent materials within Dow795 undergo thermal degradation at higher temperatures. These findings indicate the successful dispersion and the resulting interaction between poly(BCOE) and the adhesive matrix, with can be tailored to further tune the properties of the Dow795.

SF02.12.02

Additively Manufactured Epoxy/Silica Composite Coatings with Controlled Electrolyte Diffusion at the Coating/Metal Interface Karen Y. Patino Jaimes[1,2], Taegyung Park[1,2], Eugene Caldona[1,3,2], Anna Kho[1,1], Zane J. Smith[1,1,2], Demiana Barsoum[1,2], Erick L. Ribeiro[1,2] and Rigoberto C. Advincula[1,2,4]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]North Dakota State University, United States; [4]Case Western Reserve University, United States

Coating application techniques such as dipping, spraying, spin casting, and doctor blading have been widely employed, but the use of 3D printing in coating preparation has not been fully explored. Compared to conventional coating approaches, 3D printing of coatings offers finer parameter tuning with higher accuracy, precision, reproducibility, coating uniformity, and durability, all of which promote decreased porosity and defects, and controlled electrolyte diffusion. In this work, epoxy/silica composite coatings are 3D printed via direct ink writing on mild steel surface and electrochemical impedance spectroscopy (EIS) is employed to evaluate the resulting protection performance. For comparison, the same epoxy/silica coatings are prepared by spin, dip, spray coating, and doctor blade technique. Epoxy resin is chosen as the coating matrix due to its excellent mechanical, thermal, and dielectric performance at relatively low cost. Silica particles, on the other hand, are used as fillers to enhance, not only the coating's mechanical and corrosion resistance but also its thixotropy, making it amenable to be 3D printed. Results indicate that the 3D printed coating sample with 100% infill density was able to maintain a very high impedance modulus of 10^9 Ω cm^2 even after 35 days of continuous immersion in 3.5 wt% NaCl test solution. Different resistance behaviors, as evidenced by impedance measurements, were also observed for spin, dip, spray coated, and doctor bladed samples, as well as 3D printed coatings with 50% and 75% infill densities. 3D printing could be a promising coating preparation technique as it, not only affords automation, digital design, and conformability but is also an excellent approach to solving important coating failures and investigating the transport of electrolytes through thin films.

SF02.12.04

Molecular Modeling of Interfacial Structure, Kinetics and Processes of sII Gas Hydrate Systems for Engineering Applications Samuel Mathews, Andre Guerra, Phillip Servio and Alejandro Rey; McGill University, Canada

Gas hydrates are crystalline compounds composed of a hydrogen bonded backbone of water molecules enclosing guest molecules in cages stabilized by Van der Waals forces. Initially, large scale gas hydrate research was centered around flow assurance problems in hydrocarbon extraction, transportation, and processing. Interest then grew in the usage of hydrates to store hydrocarbons and hydrogen, for desalination processes, and for carbon capture and storage. Their potential use in carbon capture and storage and for energy exploitation makes gas hydrates an excellent candidate for further research. Characterizing the material properties of a crystal that requires extreme formation conditions and sublimates rapidly in standard atmosphere is experimentally challenging. While the equilibrium formation conditions lie in the megapascal range for gas hydrates, experimental conditions of formation and engineering environment involve extreme pressures in the gigapascal range. Controlling sample purity and system homogeneity is often difficult in devices designed to measure interfacial properties because they are not designed for extreme conditions and stresses. Finally, testing different guest molecules, external pressures, surface effects, and extracting fundamental information about molecular interfacial behaviors is nearly impossible without critical disruption of the structure stability. This project circumvents these issues by using molecular dynamics (MD) simulations with high experimental fidelity to study gas hydrates and provide methods to prototype new systems for implementation of efficient green technology in extreme formation environments, where the high-pressure driving force ensures the crystal formation. It is essential to understand the fundamental physical and chemical mechanisms at the molecular level and the nanoscopic behaviors leading to macroscopic properties to clarify phenomena that govern potential applications of these structures. This work uses MD as implemented in the Large-scale Atomic/Molecular Massively Parallel Simulator to characterize the temperature and pressure effects on the interfacial tension, energy of interfaces, and growth rate of natural gas hydrates to overcome the complexity of experimentally understanding their performance in extreme environments and prove that theoretical modeling, prediction, and advanced characterization techniques can explain the structural and transport properties under extreme environments. Our work has shown that there is excellent agreement between sI methane hydrates and experimental values, with the interfacial energy decreasing with temperature. Preliminary results show that the sII natural gas hydrates show the same behavior. Our work has shown that hydrates nucleate preferentially with film-shaped nucleation, then cap-shaped, lens-shaped, and homogeneous nucleation. We have confirmed the presence of a novel pre-melting layer at the interface between the structures. We have been able to produce temperature and pressure correlations of surface tension for engineering applications. The excess entropy, adsorption, radial pair distribution function, and charge distribution at the interface were calculated to confirm our findings. This information yields data to determine which conditions favor or hinder hydrate formation in applications of interest. This project studies molecular origins of macroscale, real world behavior of important energy-related materials. The impact of surface coverings is crucial in pipeline and natural gas infrastructure, and in storage technologies, but its molecular behavior is not sufficiently characterized. Using MD, statistical mechanics, and machine learning to develop an efficient workflow, interfacial behavior can be studied rapidly, effectively evaluating new green energy solutions. This provides guidance for future material development in extreme subsea environments, engineering applications, and harsh nucleation conditions.

SF02.12.05

A Beneficial Use of Basalt Fibers Douglas X. Shattuck[1,2], Vernon Robertson[3], Markus J. Buehler[1] and Haley Talbot[4]; [1]Massachusetts Institute of Technology, United States; [2]St Joseph School, United States; [3]JEOL USA, United States; [4]Malden Catholic High School, United States

Basalt fibers are easy to produce here on earth. Basalt, a common earth material, is plentiful and has been widely characterized since the 1920s. It has been processed into fiber and used in a variety of commercial products. Basalt regolith is also an abundant resource on the lunar surface and several simulants have been compounded from spectrographic data provided by NASA and the ESA.
Our goal was to investigate the physical and functional properties of basalt fibers made from simulated lunar regolith to see if it might be suitable for constructing lunar habitats. We did multiple tests on the fibers and plan to do many more in future research. Our current study includes electron microscope data and EDS analyses provided by JEOL USA. Our regolith simulants were provided by Exolith Labs and fibers were prepared by the Fiber Lab at RWTH

Aachen University.
The properties of our simulants and fibers are consistent with properties of terrestrial basalt products and to the degree that they match what is on the moon, are likely to be able to be processed on the moon in the same way they are on earth. We also believe current technology can be adapted and transported to the moon to provide competent building and insulating material as well as a host of other useful products.

Hot Hydride Superconductivity Above 500 K Stanley Tozer[1] and Audrey Grockowiak[2]; [1]National High Magnetic Field Laboratory, United States; [2]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil

Neil Ashcroft's [1] theoretical predictions that indicated alloying dense hydrogen with metals could produce conventional superconductivity at very high temperatures and pressures and recent structural search methods identifying candidates and pressure-temperature conditions for synthesis have accelerated the race to room temperature superconductivity. This led to the synthesis of binary hydrides at 1.7 Mbar with critical superconducting transition temperatures of 260 K in LaH_{10} [2,3]. Our serendipitous synthesis of a metallic La-based superhydride from La metal and ammonia borane with an initial T_c onset of 294 K is inhomogeneous as to be expected given the growth conditions, but in line with other reported work [3,4]. Thermal excursions to higher temperatures promoted a chemical reaction to a higher order system that irreversibly drove the transition onset temperature to 556 K. X-Ray structural data validate the pressure measured via Raman some six months prior and speak to the inhomogeneous growth and pressure gradient that led to the non-zero resistance whilst confirming the formation of a higher order hydride [5].

9:00 AM SF02.13.02
Electron Beam Assisted Plastic Deformation of Single Crystalline Sapphire Jeongin Paeng[1], Sung-Gyu Kang[2], Young-Kyun Kwon[3] and In-Suk Choi[1]; [1]Seoul National University, Korea (the Republic of); [2]Max-Planck-Institut für Eisenforschung GmbH, Germany; [3]Kyung Hee University, Korea (the Republic of)

Oxide materials with covalent bonds are brittle and show low plasticity at room temperature. Interestingly, it has been reported that electron-beam irradiation alters the interatomic bond nature and promotes the ductile plastic deformation of amorphous silicon oxide. However, the question remains about the e-beam effect on the deformation of crystalline oxides. In this study, we observed that electron-beam irradiation affects the deformation behavior of crystalline oxide material. In-situ mechanical tests of single-crystalline aluminum oxide (sapphire) show that electron beam irradiation reduces the critical resolved shear stress required for dislocation activation. Furthermore, the corresponding atomic-scale simulation (density functional theory) demonstrates that excess electrons generated by incident electron-matter interaction are concentrated in the defect state and reduce the Al-Al repulsion during deformation, reducing the general stacking fault energy.

SESSION SF02.14: Materials and Magnetic Fields I
Session Chairs: Doan Nguyen and Sergei Zherlitsyn
Thursday Morning, December 1, 2022
Sheraton, 3rd Floor, Commonwealth

10:00 AM *SF02.14.01
Material Requirements and Choices for Non-Destructive Pulsed Magnets Sergei Zherlitsyn; Helmholtz-Zentrum Dresden-Rossendorf, Germany

The Dresden High Magnetic Field Laboratory (HLD) is a pulsed-field user facility, which provides external and in-house researchers with the possibility to perform a broad range of experiments in pulsed magnetic fields [1]. Being a member of the European Magnetic Field Laboratory (EMFL), HLD provides access and supports more than 100 scientific projects annually. The HLD develops, manufactures, and operates the non-destructive pulsed magnets for the field range up to 95 T and beyond. The choice of materials in magnet design plays a crucial role.

Here I will discuss various issues of material requirements and the choice of materials for pulsed magnet designs. Most of the pulsed magnets are stress

limited due to the strong Lorentz forces with a stress level of the materials very close to the ultimate tensile strength (UTS). Specifically, the conductors should possess a number of contradicting properties, such as high electrical conductivity, high UTS, high ductility, high specific heat, low fatigue, and low magnetoresistance. A very popular approach in the magnet design is a distributed internal reinforcement, which sustains the mechanical stresses inside the coil winding. Here the choice and combination of materials are very important as well. I will report on our long-standing experience with various materials for the pulsed-magnet designs. Obviously, we need novel high-strength materials to generate magnetic fields beyond 100 T with the non-destructive pulsed magnets.

I acknowledge the support of the HLD at HZDR, a member of the European Magnetic Field Laboratory (EMFL).

10:30 AM *SF02.14.03
Requirement and Development of Advanced Conductors for Ultra-High Field Pulsed Magnets Doan Nguyen, John Carpenter, Daniel Blaschke, Cody Miller and Abigail Hunter; Los Alamos National Lab, United States

High magnetic fields have been critically important research tools for condensed matter physicists. The National High Magnetic Field Laboratory's Pulsed Field Facility at Los Alamos National Laboratory is one of few research centers in the world that can create and use ultra-high pulsed magnetic fields up to 100 tesla for scientific research. Present research frontiers in quantum matter, including topological matter and superconductivity, require magnetic fields beyond 100 tesla and several high field facilities around the world are actively working toward that ambitious goal. The power and stored energy required to generate a magnetic field increase exponentially with the field amplitude. Therefore the better conductors with higher mechanical strength and electrical conductivity are required to nondestructively generate magnetic fields above 100 tesla with acceptable risk and cost. The first part of this talk will present the simulation results to understand the requirements of advanced conductors for pulsed magnets to practically achieve magnetic fields beyond 100 tesla. The second part of the talk will present our integrated experimental-modeling effort on the pathway to produce the novel conductor with tensile strength and electrical conductivity required to enable the goal of 120 T.

11:00 AM *SF02.14.04
Silver-Copper Composite Wires Prepared by Spark Plasma Sintering and Wire Drawing for Non-Destructive Pulsed High Magnetic Fields—Influence of Alloying on Electrical Resistivity and the Tensile Strength Simon Tardieu[1], David Mesguich[2], Antoine Lonjon[2], Florence Lecouturier-Dupouy[1], Nelson Ferreira[1], Geoffroy Chevallier[2,3], Arnaud Proietti[4], Claude Estournès[2,3] and Christophe Laurent[2]; [1]CNRS - Laboratoire National des Champs Magnétiques Intenses, France; [2]CIRIMAT, France; [3]Plateforme Nationale CNRS de Frittage Flash, France; [4]Centre de microcaractérisation Raimond Castaing, France

LNCMI-Toulouse produces some of the most intense non-destructive pulsed magnetic fields in the world with a European record of 98.8 T and aims at reaching more than 100 T. The generation of high pulsed magnetic requires the use of coils wound of wires with exceptional properties. To limit the heating, wires need to show a high conductivity and they also must have a high strength to be able to resist the Lorentz forces. Classical methods for strengthening copper wires involve the preparation of composite wires, such as copper-stainless steel (Cu-SS) and copper-niobium (Cu-Nb) or alloyed wires such as copper/silver (Cu/Ag). The Cu/Ag microstructure presents Cu-rich and Ag-rich solid solutions. These Cu/Ag wires exhibit a UTS value higher than 1 GPa but also a high electrical resistivity.

For several years, LNCMI and CIRIMAT have been working on the preparation of Ag-Cu composite wires by powder metallurgy, spark plasma sintering (SPS) and wire drawing with the aim of obtaining Ag-Cu wires with a low electrical resistivity. We have already shown that Ag-Cu (0.5 - 10 vol. % Ag) composite wires present an UTS similar to that of Cu/Ag alloy wires containing about 20 times more Ag, and interestingly also show an electrical resistivity about 1.5 times lower.

In the present work, we prepare and study 1 vol. % Ag-Cu composite wires and Cu/Ag alloy wires. The samples were prepared using the same silver and copper powders, mixing and wire drawing processes but the cylinders (wire precursors 8 mm in diameter and 33 mm long) were sintered by SPS at different temperature.

Ag nanowires (diameter 0.2 µm, length 30 µm) were synthesized in-house and mixed with a micrometric Cu powder. One cylinder is sintered at 400 °C, where the solubility of Ag in Cu is below 0.1 vol. %, in order to obtain a composite microstructure, i.e. pure Ag nanowires dispersed in a pure Cu matrix. The second sample is sintered at 600 °C, where the solubility of Ag in Cu is equal to about 2.4 vol. %, which allows the Ag to dissolve into the Cu to form Cu/Ag alloy nanowires.

The diameter of the cylinders is reduced by wire drawing at room temperature, in several passes, thus producing progressively finer wires (diameter 1 - 0.2 mm). Wires with ultrafine elongated (200-700 nm) Cu grains oriented along the drawing axis are thus prepared. The pure Ag nanowires or the Cu/Ag alloy nanowires are dispersed along the grain boundaries of the Cu matrix.

The 1 vol. %Ag composite wires and alloy wires show similar UTS (1100 MPa at 77 K), reflecting an equivalent strengthening effect for pure Ag and Cu/Ag alloy nanowires. However, it is shown that the formation of a Cu/Ag alloy, despite it is highly localized, results in a significantly higher electrical resistivity compared to un-alloyed wires (0.56 *vs* 0.49 µΩ.cm, at 77 K).

This study confirms the importance of preparing composite wires in order to obtain the most suitable properties for high magnetic fields.

SESSION SF02.15: Materials and Magnetic Fields II/Panel Discussion
Session Chairs: Florence Lecouturier-Dupouy and Sergei Zherlitsyn
Thursday Afternoon, December 1, 2022
Sheraton, 3rd Floor, Commonwealth

1:30 PM *SF02.15.01
Spark Plasma Sintering of Copper-Matrix Composites as Cylinders with Micrometric Grain Size towards the Preparation of High-Strength Conducting Wires for Resistive Magnets Christophe Laurent[1], Simon Tardieu[1,2], David Mesguich[1], Antoine Lonjon[1], Nelson Ferreira[2], Geoffroy

Chevallier[1,3], Arnaud Proietti[4], Claude Estournès[1,3] and Florence Lecouturier-Dupouy[2]; [1]CIRIMAT, Université Toulouse 3 Paul Sabatier, CNRS-INP-UT3, France; [2]Univ Toulouse 3, France; [3]Université Toulouse 3, France; [4]Centre de Microcaractérisation Raimond Castaing, UMS 3623, France

Spark plasma sintering (SPS) resembles hot-pressing because a uniaxial pressure is applied to the sample, but a key difference is that heating is performed by the application of a dc pulsed current to the pressing die and powder compact. Therefore, SPS allows higher heating and cooling rates than hot-pressing, allowing for lower sintering temperatures and shorter holding times. It is thus possible to avoid grain growth and prepare samples with a very fine microstructure. Moreover, a key limitation compared to pressureless sintering was lifted when the possibility to sinter complex-shape samples was demonstrated. The basics of SPS will be presented.
We will in particular present the case of cylinders that serve as precursors for the preparation of wires of pure copper, carbon nanotube - copper composites and silver nanowire - copper composites. Such wires may find some applications when ultra-high strength must be combined to a high electrical conductivity, as required for high-field magnets, or when lightweight materials are needed such as for aerospace power and engineering.
SPS allows one to prepared copper cylinders with micrometer-sized grains, typically ten times lower than conventional copper cylinders prepared by routes involving melting-solidification, and therefore a relatively high temperature, either for alloying or for the preparation of the pure copper sample to be used in a composite. SPS cylinders with only about 90% of their full density were found suitable for the rest of the study, because a too high density hampers the deformability of the cylinder during wire-drawing, resulting in sample breaking.
The microstructure of the powders, cylinders (8 or 24 mm in diameter) and wires will be presented as well as the mechanical properties and electrical resistivity of the wires measured at 293 K and 77 K.

2:00 PM DISCUSSION TIME

2:30 PM BREAK

3:00 PM SF02.15.03
Study of Fluctuation Induced Conductivity and Pseudogap State in Single Grain $GdBa_2Cu_3O_{7-\delta}$ Superconductor in Presence of External Magnetic Field Subhasis Shit[1], Devendra K. Namburi[2], Sitikantha D. Das[1] and Tapan K. Nath[1]; [1]Indian Institute of Technology, Kharagpur, India; [2]University of Cambridge, United Kingdom

In high-temperature superconductors (HTSCs), the appearance of superconducting fluctuations beyond the critical temperature (T_c) gives rise to the precursor effect of the occurrence of phase coherence even in the normal state, sometimes far from T_c. It is believed that the presence of Cooper pairs above T_c and their interactions with the normal state electrons are the primary cause of appearance of fluctuations in the sample. In earlier studies, it has been found that due to fluctuations present in HTSCs, heat capacity, conductivity, and diamagnetic susceptibility eventually enhance in the vicinity of T_c because of their high temperature, short coherence length, low density of carriers and anisotropic structures. Among various HTSCs, $YBa_2Cu_3O_{7-\delta}$ (YBCO) is the most studied and promising system both in scientific and technological aspects because of its high superconducting transition (T_c=92 K) with a high upper critical field ($H_{c2}\approx$150 T at 0 K) as well as high critical current density ($J_c\approx 0.33\times10^6$ A-cm^{-2} at 77 K). In our study, we have chosen magnetically ordered rare earth element Gd^{3+} having moment, μ_{eff}=7.97 μ_B in place of Y^{3+}. Though Gd has antiferromagnetic ordering at low temperature (T_N=2.24 K), still superconductivity arises in $GdBa_2Cu_3O_{7-\delta}$ (GdBCO) sample above the boiling point of liquid nitrogen. But, it is believed that magnetic ions have a negative impact on superconductivity. The contribution of localized magnetic moments of Gd^{3+} ion also produces tilted magnetic hysteresis loop which eventually affects the critical current density. Despite of its exceptional nature, no analysis of fluctuation conductivity and pseudogap behavior of GdBCO have been studied in the framework of existing theories. Based on the theory proposed by Aslamazov and Larkin, we have studied the fluctuation phenomenon in single grain GdBCO superconductor close to the superconducting mean field transition temperature (T^{mf}_c) in the presence of external magnetic field. It is observed that the fluctuations in GdBCO, near T^{mf}_c (in the critical field region), are beyond 3D-XY-E scaling for both zero and finite fields, indicating weakly first-order transition from normal to superconducting state. Local pairs model suggests that at $T=T'>T^{mf}_c$ (T' is the temperature below which the metallic slope in the resistivity deviates), strongly coupled bosons (SCBs) obeying Bose-Einstein Condensation (BEC) theory, are first formed in the sample. However, as the temperature approaches towards T^{mf}_c, they will evolve into the fluctuating Cooper pairs (FCPs) obeying BCS theory. So, in the temperature limit $T^{mf}_c<T<T'$ there is a transformation from BEC to BCS phase. In GdBCO superconductor, we have investigated the complete evolution process of BEC to BCS phase meticulously in the presence of external magnetic field. From the temperature dependent study of the pseudogap parameter, it is found that the transformation from BEC to BCS phase is not abrupt in the sample. Initially at $T=T'$, the SCBs are formed and remain in the sample upto $T=T_{pair}$. Here, T_{pair} is the temperature where pseudogap parameter is maximized. Thereafter, in the range $T_{2D-SW}<T<T_{pair}$ (T_{2D-SW} is the intersecting temperature between 2D fluctuation and Short-Wave region), the SCBs still exist but the number decreases rapidly because some of them initiate to pair up. Further decreasing the temperature at $T<T_{2D-SW}$, all the SCBs completely transform into weakly bounded and tightly overlapped FCPs and start to follow the classical fluctuation theories. The values of T_{pair} obtained from temperature dependent study of pseudogap parameter decrease when the magnetic field increases from zero to 4 T. Superconducting gap ($\Delta(0)$) for all magnetic fields calculated from the local pairs model are within the BCS limit, but the magnitudes reduce as the field escalates.

Investigating the Role of Interactions on the Stability of Magnetic Anisotropy in $L1_0$ Magnetic Materials Nica Jane Ferrer[1], Gursagar Singh[1], Cy Elliott[1], Benjamin J. Wieder[2,1,3] and Gregory A. Fiete[1,2]; [1]Northeastern University, United States; [2]Massachusetts Institute of Technology, United States; [3]Princeton University, United States

Recent studies have revealed the superior magnetic properties of $L1_0$ magnetic materials which lead to a vast number of applications ranging from magnetic recording to medical imaging. While there is a wealth of experimental studies and numerical simulations aimed at finding ways to tune the magnetic properties of these $L1_0$ magnetic materials, there is inadequate attention given to understanding the underlying mechanisms that govern the magnetic properties of these materials, such as their magnetic anisotropy. Hence, this study aims to elucidate how fundamental interactions such as the electron-electron interaction combined with crystal symmetry affect the magnetic anisotropy of $L1_0$ magnetic materials. To achieve this, the material is modeled by a tight-binding Hamiltonian with electron-electron interactions accounted for using a Hartree-Fock mean-field approximation. This approach allows us to calculate the magnetic anisotropy as a function of the interaction strength and work through crystal symmetry-related trends in the anisotropy. These trends can be directly compared against material-specific *ab initio* calculations.

3:30 PM *SF02.15.05
Precipitation in CuCrZr Composites Rongmei Niu and Ke Han; National High Magnetic Field Laboratory, United States

Subjecting conductors to cold-deformation usually increases their hardness but decreases their conductivity. When we deformed solution-treated samples of Cu0.66at.%Cr0.05at.%Zr wires, however, we were able to increase hardness by ~100% while also increasing conductivity by 24%. We attribute this simultaneous enhancement of hardness and conductivity to the formation of disc-shaped, semi-coherent precipitates, less than a nanometer in thickness, during cold deformation. The driving force for this deformation-induced coherent precipitation was the presence in the matrix of 78% of total alloying

elements in supersaturated solid solution. (During solution-treatment, the remaining 22% formed irregular micron-scale particles, mostly scattered distributed, that contributed only marginally to hardness.) The post- deformation aging of our samples further increased their hardness by 27%~38% and their conductivity by as much as 80%, despite the fact that the total Cr content in aging-induced coherent precipitates was only ~0.33 at.% (0.24 wt.%). These precipitates were only a couple of nanometers in thickness, but their Cr content (1.2-8.4 at.%) was relatively greater than that of deformation-induced precipitates

Advanced REBCO Conductors Customized for Ultra-High Magnetic Field Applications Venkat Selvamanickam; University of Houston, United States

High current (10-100 kA) cables are needed for magnets operating at 20 T and above for fusion, particle accelerators and other ultra-high magnetic field applications. The number of tape stands required for these cables can be greatly reduced using high critical current REBCO tapes – this is important given the high cost and limited production volume of REBCO. We have demonstrated REBCO tapes with critical currents as high as 1,836 A/4 mm at 4.2 K, 20 T using Advanced Metal Organic Chemical Vapor Deposition (A-MOCVD), which is more than 3x and 5x the critical current of the best and typical industry REBCO tapes respectively. We have recently scaled up our A-MOCVD technology to 50-meter lengths to repeatedly produce uniform and high I_c tapes. Our high-current tapes have been utilized to make round REBCO STAR® wires that exhibit engineering current density of ~ 600 A/mm^2 at 4.2 K, 30 T. At the extreme conditions of ultra-high magnetic fields, the high-current REBCO conductors experience immense mechanical forces which generally limit the maximum operating fields of the magnets. Higher strength architectures are being developed to utilize the high-current capabilities of our advanced REBCO conductors in magnetic fields of 20 T and above.

Planar Defects in High-Strength Materials for High Field Magnets Ke Han[1], Yan D. Xin[1], Bailing An[2] and Vince Toplosky[3]; [1]Florida State Univ, United States; [2]Northeastern University, China; [3]Florida State University, United States

High field magnets use certain materials with planar defects that strengthen the materials. These defects can be introduced by cold deformation that produces high densities of both dislocations and planar defects or by phase transformation that mainly helps to form planar defects and strengthening particles. These defects in crystals act as obstacles to resist dislocation motions. The increased density of these obstacles increases the mechanical strength. Under tensile loading, such as the loading condition in high field magnets or in fabrication, the materials may soften or harden depending on the interaction of the obstacles with the dislocations evolved during the loading. Studying the behaviors of such defects in such environments helps researchers to predict the maximum strength achievable of these materials, to make efficient use of them in magnets, and to manufacture materials to meet the requirements of the magnets, particularly when the magnetic stress reaches the strength of certain components in high field magnets. The goal of this research is to understand the strengthening effect of planar defect on selected materials for high field magnets. We will discuss the role of planar defects on deformation and on phase transformation.

Zn-Doped P-Type Gallium Nitride Through Nuclear Transmutation Doping Processes Jeongwoo Kim[1], Andrei S. Patapenka[2], Sergey D. Chemerisov[2] and Jae Kwon[3]; [1]University of Missouri-Columbia, United States; [2]Argonne National Laboratory, United States; [3]Infinity Power, United States

For the last decades, Zinc (Zn) has been studied as a p-type dopant for gallium nitride (GaN) as an alternative to magnesium although high-quality doping was unachievable. Here, we introduce ways to produce p-type GaN with uniformly doped Zn using nuclear transmutation doping processes.

First, we found that photonuclear transmutation doping (PNTD) is one of the promising ways for high-quality Zn doping. In collaboration with Argonne National Laboratory (ANL), GaN with a large number of Zn was obtained by controlling the beam energy for the PNTD process and we found p-type properties from the Zn-doped GaN. The uniform Zn distribution in the crystal was confirmed by using secondary-ion mass spectrometry (SIMS) measurements. In addition, the transmutation doping concentration of Zn was modeled by gamma-ray spectroscopy, Monte Carlo-based simulation program, and a nuclear data library. The concentration of Zn produced by the PNTD turns out to be 2.25×10^{17}/cm^3. Hall-effect measurement indicated that the hole carrier concentration was 8.802×10^{16}/cm^3 and I-V characteristics of diodes fabricated from Zn-doped GaN support the p-type characteristics.

Second, proton transmutation doping (PTD) is also considered to be another nuclear transmutation doping process for Zn-doped p-type GaN. Zn production through the PTD process was simulated and we found that Zn production is maximally dominating when the proton energy is around 46 MeV. Unlike PNTD, however, the PTD process will leave the radioactivity concerns due to ^{68}Ge ($T_{1/2}$ = 270.95 days).

Thermodynamic Modeling of High-Performance Adsorption-Based Atmospheric Water Harvesting (AWH) in Arid Conditions Chenyang Li, Lenan Zhang, Yang Zhong, Xiangyu Li, Bachir El Fil and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Global access to safe drinking water is a great challenge today and projected to remain so in the next decades. Atmospheric water harvesting (AWH) technologies have the potential to enable decentralized water supply in remote regions where infrastructure is lacking. Adsorption-based AWH,

specifically, could further expand water accessibility in arid climates by leveraging advances in novel sorbents materials such as Metal-organic frameworks (MOFs), which operate at low relative humidity conditions. To guide materials design towards high-performance AWH in extremely environments, a generalized thermodynamic framework that predicts the theoretical efficiency limits, based on fundamental material properties and device operating conditions, is highly valuable. In this work, we first introduce the fundamental phenomenon of adsorption isotherm shifting with temperature observed in MOF-303 and MOF-801 from both theoretical and experimental perspectives. Adsorption isotherm is the most important adsorbent property and key to modeling the energetic behavior of adsorption systems. Next, we propose a high-fidelity thermodynamic framework that incorporates this isotherm-shift effect and more accurately predicts AWH efficiency than previous models. The new predictions overall show significant improvements from literature results. Most interestingly, the upper bounds of adsorption-based AWH efficiency could exceed previous limits, and the optimization of key parameters, including desorption temperature and adsorbent adsorption enthalpy, tend to follow highly nonlinear trends that challenge popular conceptions. This work bridges the important knowledge gap between adsorbent materials development and device design, providing insights towards high-performance adsorption-based AWH technologies.

Proppant Reinforcement by Surface Polymerization—A Systematic Laboratory Investigation Wengang Li[1], Edreese Alsharaeh[2], Mohanraj Krishnan[2] and Abdullah Garni[1]; [1]Saudi Aramco, Saudi Arabia; [2]Alfaisal University, Saudi Arabia

Frac proppants, usually silica sand or ceramic spheres, have been widely applied in both conventional and unconventional oil gas production operations, with an essential function of supporting the created fractures by hydraulic pressure to keep the hydrocarbon flowing. To stand for high stress, enhancement of proppants has been performed by coating methods. Commercial resin coated proppant are mainly fabricated with novolac or epoxy resin, where the hardness and pressure resistance of product are limited by resin properties, and the pressure/temperature resistance are determined by the natural properties of commercial resins.
This paper demonstrated a novel method to fabricate coated proppants for HTHP applications by surface polymerization methods and dual coating protocol. The sand particles were firstly coated with polystyrene-polymethyl methacrylate copolymer (PS-PMMA) composite with commercial graphene (CG) (first composite layer) and subsequently coated with epoxy-CG composite (second composite layer). Chemical, mechanical, thermal and morphological characterizations for the composite layers and dual-coated sand proppants were investigated in detail by Fourier transform-infrared spectroscopy (FT-IR), nano-indentation, thermogravimetric (TGA), optical, and scanning electron microscopic (SEM) techniques.
The fabricated silica sand based proppant can hold 12-14k psi pressure and the thermal stability of the dual coating has reached as high as 368 ^{o}C. The elasticity (E), hardness (H), and the fracture toughness (K_c) of the dual coating (PS-PMMA/DVB)-(Epoxy-CG) have been investigated with a maximum of 7.78 GPa, 0.34 GPa, and 3.22 MPa $m^{1/2}$ respectively. A 3-D morphology effect has also been observed to further enhance proppant mechanical property, fulfilled by poly(styrene-methyl methacrylate)/divinyl benzene) (PS-PMMA/DVB) plus epoxy resin dual coating.
This surface polymerization coating method has been established on silica sand with wide range of size, 20/40 mesh to 100 mesh and nano-sand. The mechanically and thermally reinforced dual-coated sand particles with very high-stress resistance will be successful proppants for hydraulic fracture operations.

Topological Protected Mismatch of Mechanical Metamateirals Haning Xiu[1], Harry Liu[2], Xiaoming Mao[2], Zi Chen[1] and Jiabao Nie[3]; [1]Brigham and Women's Hospital, United States; [2]University of Michigan–Ann Arbor, United States; [3]Northeastern University, United States

Recent advances in mechanical metamaterials and topological phases have given rise to topological mechanical metamaterials (TMMs) that exhibit exotic topological properties, thus enabling promising applications such as energy absorption, impact mitigation devices, and stress-avoiding implants. Maxwell lattices, a representative class of TMMs, exhibit attractive mechanical properties at the surfaces/interfaces and distinct properties between different surfaces when they are topologically polarized. Understanding the motions and deformations of the topological Maxwell lattices is critical for designing impact resistant metamaterials for mechanical and biomedical applications. However, most studies on dynamics of TMMs focus on the linear regime and rarely take the topological effects into account. To address this knowledge gap, molecular dynamics simulations using the spring-mass system are employed to study the dynamics of the Maxwell lattices. Importantly, auxiliary springs are added on the Maxwell lattices to achieve local bistability, and to improve the impact mitigation effects of the lattices. Energy dissipation due to friction is also simulated through introducing a damping term. Various impact loadings and boundary conditions of the lattice (with/without bistable units) are studied to compare the reaction forces transmitted from the impact surface to the opposite edge and kinematic characteristics. The theoretical analysis is employed to identify how the topological polarization causes different impact resistance at different surfaces. The new findings can improve the design of topological Maxwell lattice that can exhibit high-performance impact mitigation and energy absorption properties and can enable the applications of TMMs in architected scaffolds for cell and tissue engineering, engineered bioimplants, and meta-implants for minimally invasive delivery.

A Machine-Learned Spin-Lattice Interatomic Potential for Dynamic Simulations of Defective Magnetic Iron Jacob Chapman and Pui-Wai Ma; UKAEA, United Kingdom

Critical components in many technologies for power generation, sensing, computation and communications exploit magnetic materials. Their viability in extreme environments, efficacy and performance depend upon magnetic phenomena and rely heavily on materials development for continued improvement. Theoretical understanding of how magnetic properties relate to the underlying microstructure provides valuable insight for tuning characteristic properties and determining the viability and fatigue of aged materials. Iron based alloys are particularly important industrial materials which may obtain a wide variety of complex magnetic states which significantly affect the materials mechanical properties. Nonetheless, studies often explicitly neglect magnetic degrees of freedom. The development of a general-purpose spin-lattice interatomic potential has proven to be a challenge [1,2].

We successfully develop a first of its kind machine-learned spin-lattice potential (MSLP) that can perform dynamic simulations of magnetic materials that includes explicit non-collinear magnetic and lattice degrees of freedom as well as changes in the length of the magnetic moments [3]. The physics-informed MSLP was achieved by supplementing a spin-lattice Hamiltonian with a neural network term [4]. The neural network was trained to a large database of configurations represented using a proper mix of local configurational and magnetic descriptors to provide data-driven corrections to unknown physics in the conventional spin-lattice Hamiltonian. It reproduces the energies of various magnetic states of BCC and FCC phases at different volumes as well as the complex magnetic configurations in the vicinity of a vacancy and self-interstitial atoms. This includes the reversal and quenching of magnetic moments at the defect core. The MSLP results are all in quantitative agreement with density functional theory calculations.

The Curie temperature is calculated using spin-lattice dynamics [5] and is in good agreement with experiments. The new machine-learned potential can perform scalable dynamic simulation with good stability at high temperature. We then apply the potential to study the magnetic structure near different mesoscopic scale dislocation loops in iron at finite temperatures. Such an investigation has not previously been possible with current state of the art theoretical or experimental methods. The effect of radiation induced defects on the interaction of magnetic fluctuations and lattice vibrations is examined.

The MSLP developed in this work transcends current treatments using DFT and molecular dynamics, in addition to other spin-lattice potentials which only treat near-perfect crystal cases, enabling simultaneous evaluation of mechanical deformations, magnetic fluctuations and defect properties at mesoscopic scales for the first time.

A Data-driven Discovery Pipeline for Flue Gas Separation Homopolymer Membranes Hsianghan Hsu[1], Matteo Manica[2], Ronaldo Giro[3], Binquan Luan[4], Akihiro Kishimoto[1], Lisa Hamada[1], Mathias Steiner[3] and Seiji Takeda[1]; [1]IBM Research-Tokyo, Japan; [2]IBM Research-Zurich, Switzerland; [3]IBM Research-Brazil, Brazil; [4]IBM T.J. Watson Research Center, United States

Introduction:
Flue gas generated by human activities is one of the most significant causes of global warming because a large portion of CO_2 is emitted to the earth's atmosphere yearly. To reduce the emission, separation of CO^2 is a near-term goal where polymer membranes represent a cheap and environmentally friendly approach from their fabrication to their in-situ application. Furthermore, recent advancements in machine learning (ML) enable in-silico membrane design targeted toward finding more energy-efficient and robust in-situ performance candidates. Here, we present a discovery pipeline for data-driven polymer membrane design covering several phases: data preparation, ML model training, ML model sampling, generated candidates filtering and analysis.

Data preparation:
Although an ever growing collection of datasets for small molecules are easing the process of building ML models for material design, the data coverage for polymers remains low, essentially because it's challenging to collect high-quality data. In this work, we consider a benchmark polymer database (PI1M) with ~ 1M p-SMILES (polymer-SMILES) [1] generated in-silico starting from the PolyInfo [2] database. For generating properties associated to the p-SMILES, we adopted a Quantitative Structure-Property Relationships approach implemented in our Polymer Property Prediction engine [3]. By capturing the structural information such as topological variables, connectivity indices, and group contribution, we have been able to associate to the structures physical properties accurately in a high-throughput fashion.

Generative modeling:
To generate alternative polymers, following the lead of Gòmez-Bombarelli et al. [4], we jointly trained a VAE (based on RNN cells) and an MLP on its latent space using p-SMILES representations of polymers and focusing on the following target properties: Tg, half-decomposition temp. (Tdh), and solubility. The learning process converged after 100 epochs (learning rate=1e-3 and batch size=64), and using gaussian processes it was possible to sample polymers with a solubility distribution matching the one observed for PI1M samples. The training experiments as well as the inference pipelines have been implemented using GT4SD [5].

Filtering and validation
In terms of generating innovative monomer candidates, physical validation times (from newly generated p-SMILES to CO2 permeability) are unfeasible. To overcome this limitation, we explored the chemical space of the generated p-SMILES using TMAP [6], since it allows to analyze candidates according to their local and global neighborhood in terms of structural similarity. A few candidates have been selected with their high Tg, Tdh, and a solubility value that falls into a range of interest. It is straightforward to validate the candidates using molecular dynamics simulations with software packages such as LAMMPS [7] or GROMACS [8]. Such a discovery pipeline can be easily automated and its results leveraged to establish a feedback loop to further fine-tune the model on different building blocks.

Conclusion:
Herein, we demonstrated how enriching PI1M data using simulations we can design a data-driven discovery pipeline relying on conditional generative models for homopolymer membranes. Given the generality of the components implemented the approach can be easily extended to co-polymer membrane discovery.

Modeling Fretting Wear Resistance of Surfaces Exposed to Extreme Conditions in Nuclear Reactors Ting Yang[1], T. A. Venkatesh[2] and Ming Dao[1]; [1]Massachusetts Institute of Technology, United States; [2]Stony Brook University, United States

The materials used in several parts of a nuclear reactor experience a combination of extreme conditions, i.e., mechanical stresses, radiative conditions and corrosive environments. For example, pressurized water nuclear reactors typically contain a large number of fuel rods (about 50,000). These fuel rods are cylindrical in shape, contain radioactive material in their cores and are surrounded by a cladding layer. These fuel rods are kept in place with spacer grids such that there is space between the fuel rods for water to flow through and absorb the heat from the fuel rods, which can then be used to produce power. At the regions where the spacers are in contact with the exterior of the fuel rods (i.e., the surface of the cladding that surrounds the radioactive fuel rod core), vibrational loads caused by turbulence in the water induce fretting damage, which can lead to cracking and deterioration of the cladding layer, resulting in serious radioactive leak issues. It has been reported that, of all the causes of such leaks, grid-to-rod contact fatigue damage is the most prominent, accounting for more than 70% of the problems.
In such nuclear fuel rod applications where high cyclic loads are involved [1], surfaces with high yield strength and wear resistance are required. As surfaces with homogeneous or graded nanostructures have been shown experimentally to significantly increase the yield strength and enhance surface wear resistance [2-5], in this work, we systematically investigate the potential for such novel nanomaterials for nuclear fuel-rod applications. In particular, we examine the fretting behavior of graded nanomaterials and compare them with homogeneous structures through a comprehensive computational study coupled with dimensional analysis. Using dimensional analysis, a set of dimensionless functions that takes the loading condition, the mechanical properties of the constituent materials, and geometric parameters into account are constructed to characterize surface damage on the structure with the graded nanostructured surface upon frictional sliding. Analytical expressions are proposed to explain experimental and computational observations to provide more insights into surface damage mechanisms, including shakedown behavior for nanostructured surface layers upon fretting wear. For numerical modeling, fretting sliding simulations are performed by finite element method (FEM).
A comprehensive theoretical/computational framework is established for identifying the influence of mechanical properties of the constituent materials and geometric parameters such as material hardening, friction coefficient, and gradient function vs. depth on the surface deformation and damage for structures with graded nanostructured surfaces upon fretting frictional sliding. Using this framework, the plastic shakedown behavior vs. strain hardening, friction and the plastic gradient is quantified. It is also demonstrated that graded nanomaterials exhibit enhanced resistance to frictional sliding wear with a smaller plastic deformation zone. Optimization of such nanomaterials and potential for their applications in nuclear fuel rods are discussed.

Materials Genomics Search for Possible Helium-Absorbing Nano-Phases in Fusion Structural Materials Haowei Xu[1], So Yeon Kim[1], Di Chen[2], Jean-Philippe Monchoux[3], Thomas Voisin[4], Cheng Sun[5] and Ju Li[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Houston, United States; [3]French National Centre for Scientific Research, France; [4]Lawrence Livermore National Laboratory, United States; [5]Idaho National Laboratory, United States

Civilian fusion demands structural materials that can withstand the harsh environments in fusion plasma reactors. The structural materials often transmute under 14.1 MeV fast neutrons, producing helium (He), which embrittles the grain boundary (GB) network. Adding load-bearing second-phase nanoparticles (0D) or nanowires (1D) with atomic-scale free volume and low He-embedding energy E_{emb} as volumetric He sinks may shield the 2D GBs from He segregation and combat He embrittlement; however, the ability to disperse low-E_{emb} nano-phases to screen GB from Helium embrittlement has not been fully unlocked yet due to the lack of material selection guidelines. Here we show that neutron-friendly and mechanically strong nano-phases with atomic-scale free volume can have low E_{emb} and >10 at% He-absorbing capacity, and could thus be exceptionally advantageous for soaking up He on top of resisting radiation damage and creep, provided they have thermodynamic compatibility and wettability with the matrix as well as high enough melting point. Our preliminary experimental demonstration proves that He-embedding energy is a good *ab initio* predictor of He shielding tendencies in hetero-phase materials, and can be used for computational screening. In this context, we present a list of compounds expected to be good He-absorbing nano-phases, taking into account E_{emb}, the neutron absorption, and activation cross-sections, the melting temperature, the thermodynamic compatibility, and the wetting angle of the nano-phases with the Fe matrix as an example.

10:30 AM SF02.17.03
Polychromatic Multiplexing Stress-Strain Diffractometer Sean Fayfar[1], Jay Theodore Cremer[2] and Boris Khaykovich[1]; [1]Massachusetts Institute of Technology, United States; [2]Adelphi Technology, United States

The development of new materials for extreme conditions such as high pressure or radiation requires improvements in characterization techniques, especially with in-situ measurements during synthesis. Neutron scattering techniques have been gaining popularity with the development of new smaller neutron sources and new beamline developments at national facilities. Current engineering beamlines with stress-strain diffractometers at national facilities require long measurement times due to the small gauge volumes of samples. We present our development of a stress-strain diffractometer intended to be optimized for improved efficiency compared with current designs at national facilities and to also be suitable for small research reactors such as the MIT Reactor and laboratory-based neutron generators. The diffractometer will utilize a polychromatic neutron beam to illuminate all the lattice planes within the sample simultaneously allowing for a series of bent perfect crystals to be placed after the sample; these crystals will be used as analyzers rather than monochromators. The silicon crystal analyzers are transparent to neutrons, which has the benefit of multiplexing capabilities with analyzers placed in subsequent order with each measuring the strain of a different lattice plane. Multiplexing is also accomplished by placing analyzers at 2θs ≈ ±90°, which allows the strain to be measured in two directions simultaneously. We will present results from both experimental testing and ray-tracing simulations for this instrument configuration and report on the current state of the construction of the prototype instrument at the MIT Reactor.

We acknowledge useful discussions with A. Stoica. This work is supported by the U.S. Department of Energy (DOE), Office of Science, under a Small Business Technology Transfer (STTR) Grant, Grant No. DE-SC0020555.

10:45 AM SF02.17.04
Interaction of Neutrons with Strain-Engineered Fibrous Boron-Doped Polyethylene Materials Duo Xu[1], Volodymyr Korolovych[1], Cody A. Paige[1], Lembit Sihver[2] and Svetlana V. Boriskina[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Chalmers University of Technology, Sweden

Studies of materials interactions with neutron beams are important for developing a fundamental understanding of material properties, studying materials degradation in extreme environments, and for the development of new radiation shielding materials for terrestrial and space applications. When ionizing particles, such as energetic electrons, protons, and gamma-rays interact with materials or tissue, they produce secondary particles, including thermal neutrons. As a result, neutrons are dominant near planetary surfaces and in atmospheres, induce high biological damage and present a risk factor for space exploration. The development of new lightweight multifunctional materials with simultaneous flexibility in mechanical properties, radiation shielding capability, and form factors is of high interest for aerospace, healthcare, and nuclear industries as well as for military applications.

Hydrogen is the ideal particle for stopping broad-spectrum primary radiation while also providing protection against secondary neutrons. Hydrogen is highly concentrated in polyethylene (PE) and all-hydrocarbon olefin block co-polymers, making PE a popular choice of material for radiation shielding composites [1]. It is well known that doping hydrogenated polymers with Boron-rich nanomaterials can further improve their performance for shielding both primary and secondary ionizing radiation [2]. However, the role of nanomaterial size, form-factor, and orientation as well as the effects of the melt-spinning-induced crystallinity, alignment, and phase separations within blended polymer matrices are poorly understood as most modeling approaches often do not capture this information. Multiple and inelastic scattering of neutrons by the internal structure of fibrous composite materials can affect their radiation shielding performance and material degradation pathways.

Through a combination of computer modeling, additive manufacturing via Fused Deposition Modeling (FDM) 3D-printing, weaving, and knitting, we engineer composite fibrous materials composed of PE-based blended resins as well as of PE-based polymer matrix doped by Boron-rich nano- and micro-particles. These materials are then characterized with neutron spectroscopy. We aim to develop a fundamental understanding of the role of nano-dopants as well as material- and fabrication-process-induced crystallinity and phase separations in composite PE-based fibrous materials on their wavelength-dependent multiple scattering and inelastic scattering of neutrons.

FDM printing and fiber spinning enable control over the polymer strength, stiffness by shear and strain deformations during the melt-extrusion process, resulting in aligned polymer chains and control over the material crystallinity, allowing studies of a wide range of composite materials of identical chemical composition but different internal structure. Most intriguing, such composite 3D printed materials and textiles can be recycled and reused in different form factors at the end of the product lifecycle. The developed fundamental understanding of neutron-matter interactions can be useful for engineering new composite radiation shielding materials like those developed by the Cosmic Shielding Corporation (CSC) [3] as well as PE-based textiles for terrestrial applications [4].

DX and VK contributed equally. Correspondence should be addressed to LS and SVB. This research is funded by the Cosmic Shielding Corporation (CSC), Atlanta, GA (for the Boron-doped 3D printed PE materials development). We also thank the ORNL for awarding us beam time for neutron scattering measurements (Proposal IPTS-28797.1 for NScD 2022-A) and William Heller for his help in running the experiment.

Predictions of Novel Features in X-Ray Scattering Spectra for Thermometry Alina Kononov[1], Thomas Hentschel[2], Stephanie Hansen[1] and Andrew Baczewski[1]; [1]Sandia National Laboratories, United States; [2]Cornell University, United States

Design and interpretation of inertial confinement fusion experiments rely on accurate models of material properties far from ambient temperatures and densities. Validation of these models with data from focused experiments is in turn limited by uncertainties in measured sample conditions. In particular, electronic temperatures in the warm dense matter regime are typically inferred from detailed balance of plasmon features in x-ray Thomson scattering spectra, but this approach loses sensitivity for thermal energies above the plasmon energy. Using real-time time-dependent density functional theory, we predict that spectral features arising from scattering into thermally depleted core orbitals can be used as alternative diagnostics at higher temperatures. Our first-principles calculations for aluminum and iron heated to 1 eV and 20 eV validate a simpler average-atom model modified to capture behavior near solid densities. Furthermore, we uncover subtle signatures of atomic order at comparable energy transfers, offering opportunities for simultaneous inference of ionic and electronic temperatures which may be out of equilibrium during e.g., laser heating. This work advances characterization techniques critical for understanding the performance of materials in extreme environments.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Computational Modeling of Scattering Processes in Warm Dense Beryllium Brian Robinson[1], Alina Kononov[2], Andre Schleife[1], Andrew Baczewski[2] and Stephanie Hansen[2]; [1]University of Illinois at Urbana-Champaign, United States; [2]Sandia National Laboratories, United States

Accurate predictions of electrical and thermal conductivities play an important role in the design of inertial confinement fusion (ICF) targets, where they can affect compression, instability growth, and energy losses. The warm dense matter (WDM) regime, with near-solid densities and temperatures above ~1 eV (10 kK), is particularly difficult to model due to the confluence of degeneracy, thermal, and strong coupling effects. Here, we study electron-electron (el-el) and electron-phonon (el-ph) scattering processes in beryllium, a common ICF material, in the WDM regime from first principles. Specifically, we find el-el lifetimes by fitting the imaginary part of the self-energy from many-body perturbation theory *GW* calculations to the Landau theory of the Fermi liquid. From this data, we predict el-el lifetimes on the order of hundreds of fs near the Fermi energy and tens of fs under excitations of 1 eV. We also simulate time-dependent el-ph relaxation dynamics by solving the Boltzmann transport equation, helping us to disentangle the relative importance of both processes. Revelations from this work will improve collision frequencies and scattering cross sections entering conductivity models used for ICF target design.

SESSION SF02.18: Energy Storage
Session Chairs: Christophe Laurent and Christopher Schuh
Friday Afternoon, December 2, 2022
Hynes, Level 3, Room 310

1:45 PM SF02.18.01
Design and Preparation of Halogenated Polynorbornenes via Systematic Structural Variation for Energy Storage up to 200°C Stuti Shukla[1], Chao Wu[1], Ankit Mishra[2], Gregory Sotzing[1], Yang Cao[1] and Priya Vashishta[2]; [1]University of Conneticut, United States; [2]University of Southern California, United States

High temperature flexible dielectric polymers are critical for rapid high-power needs under extreme electric fields and temperature. This work relates to the design and systematic study of halogenated polynorbornenes and the relationship that the dielectric properties have on changing the halogen from fluorine to chlorine to bromine. Further, in addition to changing the halogen systematically, the position of the halogen has been varied as well in going from the ortho to para position on a pendant phenyl derivatized imide. Variation of halogen position results in a change in energy required for a phenyl group rotation. The correlation between size, free volume, energy of rotation and position of halogen addition on the structural, thermal, and dielectric properties of the polymer will be reported. In this work, changing the pendent halogens (F, Cl, Br) at para and ortho position on the benzene increases the glass transition temperature from ~220 to 245°C, discharge energy density energy density changes from 5 to 6.2J/cm^3, dielectric constant range ~ 2.8-3.0 @100Hz frequency and charging-discharging electric field ~-625-700MV/m @200°C. The energy of rotation, free volume and loss also increase in going from fluorine to bromine at the para position. As a result, electrical breakdown and loss phenomena are better understood for designing novel high temperature polymer dielectrics with high energy density and low loss at elevated temperature.

2:00 PM SF02.18.02
Optimizing Performance of Low-Quality Graphite for High-Temperature Thermal Storage Shomik Verma, Colin Kelsall, Kyle Buznitsky, Alina LaPotin and Asegun Henry; Massachusetts Institute of Technology, United States

Energy storage is a critical component of achieving the clean energy transition, due to the intermittency of common renewable generation technologies like wind and solar. Thermal energy storage (TES) is one cost-competitive option for large-scale, long-duration energy storage. TES stores energy in the form of heat, allowing use of a wider variety of cheaper storage materials than traditional electrochemical batteries.

The specific TES technology considered in this work is called thermal energy grid storage with thermophotovoltaics (TEGS-TPV). In the charge cycle, resistance heating is used to heat liquid tin to high temperatures (~2400°C), which is then flowed through graphite blocks to heat them. As the thermal storage medium, the graphite retains this heat for several (>10) hours. During discharge, colder tin (~1900°C) is flowed through the graphite, and the heated tin at the outlet is flowed past TPV cells which convert the light emitted by the tin pipes at these high temperatures to electricity. Technoeconomic analysis indicates the cost per energy of TEGS-TPV is <$20/kWh-e and the cost per power is <0.40/W-e.

These promising technoeconomics are enabled by cheap (<$0.50/kg) graphite as the storage material. However, this graphite is often low quality, formed by molding machining scraps or recycling used graphite. It is therefore porous, has poor mechanical strength, and may contain impurities. Understanding the high-temperature thermal properties of low-quality graphite is critical to evaluating its performance as a thermal storage material.

The first part of this study measures graphite's high-temperature thermal properties including density, specific heat, and thermal conductivity, following ASTM standards. We use machines that measure properties up to 1500°C, and we extrapolate the measurements to the temperature region of interest with physics-based correlations. Using these properties, we can calculate the thermal diffusivity of the graphite, which directly correlates with thermal performance. Based on the measurements taken, we find low-quality graphite has low thermal conductivity (~10 W/mK) at room temperature, and worsening qualities with increasing temperature. In comparison, high-quality graphite has room temperature thermal conductivity around 100 W/mK.

The second part of the study investigates how best to operate the charge and discharge cycles given the less ideal properties of low-quality graphite. A transient 3D multiphysics simulation is set up coupling the liquid tin fluid flow to the conductive heat transfer within the graphite. Several flow configurations were tested, including varying the spacing and diameter of tin tubes within the graphite, considering flowing tin through several graphite blocks in series, or changing the flowrate as a function of time. An optimal design was determined to ensure near-constant power output through the storage duration.

Finally, the third part of the study develops a lumped capacitance model to accelerate computation of transient liquid metal and graphite temperatures. The developed model splits each block into 5 pieces and considers each as isothermal. This results in errors of less than 1% through the transient storage duration when compared to the 3D multiphysics model, with 3 orders of magnitude faster computation time. This allows rapid calculation of transient graphite and tin temperatures for varying charge/discharge profiles, for example based on daily generation and demand curves.

In conclusion, this study investigates the high-temperature properties of low-quality graphite to optimize its performance as a thermal storage material. By combining measurements with modeling, we determine ideal charge and discharge geometries, and develop a lumped capacitance model for accelerated transient calculations. Overall, our study helps to enable cheap long-duration storage to ease the transition to a clean energy future.

2:15 PM SF02.18.03
High Energy Density Hygroscopic Hydrogel Thermo-Adsorptive Storage Bachir El Fil, Xiangyu Li, Xinyue Liu, Carlos D. Diaz, Gustav Graeber, Liliosa Eyang Cole, Leon C. Gaugler and Evelyn N. Wang; Massachusetts Institute of Technology, United States

Despite significant interest in thermal storage devices, state-of-the-art phase change material (PCM) systems lack the high energy densities, while the low temperature of the building waste heat cannot charge thermos-chemical material (TCM) systems. Here, we transform thermal energy storage (TES) by proposing a new approach with the adsorption of hydrogel/salt composites. Hydrogel adsorbents are hydrophilic dry polymer networks with hierarchical pore structures. Through swelling, it enables a much higher water uptake and significantly lower cost compared to traditional adsorbents including the commercial zeolites and MOFs, at high water vapor pressure. Salts, on the other hand, adsorb water vapor efficiently at low vapor pressure, but after deliquescence, the salt solutions are strongly corrosive. Here we incorporate hygroscopic salts into a hydrogel matrix to prevent the hydrated salts from deliquescence while greatly enhancing the hydrogel's adsorption capacity at low relative pressure levels. As a result, a water uptake of about 1.0 g/g at the operating relative pressure level (~ 30%) with high cyclability can be achieved by a unique hydrogel/salt combination. To achieve superior kinetics, several methods were considered to tune the porosity of the hydrogel such as freeze drying and ice templating. Additionally, we fine-tune the low critical solution temperature (LSCT) of the hydrogel in such a way to minimize its regeneration temperature significantly. Finally, we leverage the high-water uptake,

superior kinetics, and low desorption temperature of the hydrogel to design and demonstrate a high energy density thermal storage system. Due to the favorable properties of the hydrogel adsorbent, not only does our proposed TES unit have more than 3 higher energy density compared to state-of-the-art PCM solutions, but it is also cost-effective.

Towards Quantitative Understanding of Melting and Erosion Caused by Hypervelocity Impacts Jasper Lienhard, Keith A. Nelson and Christopher A. Schuh; Massachusetts Institute of Technology, United States

If a material experiences a high-rate impact with enough kinetic energy, the resulting plasticity and adiabatic heat generation can lead to local melting. Such melting is a source of erosive wear, because liquid is easily ejected from the impact site, and can also facilitate the removal of solid matter. Our recent works have aimed at understanding the melt-induced erosion process during hypervelocity impacts of microparticles. With impactors including hard particles as well as soft metals, we explore the heating, melting, and ejection of matter for microparticles launched and imaged with a laser system. In-situ videography provides insight on the development of ejecta during the impact event, as well as the kinetic energy associated with plasticity. Ex-situ quantitative measurements of impact sites provide accurate assessment of the volume of ejected matter. By combining in- and ex-situ quantitative measurements, we are able to conclude that only a small amount of liquid formation is needed to achieve remarkable phenomenological changes in erosion behavior.

3:30 PM SF02.19.02
Comparing High Strain Rate Shear Response and Resistance to Adiabatic Shear Bands in 3D Printed and Wrought Inconel 718 Russell Rowe[1], Anthony Palazotto[2] and Keivan Davami[1]; [1]The University of Alabama, United States; [2]Air Force Institute of Technology, United States

With the increased demand for additively manufactured components in the aerospace industry, the necessity for characterization of 3D printed materials under nominal and off-nominal loading conditions grows rapidly. In this research, the resistance to adiabatic shear band (ASB) formation in 3D printed and wrought Inconel 718 will be compared. Reliable turbine fan-blade containment systems, which are required on many aircrafts for safe operation of gas turbine engines, are commonly made from high-strength titanium or nickel-based superalloys. When engine fan blades fail, the fragments impact the containment systems walls at high velocities and either cause global plastic deformation, which is preferred, or localized plastic deformation, in the form of shear plugging. During plugging, intense plastic shear strains may cause ASBs, which is the localization of shear strain into a very narrow band of material, which can cause premature catastrophic failure. In a region of intense shear strain, both work hardening and thermal softening occur causing a thermo-mechanical instability. At a critical value of shear strain, thermal softening effects dominate and any increased hardness from work hardening effects is completely mitigated, thus forming an ASB. Dynamic shear tests were carried out using a split Hopkinson pressure bar to compress “top-hat geometry” shear samples and high strength steels stopper rings were attached to the samples to limit their deformation. After mechanical testing, each sample was sectioned and prepared for microscopy to characterize the ASB formation based on the strain in the sample. A shear strain value of 3.23 was observed to result in ASB formation across the entirety of the shear region. The samples that experienced a higher strain clearly showed cracks that traveled partially along the ASB. One sample was tested without the shear stopper ring, and this allowed the crack to travel along the ASB across the entire shear region breaking the sample into two pieces. The ASBs observed in the printed samples were approximately 4-microns wide which are markedly narrower than the 7-micron wide bands in the wrought material. Microhardness tests conducted on the material surrounding the ASB revealed that the material hardness increases around the ASB with a peak in microhardness at the center of the ASB. This hardness peak in the ASB center is often attributed to nanoscale grains that formed by dynamic recrystallization occurring when ASB forms. Determining at what shear strain an ASB may form will help future fan-blade containment system designs ensure the safety for future aircraft.

3:45 PM SF02.19.03
Permanent Bandgap Engineering in Quasi-2D Tellurium Synthesized via Hot-Pressing Naveed Hussain[1], Ahmed Shehzad[2] and Maxim Shcherbakov[1]; [1]University of California, Irvine, United States; [2]Shenzhen University, China

Two-dimensional (2D) tellurium (Te) is an emerging 2D semiconductor [1] with attractive characteristics, such as high carrier mobility, large electro-optic activity, superior air-stability, and strong spin–orbit coupling, etc. [2-3] The application of quasi-2D Te in optics and optoelectronics has been restricted due to its narrow indirect band gap of ~ 0.35 eV. Quasi-2D Te has been theoretically predicted to undergo dramatic indirect-direct bandgap transition [4] (0.35 eV to 1.92 eV) through strategies such as confinement effect [5] and external strain, [6] making it promising for nano-optoelectronics. [7] Another study predicts enabling of a colossal bandgap opening, resulting in strong absorption of UV to UV-blue visible lights upon induction of a biaxial compressive strain in quasi-2D tellurium.[8] However, experimentally achieving such massive yet irreversible bandgap modulation has remained a daunting task. Bandgap modulation through mechanical straining in ultrathin 2D materials has long remained an exciting avenue to achieve desired functionalities at nanoscale.[3] However, most of these demonstrations have reported volatile or short-lived strains, causing a reversible narrow bandgap modulation and temporary tailoring of their properties. By maintaining a high-pressure enforced non-slipping condition and exploiting the coefficient of thermal expansion (CTE) mismatch between tellurium and the growth substrates at elevated temperatures, we report a strategy that yields non-volatile strain induction in ultrathin 2D nanoflakes of tellurium, achieving an optimal irreversible biaxial compressive strain as high as -4.7 % on a sapphire substrate. Consequently, UV-Vis absorption and photoluminescence (PL) spectroscopy studies reveal a permanent indirect-direct bandgap modulation from 0.35 eV (bulk) to 3.18±0.1 eV (2D) at a modulation rate of 691 meV/%, which is ~400% larger than that of highest ever reported value is achieved in strained tellurium nanoflakes.[9] Our micro-Raman, micro-PL and high-resolution transmission electron microscopy studies further confirm the long-lived retention of modulated bandgap, resulting in superior absorbance and ultrabright photoemission in UV spectral region. Strained 2D tellurium exhibits robust band-to-band radiative excitonic recombination and high intrinsic quantum efficiency of c.a. 79.5±0.5%, calculated by using the following formula: [10]
PL Quantum Yield (%)=τ/τ_r=79.5±0.5%
Where τ_r and τ_{nr} are radiative and non-radiative recombination lifetimes.
Our findings indicate the superior performance of strained 2D tellurium for optoelectronic applications and its possible utilization for UV sources in the classical and quantum optical regimes. The strategy suggests that controlled and non-volatile bandgap engineering can be generalized to other 2D

semiconductors for on-demand applications in nano(opto)-electronics.

4:00 PM SF02.19.04
A New High-Resolution Launch Pad for Laser-Induced Particle Impact Testing Alain S. Reiser and Christopher A. Schuh; Massachusetts Institute of Technology, United States

Laser-induced particle impact testing (LIPIT) has unveiled the behavior of a wide range of materials at high strain rates and small scales since its introduction ten years ago. In this first decade of high-velocity microparticle impact research, hardly any modification of the original experimental setup has been necessary. However, future avenues for the field require advancements of the experimental method to expand its breadth. Here we introduce a new design concept for the launch pad that offers a number of improvements. First, it enables precision of the impact location better than typical particle diameters. Second it paves the way to patterning of advanced impactors to be used for LIPIT. Third, it unlocks experiments at higher temperatures than previously possible. This talk will review these new capabilities and others more generally enabled by evolution of the LIPIT launch structure.

4:15 PM SF02.19.05
Exploring the Deformation Mechanism of Metals at Ultra-High Strain Rate Nanoindentation Testing Yuwei Zhang, Benjamin Hackett and George Pharr; Texas A&M University, United States

In this study, we performed nanoindentation on single crystal aluminum at various indentation depth through impact (strain rate > 10^3 1/s) and quasistatic (strain rate = 10^{-2} 1/s) nanoindentation. With the help of FIB lift out and STEM detector in SEM, we found distinct microstructure under the indents at two extreme strain rate. The subgrain structures under the indents from impact test extends deeper than the indents deformed at low strain rate. Informed by Orowan equation, we think the large strain rate(~10^3 1/s) from impact test is largerly accommodated by the increase of mobile dislocation density. This work highlights the importance of scrutinizing the microstructural evolution in understanding the plastic deformation of materials at extreme conditions.

4:30 PM SF02.19.06
Architected Materials under Extreme Impact Conditions Thomas Butruille and Carlos M. Portela; Massachusetts Institute of Technology, United States

Ultralight mechanical metamaterials enabled by advanced manufacturing processes have previously achieved density-normalized strength and stiffness properties that are inaccessible to bulk materials, but the majority of this work has focused on static loading while the mechanical properties of these metamaterials under dynamic loading conditions have remained largely unexplored. Properties such as energy absorption of these metamaterials are of high interest for protective applications and recent works on their dynamic response have demonstrated the benefit of architecture for impact mitigation.

Here, we systematically study the response of metamaterials under microprojectile impact using two-photon lithography as a rapid prototyping technique for microscopic polymeric microlattices. We fabricate suspended thin-plate lattice architectures of varying thicknesses and morphologies to characterize their response to microparticle impact. We employ the laser-induced particle impact test method to accelerate ~30 µm-diameter microparticles to velocities of up to 800 m/s, and use ultra high-speed imaging of the impact process to measure impact energetics. To isolate the effect of architecture, we maintain a constant relative density across prototypes and probe them with a range of impact energies. Additionally, we analyze our experiments in a dimensionless framework to provide a first-order estimate of impact response across materials and length scales. Lastly, we study the impact response using an explicit dynamics finite-element representation to provide insight on the impact mechanisms. This investigation provides a framework for the rapid design and characterization of future metamaterials for a variety of energy absorption applications.

4:45 PM SF02.19.07
Understanding Dynamic Recrystallization-to-plasticity Linkages in Cold Spray via Nanomechanical Property Mapping and Profilometry-Based Indentation Plastometry Bryer C. Sousa and Danielle L. Cote; Worchester Polytechnic Institute, United States

The high-strain rate impact phenomena underpinning solid-state metallurgical cold gas dynamic spray processing introduces severe plastic deformation states, which results in the formation of heterogeneous strain gradients throughout the consolidated microstructure. In addition, particle-particle interfacial dynamic recrystallization has been observed in various cold sprayed material systems. However, the degree of dynamic recrystallization achieved as a function of the impact velocity and the applied stress upon particle impact has yet to be linked to the plasticity of resultant consolidations. In turn, the present work utilizes various gas-atomized Al alloy feedstock powders, coupled with a range of particle impact velocities tuned through changes in carrier gas pressure and temperature to generate an array of fully dense consolidations with various degrees of interfacial dynamic recrystallization achieved. Consolidations will be studied through profilometry-based indentation plastometry testing and analysis and nanomechanical property mapping and clustering analysis methods. Consequently, a clear linkage between recrystallization and resultant uniform plastic stress-strain behavior will emerge through coupling mechanical property evaluation with dynamic recrystallization during cold spray processing.

Pressure-induced Dramatic Changes in Optoelectronic Metal Halides Xujie Lü; Center for High Pressure Science and Technology Advanced Research, China

Perovskite-related metal halides exhibit unique structures and outstanding optoelectronic properties that have enabled a wide range of technological applications including solar cells, light-emitting diodes, lasers, and radiation detectors. Two main focuses include understating the structure-property relationships and exploring advanced new materials with enhanced and/or emergent functionalities. In this talk, I will present our recent efforts in investigating metal halides using high pressure, an alternative approach to exploring novel materials with desirable properties that also permit a deeper understanding of a wide range of phenomena. Using the state-of-the-art high-pressure techniques coupled with *in situ* synchrotron-based and in-laboratory property measurements, we characterized the changes in the lattice, electronic, optical, and optoelectronic properties of various metal halides with different dimensionalities including 3D, 2D, and 1D, and further revealed their structure-property relationships. High-pressure research opens a new way to understand the fundamental mechanisms of optoelectronic metal halides and explore novel materials with superior properties.

8:30 AM *SF02.20.02
Emergent Magnetic Phase in Pressure-Tuned Antiferromagnetic Topological Insulator Mingliang Tian[1,2], Xuliang Chen[2] and Zhaorong Yang[2]; [1]Anhui University, China; [2]Hefei Institutes of Physical Science, CAS, China

Zintl material EuCd2As2 attracts much recent research interest as it can manifest various ideal topological quantum states under certain conditions just within the same host. While the ground state of this material is expected to be an antiferromagnetic (AFM) topological insulator or axion insulator as outlined by the Zintl concept and theoretical band calculations, yet all samples from previous works experimentally show an AFM semimetal state. Based on successful synthesis of single crystals of EuCd2As2 having an AFM insulating state and a negative colossal magnetoresistance (CMR, ~10,000%) effect, here we present a comprehensive high-pressure study of this unique material. We found that the AFM transition temperature is raised linearly from ~9.5 K at ambient pressure to ~55.0 K at 24.0 GPa; meanwhile, the CMR persists whereas its maximum magnitude first increases, reaching ~40,000% at 12.6 GPa, and then decreases significantly. Beginning at ~24.0 GPa, a ferromagnetic metallic phase with an ordinary negative MR shows up, which is accompanied by a trigonal P3m1 to monoclinic C2/m structural transition. The emergent phase dominates over the pristine AFM insulating one upon completion of the structural transition beyond ~40 GPa. Our results demonstrate the tunability of quantum states by pressure and may offer crucial insights into understanding of the interplay of magnetism and transports in EuCd2As2 and its derivatives.

9:00 AM SF02.20.03
Characterization and Performance Evaluation of Geocomposite Materials Under Extreme Environmental Conditions S A K V Miyurudarshi Piyathilake and Christopher Bareither; Colorado State University, United States

Waste containment infrastructure is essential to protect human health and the environment. This infrastructure should consist of robust barrier systems that can isolate municipal, industrial, medical and hazardous waste to avoid contaminant leakage and pollution under extreme environmental conditions. Thus, it is essential these barrier systems withstand high temperatures, pressures and strain deformations that can impact their long-term resilience. Recently, geocomposite materials that consist of geomembranes (GMX) and geosynthetic clay liners (GCL) have emerged as a promising barrier system due to their durability and low cost. GMX is usually made of High-Density Polyethylene or Low-Density Polyethylene while GCL consist of a layer of bentonite clay encapsulated between two polypropylene geotextiles. The promising combination of GCL and GMX gives rise to a durable, cost-effective barrier system under extreme environments.

This research focus on the degradation of GCL and GMX polymers in real-world applications. We simulated harsh, real-world conditions and studied oxidation, free radical formation, crystallinity and tensile properties to understand the material performance. Geocomposites were exposed to Cu (pH=2), Bauxite (pH=12) based mineral process solutions and DI water for 1, 6 and 10 months while applying a 20 kPa normal stress. Next, they were subjected to 2 GPa normal stress to mimic the strain these materials experience under high load in the field. This was followed by imaging, spectroscopy and mechanical characterization to analyze material stability.

SEM images show that GCL exists as bundles of fibers with an average diameter of 40 µm while GMX is a textured film with a thickness of 1.6 mm. Thermal studies via DSC revealed that GMX is composed of antioxidants while GCL does not contain antioxidants. We also quantified the heat of fusion and extracted polymer crystallinity. Both materials showed an increase in crystallinity (9.5% for GCL and 6% for GMX after 10-month immersion) following chemical and stress treatments. This increase in crystallinity was directly proportional to immersion time and solution strength. Higher crystallinity suggests higher degradation since free radicals formed during oxidation create crystalline regions/clusters that makes it more brittle.

FTIR results showed that Carbonyl Indices for both the Carbonyl compounds band (1650-1850 cm^{-1}) and Hydroperoxide/Alcohol band (3200-3550 cm^{-1}) increase for GMX and GCL with solution immersion and stress. This suggests that hydroperoxides, alcohol, and carboxyl groups form as a result of oxidation. XRD was performed to extract the crystallinity of the polymers. For GMX, we see a crystallinity increase of 10.5% and 5.5% in Cu and Bauxite solutions respectively, and for GCL it is 10.7% and 18.7%. We notice the impact is higher for GCL due to the lack of antioxidants. XPS confirmed the above results and revealed that C-C bonding has reduced in percentage after exposure, where alcohols (-OH), ketones (-C=O) and carboxyl groups (O-C=O) have increased in percentage, which is a clear indication of oxidation after treatment.

The mechanical properties were also consistent with spectroscopic and thermal results. Young's modulus gradually increased for 1-, 6-, and 10-month samples. This is severe for 10-month samples: 23-27% for GMX and 37-41% for GCL. Yield strength and tensile strength also showed a similar trend. This proves that harsh chemicals and stress can deteriorate overall mechanical performance. Our research sheds light on micro-level chemical reactions and correlates that to macro-level catastrophic failure in barrier systems. We envision to extend our fundamental understanding and develop a universal model that can predict the life-time of geocomposites for harsh environmental conditions. The impact of this research is significant; it can reduce pollution and protect the environment from toxic, hazardous waste materials under extreme conditions.

Structure and Dynamics of Supercritical Water Determined Using Quantum Molecular Dynamics Nitish Baradwaj, Aravind Krishnamoorthy, Ken-ichi Nomura, Aiichiro Nakano, Rajiv Kalia and Priya Vashishta; University of Southern California, United States

Water subjected to very high temperatures and pressures inside the Earth's Mantle exists in it's supercritical form. It exhibits extraordinary properties such as having a low dielectric constant, which stems from the breakdown of hydrogen bonds at supercritical temperatures. This makes supercritical water a non-polar solvent and the basis for many innovative technologies. In this study we investigate the hydrogen bonds, its lifetime in supercritical water (0.1

gr/cc to 1.0 gr/cc) at 1000K, along with structure and various dynamical correlations studied through the velocity autocorrelation function, current-current correlation function, and their Fourier transforms from position and velocity trajectories calculates using SCAN Exchange-Correlation functional within DFT.

This work was supported as part of the Computational Materials Sciences Program funded by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, under Award Number DE-SC0014607.

Microstructure Characterization of Oxide-Particle-Dispersion Strengthened Copper Matrix Composite Glidcop® Yan D. Xin, Jun Lu and Ke Han; Florida State Univ, United States

Glidcop® is an oxide-particle-dispersion strengthened copper composite that has a combination of high mechanical strength and high electrical conductivity. It has been used as a conductor for 60 T and 100 T ultrahigh field pulsed magnets by the National High Magnetic Field Laboratory, USA. In the quest for even higher magnetic field, material development is crucial. Since the mechanical properties of a material are often determined by its microstructure, comprehensive characterization of the microstructure of the material is necessary. In this work, we studied the microstructure of Glidcop® AL-60, AL-25 and AL-15, using both scanning electron microscopy (SEM) and transmission electron microscopy (TEM).
We identified crystal phases of the alumina in these composites and investigated their size and density distribution. We confirmed that Orowan strengthening where dislocations bowing around alumina particles is the main strengthening mechanism. In addition, we carried out studies of samples after plastic deformation to investigate the origin of wire breakage during wire drawing.

Superconductivity in Superhydrides—New Experimental Developments Mikhail Eremets[1], Vasily Minkov[1], Vadim Ksenofontov[1] and Sergey Bud'ko[2,3]; [1]Max Planck Institute for Chemistry, Germany; [2]Ames Laboratory, U.S. Department of Energy, Iowa State University, United States; [3]Iowa State University, United States

Since the discovery of superconductivity at ~ 200 K in H_3S [1], similar or higher transition temperatures, T_cs, have been reported for various hydrogen-rich compounds under ultra-high pressures [2]. Superconductivity was experimentally proved by different methods, including electrical resistance, magnetic susceptibility, optical infrared, and nuclear resonant scattering measurements. The crystal structures of superconducting phases were determined by X-ray diffraction. Numerous electrical transport measurements demonstrate the typical behavior of a conventional phonon-mediated superconductor: zero resistance below T_c, the shift of T_c to lower temperatures under external magnetic fields, and pronounced isotope effect. Remarkably, the results agree with the theoretical predictions, which describe superconductivity in hydrides within the framework of the conventional BCS theory.
Magnetic properties, one of the most important characteristics of a superconductor, have not been satisfactory defined. Recently, we developed SQUID magnetometry under extreme high-pressure conditions [3] and report characteristic superconducting parameters for H_3S and LaH_{10}—the representative members of two families of high-temperature superconducting hydrides. In particular, we determine a London penetration depth λ_L of ~20 nm in H_3S and ~30 nm in LaH_{10}. These compounds have the values of the Ginzburg-Landau parameter κ ~12–20 and belong to the group of "moderate" type II superconductors. We further develop magnetic measurements with the trapped magnetic flux. This technique provides a strong magnetic response and, what is more important, eliminates the huge background of a bulky diamond anvil cell.
A large part of the report will be a discussion of possibilities of further increasing T_c to room temperature and above, with emphasis on experimental espects.

Development of a Novel Insulating Coating Formulation Rashmi R. Wijayarathna and Madhubhashini Maddumaarachchi; University of Sri Jayewardenepura, Sri Lanka

Large buildings consume plenty of energy and cost for cooling purposes per year. For this, a variety of thermal insulation strategies would be appealing solutions. This study provides new insights into thermal insulating coatings. This research demonstrates the development of a thermal insulating coating containing a porous membrane created by poly(methyl methacrylate) binder. Ammonium bicarbonate (NH_4HCO_3) was used as the readily available, inorganic pore-forming agent which was incorporated into the organic binder using a water-in-oil (W/O) emulsion. A series of 0%, 1%, 5%, and 10% (w/v) concentrations of ammonium bicarbonate incorporated paint films were prepared. Decomposition of NH_4HCO_3 produces ammonia and carbon dioxide gas bubbles which developed porous structures within the binder during the solvent evaporation process. Air is trapped inside the pores and makes an air layer that can act as the thermal barrier layer in the paint film. Optical microscopic images and SEM images were taken to confirm the formation of W/O emulsion and the formation of porous structures inside the paint, respectively. When the concentration of pore-forming agents increases, more interconnected porous structures in the paint film have resulted. It can be suggested that 5% of NH_4HCO_3 was the optimal value. The insulation property of these paint films was tested using a self-developed thermal insulating property measurement device having four DHT 11 temperature sensors. The data were collected and reported using Arduino UNO software and Processing 3 software, respectively. Results demonstrated that there is no gradual increase of the insulation property while increasing the NH_4HCO_3 content. Nevertheless, 1% and 10% of NH_4HCO_3 incorporated paint films showed a 2°C to 4°C of absolute temperature difference, indicating a good thermal insulating property of the paint film. This research work provides insights into a good cost-

effective solution for thermal insulation enhancement in the conventional paint formulation.

Novel High-Strength Bioinspired Coatings for Hypervelocity Debris Mitigation Chad A. McCoy, Guangping Xu, Hongyou Fan, Jens Schwarz and Jenny Xiong; Sandia National Laboratories, United States

Materials designed for use in extreme environments must have strong mechanical and/or thermal resistance to withstand the insults experienced for their desired application. Some of the most stressing environments, which require both mechanical and thermal resistance, are use in pulsed power facilities, magnetic fusion reactors, and space debris and radiation protection. Ideal materials for these applications must combine high strength and thermal resistance with low weight high x-ray transmission. Materials which meet these needs and do not cause significant hazards to personnel and the environment are not presently available.
Novel layered nanocomposite coatings have been fabricated from silica and sugar-derived carbon biomimic natural seashell structures. These coatings have been demonstrated to have high x-ray transmission, which enables their use as diagnostic windows for pulsed power facilities and magnetic fusion reactors. The coatings are stable to temperatures exceeding 800 °C, which outperforms other high-strength, low-weight materials. The materials are environmentally friendly and do not pose any health risks to personnel, which enables them to be used for diagnostics in extreme environments.
Testing of their functionality as debris shields for pulsed power facilities, magnetic confinement fusion reactors, and micrometeoroid impact is ongoing. Variable thickness of coatings on silicon substrates were exposed to debris generated on the Z Pulsed Power Facility at Sandia National Laboratories and the deformation to a witness plate shielded by the coatings was measured. Deformation of the witness plate behind a 50 µm thick substrate coated with 35 µm of this material was less than that of a 100 µm thick bare substrate. Coating of 40 µm of material on a 100 µm thick substrate resulted in no measurable deformation to the witness plate. The results demonstrate that this coating is viable for use as debris shields in extreme environments.
Sandia National Laboratories is a multimission laboratory managed and operated by National Technology & Engineering Solutions of Sandia, LLC, a wholly owned subsidiary of Honeywell International Inc., for the U.S. Department of Energy's National Nuclear Security Administration under contract DE-NA0003525.

Morphology Dependent Microstructural Deformation and Structure-Property Relationship Studies on Styrenic Thermoplastic Elastomer Films Khadar B. Shaik, Abul Huq, Alamgir Karim and Anil Bhowmick; University of Houston, United States

Thermoplastic elastomers (TPEs) containing polystyrene (PS) hold a special class of molecular chain arrangements of the hard and soft segments giving rise to many well-defined nanostructures. The orientation and ordering of these nanodomains affect the mechanical properties of TPEs to a very large extent. Accordingly in this work, we investigated this behavior and characterized the impact of different morphologies on the uniaxial tensile properties as well as the deformation of PS domains within the rubbery matrix. Various phase-separated morphologies have been obtained by solution casting bulk films of different thicknesses using four different solvents. The extent to which PS domains order and orient have been varied from 70 - 92 nm in grain sizes and parallel to vertical orientations. The domain periodicities also range from 22 nm to 26 nm. This has been correlated to the interactions of polymers and solvents and the solvent volatilities. Further, the elastic modulus decreased for laterally oriented domains compared to vertical ones and their tensile strength also reduced. Deformation resulting in anisotropic Small Angle X-ray Scattering (SAXS) has been evaluated along equatorial and meridional axes for strains until 500%. The degree of deformation (inter-domain spacing, domain distortion) swifts linearly for small strains (less than 50%) as the polystyrene domains deform in a non-affine manner throughout the extension. The study of such property dependencies play an important role in designing materials needed to withstand the requirements of specific applications.

11:45 AM SF02.21.05
Recent Progress in the Potential of Ionic Liquids as High Temperature Electrolytes for Energy Storage Systems Kallidanthiyil Chellappan Lethesh, Ahmed Bahaa, Musbaudeen O. Bamgbopa and Rahmat Agung Susantyoko; Dubai Electricity & Water Authority, United Arab Emirates

Ionic liquids are low-temperature molten salts with unique properties such as low volatility, extensive liquid range, high thermal stability, and high solubility of organic, inorganic, and polymeric materials. Ionic liquids find applications both in industry and academia because of the flexibility to tune their properties according to the requirements. Ionic liquids are promising electrolytes for energy storage systems because they can address the safety concerns associated with using organic electrolytes. Because of the growing interest in ionic liquids-based electrolytes, many ionic liquids are available on the market. The electrochemical properties of ionic liquids are susceptible to their purity, and there is no systematic study on the electrochemical properties of commercially available ionic liquids.

In this MRS submission, we are going to present the recent progress of research and development of ionic liquids as high temperature electrolytes for energy storage. The progress will be based on the literature from other's works as well as from our research group's works. We have published an important milestone where the electrochemical stability of 22 commercially available and commonly used ionic liquids were studied using cyclic voltammetry in the temperature range 288.15 K to 358.15 K. Ionic liquids based on imidazolium, pyrrolidinium, piperidinium, and tetraalkylammonium cations combined with bis(fluorosulfonyl) imide and bis(trifluoromethanesulfonyl) imide were selected because of their hydrophobic nature. The temperature sensitivity of the anodic and cathodic potential limits was evaluated by combining the cyclic voltammetry experiments and a linear regression model. The ionic liquids under investigation displayed an electrochemical stability window of 4.1 V to 6.1 V. This study revealed that temperature had a mixed effect on the electrochemical stability of the ionic liquids. Despite the structural similarity of anions used in the study, bis(trifluoromethanesulfonyl) imide anion-based ionic liquids showed better electrochemical stability than the bis(fluorosulfonyl) imide anion analog due to the presence of more fluorine atoms. The increase in the alkyl chain length on the cation increased the electrochemical stability of the ionic liquids due to their ability to transfer electrons to the hetero atom on the cation. It was speculated that the presence of ether functionality could increase the electrochemical window of the ionic liquids because of the interaction between the oxygen atom on the ether group and the positively charged nitrogen atom on the cation. On the contrary, introducing the ether group to the cationic core reduced the electrochemical stability window. The inability of the ether functionality to donate electrons to the positively charged nitrogen atom and decrease in the electron density on the positively charged hetero atom due to its interaction with the ether group was responsible for the lower electrochemical stability of ether-containing ionic liquids. A similar effect was observed with the functionalization of the cation with aromatic groups. Pyrrolidinium and piperidinium-based ionic liquids showed higher electrochemical stability windows among the different cations studied. This might be because of the difference in their electrochemical degradation mechanism compared to imidazolium and tetraalkylammonium cations.

Measurement of Powder Thermal Diffusivity by Laser Flash Method Ummay Habiba and Rainer Hebert; University of Connecticut, United States

In laser powder bed fusion (LPBF) additive manufacturing, the thermal diffusivity of the powder bed is a very important factor. The thermal characteristics of the powder bed have a significant impact on the mechanical characteristics of the products created by LPBF. This work uses a laser flash three-layered analysis in the DLF1600 instrument, which has a special powder cell to enclose the powdered sample, to assess the thermal diffusivity of metallic powder, nickel-based super alloy Inconel718 (IN718). Measurements were performed at different temperatures. Test data were also analyzed in the R software for further verification.

New Findings on Cu-Ag Wire for the Pulsed High Field Magnet Koichi Kindo[1], Kazuki Matsui[1], Yoshikazu Sakai[1] and Akihiro Kikuchi[2]; [1]Univ of Tokyo, Japan; [2]National Institute for Materials Science, Japan

Non-destructive pulsed magnet is the most important tool for a precise measurement under very high magnetic field. Generating high magnetic field, however, has been hard task because the magnet is destroyed due to considerable Maxwell stress. The stress reaches about 2 GPa in the field of 70 Tesla(T). The simplest solution for generating high field non-destructively is making a coil by use of the wire having higher strength. The Cu-Ag wire has been one of the best candidate for the coil-wire because the wire has the tensile strength of about 1.1 GPa and the conductivity of about 80% of pure copper. By using the wire, we succeeded in generating a field of 85.8 T in 2011 by mono coil system. The coil-wire of the same bobbin generated the 85 T-class field many times, but the wire of another bobbin could not reach to the same class field. The best wire could not be reproduced although we continued to produce wires with similar physical properties. There were many wires having the same strength and conductivity as to the best wire but nothing could generate the field exceeding 80 T. This would be a mystery because the maximum field mainly depends on the tensile strength of the wire. Our efforts to reproduce the best wire were in vain. 10 years have passed since it became mystery.
To solve the mystery, we firstly classified the wires into good ones and bad ones. This classification indicated clearly that the quality of the wire depends on the manufacturing process, especially drawing one. In November 2021, we tested a wire regarded as an ideal combination of manufacturing process. The result was satisfactory. We succeeded in generating a magnetic field of 85.97 T completely non-destructively, breaking the previous record in 2011. The mystery of Cu-Ag wire was solved. The key for solving the mystery lays in the manufacturing process, especially drawing one. Based on these results, we are producing wires that have undergone the ideal manufacturing process to generate the 85 T-class magnetic fields stably. After reproducing the best wire, we have succeeded in making the 85 T-class fields repeatedely. Our progress in the wire production will be presented.

8:30 AM SF02.22.02
Effect of Heat Treatment on Laser-PBF Ti-6Al-4V Microstructure Sayaka Maruta; Mitsubishi Heavy Industries, Ltd., Japan

Ti-6Al-4V is widely used in the aerospace industry because of its high specific strength, excellent heat resistance and corrosion resistance. On the other hand, the manufacturing cost is higher than other alloys due to its high cutting and material cost. AM (Additive Manufacturing), which can provide them with enhanced functionality through high flexibility of design and improvement of material yield by near-net shape, is expected to be a solution to the above problem. In particular, the Laser-PBF (Powder Bed Fusion) method enables high-precision building of complex shapes, so this method is being applied to products.

However, since process of AM is a new technology, there are many unclear points regarding the relationship between manufacturing conditions, quality, and mechanical properties, and it is important to clarify the fundamental phenomena in order to obtain stable material properties. The purpose of this study is to control the material properties by optimizing the microstructure. The effect of different process parameters (power, scan speed, hatch spacing, layer thickness) and heat treatment conditions on the microstructure was evaluated experimentally. The test specimens were built by L-PBF method under several conditions of process parameters. After observing the as-built microstructure, heat treatment was carried out under several conditions (with reference to the β transformation temperature). Microstructures after building and heat treatment were compared to evaluate the effect of different building conditions on the microstructure after heat treatment. Also, the heat treatment condition in which the improvement in the fatigue property was expected from the microstructure after the heat treatment was shown.

As a result of the above tests, it was suggested that the influence of process parameters on the as-built microstructure was small compared with the change of heat treatment conditions, but the as-built microstructure may have a slight influence on the microstructure after heat treatment. In addition, it was clarified that the selection of the heat treatment condition at the temperature in which the α colony formation by the coarsening of the α lath did not occur was an effective means for the fatigue property improvement.

Defect Evolution Evolution Under High-Velocity Impact in the Metal Cold Spray Process Damodara Reddy, Zhi-Qian Zhang and Sridhar Narayanaswamy; IHPC, Singapore

In this talk, we present defect-mediated microstructural evolution for high-velocity impact, as is applicable for the metal Cold Spray process. With molecular dynamics simulations, we simulate the complex bonding mechanisms under extreme conditions of large localized plastic deformation, localized melting, and extremely high strain rate. We show that for copper/copper system, impact induced local melting leads to adhesive bonding at the interface. More importantly, we probed the bonding over a range of impact velocities and find the grain boundary-like amorphous phase interlocking and metallurgical bonding are dominant at low and medium impact velocities, while metallurgical bonding and mechanical interlocking are dominant at high impact velocities.
We also present an experimentally validated computational model for microstructural evolution with the characteristics determined using a dislocation density-based model implemented in a Eulerian finite element framework. A comparison of the numerical and experimental results from Scanning Electron Microscope (SEM), Electron Backscatter Diffraction (EBSD) and Kernel Average Mis-orientation (KAM) analyses, reveal the evolution of cell size and mis-orientation resulting in grain refinement at the particle–substrate and particle–particle interfaces. Although there is a large plastic deformation due to high speed impact, the dislocation density in the particle decreases with distance from the impacting interface and this feature is observed in both the simulation results and the experimental characterization data. The validated model can be effectively leveraged to predict microstructural evolution under different process conditions including spray angle, pre-heat temperature, and impact velocity.

10:45 AM SF02.23.03
Multi-Scale Piezo-Elasticity of sI Methane Gas Hydrates—From Bonds to Cages to Lattices Xiaodan Zhu, Alejandro Rey and Phillip Servio; McGill University, Canada

Research and exploration of new green energy have become critical to addressing the current focus on energy sustainability and scarcity. Gas hydrates, found in deep ocean or permafrost areas under high pressures and low temperatures, are a competitive alternative. This is because it has approximately twice the amount of energy stored in fossil fuels and oils and provides a significant storage capacity due to its unique guest-host structure. Because of hydrates' high energy content and excellent storage capacity, they are a strong candidate for supplying energy while mitigating the effects of global warming. However, these extreme environmental factors create a solid barrier to studying the properties of hydrates in the laboratory and for commercial explorations. As a result, We use multi-scale theory-modelling simulation to explore the piezo-effect of sI methane gas hydrates and investigate the stability limits at 0 Kelvin.
This work uses density functional theory (DFT) in conjunction with homogenization methods and the theory of mixtures to investigate the structure, thermodynamics, and elasticity of sI methane hydrates subjected to pressure loads at three scales, atoms, cages, and lattice at 0 Kelvin. In the hydrate system, the distribution functions of bond parameters are characterized, providing a novel understanding of the spread of values at the smallest scale. The roles of various cages at the mesoscale, such as continuous phase and disperse inclusion, have been identified. Different deformation mechanisms (affine and non-affine) are observed at the continuum scale, corresponding to different fracture mechanisms (brittle and ductile) under tensile and compressive pressures.
Taken together, the systematic atomic-cage-lattice multi-scale characterization proves fruitful in linking processes that connect mechanical properties, cage geometry, and hydrogen bonding. The multi-scale methodology can be generalized to other gas hydrates or water-based systems to improve the fundamental understanding and obtain engineering correlations.

11:00 AM SF02.23.04
Magnetotransport Measurements for Infinite-Layer Nickelate Superconductors—Rare Earth Dependence Lin Er Chow[1], King yau Yip[2], Mathieu Pierre[3], Shengwei Zeng[1], Zhaoting Zhang[1], Tobias Heil[4], Julia Deuschle[4], Proloy Nandi[1], Sujith Kunniniyil Sudheesh[1], Zhi Shiuh Lim[1], Zhaoyang Luo[1], Marc Nardone[3], A. Zitouni[3], Peter A. Van Aken[4], Michel Goiran[3], Swee Kuan Goh[2], Walter Escoffier[3] and Ariando Ariando[1]; [1]National University of Singapore, Singapore; [2]The Chinese University of Hong Kong, Hong Kong; [3]Université de Toulouse, France; [4]Max Planck Institute for Solid State Research, Germany

Standing beside copper in the periodic table, Ni^{1+} state in infinite-layer phase hosts $3d^9$ electronic structure with lifted orbital degeneracy that resembles Cu^{2+} state in the high-T_c cuprate superconductors [1,2]. Realizing and studying superconductivity in nickelate has been one of the most strategic paths to a closer step toward the secret makeup of high-temperature superconductivity. Despite more than two decades of theoretical predictions, superconducting infinite-layer nickelate was only successfully synthesized in 2019 in the thin-film form [3]. Obstructed by challenging material synthesis and various structural defects, many critical parameters such as the upper critical fields and superconducting anisotropies for this newfound quasi-two-dimensional layered superconductor remain poorly understood. In continuation of our efforts in optimizing the stabilization of the superconducting infinite-layer phase, we successfully fabricate high crystallinity samples with virtually a monocrystalline infinite-layer phase with thickness > 10 nm, more than twice the previously achieved thickness. We perform a series of magnetotransport measurements using magnetic fields up to 55 T at a temperature down to 30 mK.

In contrast to the expected trend from cuprates, we observed a strong dependence of the upper critical fields on the rare earth ion [4]. The intrinsic angular dependence of the superconducting observables will also be discussed.

11:15 AM SF02.23.05
Dimensionally and Environmentally Ultra-Stable Polymer Composites Reinforced with Carbon Fibres for Extreme Conditions Michal Delkowski[1,2], Christopher T. Smith[1], Jose Anguita[1] and S. Ravi P. Silva[1]; [1]University of Surrey, Advanced Technology Institute, United Kingdom; [2]Airbus Defence and Space, Germany

Highly stable composite and polymeric materials are essential in advanced applications. For many space missions, carbon-fibre reinforced polymers (CFRPs), which feature high strength to weight ratio are important, easing mass budget requirements for heavier payloads. Satellites use CFRP for various components including support structures, optical benches, telescope tubes and parabolic reflectors. However, it is important that these materials withstand the harsh space environment such as thermal cycling in vacuum (from cryogenic to hot), UV radiation and mechanical loads, while simultaneously maintaining their structural integrity and material dimensionality.

While today's ultra-high performance composites are able to exhibit a near-zero (even negative) coefficient of thermal expansion, the dimensional instabilities that result from moisture ingression and release, remain the fundamental vulnerability of composite materials. This restricts many applications particularly for spacecraft constructions. Here we address this challenge by developing a space-qualifiable physical superlattice nano-barrier structure, which is deposited via a custom-built deposition system and without vacuum interruption. The structure blends within the mechanical properties of the composite, thus becoming part of the composite itself. The resulting enhanced composite features mechanical integrity and a strength that is superior to the underlying composite, while remaining impervious to distortions caused by moisture, outgassing and other environmental effects. We demonstrate production capability for a model-sized component for the Sentinel-5 mission and demonstrate such capability for future European Space Agency (ESA) and National Aeronautics and Space Administration (NASA) programmes such as Copernicus Extension, Earth Explorer and Science Cosmic Visions.

Oxidation Resistance of Atomically Flat Cu(111) Surface—A First Principles Study Bipin Lamichhane and Seong-Gon Kim; Mississippi State University, United States

Copper is one of the important materials used in modern technology and industries, but oxidation of copper deteriorates its application in nanotechnology. Our recent first principles total-energy calculations based on density functional theory is used to investigate the oxidation resistance of atomically flat Cu(111) surface. The exchange-correlation energy is described by the generalized gradient approximation (GGA) of Perdew–Burke–Ernzerhof (PBE) and projected augmented wave (PAW) method is employed. Our results show that atomically flat Cu(111) without multi-atomic steps is oxidation resistant. The energy barrier for oxygen penetrating flat surface and mono-atomic step is very high in comparison to multi-atomic steps. Also, incremental oxygen adsorption energy for the fcc site of the flat surface becomes positive and oxygen resistant above the oxygen coverage of 50%. These calculated results are consistent with the recent experimental finding.

11:45 AM SF02.23.07
Surfboards Under Extreme Conditions—Why Do They Fail? Brett Connellan and Marc In het Panhuis; University of Wollongong, Australia

Surfing waves with boards either for sport, culture or religious purposes was first practiced by the Polynesians. Surfing with surfboards consisting of balsa wood started to spread from Hawaii to mainland USA and Austral. Modern surfboards with a foam core were introduced at the end of the 1950's.

It is convenient to think of surfboards as composite materials, for example, a PU surfboard consists of a foam-wood core encased in fibre glass and sealed with resin. In addition, surfboards are also fitted out with up to five fin boxes and a leash plug. The former is used to fit surfboards fins, while the latter is used to connect the surfer to the board using a so-called leash.

The mechanical characteristics of surfboards most valued by surfers is mechanical stiffness and is generally referred to as flex. During characteristic surfing manoeuvres (bottom turns) a surfboard will bend either due to the shape of wave or the force exerted on the board by the surfer or a combination of both effects.

Surfers routinely put their surfboards under extreme wave conditions which results in mechanical failure of surfboards (generally referred to as "snapping").

In this presentation we discuss the mechanical characteristics of surfboards in terms of damping, flex, recovery and modal analysis. We present a detailed analysis of the mechnical recovery behaviour and mechanical failure mechanisms of surfboards under extreme wave conditions.

Abstract: Reactive multilayer systems signify as an energetic materials potentially for extremely short thermal treatment compared to standard reactive techniques. As there are several factors leading the reaction front velocity, released energy, microstructural and morphological changes are of great interest. In the current investigation, alternative Al and Ni layers depositated by magnetron sputtering techniquie where Al is starting layer with a 1:1 atomic ratio of Al and Ni onto different substrate. In order to elucidate the influence of different enviormental condition, a two-dimensional numerical model was developed to study convective heat loss and thermal properties on the self-propagating reaction in Al/Ni multilayer foils. Reaction heat of the fabricated foils were determined by Differential Scanning Calorimetry (DSC). Self-propagating reaction was introduced on the surface of the foils by an electrical spark. The reaction front velocity was noted with a high speed camera. Activation energy is set with these velocity data to modify the numerical model. Temperature of reaction front of the self-propagating reaction was calculated and compared with the obtained temperature by time-resolved pyrometer measurements. X-ray diffraction investigation of reacted multilayers confirmed that all reactants reacted and formed AlNi phase as a finale phase. Finally, it is predicted that (1) increasing thermal conductivity of the suroundings can increases the transfer of the reaction front; (2) effect of heat convection losses on reaction properties are insignificant, e.g., the foils can maintain their properties in liquid environment.

Keywords: reactive multilayers; self-sustained reaction; nickel; aluminum; propagation velocity; phase transformation; magnetron sputtering

SESSION SF03.01: Plasma-Surface Interaction
Session Chairs: Wei-Hung Chiang and Chi-Chin Wu
Tuesday Morning, November 29, 2022
Sheraton, 3rd Floor, Hampton

10:15 AM SF03.01.02
Atomic Layer Control of MoS_2 by RIE with Mixed ($Ar+O_2+CF_4$) Plasma and Its Etching Mechanism with Numerical Analysis Changmin Kim[1], Muyoung Kim[2], Donghyun Cho[2], In-Young Park[2], Sungkwon Jo[2], Daewoong Kim[2], Woo Seok Kang[2], Taesung Kim[1] and Hyeong-U Kim[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Institute of Machinery and Materials, Korea (the Republic of)

The two-dimensional transition metal dichalcogenides (2D TMDs) has been researched actively because their unique characteristic which is tunable band gap and uniform band edge through a number of layers can be used to make optoelectronics, photonics, sensing, and nanoelectronics. To control the number of layers of 2D material, the various method of plasma synthesis and etching technologies are being studied. Especially, the MoS_2 has high electron mobility and high current. Also, the band gap depends on the number of layers of MoS_2. The band gap is changed from bulk layers (1.2eV) to monolayer (1.8 eV) of MoS_2. Among the various method of plasma synthesis and etching, plasma-enhanced chemical vapor deposition (PECVD) and reactive ion etching (RIE) is one of the effective techniques for synthesis and control of the layer of 2D material. The PECVD is the instrument in which thin films of

various materials can be synthesized on the substrates at low temperatures than chemical vapor deposition (CVD). The low deposition temperature, high purity of material, good step coverage, and easy control of reaction parameters are the advantage of PECVD. The RIE is one of the popular etching methods. The etching rate and selectivity are higher than normal physical and chemical etching. Especially, RIE is the anisotropic etching which is a technique of microfabrication. The advantage of anisotropic etching is possible to fabricate a fine pattern. In this study, we tried to find an optimized condition for controlling the layer-by-layer of MoS_2 by using the PECVD and RIE systems.
The density functional theory (DFT) which is a computational quantum mechanical modeling method is used to determine the suitable reactive gas for plasma etching of MoS_2. First the post-analysis, the MoS_2 was measured to confirm the number of layers of MoS_2 by Raman spectroscopy. In addition, the chemical structure of MoS_2 was confirmed by X-ray photoelectron spectroscopy (XPS). Also, the layers of mos2 are directly confirmed by Transmission electron microscope (TEM) and atomic force microscope (AFM). Second in-situ analysis, the Optical emission spectroscopy (OES) was conducted to check the element of gas that is affected to plasma status during the process of plasma etching. The numerical simulation was used to figure out the plasma etching mechanism of MoS_2. The effect of each element of MoS_2 and reactive gases are analyzed by the numerical simulation.

10:30 AM SF03.01.03
Plasma-Enhanced Spatial ALD of SiO_2 Investigated by Gas-Phase Infrared and Optical Emission Spectroscopy Maria Mione[1], Vincent Vandalon[1], Alfredo Mameli[2], Fred Roozeboom[1,2] and Erwin Kessels[1]; [1]Eindhoven Univ of Technology, Netherlands; [2]TNO/Holst, Netherlands

Atomic layer deposition (ALD) has become a true enabling nanotechnology with many applications in the semiconductor industry. Often the process is plasma-enhanced (i.e., plasma-enhanced ALD) as this allows for the deposition of more materials (such as SiO_2) and also at lower substrate temperatures. In this presentation a spatial ALD process for SiO_2 will be reported which enables a higher productivity. Nanoscale SiO_2 films have many applications in self-aligned patterning, trench filling, encapsulation and passivation etc. in both nanoscale semiconductor devices but also in large-area electronics, displays, and photovoltaics.

The spatial ALD process was developed in a rotary spatial ALD reactor using bisdiethylaminosilane (BDEAS, $SiH_2[N(C_2H_5)_2]_2$) and an atmospheric O_2 plasma [1]. Within the substrate temperature range of 100-250 °C, the process demonstrates self-limiting growth with a growth-per-cycle between 0.12 and 0.14 nm and SiO_2 films exhibiting material properties *on par* with those reported for low-pressure plasma-enhanced ALD [2].

Gas-phase infrared spectroscopy on the reactant exhaust gases and optical emission spectroscopy on the plasma region are used to identify the species that are generated in the ALD process. Based on the identified species and a calibration procedure, we propose a reaction mechanism where BDEAS molecules adsorb on –OH surface sites through the exchange of one of the amine-ligands upon desorption of diethylamine (DEA, $HN(C_2H_5)_2$). The remaining amine ligand is removed through combustion reactions activated by the O_2 plasma species leading to the release of H_2O, CO_2, CO in addition to products such as N_2O, NO_2, and CH-containing species. These volatile species can undergo further gas-phase reactions in the plasma as indicated by the observation of OH*, CN* and NH* excited fragments in emission. Furthermore, the infrared analysis of the precursor exhaust gas indicated the release of CO_2 during precursor adsorption. Moreover, this analysis has allowed the quantification of the precursor depletion yielding values between 10 % and 50 % depending on the processing parameters. On the basis of these results, the overall surface chemistry of the spatial ALD process of SiO_2 will be discussed.

Controlling Surface Oxidation States for Precise Nanoscale Patterning of Etch-Resistant Materials Taylor Smith[1], Ethan Crumlin[2,2] and Jane P. Chang[1]; [1]University of California, Los Angeles, United States; [2]Lawrence Berkeley National Laboratory, United States

Copper is the primary material used for the interconnects of an integrated circuit (IC). The dual damascene process was initially developed to deposit and pattern copper due to the difficulties of using traditional dry etching techniques, but the dual damascene process is reaching its practical limits. Atomic layer etching (ALE) is emerging as a process that could help replace the dual damascene process. In this work, we examine an ALE process that uses directional ions from reactive plasmas (oxygen or nitrogen) coupled with formic acid vapor exposure to precisely etch copper films. During the modification step, oxidation or nitridation changes the oxidation state of copper, thereby changing the free electron characteristics of metallic copper into localized chemical bonds that facilitate the subsequent reaction with the organic vapor. Plasma oxidation or nitridation of copper has been accomplished using an ICP plasma source, and the resulting copper oxide and nitride film has been characterized by X-ray photoelectron spectroscopy (XPS) to quantify the composition. Angle-resolved XPS (AR-XPS) is used to determine a depth profile of the oxidized and nitridized copper surface. The FA vapor exposure is carried out using a custom-built reactor, with scanning electron microscopy (SEM) used to determine total thickness removal and XPS used to confirm the chemical removal of copper nitride. In addition, amAmbient pressure X-ray photoelectron spectroscopy (AP-XPS) was used to examine the FA vapor exposure step in particular detail. These in operando measurements aided in proposing the surface reaction mechanism of the modified copper surface during the vapor phase removal.

11:00 AM SF03.01.05
Plasma Synthesis of High Entropy Boride via Thermal Reduction of Metal Oxides Bria C. Storr[1], Carolina Amezaga[2] and Shane A. Catledge[1]; [1]University of Alabama at Birmingham, United States; [2]Auburn University, United States

Metal oxide thermal reduction enabled by microwave-induced plasma was used to synthesize high entropy borides. This approach capitalized on the ability of microwaves to efficiently transfer thermal energy to enhance reactions in the presence of low-temperature plasma. The precursors, metal oxides and reducing agents, were blended by a high-energy ball mill and annealed via microwave plasma. A single-phase hexagonal AlB_2-type structure characteristic of high-entropy borides was produced by utilizing either boro/carbothermal reduction or borothermal reduction. The microstructural and mechanical properties were compared using the different thermal reduction approaches with and without carbon as a reducing agent. The plasma annealed HEB with configuration $(Hf_{0.2}, Zr_{0.2}, Ti_{0.2}, Ta_{0.2}, Mo_{0.2})B_2$ yielded a higher measured hardness from boro/carbothermal reduction compared to that from borothermal reduction (38 ± 4 GPa vs. 28 ± 3 GPa, respectively). To further examine the effect of the plasma on the homogeneity of HEB transformation, several sample cross-sections of the annealed HEB pellets were analyzed. The cross-section of the sample that is most exposed to the plasma is less porous than the least exposed portion of the sample.

Vertically Extended Channel Thin-Film Transistors Using Dry Etched Tungsten Gate for Ultra-High-Resolution Display Sein Lee, Se-Yeon Jung, Jeong-Min Park and Jang-Yeon Kwon; Yonsei University, Korea (the Republic of)

The significance of backplane devices for ultra-high-resolution (UHR) displays has increased with the recent development of augmented reality (AR) and virtual reality (VR) devices. Since the human visual resolution can distinguish up to 60 pixels per degree (PPD), the AR/VR device panel needs at least

3000 pixels per inch (PPI) to exceed the human retina resolution limit for a clear display without screen effect. As a result, the unit pixel pitch of thin film transistor (TFT) for UHR display should not be only smaller than a few micrometers (~3 μm), but TFT channel length should also be sub-micrometers level. In active-matrix organic light emitting diode (AMOLED) display type, self-aligned top gate (SATG) TFT has been widely used as a planar backplane device structure because of its low parasitic capacitance and tolerance of illumination degradation caused by the light from emitting layer [1-2]. However, SATG TFT has fundamental disadvantages for device miniaturization due to its essentially required area of metallization region for reducing contact resistance and scaling limit of channel induced by carrier diffusion shrinking effective channel length. For this reason, we suggested a size-tunable oxide channel VTFT structure that can achieve a high pixel density on account of structural benefit on device footprint.
In this work, we fabricated scalable amorphous indium gallium zinc oxide (a-IGZO) based VTFT with a dry etched gate layer. In the previously published VTFT structure, the channel length is determined by the thickness of the spacer between the source and drain electrodes [3]. Owing to the spacer etching process, uneven backchannel roughness and high off current have become well-known issues of VTFT. On the contrary, the proposed vertically extended channel (VEC) TFT structure has controllability of an effective channel aspect ratio because the source and drain electrodes could be patterned by a photolithography process. Also, VEC TFT has a small device footprint (4.5 F^2), so it is suitable for high-density applications. Furthermore, since the sidewall profile of the dry-etched tungsten gate was optimized by several etchants such as fluorine-based and chlorine-based gases, the electrical performance of the vertical channel could be improved by the anisotropically etched gate metal.
To sum up, we not only realized the oxide channel VTFT that meets high performance for AR/VR display, but opened new application possibilities to UHR electronic devices platform.

SESSION SF03.02: Plasmas for Energy Related Nanostructures
Session Chairs: Jane Chang and Wei-Hung Chiang
Tuesday Afternoon, November 29, 2022
Sheraton, 3rd Floor, Hampton

1:30 PM *SF03.02.01
Design of Composite Nanoparticles by Plasma Spraying for Solid-State Lithium-Ion Batteries with High Densities and High Cyclabilities Makoto Kambara[1,2], Ryoshi Ohta[1,2], Takeo Hiraoka[2], Toshimi Tanaka[3] and Masashi Dougakiuchi[4]; [1]Osaka University, Japan; [2]The University of Tokyo, Japan; [3]Takeuchi Electic Co, Japan; [4]Shimane Institute for Industrial Technology, Japan

Silicon is the strongest candidate for the anode of high density lithium ion batteries (LiB) owing to its high theoretical capacities and have been extensively investigated from the “nanostructure” material design perspectives to cope with fracturing during long recharging cycles and to attain both high capacity and high cycle stability. Such nanomaterials are also expected to be the potential anode of the next generation all solid state LiB with the so-called “bulk cell” structure which carries higher unit capacities. In particular, since unstable formation of solid electrolyte interphase (SEI) that is a detrimental issue for long life operation of the cell with the liquid electrolyte could be no longer the problem for solid state LiB, electrode design to maximize the capacity and cycle stability maintaining high ionic conductivities becomes the major target of the recent research. Even so, the ideal structure of silicon active materials for solid state LiB is not yet identified. Furthermore, to respond to the demands from ever-growing EV markets, the affordable processing of such structured nanomaterials at large quantity has become the practical and essential issues. With these issues in mind, we have successfully produced silicon nanoparticles from low-cost powder feedstock by plasma spraying at throughputs as high as 1.5 kg/h. Furthermore, with particular attention to oxidation of nanoparticles during collection from the reaction reactors, the size and the oxygen content of these nanoparticles are independently controlled. As a result, the important effect of the size and the oxygen content of nanoparticles on the battery properties of the all solid state LiB are separately identified. These characteristics of the nanoparticle structures on the battery performance and the possible ideal nanocomposite particle design will be discussed during presentation.

2:00 PM SF03.02.02
Carbon Nano Onions by Plasma Enhanced Nanoparticle Jet Deposition—Synthesis and Application as High Current Density Electrodes for Redox Flow Batteries Fabio Di Fonzo[1], Simone Fiorini Granieri[1,2], Gerardo M. Pagano[1,2] and Matteo Zago[2]; [1]Italian Institute of Technology, Italy; [2]Politecnico di Milano, Italy

Carbon Nano-Onions (CNO) are carbon nanoparticles with an inner structure constituted of curved graphene sheets, arranged in a concentric arrangement resembling an onion. CNO has shown remarkable characteristics in many fields and electrochemistry in particular. Despite this, CNOs are still produced mainly by annealing at temperature higher than 1500°C nanodiamonds in high vacuum condition [Kuznetsov, V.L. et al. Carbon 32, (1994)].
In this work we describe a new production method for CNOs, called plasma enhanced nanoparticle jet deposition, NanoJeD, which allows high throughput and tunability of both CNO structure and of their self-assembly in mesostructures useful for electrochemical energy storage.
The NanoJeD system was invented [US2013017342] about 10 years ago and it has been used so far for the deposition of functional mesoporous films of TiO2 [I. Biganzoli, J. Modern Phys., 2012], Si [G. Nava et al., J. Mater. Chem. C., 2017] and SiOx [Nava et al., Nanotechnology, 2018]. Simply speaking, the NanoJeD source is a two-stage nanoparticle source comprising a high-pressure reaction chamber and a low-pressure deposition chamber, separated by a rectangular slit nozzle. The pressure ratio between the two chambers is kept above 3 so to ensure a supersonic expansion across the slit. In the high pressure chamber the process gas, an Ar-C2H2 mixture, is injected perpendicularly to a capacitively coupled, radiofrequency (RF) low pressure plasma operating in dusty mode. Acetylene decomposes within the plasma region and hydrogenated carbon clusters nucleate and grow. The size of the H:C clusters can be controlled by varying the residence time within the plasma region and C2H2 partial pressure. The clusters are quenched, focused and accelerated in the supersonic expansion across the slit. The size distribution follows the typical lognormal distribution of a plasma induced chemical reaction, even if the distribution of sizes is quite narrow around 20 nm. The inertial deposition onto the substrate is defined by the Stokes number of each nanoparticle. Moreover, the pressure ratio among the two chambers defines the impaction kinetic energy of the clusters upon a substrate placed perpendicularly to the slit nozzle. As previously reported with other materials, high pressure ratios lead to dense mesoporous films, whilst low pressure ratios establish the growth of arrays of hierarchical nanostructures [Nava et al., Nanotechnology, 2018]. The resulting functional thin film is then thermally treated in vacuum in order to optimize the graphitization degree and defect density. The geometrical constrain of the NP, allow only the formation of curved graphitic planes, in a so

called turbostratic CNO structure. For 800 °C<T<1100 °C this process grants a high level defectiveness on the graphitic planes, while preserving high electronic conductivity and specific surface areas in excess of 400 square meter per gram. The above-described process has been characterized by RAMAN, TGA, FTIR, in situ TEM, BET, XPS.
We demonstrate the use of optimized CNO functionalized gas diffusion electrodes for redox flow batteries (RFB). In particular, the mesostructured CNO electrode showed remarkable performances in vanadium RFB applications. The forementioned film, deposited over a carbon paper, has been thoroughly characterized by cyclic voltammetry, symmetric cell and finally in full cell. From charge/discharge curves of full cell test, the system efficiencies have been calculated and a nominal current density as high as 600mA/cm2 with 70.8% energy efficiency was obtained, with a stability over 1000 cycles. This result is the best performance reported in the literature for an electrode of pure C and demonstrate the high potential impact of the plasma based NanoJeD technology in the field of energy storage.

2:15 PM SF03.02.04
Low-Pressure Plasma Induced A-Site Exsolution of Ag Nanoparticles from Perovskite Oxide Platform Hessan Khalid, Attaul Haq, Paul Maguire and Davide Mariotti; Ulster University, United Kingdom

Nowadays research on the synthesis and application of nanostructured perovskite oxide has drawn great attention. Among them, exsolution of nanoparticles (NPs) from oxide platform is considered as an effective method for various energy conversion/storage, and catalytic applications. Exsolution offers great controllability on the NPs size and distribution along with displaying good anchorage with the oxide support. Conventional exsolution routes often require extreme processing conditions i.e., elevated temperature and lengthy processing times. Recently, our group has demonstrated a new pathway to exsolution of Ni NPs, within minutes rather than hours, from perovskites ($La_{0.43}Ca_{0.37}Ti_{0.94}Ni_{0.06}O_{2.955}$) using plasmas operating at room temperature.[1] Herein, we have demonstrated the exsolution of silver (Ag) NPs from perovskite oxide scaffold through low pressure plasma. Perovskite oxide (POx) having a composition of $La_{(1-x)}Ag_xFeO_3$ (LAFO) with varying Ag doping (0.01 - 0.05 %) was synthesized to understand the maximum solubility of Ag in the perovskite matrix. LAFO was then treated in low-pressure plasma for 15 min resulting in the exsolution of Ag NPs from LAFO matrix at room temperature. The average size of Ag NPs lies within the range of 10-20 nm with a uniform exsolution over the entire exposed surface. The nature of exsolved NPs were found to be metallic as supported by XPS analysis. The strong socketing nature of such NPs were observed in high-resolution TEM. Plasma exsolution of Ag will open new dimension of research in the field of exsolution and provides future solutions in electrocatalysis and in many plasmonic based applications.

3:15 PM *SF03.03.01
Plasma Synthesis of Nanostructure-Supported Metal Nanoparticles for Energy Storage and Conversion: PLA-PECVD Approach and Outlook for Enhanced Sustainability Sylvain Coulombe; McGill University, Canada

The plasma medium enables the direct coupling of renewable (possibly intermittent) electricity sources with chemical reactors providing processing conditions not achievable with traditional approaches. The full gamut of gas phase chemistry, from nonequilibrium to equilibrium is achievable through an almost unlimited number of combinations of reactor and power supply designs, volume and surface interactions, reactants and energy delivery schemes, and materials combinations. Multiphase and multi-stage reactors add even more options. In the context of the energy transition, processing plasmas play multiple roles, from the direct conversion and synthesis of gases (e.g., CO_2 methanation, CH_4 pyrolysis, NH_3 synthesis from and cracking to H_2) and liquids to the synthesis of advanced materials acting as catalysts, selective (ab)adsorbers, energy storage and transport vectors, to name a few applications. Of particular interest is the synthesis and functionalization of nanomaterials and nanostructures with optimal performances and minimal uses of resources. We developed a dual-plasma source approach for the synthesis, deposition and functionalization of fine nanoparticles (NPs) onto nanostructured substrates with minimal use of resources. Pulsed laser ablation (PLA) of a metal target under an inert low-pressure environment leads to the formation of fine (3-5 nm) nanoparticles from the metal vapor plasma plume expansion and supersaturation. Surface charging by the plasma electrons ensures electrostatic repulsion of the as-produced nanoparticles and uniform dispersion over the collecting substrate. The background pressure and ablation time are varied to adjust the granularity and open porosity of the coatings. An alternating system of two pure metal targets allows the synthesis, deposition and formation of triple-interface nanomaterials (Metal A + Metal B) NPs@substrate for optimal adsorption (immobilization) of dissimilar gaseous molecules and catalytic activity. Pre- or post-PLA radiofrequency (RF) plasma-enhanced chemical vapor deposition (PECVD) of the substrate enables surface activation, tuning of the adsorption properties and compatibility with host materials. Simultaneous PLA and RF plasma in reactive gas atmospheres enables the formation of compound nanoparticles (metal oxide, nitride) and thermodynamically unfavorable phases. Several examples of successful nanoparticle decoration (low NP loading) and granular coating formation (high NP loading) will be presented, including platinum nanoparticles on multiwalled carbon nanotubes (Pt NP@MWCNT) as electrocatalysts, ruthenium oxynitride on MWCNT (RuN NP@MWCNT) as supercapacitor electrodes, and cobalt-molybdenum and ruthenium-iron on boron nitride nanotubes as gas conversion catalysts (CoMo NP@BNNT and RuFe NP@BNNT). Preliminary results on the deposition of dual function materials for optimal gas adsorption and catalytic activity will be presented.
Though the PLA-PECVD approach enables the synthesis of nanostructures with extraordinary performances and with high energy and material efficiencies, the sustainability of the process and produced nanomaterials are questionable. Looking ahead, truly sustainable plasma-enabled technologies and materials will need to be circular. Material structure upgradability or at the very least, recyclability, needs to be added as a hard-coded process and material design constraint. Life cycle and circularity assessments shall become as important as the performance and economics in the decision-making processes. This requires a paradigm shift in our usual linear way of thinking which will undoubtedly lead to innovation in plasma processing and material selection and assembly.

3:45 PM SF03.03.02
Plasma-Bioresource-Derived Multifunctional Porous NGQD/AuNP Nanocomposites for Water Monitoring and Purification Darwin Kurniawan[1],

Michael Ryan Rahardja[1], Kostya (. Ostrikov[2] and Wei-Hung Chiang[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]Queensland University of Technology, Australia

Metal-organic composites with controlled structures and properties are actively pursued for diverse applications such as optoelectronics, sensing, imaging, drug delivery, cancer therapy, energy generation and storage, environmental monitoring and purification, and many others. Among those applications, stable 3D architectural multifunctional metal-organic composites with high efficacy in water treatment are highly desired for next-generation clean and sustainable technologies. Current synthesis methods of metal-organic composites face major problems including long preparation time, laborious step, toxic chemicals, harsh solvent, high temperature, uncontrolled structures and properties.

Here we report rapid and environment-friendly plasma engineering of lightweight and porous 3D NGQD/AuNP composites from chitosan using non-thermal microplasmas at ambient conditions without toxic chemicals and high temperature treatment. The highly reactive species generated by the plasma are used to simultaneously synthesize both NGQDs and AuNPs from chitosan containing gold salt. Moreover, synergistic effect of the NGQDs and AuNPs as the nanocross-linkers can accelerate the cross-linking of chitosan to form a 3D porous composite without the need of toxic chemicals and high-temperature treatment. The engineered composites exhibit multifunctional properties including stable solid-state PL emission, tunable surface functionalities, catalytic ability, high porosity, and mechanical robustness, having potential for water treatment including selective PL detection of Hg^{2+}, remarkable adsorption of remazol brilliant blue R (RBBR), and catalytic reduction of 4-nitrophenol (4-NP). Furthermore, our method can also yield colloidal NGQDs used for Cr(VI) detection in solution, ranging from 1 to 100 μM with a 61 nM limit of detection (LoD). Our work provides not only a general method to engineer organic-metal composites with defined structures and properties, but also a new insight into their rational design for emerging applications.

4:00 PM SF03.03.03
Oxygen Plasma Induced Heterostructure of 1T-WS_2/a-WO_3 with Hydrogen Spillover Effect as an Advanced HER Electrocatalyst Jinill Cho[1], Hyunho Seok[2] and Taesung Kim[1,2]; [1]SungKyunKwan University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

The usage of tungsten disulfide (WS_2) as a hydrogen evolution reaction (HER) electrocatalyst provides several ways to outperform its intrinsic catalytic activity. This study introduces a nanodomain tungsten oxide (WO_3) interface with 1T-WS_2 to improve HER performance by facilitating the transport of protons to the active site. H_2S plasma sulfurization on W layer fabricated 1T-WS_2, and subsequent O_2 plasma was treated to form amorphous WO_3 (a-WO_3), resulting in heterointerface of patchwork structure of 1T-WS_2/a-WO_3. The introduction of a-WO_3 in 1T-WS_2 promotes the hydrogen spillover effect, which indicates the transfer of absorbed protons from a-WO_3 to 1T-WS_2. As a result, 1T-WS_2/a-WO_3-1.2 (ratio of 1T-WS_2 to a-WO_3) exhibits remarkable HER performance in that 1T-WS_2 consumes more protons supplied from a-WO_3 with an overpotential of 212 mV at 10 mA/cm^2. From density functional theory calculation (DFT), it can be concluded that the WO_3 region shows a higher binding energy for intermediate hydrogen compared to 1T-WS_2. This means a-WO_3 with strong hydrogen affinity plays an important role in hydrogen spillover effect. This approach paves a new way to induce efficient proton transport for high catalytic activity and energy storage.

4:15 PM SF03.03.04
Decoupling Mass Transport and Catalytic Effects in the Plasma-Driven Reduction of CO_2 to CO on Heterogeneous Catalysts Formed by Atomic Layer Deposition Samuel K. Conlin, David Parette and Robert H. Coridan; University of Arkansas, United States

Plasma catalysis has been traditionally used for processes such as the removal of volatile organic compounds (VoC's) from industrial waste streams and the production of ozone. Recently, significant work has studied the use of heterogeneous plasma catalysis for CO_2 conversion. This process can be used to generate chemical fuels from CO_2, such as CO, CH_4 and alcohols. The role of the heterogeneous catalyst to CO_2 reduction in a plasma system is typically the convolution of a number of simultaneous effects. In considering the performance of a catalyst, the effects of surface catalysis, mass transport due to multiscale structure, and local electric field enhancements can each contribute to the overall chemical transformation. The complex nature of these reactors makes it difficult to determine the true reason for differences in performance. Atomic layer deposition (ALD) is a technique capable of depositing layers of catalyst materials with nearly atomic precision in the layer composition. By controlling the composition of nanometer-scale thin films of catalyst onto high surface area scaffolds, we decouple the effects of mass transport and catalysis while having atomically precise control over their composition. Here we intend to develop an experimental scheme for comparing the catalytic effects of plasma CO_2 reduction catalysts without the introduction of significant structural variability. We will describe recent work to use ALD-derived plasma CO_2 reduction catalysts onto high surface area scaffolds. We show how to decouple the mass transport and catalytic effects in these catalyst-scaffold systems using gas chromatography and optical emission spectroscopy. Finally, we compare this approach to more traditional synthesis and coating methods such as sol-gel and wet impregnation methods. As a result, we can unambiguously identify the role that heterogeneous catalysis in plasma-driven transformations of CO_2.

Plasma Catalysis—An Emerging Technology for Power-to-X Xin Tu; University of Liverpool, United Kingdom

The activation of small, inert molecules with strong chemical bonds (e.g., CO_2, CH_4, and N_2) for the production of higher-value fuels and chemicals has attracted significant interest. However, the activation of these molecules remains a great challenge as they are thermodynamically stable and require a significant amount of energy for activation. Non-thermal plasmas (NTPs) offer an emerging and attractive alternative for the activation of strong chemical bonds under ambient conditions. The combination of NTP with heterogeneous catalysis has great potential to generate a synergistic effect from the interactions between the plasma and catalysts, which can activate catalysts at low temperatures and improve the activity and stability of the catalysts, resulting in the remarkable enhancement of conversion, selectivity, and yield of end-products, as well as the energy efficiency of the process. Moreover, plasma processes can be turned on and off instantly, providing great flexibility for decentralised chemical production and energy storage via Power-to-X using renewable energy, particularly intermittent renewable energy. In this presentation, we will show the potential of plasma-catalytic Power-to-X technologies for the synthesis of fuels and chemicals, including CH_4 activation, CO_2 conversion, and ammonia synthesis.

Fabrication and Performance Evaluation of Lithium Cobalt Oxide ($LiCoO_2$) Thin-Film Electrodes by PE-PLD Method Yuya Sumiyoshi, Kenzo Ibano, Yuki Yamada, Yasuyuki Kondo, Heun T. Lee and Yoshio Ueda; Osaka University, Japan

Lithium Cobalt Oxide (LiCoO2) thin films are widely used as cathode materials in lithium-ion and all-solid-state batteries due to their high operating voltage, excellent capacity, and superior cycle characteristics. Pulsed laser deposition (PLD) is one method for synthesizing such thin film electrodes. Many process parameters exist for PLD, including oxygen gas pressure, laser power, target/substrate position, deposition time, and post-annealing temperature. However, wider flexibilities are needed to further control the crystallinity and composition of the functional electrodes. Here, another extension of PLD technology is plasma enhanced pulsed laser deposition (PE-PLD). In this method, PLD is performed in a plasma environment to control film stoichiometry and optimize crystal structure growth. In particular, the use of reactive oxygen plasma results in interaction with both substrate and PLD ablation plume. In PE-PLD, the oxygen plasma is not only a source of oxygen atoms needed for thin film growth, but also a source of thermal energy to the substrate (including surface activation) to assist in the growth of the oxide thin film without additional substrate heating [2]. To date, thin films deposited by PE-PLD using pure transition metal targets have shown favorable properties such as lower resistivity, fewer cracks, and improved crystallinity with increasing oxygen pressure [3]. However, the use of Lithium Cobalt Oxide targets and their effects on thin film electrochemical performance has not yet been reported. In this study, we report on the effect of using LiCoO2 targets on the deposited thin film crystal structure properties (e.g. lattice constant, texture) and its effect on the electrochemical performance.

SF03.04.02
Deposition Kinetics in the Magnetron Sputter Deposition of Aluminum Doped Zinc Oxide Thin Films Yifei Sun[1], Nadia Foo Kune[2], Michael Klysinger[2] and James R. Doyle[2]; [1]Cornell University, United States; [2]Macalester College, United States

We study the growth mechanism of aluminum-doped zinc oxide films deposited using magnetron sputtering by examining the effects of precursor gas phase scattering and substrate temperature on the film properties. The best quality films, deposited at a substrate temperature of 240° C and an argon pressure substrate distance product of 80 mTorr-cm, have a resistivity of 5.4 x 10^{-4} Ohm-cm and an average transparency in the visible-near IR spectrum (400-1100 nm) of 90%. In general the properties of films deposited on unheated substrates were much more sensitive to working gas pressure than films deposited on heated substrates. The unheated substrate films exhibit a pronounced maximum in carrier concentration and mobility at a pressure-target distance product of 50-80 mTorr-cm, but surprisingly x-ray diffraction and optical transmission results imply that this maximum corresponds to a minimum in film structural quality. This result is consistent with modulation of Zn concentration in the films and electron transport limited by grain boundary scattering. We propose that the strong dependence of film properties with working gas pressure on unheated substrates is due to changes in the properties of the precursor flux due to the differential scattering with the working gas. The unheated films retain a strong memory of the properties of the incident flux, whereas the films deposited at high temperatures are less sensitive to the incident flux due to temperature activated surface reactions. We will present preliminary gas transport and film growth simulation results to support this proposal.

Electric Field Measurements in High-Pressure Hydrogen and Nitrogen Environments by Detecting Visible Lights Induced in Coherent Anti-Stokes Raman Scattering Scheme Takeru Koike, Hitoshi Muneoka, Kazuo Terashima and Tsuyohito Ito; The University of Tokyo, Japan

Electric field is one of the most important parameters for controlling plasma materials processing. It accelerates charged particles and the energetic particles are taking various important roles. For example, they are colliding with background species to create reactive species and/or with solid materials to proceed sputtering and/or implantations. Therefore, knowing electric field is essential for advance control of plasma processing. Since various plasma processing in high-pressure environments have been developed, further development of electric field measurements in high-pressure environments are desired.
In this study, we are demonstrating electric field measurements by using coherent anti-Stokes Raman scattering with visible light detections. With irradiations of an infrared laser whose energy is matching to the Raman transition energy of probe molecules and a laser at 532 nm, a light whose energy is sum of ones of two irradiated lasers is induced with electric field with the electric-field-dependent intensity. It has been demonstrated that this method is suitable for high-pressure environments and highly sensitive measurements, e.g. 0.5 V/mm detection, have been realized with an atmospheric-pressure hydrogen environment [1]. It has been also confirmed that the measurement scheme works also in nitrogen-containing environments [2]. Further details will be presented in the symposium.

SF03.04.04
Hierarchical Wrinkling on Elastomer with Plasma-Polymer Fluorocarbon Thin Film for High-Performance and Transparent Triboelectric Nanogenerator Eunmi Cho[1,2], Jin-Seong Park[2] and Sang-Jin Lee[1]; [1]Korea Research Institute of Chemical Technology (KRICT), Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Triboelectric nanogenerators (TENGs) have recently received extensive attention as a new technology of energy harvesting to serve the increasing demand of energy in the internet of things (IoT) era. Polytetrafluoroethylene (PTFE) is a representative triboelectrification material because of F atom makes it the most attractive to electrons. In addition, properties of PTFE, which are chemical resistance, thermal resistance, low coefficient of friction or good lubricity, and biocompatibility also provide a variety of applications in TENG device. However, PTFE has limited applications in various devices the low flexibility due to its thickness, difficulty in adhering to a substrate due to its low surface energy, and low transparency due to haze. In this study, a plasma polymer fluorocarbon (PPFC) thin film is suggested as a high-performance triboelectrification material for TENG. The PPFC thin film fabricated by sputtering using a carbon nanotubes (CNT)-PTFE composite target exhibits properties similar to those of PTFE, such as hydrophobicity, high surface charge potential and chemical resistance. Additionally, the PPFC thin film shows ultrathin thickness and transparency. Not only that, when a PPFC thin film is coated on a stretchable and biocompatible styrene-ethylene-butylene-styrene (SEBS) substrate, wrinkles are simultaneously generated on the surface, which increases the surface contact area and hydrophobicity. The surface contact area is regarded as a crucial factor that influences TENG performance by increasing

surface charge density upon electrification event. We fabricated a PPFC coated hierarchical wrinkled architecture (HWA) TENG with dual-wavelength wrinkles though additional plasma surface treatment. HWA-TENG shows a high output performance of 200V and 30 μA due to the combination of increased surface area effect of HWA and high surface charge potential characteristics of PPFC thin film. It has been demonstrated that HWA-TENG can be successfully applied to a transparent triboelectric rain drops energy harvester and a conformal artificial triboelectric skin. HWA-TENG, which has eco-friendly, simple fabrication process and high output performance, is expected to be applied to various devices such as conformal human body sensors.

SF03.04.05

Gas Sensing Properties of Tungsten Oxide with Helium-Induced Nanostructure Hayato Hikota, Kenzo Ibano, Heun T. Lee and Yoshio Ueda; Osaka University, Japan

Ethylene is a known plant hormone that is produced in fruits and vegetables at 10-100 ppm levels. It promotes ripening of fruits and vegetables, but its excessive presence can lead to progressive spoilage.
Monitoring ethylene production is important to properly control the quality of fruits and vegetables.

There are many types of gas sensors, including semiconductor, catalytic combustion, and thermal conduction types. Among them, semiconductor gas sensors using metal oxides are advantageous for low-concentration gas detection, and their sensitivity increases with larger surface area and more complex structure.

It has been confirmed that characteristic nanostructures are formed when tungsten is irradiated with helium plasma under certain conditions. The nanostructures are called "Fuzz" and show changes in physical properties such as significant increase in surface area and blackening of the surface. Semiconductor sensors using the nanostructures have been extensively researched and developed, and in fact, nanostructures formed by helium plasma have been confirmed to respond as sensors.
Furthermore, the addition of metal nanoparticles to the sensor increases the change in resistance when gas is introduced due to chemical sensitization. This technique has been studied as a method for improving gas sensor performance, and gold, palladium, and platinum were employed as catalyst metals in this experiment.

Based on the above background, this study was conducted to verify the ethylene sensing performance of a sensor using helium-induced nanostructures and to study the reaction rate change when a metal catalyst is added to the sensor.
The gas sensor used in this study was manufactured through a five-step process.
1. a thin film of W was deposited on a glass substrate by magnetron sputtering to a thickness of about 1 μm.
2. the deposited metal surface was irradiated with He plasma to induce fine nanostructures on the surface.
3. oxidation of the metalic thin film with fuzz structures was performed.
4. Au electrodes were placed at both ends of the sample by electron beam deposition.
5. catalytic metals (Au, Pd, Pt) were added by PLD method.
The fabricated gas sensor samples were placed in a quartz furnace and air containing the sensing gas and dry air were introduced alternately every 10 minutes, and the change in resistance was measured to evaluate the sensing characteristics.

SF03.04.06

Plasma Discharge in Solution for the Synthesis of Highly Dispersed Graphene-Supported Palladium Catalysts for the Fuel Cell Applications SangYul Lee[1], Jung-Wan Kim[2] and Sungmin Kim[3]; [1]Korea Aerospace University, Korea (the Republic of); [2]InCheon National University, Korea (the Republic of); [3]KITECH, Korea (the Republic of)

The direct formic acid fuel cell (DFAFC) has attracted considerable attention due to their high energy efficiency, low operating temperature, and low pollutant emission. Platinum (Pt) is the most commonly used anode catalyst in DFAFC. However, the high cost of Pt based catalysts has been one of the major barriers to limit the commercial application of DFAFC. Palladium (Pd) catalysts were supposed to be promising alternative catalysts in formic acid oxidation reaction due to their lower cost, superior activity and greater resistance to CO compared with Pt-based catalysts. The main interests in preparing Pd catalysts for DFAFC have focused on using graphene sheets as a carbon based supporter of Pd catalysts because of their good dispersibility and high conductivity. Recently, a method for the synthesis of the nanocrystals by means of plasma discharge in liquid phase, so-call solution plasma process (SPP) is introduced and SPP is an attractive method for the synthesis of nanoparticles because it is faster (microseconds), simpler (one-step method) and more cost-effective (only requiring an ion source) than traditional colloid methods. In this study, graphene supported Pd catalysts (Pd/G) were synthesized via a facile one-step SPP process. Palladium(II) chloride ($PdCl_2$) were used as precursor for the plasma discharge in graphene dispersed D.I. water and the effects of various discharge conditions on the dispersibility of Pd nanoparticles (Pd NPs) on the surface of graphene were investigated. The crystalline structures and morphologies of synthesized catalysts were characterized using X-ray diffraction (XRD) and high resolution transmission electron microscopy (HR-TEM). XRD result shows that Pd/G was successfully synthesized without any impurities and oxides. The peak of graphene (002) was detected near 25° with typical XRD pattern of Pd NPs. In the HR-TEM images, Pd NPs was well dispersed on the surface of graphene, which could be possible via the mono-layer structure of graphene. The dispersibility of Pd NPs increased as applied voltage increased from 1.6 to 3.2 kV and also strongly affected by the discharge time, as well. The high dispersibility at high voltage and increased discharge time could be attributed to the repulsive force caused by the high electric charge on the Pd NPs. Detailed experimental results will be presented.

Biological Functions of Oligo-alginate and Its Derivative Nanoceria Biocomposite Synthesized Using Solution Plasma Jung-Wan Kim[1,2,3], Ji Min Kim[3], Su-Jin Kang[2], Davoodbasha MubarakAli[4] and SangYul Lee[5]; [1]Incheon National University, Korea (the Republic of); [2]Graduate School of Incheon National University, Korea (the Republic of); [3]Research Center for Bio Materials & Process Development, Incheon National University, Korea (the Republic of); [4]B.S.Abdur Rahman Crescent Institute of Science and Technology, India; [5]Korea Aerospace University, Korea (the Republic of)

Solution plasma process (SPP) is an efficient and safe method for the development of functional biomaterials via synthesis of various nanometal particles, depolymerization of bio macromolecules such as alginate and chitosan, or synthesis of various nanometal-macromolecule biocomposites. Alginate is an acidic hetero-polysaccharide with potentials in biomedicine and foods due to non-toxicity and biocompatibility. However, its application as biomaterials is limited due to low solubility and high viscosity. SPP had been employed to depolymerize alginate to oligoalginate (OA) without adding any hazardous chemicals to solve the problems. In previous studies, OA enhanced the growth of lettuce and HEK293 human cells. In this study, alginate solution (0.75%) was discharged by plasma at 800 V, 35 kHz for 15-90 min. The resulting OAs were excellent antioxidants as DPPH and superoxide radical scavengers. OA prepared by discharging plasma for 60 min promoted growth of *Bacillus licheniformis* greatly. The bacterium grew to OD_{600} of 11.8 in tryptic soy broth (TSB) and to OD_{600} of 20.6 in TSB supplemented with 2.0% OA in 72 hr of cultivation. Sporulation rate was greatly enhanced by 2.0% OA (162 folds) in

24 hr of cultivation. Transcriptome analysis revealed that 904 genes out of 4,350 genes were expressed more than two-folds by OA. The most affected genes were those for metabolic process (270 genes) and the genes related to biotin synthesis were expressed 139.5 folds higher. In the meanwhile, expression of *N*-acetylmuramoyl-L-alanine amidase, one of autolysins, decreased by 19.5 folds. Most of the sporulative genes (55/58) were expressed by more than two folds, supporting the stimulation of sporulation by OA. Nanoceria (nCe) has potential in biomedical applications due to their distinctive low redox potential of the Ce^{4+}/Ce^{3+} redox couple. Synthesis of OA-nCe biocomposites was attempted using SPP to enhance antioxidant activities of each component. Plasma was discharged in the OA solutions (0.6-0.8%) containing 1-5 mM $CeNO_3$ at 800 V, 30 kHz for 15 min. UV-Vis spectroscopy showed two peaks at ~330 nm and ~360 nm with absorbance of 2.1-5.3 and 2.8-4.4, respectively. Among the biocomposites synthesized, 0.8% OA/5 mM nCe showed the highest peaks. FT-IR analysis indicated that chemical bonds of OAs were not affected by plasma discharge. Prevalence of nCe as Ce^{3+} and Ce^{4+} was detected in the 0.8% OA/5 mM nCe biocomposite by the XPS analysis, and cubical nCes well-dispersed in the OA matrix were observed by SEM/EDS and TEM. The average size of nCes in the biocomposite was 6.4±2.9 nm with the zeta-potential of -45.1±1.3 mV. DPPH, hydroxyl, super oxide, and H_2O_2 radical scavenging activity of 0.8% OA/5 mM nCe was 75.1%, 100%, 79.1%, and 100%, respectively. The biocomposite inhibited biofilm formation of *Vibrio vulnificus* by 95.9%. Therefore, more effective antioxidant and antibacterial biocomposite was obtained by using OA and nCe via SPP that can be utilized as a ROS quencher and a biofilm inhibitor.

SF03.04.08
Low-Temperature Plasma Synthesis of Plastics-Derived Graphene Quantum Dots Ren-Jie Weng, Darwin Kurniawan, Yu-Yuan Cheng, Yi-Ju Chang, Rong-Chen Jhang and Wei-Hung Chiang; National Taiwan University of Science and Technology, Taiwan

Plastic waste(PW) recycling is an important factor for environmental protection and zero carbon-emission society. However, about 80% PW is not properly-recycled, causing serious environment issue. Traditional recycling methods such as methanolysis, glycolysis, hydrolysis, ammonolysis, aminolysis, and hydrogenation are usually low efficiency, and the products are low economic value added. Graphene quantum dots (GQDs) have obtained a tremendous research interest owing to their unique material properties including tunable bandgaps, biocompatibility, chemical and photo-stability, making then promising candidate for next generation optoelectroncis, biomedical-based sensing and imaging, energy conversion and storage, and nanocatalysis. However the current synthesis methods are usually time-consuming, complicated and not environmental-friendly.
Here we demonstrate a simple, scalable and generic low-temperature plasma synthesis of PW-derived GQD (PWGQD) using microplasma-assisted electrochemical process. Recently microplasma-based technologies have attracted a lot of attentions due to the advantages for nanomaterials synthesis and processing. Detailed absorbance, photoluminescence (PL), Raman spectroscopy and transmission electron microscopy (TEM) studies suggest the PWGQDs can synthesized from various PW including polyethylene terephthalate (PET), high density polyethylene (HDPE), polyvinyl chloride (PVC), low density polyethylene (LDPE), polypropylene (PP), polystyrene (PS), polylactic acid (PLA), poly carbonate (PC). The morphologies, surface functionalities, defect densities, and optical properties can be controlled by the plasma condition and precursor types. *In situ* optical emission spectroscopy (OES) and *ex situ* mass spectrometry study reveals that plasma-generated reactive species play a role and can interact with the pressors for GQD synthesis in a cascaded chemical reaction.

SF03.04.09
Microplasma Engineering of Bioresource-Derived Surafce-Functinoalized Graphene Quantum Dots as Ultrahigh Sensitive Optical Nanosensors Neha Sharma, Darwin Kurniawan and Wei-Hung Chiang; National Taiwan University of Science and Technology, Taiwan

Recently, graphene quantum dots (GQDs) caught attention due to their a vast range of application in different fields of science and technology. It is a new type of cgraphene-based nanomaterials with lateral size less than 10 nm. GQDs have attracted many researchers because of its tunable fluorescence, chemical and photo stability, low toxicity and biocompatibility. Synthesizing GQDs using bioresource-containing precursors is an environment friendly and green route. Graphene quantum dots show high conductivity, larger surface area and long life. Therefore, GQDs can be used as catalysts, fuel cells, drug delivery as well as fluorescence based sensor for sensing of different pollutants, Metal ions, dyes which are very toxic to environment as well as human being as it pollute mainly water sources can cause health issues. It is very harmful to life of plants, animals and also human being. Detection of these metal Ion using GQDs can help preventing diseases in human and harmful impact on environments.
There is a number of techniques for the synthesis of GQDs using biomass precursors. However most of them are time consuming, costly, harsh reaction condition and includes use of toxic chemicals. Here we approached microplasma method for synthesis of GQDs from different biomass precursors, which is one of the most promising approaches for nanomaterial synthesis due to its simple approaching and stable and low cost. High electron density in microplasma provides non-thermal dissociation of molecular gases to form reactive species such as OH radical, O radical, O_2^- radical. These reactive species in precursor solution interact with chemical species and form GQDs.
Here we report an effective synthesis of tunable GQDs under ambient condition by using microplasma. Here we used different biomass precursor for the synthesis of GQDs, including chitosan, fructose, lignin, citric acid and starch. Tunable fluorescence can be explored by controlling the chemistry of reactions during the synthesis. This method leads to highly crystalline particles with tunable properties and high reproducibility from simple biomass. GQDs synthesized from different biomass shown selectivity to different metal ions due to their surface functional functionalities. This work shows a promising method to synthesis of GQDs with different functionality and not only for metal ion detection but also for many other future applications such as drug delivery, nanomedicines, disease detection and therapy.

SF03.04.11
Tunable 3D Cone or Corn Seed Shape Nanostructure on Polydimethylsiloxane Surface with Oxygen Plasma Treatment Mina Shanbedi and Alamgir Karim; University of Houston, United States

We report on a plasma-based method to fabricate a repeatable three-dimensional structure on polydimethylsiloxane (PDMS) surfaces. The pattern shape and its radius and height are controllable, and the shape can vary between rounded head corn seed shape and cone shape. The PDMS film has a periodic channeling pattern as the base pattern, and then the plasma treatment creates the cone shape with a specific method to impose the film to air plasma. By controlling the time and plasma power and also controlling the physical position of the film to plasma, a 3D shape pattern with a high surface area is shaped on the PDMS surface. This plasma-based procedure provides a simple, fast, and inexpensive method for creating patterned chemical functionalities on 2D and 3D PDMS surfaces for directed assembly and the development of micro-scale sensors and bio-chip devices. The film wrinkling bilayer is characterized by morphology and topography characterizing methods such as atomic force microscopy imaging and scanning electron microscopy. The roughness and the size of the film pattern have been related to the time and power of the plasma device and encountering position. The wrinkling amplitude and the phase grating were also mathematically modeled by considering the wrinkling of the oxidized layer and glassy behavior.

SF03.04.12
Patch Repair of Composites Using Electric Field Plasma Induced Heating and Curing Anubhav Sarmah, Smita Dasari and Micah Green; Texas A&M University, United States

Here, we demonstrate a novel methodology of repairing cracks or damages in carbon fiber reinforced composites (CFRCs) using Dielectric Barrier

Discharge (DBD) induced heating and curing. This study involves the use of a epoxy-impregnated carbon fiber patch or prepreg, which is laid upon the cracked or affected area of a composite in order to eventually mitigate the damage. The DBD applicator generates an electric field plasma; conductive carbon fibers heat up when exposed to this plasma, and the heat is transferred to the surrounding epoxy, thus curing the patch. This cured patch acts as a structural additive to the damaged part, significantly improving its mechanical properties and rendering it fit for further use. Differential Scanning Calorimetry (DSC) experiments show that the glass transition temperature and degree of cure of the exposed patch can be controlled by adjusting the target temperature and residence time of the DBD-induced heating process; patches of varying initial degrees of cure allow for repairs in damaged composites with varying curvatures. Furthermore, the mechanical properties of damaged and repaired samples were compared using tensile testing; a ~78% increase in ultimate tensile strength of the DBD-repaired sample was observed compared to the damaged sample. This study establishes Dielectric Barrier Discharge generated plasma as an energy efficient, out-of-oven alternative for damage repair in carbon fiber composites.

SF03.04.13
Vacancy-Rich Palladium Hydride Synthesis Using Tandem Electrochemical Loading and DC Plasma Metal Sputtering Oliver Horner and Curtis Berlinguette; The University of British Columbia, Canada

Metal hydrides with lattice vacancies, such as palladium hydride, can exhibit superconductivity with a high transition temperature. The study of these metal hydrides, however, has been limited as their synthesis requires experimentally inaccessible high pressure and temperature conditions. Vacancy formation in metal hydrides can be promoted by two methods: high hydrogen contents within the metal hydride, and sputter-depositing metal in a hydrogen rich atmosphere.
Here, I report the development of a bespoke platform for rapid fabrication of vacancy-rich metal hydrides leveraging metal sputtering and high hydrogen concentration. A pulsed DC argon plasma will sputter deposit metal onto a hydrogen-permeable Pd target that is simultaneously electrochemically-loaded with hydrogen from the opposite face by water electrolysis. This provides a hydrogen-rich atmosphere during sputter deposition and promotes high hydrogen loading.

SF03.04.14
Atmospheric Pressure Plasma Surface Processing of Metals for Water Condensation Antonella Uricchio[1], Teresa Lasalandra[1] and Fiorenza Fanelli[2]; [1]University of Bari "Aldo Moro"- Department of Chemistry, Italy; [2]National Research Council (CNR), Institute of Nanotechnology (NANOTEC), Italy

Water vapor condensation on solid surfaces is a well-known phase-change phenomenon essential in a wide range of applications such as in thermal power plants, chemical industries, water harvesting, refrigeration, electronics cooling, and seawater desalination [1]. In the last decades, several processes have been optimized to modify metal surfaces in terms of chemical composition, morphology and wettability, in order to modulate their water condensation performances [2].
In this contribution we propose the use of low-temperature atmospheric pressure plasma (APP) for fine tuning the surface properties of aluminum (Al) samples with the aim of developing novel materials for enhanced water condensation. In particular, various APP deposition processes, including plasma-enhanced chemical vapor deposition (PECVD) and aerosol-assisted plasma deposition (AAPD), were used to coat Al samples with both smooth hydrophobic polymer thin films (i.e., hydrocarbon and fluorocarbon films) and superhydrophobic organic-inorganic nanocomposite coatings [3,4]. The chemical composition, morphology and wettability of the different samples was studied by various techniques, such as Fourier-transform infrared spectroscopy, X-ray photoelectron spectroscopy, scanning electron microscopy, white-light vertical scanning interferometry and water contact angle goniometry. The condensation mode, the droplet growth kinetics and the condensate removal mechanism were investigated performing experiments in a purposely designed condensation chamber under controlled conditions (e.g., relative air humidity and subcooling temperature).
Preliminary results revealed that water vapor condensation on hydrophilic pristine samples occurs via filmwise mechanism. In contrast, on hydrophobic plasma-coated samples a stable dropwise condensation mode is obtained. On the other hand, flooding condensation is observed on the superhydrophobic samples coated with nanocomposite films. Here, large pinned droplets form due to condensation within the film micro/nanostructures, leading to surface flooding. Interestingly, by depositing on the nanocomposite coating a thin fluorocarbon layer, coalescence-induced jumping-droplet condensation is achieved. In this case small droplets merge and undergo a self-propelled out-of-plane jumping induced by the surface energy release upon droplet coalescence. Overall, these findings provide novel insights into the use of plasma-assisted deposition processes for the tuning of the water condensation performances of metal surfaces towards industrially relevant applications.

3D-Printed Plasma-Treated Super-Amphiphilic Surface for Fog Harvesting Van-Tuan Nguyen, Sayed Sajid Hussain, Eunhee Park, Ngoc-Anh Nguyen, Oleksii Omelianovych and Ho Suk Choi; Chungnam National University, Korea (the Republic of)

The development of super lyophilic surfaces has received tremendous attention due to its wide application in industry and engineering. However, there are still difficulties in preparing super-amphiphilic surfaces, especially those with microstructures. This study reports the fabrication of versatile super-amphiphilic microgroove surfaces (SAMS) through physical and chemical modification. The microgroove structure is achieved through the Fused Deposition Modeling 3D printing method using layer-by-layer (XZ direction) printing, and the surface chemical composition is adjusted through vacuum argon plasma treatment. It also controls the surface roughness coefficient and hydroxyl content through the printed layer height/nozzle diameter ratio and plasma treatment time to optimize the capillary force between the grooves to obtain the most appropriate SAMS. The achieved SAMS demonstrates versatility to absorb common solvents of various polarities, including carbon tetrachloride, ethylene glycol, and water. SAMS showed high fog collection performance of 678 g m^{-2} h^{-1} due to its super amphiphilic properties and microgroove structure, and improved the collection rate by 51.30% and 16.41%, respectively, compared to planar and microgroove surfaces.

SF03.04.16
Plasma-Ionic Liquid Reduction for Synthesizing High-Entropy Alloy Nanoparticles Gilhwan Lee, Enkhjin Chuluunbat, Eunhee Park, Ngoc-Anh Nguyen and Ho Suk Choi; Chungnam National University, Korea (the Republic of)

We report a novel cost-effective and scaling process for syntheses of the quinary IrPdPtRhRu HEA-NPs. The process is based on the plasma ionic liquid

reduction strategy. The combination of PXRD, HRTEM, XPS, and EDX analyses confirms that the application of the developed wet plasma reduction method yields the IrPdPtRhRu HEA-NPs. HEA-NPs with the size of ≈5 nm were synthesized under mild temperature, and atmospheric pressure, and without support assistance. All elements constituting the as-prepared IrPdPtRhRu HEA-NPs are uniformly distributed in the FCC single-phase nanostructure. The valence band emission suggests the hybridization of the metal orbitals in the IrPdPtRhRu HEA-NPs. The work function (WF) of 4.63 eV for the HEA is determined by UPS. WF value is lower than the WFs of the metals from which the HEA consists, suggesting higher catalytic activity. The IrPdPtRhRu/C electrocatalyst shows excellent catalytic performance toward hydrogen evolution reaction (HER) with the overpotential of 60 mV at a current density of 10 mA cm^{-2}. Tafel slope of 40 mV dec^{-1} was recorded in the alkaline electrolyte. HEA electrocatalyst exhibits long-term stability for 6 h without significant decay under a high constant current density of 100 mA cm^{-2}. The findings in this study contribute to the basic scientific understanding of catalysts and provide a platform for further development of HEA-NPs electrocatalysts for large-scale applications.

SF03.04.17

Synthesis of Nano-Size Glass Frit Powder by DC Thermal Plasma for Cu Termination in MLCC Kyu-Hang Lee[1], Tae-Wook Kim[1], Ye-Jin Jin[1], Soo-Min Lee[1], Gye-Young Jo[1], Kyu-Hoon Lee[1], Young-Hwan Jeon[2], Weon-Chae Seo[3] and Byung-Koo Son[1]; [1]Cheorwon Plasma Research Institute, Korea (the Republic of); [2]AMOGREENTECH, Korea (the Republic of); [3]AMOTECH, Korea (the Republic of)

With the miniaturization and multifunctionalization of electronic devices,MLCC (Multilayer Ceramic Capacitor), which is used as a passive element, is also required to be miniaturized and high-capacity.For this reason, thinning technology of Cu termination is becoming important. In this study, we synthesized nano glass frit powders of 150 nm or less to apply to MLCC 1005 size products and used these nano glass frit powders to manufacture paste.The characteristics of the manufactured paste were evaluated after the Cu termination was applied. Nano-size glass frit powders have been synthesized by DC (Direct Current) thermal plasma. A micro-sized glass frit powders powder was fed in the DC thermal plasma. In the high temperature of DC thermal plasma that is of higher than 6,000 K, the glass frit powder was vaporized. The size of produced glass frit particle can be controlled by the working power, the flow of working gas and quenching gas, the process pressure in a reactor and the feeding ration of raw materials. In this study, the conditions for producing nano glass frit powder with a size of 150 nm or less were set to 60 kW for DC power, 80, 100, 120 lpm for working gas flow, 50, 100 lpm for quenching gas flow, 300 torr for process pressure, and 300 g/hr for feeding rate.The produced nano glass powder was produced in paste using high pressure homogenizer and 3-roll-milling equipment. The manufactured paste was dipping and blotting simultaneously through dipping equipment to manufacture Cu termination. Nano glass frit powders that were less than 150 nm in diameter were observed morphology and the paste and Cu termination were observed by morphology, melting temperature and density.

Introducing Durable and Uniform Surface Coatings on Garments with Complex Contours Using Low Pressure Plasma Enhanced Chemical Vapor Deposition (PECVD) Dilru R. Ratnaweera, Ranitha Fernando, Samith Amarasena, Malindu Ariyasinghe and Rajitha Botheju; Twinery, Innovations by MAS, Sri Lanka

Textile industry is responsible for about 20% of the global clean water pollution due to the traditional dyeing and finishing processes. After many years of research and development, water free and effluent free surface functionalization of garments is now possible with our patented low pressure PECVD technology. This specific PECVD system consists of a 2000-liter vacuum chamber, which accommodates about 100 medium size t-shirts at once, a chemical dosing system, two parallel radio frequency (RF) electrodes and a dynamic vacuum system. The chemical inlets, chemical guiding system and dynamic vacuum outlets were placed in a manner to assure uniform distribution of activated chemicals within the plasm chamber to functionalize inner and outer surfaces of garments with complex and nonuniform contours. Two main energy sources were used to bring the selected chemistries into the plasma form. First chemicals were introduced into the plasma chamber via a preheating chamber to boost the kinetic energy. Then RF waves were used to bring the preheated chemicals to the plasma stage. Surface functionalizing chemicals were continuously pumped into the change with the flowrates of 0.1 to 1 g/min while maintaining the pressure of the chamber in between 0.1 to 1 mbar. Garments were hanged within the chamber while keeping at least 2 cm gaps among each other.
Surface functionalization was done at two stages. At first, substrates (garments) were activated with Argon plasma for about 5 to 10 minutes. Then the surface functionalization was done for about 20 to 30 minutes with selected chemistries. Surface functionalizing chemicals were carefully selected, where each molecule has two regions, a region that easily activates with the RF source to create plasms and a region that provides the required end functionality to the fabric surface. The selected chemistries were anchoring to the substrates with covalent bonds while making crosslinked network with adjacent chemisorbed molecules. Different functionalities such as super hydrophobic, oleophobic, hydrophilic, bacteriostatic were introduced on to inner and outer surfaces of the garments in uniform and substrate agnostic manner with the above PECVD system. Process parameters were tuned to assure the performance and wash durability of the surface functionalized garments while maintaining aesthetic intact.

Enviromentally-Friendly Plasma-Enhanced Chemical Vapor Deposition (PECVD) Processes for Industrial Applications Daphne Pappas[1], Dhia B. Salem[2], Ryan Robinson[1], Andrew Sy[1], Vitalij Hieronymus-Schmidt[2] and Bjorn Kolbe[2]; [1]Plasmatreat USA, United States; [2]Plasmatreat GmbH, Germany

Industrial emissions of hazardous air pollutants have attracted the attention of environmental protection agencies in most countries around the world. Efforts focus on the enforcement of tight regulations related to the operation of wet chemical stations, paint and coating applications, gaseous manufacturing, photolithography, and electronics packaging processes.
Plasma-Enhanced Chemical Vapor Deposition (PECVD) has been the preferred method for the deposition of thin coatings of well-controlled properties for several decades. It is considered a dry chemistry method as the coatings produced by this technology do not require drying or curing. Also, as nanoscale materials are being produced, they require minimal volumes of precursor chemicals. The low energy requirements and minimal consumption of chemicals classify PECVD processes as environmental-friendly. Additionally, plasma-based processes are used as surface preparation methods for several different types of materials and can replace solvent cleaning which is typically used to improve the wettability and bonding to adhesives, paints, and various

coatings.
Depending on the treated material and the type of adhesives used, plasma surface activation or cleaning are not always sufficient to provide stable long-time adhesion, especially under various environmental conditions, where the variation of temperature and humidity can be detrimental. To overcome this challenge, recent research work has focused on the combination of specialized precursor chemistries and plasma reactive species to generate nanocoatings of tunable properties and functionality.
In this work, the results from a study focusing on adhesion-promoting PECVD coatings on metal surfaces will be presented. Stainless steel and 6061 aluminum alloy substrates were treated with atmospheric-pressure plasma processes utilizing siloxane-based precursor chemistries for the development of nanocoatings. Following the plasma treatment, a polyurethane-based adhesive (Sikaforce-840) was applied on the metal coupons for lap shear testing. Results from the mechanical testing showed an increase of the adhesive strength of steel from 3 MPa to 12MPa, while the aluminum coupons exhibited a 10x increase compared to the untreated materials. Examples from the testing of various organosilicon coating chemistries on on a 2-part epoxy adhesive will also be presented. An overview of the fundamental plasma-surface interactions will be discussed to provide a better understanding of the adhesion mechanism.

Corona Discharge-Enabled Electrostatic Printing for Ultra-Fast Patterning Zijian Weng[1], Marcelo Farfan[1], Parinitha Giridharan[1], Evan Williams[1], David Murphy[1], Long Wang[2] and Ying Zhong[1]; [1]University of South Florida, United States; [2]California Polytechnic State University, Pomona, United States

Substrate pattern printing techniques have been widely studied among the flexible electronics field due to their contributions to vast multifunctional applications. A vast amount of printing techniques has been developed to create complex 2D patterns to achieve different functionalities. However, some current printing techniques require study on the formulation of ink, compatibility of the printing nozzles, and the cleaning process of direct contact method, which are time consuming. In this paper, a novel Corona discharge-enabled electrostatic printing (CEP) ultrafast non-contact method is introduced to print a sub 100 microns resolution pattern within 1 second with the help of “sandstorm” and “net” effects. A detail mechanism study of these effects is shown in this paper to demonstrate the printing principle of CEP by using equation derivation, COMSOL simulations and high-speed camera capturing studies. The Roll-to-Roll-Compatible and binder-free features of CEP enable an ultrafast, simple and pure printing process, patterning high quality flexible electronics with temperature, strain and humidity multifunctional sensing abilities.

Flowable Chemical Vapor Deposition of Lightly Porous Low k SiCOH Dielectrics—Remote Plasma Deposition Processing, Film Analysis and Gap-Fill Application in Nano Device Fabrication Son V. Nguyen[1], Thomas J Haigh[1], Matthew T. Shoudy[1], Yiping Yao[1], Huai Huang[1], Hosadurga Shobha[1], Michael Rizzolo[1], Donald Canaperi[1], Jean Wynne[1], Steve Bedell[2], Kevin Wynne[3] and William Lanford[3]; [1]IBM Research-Albany Nanotech, United States; [2]IBM T.J. Watson Research Center, United States; [3]University at Albany, State University of New York, United States

Low k and porous low k SiCOH dielectrics have been implemented in Cu_Low k metallization of integrated circuits for high-performance nanoelectronic CMOS devices for more than two decades (1). For the last several years, the low k SiCOH dielectric plasma deposition process normally involves the deposition of blanket planar film for using copper damascene interconnects fabrication. Due to the low conformality of plasma deposited in SiCOH film, the dielectric deposition process is normally limited to blanket planar film deposition. For the new generation of 3-D nano device fabrication in which both logic and memory are integrated into a single chip, there is a need to develop an advanced low-temperature low k SiCOH film that enables advanced high aspect ratio gap fill properties. In recent a study, we briefly described an advanced development of the Fully Aligned Via (FAV) process using flowable chemical vapor deposition (FCVD) low k SiCOH and laser/nitrogen implanted FCVD SiCOH film capable of filling recess gaps with self-planarization (2,3) with decent device performance. This inventive FAV approach enables the advanced fabrication of robust 5 nm node device structure fabrication. The advanced remote plasma porous low k p-SiCOH with post UV treatment dielectric, robust reliability, and fabrication integration robustness is needed for the critical and top requirements in the device’s reliability and performance.
This paper presents the comprehensive deposition processes, post-deposition UV cure, and film analysis by advanced nuclear reaction analysis, FTIR, RBS, and MIS electrical measurement to optimize the film’s stability and composition. The flowable film was engineered for advanced gap-fill application of low k porous SiCOH that can achieve high aspect ratio gap-fill (>10:1 aspect ratio) with low dielectric constant (k<= 2.75) while still maintaining about the same excellent electrical, mechanical, fabrication integration robustness and reliability of conventional plasma CVD SiCOH film. The optimal FCVD process was developed for manufacturing worthy 300 mm CVD system to deposit SiCOH using organosilicon precursors with remote O2 plasma at low deposition temperature (80-100C) and the UV cure at higher temperature (385-400C).
This FCVD SiCOH film with varying compositions was engineered to create a good low k dielectric capable of excellent high aspect ratio nanostructure gap fill performance but with a lower dielectric constant with good mechanical properties, interface adhesion, and excellent electrical properties.

Plasma Initiated Chemical Vapour Deposition—From the Growth Mechanisms to Ultrathin Low-k Polymer Insulating Nicolas Boscher, Dominique Abessolo Ondo and François Loyer; Luxembourg Institute of Science and Technology, Luxembourg

Plasma processes are highly versatile methods that enable the formation of a vast variety of materials directly in thin films form. Nevertheless, the many reactive species composing plasmas are responsible for a non-negligible number of side reactions, yielding altered chemistries compared to conventional polymerization processes. In this work, we demonstrate how the combination of ultrashort nanosecond plasma discharge ($t_{ON} \approx 100$ ns) and long plasma off-time ($t_{OFF} = 0.1 – 100$ ms) promotes plasma-induced polymerisation over plasma-state polymerisation. During the plasma on-time, a defined number of radical and neutral fragments, which can play both the roles of polymerization initiation or termination groups, are produced. When using vinylic monomers, the conventional polymerization pathway is strongly favoured during the off-time, yielding linear polymer core and unprecedented molecular weights for an atmospheric-pressure plasma processes. In addition to the significance of the monomer structure, the saturation ratio, i.e. the monomer partial pressure over its saturated vapour pressure (P_M/P_{sat}), is demonstrated as a key parameter of the thin film’s growth. While low P_M/P_{sat} values result in the prevalence of gas phase reactions, excessively high P_M/P_{sat} values lead to the formation of poorly cured polymer layers, when operating at low plasma

pulse frequency. Taking advantage on the understanding gained on the nanosecond pulsed plasma deposition of polymer layers, ultrathin (*ca.* 10 nm) and conformal polymer layers with low leakage current densities (*ca.* 10^{-9} A/cm^2 at 20 V) are prepared. The careful selection of the monomer structure enables to decrease the dielectric constant from 4.2 to 2.8.

Rapid Plasma Synthesis of Blackened Oxygen-Deficient Zinc Oxide Ruairi McGlynn[1], Paul Brunet[1], Praveen Kumar[2], Quentin Ramasse[3], Miryam Arredondo-Arechavala[2] and Davide Mariotti[1]; [1]Ulster University, United Kingdom; [2]Queen's University Belfast, United Kingdom; [3]SuperSTEM, United Kingdom

Zinc oxide (ZnO) has long attracted attention in a range of fields such as electronics, solar cells, photocatalysis and biological applications.[1] It has a characteristic large bandgap of 3.1-3.4 eV giving rise to absorption of light in the UV range below 400 nm. However, for applications which favour absorption over a wider energy range such as photocatalysis, solar thermal harvesting this restriction to UV is a limitation to application. Therefore, increasing the range of absorption represents a necessity to drive these technologies further. More recently it is emerging that modifying the number of defects in the Zinc material can give rise to enhanced photocatalytic activities and even absorption in the visible range.
Several groups have utilised chemical methods to formulate hydrogenated ZnO and other forms of defect-rich ZnO by chemical methods.[2–4] These materials do not display the characteristic white colouration, appearing visibly black, further demonstrated by a reduction from 94% to sub-45% reflection in the visible light range.[2] These materials demonstrated enhanced photocatalytic properties when compared to traditional ZnO with test cases of methylene blue[2] or methyl orange degradation[3] and hydrogen evolution.[5] Thus far the theories presented in literature have highlighted the key role of defects in the crystal lattice, in particular oxygen deficiencies or vacancies in the colour change from the typical ZnO white to black.[2,6]
In this work we report a new method to produce Zn-rich ZnO complex produced using atmospheric-pressure plasma. The addition of a 2% H_2/Ar mixture at 0.1 litres per minute into the standard 1 litre per minute flow of helium gas is critical to the formation of the darkened powder. We have characterized the synthesised material, utilising transmission electron microscopy, alongside X-ray diffraction and X-ray photoelectron spectroscopy to characterise the structural information including defects and surface chemistry respectively. The material we produce is determined to contain two long-ordered and well-defined structures, a shell of Wurtzite ZnO and a core that is comprised of either O-deficient Zn or Zn in a hexagonal lattice. There is a clear and sharp change in atomic plane between these regimes. In addition, the stability of the material in several typical solvents or under thermal annealing at several hundred degrees Celsius is explored, before we test the material for several different applications, such as solar thermal and biological applications.

Opportunities for Metal Oxide Synthesis with Atmospheric Pressure Microplasmas Davide Mariotti; Ulster University, United Kingdom

Metal oxides are an extraordinary class of materials that have found wide applicability for a number of century-defining technologies (e.g. flat-panel display, capacitors and energy storage) mainly due to their dielectric properties and chemical inertness. Doping, defect engineering, quantum confinement and extending to clusters, ternary or high entropy oxides can create disruptive materials with new or improved properties. Atmospheric pressure microplasmas represent a viable synthesis platform to achieve exceptional tuning capability therefore achieving an exquisite control of the size, composition and defects of metal oxide nanoparticles. In this contribution we will report on the synthesis and properties of metal oxide nanoparticles spanning a wide range of chemical compositions including oxides from Ca, Co, Cu, Mn, Mo, Ni, Sn, and Zn. We will report on the technological and application opportunities as well as on the fundamental aspects that relate to the synthesis methodologies and material structural properties. Future prospects involving complex oxides will also be presented and discussed.

High-Strength Composites Fabricated Using Graphene Synthesized in Atmospheric Plasmas Arpita Bhutani, Jonathan Griffin, Sidney Chenevert, David Miller and Albert Dato; Harvey Mudd College, United States

Graphene created using atmospheric-pressure microwave-generated plasmas can enhance the strength of acrylonitrile butadiene styrene (ABS), which is a thermoplastic polymer that is widely used in automotive components, electronic devices, and 3D printing. Here we present new knowledge on the relationships between the processing, structure, and properties of ABS reinforced with gas-phase-synthesized graphene (GSG). The process of dispersing GSG into ABS and the injection molding of ABS-GSG composites will be discussed. Additionally, transmission electron microscopy images of the filler-matrix interfaces in ABS-GSG specimens will be shown. We reveal that loading ABS with a relatively small amount of GSG (0.1 wt%) results in a remarkable 19.4% increase in tensile strength. The results suggest that unique strengthening mechanisms exist in ABS reinforced with graphene obtained using microwave plasma technology. This presentation highlights how substrate-free plasma-based techniques produce graphene that can greatly contribute to the development of high-strength composites.

1:45 PM SF03.07.02
Influence of the Surface Roughness on the Adhesion of Thermal Plasma Spray Al_2O_3 Coatings Tony Krüger[1], Holger Testrich[1], Rüdiger Foest[1], Thorben Kewitz[1] and Franz Faupel[2]; [1]Leibniz-Institute for Plasma Science and Technology, Germany; [2]Christian-Albrechts-University of Kiel, Germany

Atmospheric thermal plasma spraying is an innovative coating process, widely used in aerospace, medicine, and other industries to enhance the characteristic work piece surface properties, e.g. wear resistance, corrosion resistance, thermal insulation, etc. For surface customization, masks are used to protect areas of the workpiece from unwanted coatings. However, due to the nature of plasma spraying, a gradual accumulation of spray material on masks can lead to a change in the flow dynamics near the edges causing a loss of contour accuracy and thickness homogeneity of the actual coating. Additionally, accumulated particles can fall off the masking and get embedded in the coating. This poses a problem, e.g. for conductive coatings, as these particles represent impurities that can lead to a change in the conductivity or resistance.
To tackle this problem, research is done on generating masks' surface conditions that affect film adhesion and promote swift delamination, while optimum plasma spraying conditions are maintained. Samples were spray coated with Al_2O_3 (2kg/h) using atmospheric pressure plasma spraying. As device served an Oerlicon Metco F4MB-XL Spray Gun (DC, I=600A, U=32V, gases: Ar, H2). In thermal spray processes, adhesion between the coating material and the substrate surface is of complex character. However, besides of physical (van der Waals) and chemical interactions, and metallurgical processing, adhesion of coatings to a substrate surface is mainly established by mechanical anchoring [1, 2].
In order to improve the understanding of relevant coating mechanisms, the influence of the surface roughness on coating adhesion is studied on a methodical basis. For this reason, prior to applying the spray coating, the surface roughness R_a of stainless steel (Type: 1.4301) was enhanced by using corundum blasting to provide a defined reference value. Subsequently, R_a was systematically reduced by means of Plasma Electrolytic Polishing (PEP), in order to provide a sample series with a defined range of surface roughness. PEP is an environmentally friendly hybrid process, assumed to combine classical electrolysis and atmospheric plasma processes. It is used to efficiently smooth out surfaces, clean off surface residues, and deburr edges, by using an electrolyte that is harmless during disposal and therefore relatively environmentally friendly, compared to classical electrolysis.
Tactile profilometry was carried out to measure the surface roughness obtained in PEP treatment (measured with KLA+ Alpha-Step® D-600). Moreover, the effects of additional interface layers (SiOx, TiN) and substrate materials (quartz glass) on film adhesion were investigated. During PEP, with increasing polishing time the surface roughness could be reduced to a minimum of $R_a \approx 0.05$ µm. Further reduction was not achieved, presumably, because the (selective) material removal during PEP of steel stimulates both processes; surface smoothing and roughening.
Whereas the sandblasted specimens provide sufficient coating adhesion, the formation of adhering coatings is efficiently suppressed at smaller R_a. Below a critical roughness, swift and complete delamination is observed for Al_2O_3 coatings with a typical thickness above 100 µm. Additionally, it was observed that Al_2O_3 coatings exhibit low adhesion on smooth quartz glass, whereas solid coatings on corundum blasted glass surfaces could be attained.

(Funded by the European Union and the State of Mecklenburg-Western Pomerania, TBIV-1-321).

2:00 PM *SF03.07.03
Laser-Assisted Mass Spectrometry in Open Air Yong-Feng Lu; Univ of Nebraska, United States

Laser-assisted mass spectrometry (LAMS), based on laser ablation of solid samples, has been one of the most powerful analytical techniques for atomic and molecular analyses. However, conventional mass spectrometry (MS) needs to be carried out in a vacuum, which largely limits the analysis efficiency. To extend the applications of LAMS and make it fit for open-air and in situ applications, we investigated open-air operated LAMS (OA-LAMS) for simple and fast analyses. However, OA-LAMS brings challenges. The ambient gases, such as O_2 and H_2O, react with the ions and atoms produced by laser ablation during the plasma cooling process which leads to the formation of compound ions and complicates the spectra and analyses. The lifetimes of the ions and atoms are also reduced due to the fast recombination in the open-air environment, resulting in low sensitivity. The signals detected in OA-LAMS also show nonlinear trends which complicates the subsequent analyses.
Analyzing signatures of an isotope, used for deciphering nuclear events, controlling radioactive wastes, etc., is one of the most powerful abilities of MS. Therefore, open-air interference on isotope analyses in OA-LAMS needs to be addressed. The primary cations, such as Pb^+ and UO_2^+, demonstrate obvious light-isotope enrichments. On the other hand, the secondary cations, such as $PbOH^+$ and UO_2OH^+, yield isotope signatures close to the bulky samples. Isotope signatures were also investigated under different conditions, such as humidity, laser power, and sampling distance. The results demonstrate a potential methodology for characterizing isotope signatures in OA-LAMS.

Three approaches were investigated to improve the OA-LAMS sensitivity using magnetic field, resonant excitation, and external ion source.

In magnetic-field-enhanced OA-LAMS, a magnetic field is used to confine the laser-induced plasma (LIP). The increased collision in plasma enhances the ionization rate of the analytes. In addition, the nonuniform nature of the magnetic field generates a force to drive the positive ions toward the weaker field, which is the direction of the MS inlet orifice. Obviously improved signature-to-noise rations (SNRs) are observed for Al, Si, and Pb. With the magnetic field, the limit of detections (LODs) at a low ppm level have been achieved.

In resonant-excitation-enhanced OA-LAMS, a wavelength-tunable pulsed laser is used to match the specific atomic and molecular excitation states of the analytes. Through resonant excitation, the analytes in the LIP are more likely to form detectable ions. Different atomic excitation and molecular excitation states of U were investigated. The results indicate that molecular excitation of uranium dioxide (UO_2) at 314.09 nm can reach the best LOD for U (10 ppb).

In ion-enhanced OA-LAMS, an external DART ion source is incorporated. Analytes are vaporized from the solid phase through laser desorption. They are ionized by the external DART ions (protonated water) through penning ionization and charge transfer. In addition, the DART ions are also activated by laser irradiation since the wavelength of the laser is in the range of the OH bending vibrations. Rhodamine 6G, urea, and testosterone were investigated. The results show obvious sensitivity enhancements for all analytes. The enhancement factors for R6G, urea, and testosterone were 31, 11, and 4, respectively.

Graphene Synthesized in Atmospheric Plasmas is Inherently Superhydrophobic Albert Dato, M. Weston Miller and Makenna Parkinson; Harvey Mudd College, United States

Graphene produced in the gas phase using atmospheric-pressure microwave plasma technology exhibits a remarkable lotus-like water repellency. The ability of lotus leaves to repel water is desired in a wide range of applications, such as self-cleaning surfaces, waterproof textiles, anti-icing coatings, and biomedical devices. Creating artificial materials that exhibit the nonwettability of natural lotus leaves has been challenging. Superhydrophobic surfaces have been fabricated by mimicking the structure and chemistry of lotus leaves. Additionally, water-repellent coatings have been created by modifying graphene obtained through the exfoliation of graphite or substrate-based processes. However, the large-scale manufacturing of a broad range of nonwettable applications through biomimicry or modified graphene is neither sustainable nor practical. In this presentation, we reveal that gas-phase-synthesized graphene (GSG) is inherently superhydrophobic. The comparable static contact angles and roll-off angles of water droplets in direct contact with lotus leaves and as-synthesized GSG will be shown. Fascinating high-speed camera videos of water droplets impacting and rebounding from lotus leaves and GSG will be discussed. Furthermore, we demonstrate that hydrophilic materials instantly become superhydrophobic when coated with GSG. These results indicate that graphene sheets created through substrate-free plasma-based techniques have unique water-repelling mechanisms. This presentation highlights how plasmas can greatly contribute to the development of highly water-repellent surfaces.

Pulsed Plasmas in Liquids for Materials Applications Achim von Keudell; Ruhr University Bochum, Germany

Plasmas inside and in contact with liquids are a promising field for material synthesis and electrolysis. The understanding of the physics of the plasma ignition and sustainment is, however, still in its infancy due to the complexity of the phenomenon. For example, in the case of nanosecond high voltage pulses applied to a sharp tungsten electrode, electrostriction is very large so that rupture of the liquid occurs at a negative pressure of at least 24 MPa. Cavitation voids are formed and ignition inside these voids may occur. However, also field effects inside the liquid or a the tungsten liquid interface may cause ignition. Ignition converts the liquid spontaneously in the plasma state, which then expands this initial void to form a bubble. This creates a pressure pulse of the order of 10s of GPa depending on the HV voltage and the emission of acoustic waves that can be observed via shadowgraphy. The plasmas are observed with emission spectroscopy using a temporal resolution of 2 ns. This reveals a broad continuum consisting of black body radiation and line radiation of the hydrogen Balmer series. The hydrogen emission lines are significantly broadened from Stark broadening and affected by self absorption. It is shown that the plasma behave very similar for positive and negative polarity applied to the tungsten electrode. The temporal evolution of the electron density does not significantly depend on the polarity. This indicates that plasma generation follows similar mechanisms for both polarities. It is proposed that field ionization of water molecules or field emission at the internal surfaces of nanopores drives ionization and plasma propagation. Examples for the use of such plasma for electrolysis are given.

Low-Temperature Plasmas for Materials Discovery—InGaN Nanoparticles with Tunable Properties Rebecca J. Anthony; Michigan State University, United States

Nanomaterials continue to offer exciting opportunities to explore materials properties that could enable a vision of sustainable energy production, personalized health care, and new technologies for enhancing the success and well-being of global populations. Further, as devices and applications enabled by nanomaterials mature, there is a need to use scalable and efficient manufacturing strategies for production, which is where plasma reactors enter the picture. Research teams across the world have demonstrated the vast range of nanomaterials that are accessible using plasmas, including some nanoparticles that are difficult or impossible to synthesize using colloidal approaches, and with precision in size, surface properties, and functionality that are prohibited by other vapor-phase methods. One emerging area is in the tunable synthesis of alloyed nanoparticles, which can exhibit complex process-property-function relationships. Here, we present on alloys of indium and gallium nitride nanoparticles made using a flow-through nonthermal plasma reactor.
GaN is a wide-bandgap semiconductor, making it important as a UV source for lighting and communications, and for power transistor applications, as well as potential use as a photocatalyst and in other energy technologies. By contrast, indium nitride (InN) has a bandgap in the infrared, and is an effective optical absorber and can be used in solar photovoltaics and high-speed electronics. Alloyed indium gallium nitride (InGaN) has a tunable bandgap between these extremes, spanning the visible spectrum based on composition. This bandgap tunability has been used in light emission technologies for epitaxially grown layers and fabricated quantum well structures. Previously we have reported on gallium nitride (GaN) nanoparticle synthesis using plasmas, demonstrating size control via adjusting the residence time of the nanoparticles in the plasma. More recently we have synthesized InN nanoparticles in a similar reaction pathway, and we present our results exploring InGaN nanoparticle synthesis including demonstrating bandgap tunability. However, the competing influences of quantum confinement-based bandgap widening, composition-based bandgap adjustment, and internal strain and surface effects introduce a large degree of uncertainty in predicting the bandgap of these materials. This brings about an important opportunity to use the versatility of plasma reactors to uncover the physical, chemical, and mechanical contributions to property and function for InGaN nanoparticles, towards predictable nanomanufacturing. In this presentation, we share our findings on controlling composition, size, and surface of plasma-produced InGaN nanoparticles using a nonthermal plasma reactor, with perspectives on the potential for materials discovery using plasmas.

9:15 AM SF03.08.02
New Plasma-Enabled Synthesis of Designer Nanoporous Metallic Films Peer Fischer[1,2], Hyunah Kwon[1], Hannah N. Barad[3,1], Alex R. Silva Olaya[4], Mariana Alárcon-Correa[1,2] and Gunther Wittstock[4]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Heidelberg University, Germany; [3]Bar-Ilan University, Israel; [4]Carl von Ossietzky University of Oldenburg, Germany

Nanoporous metal films (NPMFs) are metallic layers of nanometric thickness containing voids, similar to pores in three-dimensional materials. This structure allows the presence of a high number of low coordinated atoms that determine the physicochemical properties of the films. NPMFs are used in transparent electrodes, plasmonically active materials with very high surface-to-volume ratios, and as active electrode materials for energy conversion and sensing. Generally, NPMFs are obtained by wet chemical dealloying, which involves the selective chemical etching of the less-noble metals from the alloy, which cannot be completely removed for thermodynamic reasons. The remainder of the less noble element (usually dopant levels) is difficult to precisely control and affects the characteristics of the resulting NPMFs. Additionally, the requirement of an alloy restricts the minimum thickness that can be manufactured with the desired porous structure/interconnected solid phase.
Here, we report a novel dry synthesis method based on the plasma treatment of metal nanoparticles formed by physical vapor deposition that produces ultra-thin NPMFs with highly curved and adjustable pore structures, and thicknesses in the order of the diameter of the original nanoparticles. Our approach is general, requires no solution-processing or harsh chemicals, and can be applied to many metals including non-noble ones (e.g. Au, Pt, Ni, and Fe) and their combinations. Nanopore and ligament sizes can be easily tuned by control of plasma conditions (type of gas, pressure, etc.). The resulting NPMFs are impurity-free, remarkably stable, and highly active for electrocatalysis. We demonstrate various NPMFs using different metals and their combinations, including several that have thus far not been shown to form NPMFs. We also present their remarkable performance, including their optical and electrical properties, as well as their exemplary electrocatalytic performance. We expect that these novel nanomaterials, synthesized by the plasma-based dry method we developed, will allow for their incorporation into many new applications and extensively advance the NPM field.

Hydrogen Plasma Reduction of Iron Ore for "Green Steel" Production Zichang Xiong, Sachin Kumar, Julian Held, Peter Bruggeman and Uwe R. Kortshagen; University of Minnesota-Twin Cities, United States

In 2020, steel production accounted for 7-9% of anthropogenic CO_2 emissions. Decarbonizing steel production is a priority for both governments and industry. Before this background, the direct reduction of iron ore with "green hydrogen", produced via electrolysis of water with renewable energy, could make important contributions towards green steelmaking. In this presentation, we present results of the reduction of iron oxide, both hematite and magnetite, with hydrogen microwave plasma. The plasma is maintained by coupling microwave power in the kW range into an argon:hydrogen gas mixture. Micrometer-sized iron oxide particles are entrained in this gas stream and pass through the plasma on timescales of hundreds of milliseconds. We demonstrate more than 90% reduction of both hematite and magnetite under optimal conditions. The proposed plasma technology is fully electric and does not rely on carbon-based fuels for heat or reduction. It also eliminates the energy required and emissions related to pelletization of iron ore concentrates. As such, it may provide a pathwath towards carbon-free steel production with "green hydrogen."

Green Steel Making Through Hydrogen Plasma Reduction of Iron Oxides Dierk R. Raabe, Isnaldi S. Filho, Yan Ma and Hauke Springer; Max Planck Institute for Iron Research, Germany

We present a study about the reduction of iron oxide (hematite) using a hydrogen-based plasma, produced in an electric arc furnace. The evolution of chemical composition and phase transformations was investigated in several intermediate states. The balance between the initial input mass and the arc power determines hematite reduction kinetics. Within 15 minutes of exposure to hydrogen plasma, full reduction is achieved. The wüstite reduction is the rate-limiting stage towards complete reduction. The reduction reaction is exothermic, and the total conversion rates (i.e. iron production) are equivalent to hydrogen-based direct reduction. Micro- and nanoscale chemistry and microstructure probing as well as energy dispersive spectroscopy and atom probe tomography show that the gangue elements partition to the remaining oxide regions. Si-enrichment was observed in the interdendritic fayalite domains, at the wüstite/iron hetero-interfaces and in the oxide particles inside iron. With proceeding reduction, however, such elements are gradually removed from the samples so that the final iron product is nearly free of gangue-related impurities. Our findings provide microstructural and atomic-scale insights into the com- position and phase transformations occurring during iron ore reduction by hydrogen plasma, propelling better understanding of the underlying thermodynamics and kinetic barriers of this essential process (1).

11:00 AM SF03.09.03
Challenges in Plasma-Based Low-Temperature Synthesis of MAX-Phase Protective Coatings for Metallic Bipolar Plates Martin Rohloff[1], Uwe Lindemann[1], Antje Quade[1], Anja Albrecht[1], Manoj Prabhakar[2], Chun-Hung Wu[2], Julian Kapp[3], Verena Lukassek[3], Michael Rohwerder[2] and Angela Kruth[1]; [1]Leibniz Institute for Plasma Science and Technology, Germany; [2]Max Planck Institute for Iron Research, Germany; [3]Zentrum für BrennstoffzellenTechnik, Germany

For the transition from a fossil-based to a sustainable energy economy, humanity urgently needs a clean energy supply. In this context, hydrogen plays a

key role as it serves as chemical energy carrier which solely produces water as reaction product in cold combustion processes in fuel cells. A maximum voltage of 1.23 V can be harnessed from such a fuel cell in theory. To increase gained power from fuel cells, the number of single fuel cells needs to be multiplied and combined to a fuel cell stack.
Bipolar plates are considered as crucial components in fuel cell stacks as they establish electric connection between the single cells. Moreover, bipolar plates also need to supply reaction gases and distribute them all over the whole electrode areas, have to take care for gas separation between the single cells, serve for cooling of the cells, and need to provide fluid and gas tight sealing of the system. For this purpose, bipolar plates made of metals and alloys are most promising alternatives for conventional graphite-compound-based bipolar plates. However, the biggest drawback of a metallic bipolar plate is its insufficient resistance to the harsh chemical conditions in fuel cell stacks under operation conditions. In consequence, corrosion resistant coatings need to be applied onto the surface of metallic bipolar plates. Recently, research on novel materials and materials processing routes for corrosion protection of metallic bipolar plates is intensified. In this context, MAX-phases are of emerging interest.
By discovery of the novel complex carbide Ti_3SiC_2 by Jeitschko and Novotny [1] and subsequent intensive research by Barsoum et al. [2-5] it was shown that a class of ternary materials comprised of an early transition metal ("M"), an A-group element (mostly group IIIA and group IVA, "A"), and C and/or N ("X") according to the general formula $M_{n+1}AX_n$ (n = 1-3) exhibits remarkable properties. Due to weak metallic bonds between M and A as well as due to covalent bonds between M and X, these materials exhibit tremendous combination of ceramic and metallic properties like corrosion resistance, hardness and high electric conductivity. The unique combination of electric conductivity and chemical inertness enables MAX-phase compounds to be applied as corrosion resistant coatings for electrical components working under harsh chemical conditions, e.g. as thin corrosion resistant coatings for metallic bipolar plates.
However, biggest challenge in application of dense MAX-phase coatings on metallic substrates are high temperatures of usually about 750 °C required for crystallization of amorphous precursors – temperatures which cause unfavorable changes in the metallic substrates, e.g. recrystallization processes in steel. Hence, development of a low-temperature synthesis route for MAX-phase-based coatings is crucially required to enable their application as protective coating and to draw benefit from their unique set of properties.
In this work, we will elucidate our low-temperature plasma-process-based approaches to deposit MAX-phase coatings by means of high power impulse magnetron sputtering in combination with plasma immersion ion implantation. Biggest challenges will be derived by in-depth characterization (XRD, XPS, SEM/EDX, TEM/EDX/SAED) of obtained coatings in correlation with locally and compositionally resolved electrochemical corrosion testing.

11:15 AM SF03.09.04
Influence of a Remote Plasma on the Chemical Vapour Deposition of ZrO_2 Based Layers Philipp A. Maaß, Vitali Bedarev, Sebastian M. Beer, Marina Prenzel, Marc Böke, Anjana Devi and Achim von Keudell; Ruhr-University Bochum, Germany

Chemical vapour deposition (CVD) is a widely applied technique used for thin film deposition. The combination with a plasma source (PECVD) enables the fine-tuning of parameters, opening new possibilities for the fabrication of functional coatings, such as thin thermal barrier coatings.
An evaporated metalorganic precursor is transported into the reaction chamber by a nitrogen-flow of 50 sccm at pressures of about 100 Pa. A ZrO_2 layer is deposited onto a heated substrate in the centre of the chamber with a growth rate of several 100 nm/h.
To influence and improve the reaction chemistry, a microwave plasma source is mounted opposite the substrate surface. The discharge interacts with the incoming precursor molecules, with the aim to reduce the reaction temperature and change the deposition properties.
During this process, the growth rate and substrate temperature are monitored by in-situ ellipsometry to obtain insights into chemical kinetics and mass transport phenomena. The deposited layers are characterised in stoichiometry and crystallinity, using X-ray photoelectron spectroscopy (XPS) and X-ray diffraction (XRD).
Depositions are carried out with and without the use of the plasma source. This enables the investigation of the plasma's influence on the precursor, the layer growth and the layer characteristics. It is shown that the growth species in the PECVD case are more reactive than in the CVD case leading to more efficient carbon removal from the film and to the growth of higher energy facets.

11:30 AM SF03.09.05
Biocide Nano Copper-Silver Layer Active Against Surrogate Virus and Bacteria Lorena Reyes-Cardona[1], Omar Sepulveda-Robles[2], Argelia Almaguer-Flores[1] and Sandra E. Rodil[1]; [1]Universidad Nacional Autonoma Mexico, Mexico; [2]Centro Medico Nacional Siglo XXI, Mexico

Bacteria and respiratory viral transmission by expelled saliva microdroplets and aerosols are essential concerns for health care workers, situation has been exacerbated by the SARS-CoV-2 pandemic. The development of nanomaterials with antimicrobial activity to use it as nanolayers in personal protection equipment (PPE), such as facemasks, respirators, protective clothing, or helmets, could be an option against the transmission of these pathogens. For this purpose, a silver and copper nanolayer named SakCu® was deposited on one side of a 70 gsm spun-bond polypropylene using the magnetron sputtering technique. Here, we evaluate the antibacterial and antiviral activity of SakCu® against drops (emulating sneeze or coughing secretions) falling on the material or aerosols passing through it. Virus viability assays were used to study the survival of PaMx54, PaMx60, and PaMx61 (ssRNA, *Leviviridae*) and PhiX174 (ssDNA, *Microviridae*) as surrogates for non-enveloped viruses. Colony forming unit determination was used to evaluate the survival of aerobic (*Escherichia coli, Pseudomonas aeruginosa, Staphylococcus aureus, Staphylococcus epidermidis*) and anaerobic (*Porphyromonas gingivalis, Aggregatibacter actinomycetemcomitans serotype b, Streptococcus mutans, Actinomyces israelii*) bacteria. Since the aerosols and microdroplets can be filtrated by the polypropylene, it was essential to determine the effect of the SakCu® nanolayer on its filtration efficiency. Therefore, measurements of the filtration efficiency using assorted sizes of NaCl particles (0.3, 0.5 and 1.0 mm) were done.

Viral viability assays with phages PaMx54, PaMx60, PaMx61, and PhiX174 showed a total reduction of viral viability between 2 - 4 h contact incubation with the silver and copper nanolayer; viral replication of both viruses was inhibited between 42% and 64% after pass through the SakCu® using a simulated viral filtration system. Bacteria growth inhibition by contact with nanomaterial and through-pass varied according to the specie, showing a range reduction between 70% to 92% for aerobic bacteria and >90% for anaerobic strains. Similar percentages of bacterial inhibition were obtained after 24 h of bacteria-contact incubation with the coated polypropylene. The results of the filtration efficiencies indicate that no significant differences were observed between the uncoated and coated polypropylene for the three measured sizes. The filtration efficiencies were 12.7 % for 0.3 microns, 32.5 % for 0.5 microns, and 55.7 % for 1.0 microns, indicating that despite a significant fraction of the viral and bacterial aerosol could go through the polypropylene textiles with or without the nanocoating, the antimicrobial efficiency was caused by the presence of the SakCu® nanolayer. In conclusion, our results showed a high bactericidal and antiviral activity of SakCu® by either contact or aerosol pathogens. Therefore, the Ag-Cu nanolayer (SakCu®) could be adapted for different PPEs to reduce and prevent the transmission of aerosol-borne pathogenic bacteria and respiratory viruses, including SARS-CoV-2.

11:45 AM SF03.09.06
Rapid Fabrication of NiO Nanoparticle Film as Hole Transport Layer Using Gas Phase Microplasma Dilli Babu Padmanaban[1], Subha Sadhu[1], Warda Mushtaq[2], Zachary Holman[2] and Davide Mariotti[1]; [1]Ulster University, United Kingdom; [2]Arizona State University, United States

There is always a challenge in direct application of nanomaterials. Many nanoparticle synthesis techniques are intrinsically accompanied with post and pre-processes that are costlier and time consuming. In the light of this, atmospheric pressure microplasmas-based techniques are simple and could provide rapid, time efficient solutions for a wide range of applications. Microplasmas are special kind of sub-millimetre plasmas that have achieved attractive performance in nanomaterial processing.[1,2] This technique has been used for synthesis of several nanomaterials such as metals and transition metal oxides.[3] In this talk, we want to show the synthesis of nickel oxide (NiO) nanoparticle using gas phase microplasmas and demonstrating its application as a hole transport layer for perovskite solar cell. NiO is a well-known p-type semiconductor used widely as electrode materials for solar cells, batteries, and supercapacitors.[4,5,6] Although NiO nanoparticles and films were synthesised by other physical and chemical based techniques, these often present drawbacks such as precursor toxicity and post-synthesis steps.[7] Here we show the one-step preparation of NiO nanoparticles with a solid metallic Ni wire as main precursor and He/O_2 gas mixture. The nanoparticles were characterised and found to have a particle size distribution around ~5 nm and consists of mostly NiO cubic 'Bunsenite' crystal phase for various inlet oxygen gas fraction. When directly deposited, nanoparticle films show a planar or columnar features depending on process duration and O_2 gas concentration. Further, we will also present the preliminary results on the application of NiO nanoparticle film as a transport layer for solar cell.

10:30 AM *SF03.10.01
Unraveling Surface Chemistry in Plasma Catalysis by Microscopic Modeling Erik Neyts; Univ of Antwerp, Belgium

Plasma catalysis is a promising technique for - in particular - conversion of harmful or useless gases into value-added compounds. Typical examples include conversion of CO2 and CH4 into CO, formaldehyde or CH3OH, and nitrogen fixation, i.e., conversion of N2 into NH3 or NOx compounds. The overall bottlenecks of these processes, i.e., to make the plasma catalytic processes competitive with existing technologies, are often the conversion yield and the energy conversion. These are determined by a large variety of variables - which are ultimately determined by the underpinning microscopic mechanisms.
Microscopic modeling may provide a means to investigate these mechanisms. In particular, molecular dynamics and derived techniques offer a unique insight into these mechanisms. This talk will highlight various techniques that address the unique plasma/surface interactions that form the foundation of the microscopic surface process mechanisms.

11:00 AM *SF03.10.02
Synthesis of Nanocomposite Thin Films in an Atmospheric Pressure Plasma Francoise Massines[1,2], Alexandre Perdrau[1,2], Beatrice Plujat[2,3] and Noemi Barros[2,1]; [1]CNRS, France; [2]UPVD, France; [3]CNRS PROMES, France

Atmospheric pressure PECVD (AP-PECVD) combines the advantages of PECVD: low temperature process and low temperature, and AP: no pumps and in-line coating. A configuration like that of industrial corona treatment, useful for in-line coating of large surface, appears as the best one. It is based on a linear dielectric barrier discharge directly interacting with the substrate and typically working in a range of frequency of several tens of kHz. As example, in a Penning gas mixture like Ar with some tens of ppm of NH3, by adding SiH4, it leads to high quality SiNx:H thin films for photovoltaic cells.
Another advantage of being at atmospheric pressure is that liquid or colloidal solution are easily injected in the plasma using an aerosol. To produce a nanocomposite, two different precursors should be used, one to synthesize the matrix and the other for the nanoparticles (NPs) that are embedded in the matrix. At first a colloidal suspension of pre-synthetized NPs in a solvent was tried. The study of the coatings made from an aerosol of TiO2 NPs in isopropanol showed that all the NPs contained in a droplet aggregate, leading to porous thin films. However, this study also showed that the matrix growth and the NPs transport onto the substrate can be controlled by the alternation of two plasma frequencies: a high one to polymerize the matrix and a low one to control the NPs transport. This was confirmed using SiO2 NPs in ethyl lactate as precursors.
Then, to try to avoid NPs aggregation, the possibility of forming NPs directly in the plasma is explored. A great advantage of this solution is to be safe by design as NPs are not at all manipulated. Thus, an aerosol of a solution of metallic salt in a solvent able to form a polymer thin film is used. The first results made with a gold salt in isopropanol will be presented. They show that plasmonic layers are easily obtained. The frequency alternation is also useful to transport NPs on to the surface and have enough power to reduce the salt and induces the growth of the matrix. Gold NPs are formed in the plasma, their aggregation is avoided and plasmonic resonance peaks range from 540 nm to 750 nm depending on the process parameters. Thus the coupling of a dielectric barrier discharge in a configuration useful for in-line treatment and an aerosol of metallic salt in a polymerizable liquid appears as promising solution to synthesize dense nanocomposite thin film in safe by design and ecofriendly manner at atmospheric pressure.

11:30 AM *SF03.10.03
Active Machine Learning to Guide Discovery of Non-Equilibrium Plasma Interactions with Complex Interfaces Ali Mesbah; University of California Berkeley, United States

Active learning (AL) is the branch of machine learning concerned with systematically querying samples from an experimental system (or a computational model) to train a data-driven model that maps (experimental) design parameters to process performance measures. AL has emerged as a useful tool for guiding high-throughput experiments and expensive computations in a variety of science and engineering fields. In this talk, we will discuss the promise of constrained and multi-objective Bayesian optimization methods for AL-guided exploration of the multivariable and highly nonlinear parameter space of non-equilibrium plasmas (NEPs) in a systematic and resource-efficient manner. We will demonstrate how AL approaches can pave the way for automated and "optimal" exploration of the parameter space of NEPs, towards establishing insights into the complex behavior of the plasma when interacting with interfaces.

12:00 PM SF03.10.04
Breakthrough Science on Transformation of Fungal Mycelium into Nanostructured Ultrananocrystalline Diamond Material via Microwave Plasma Pyrolysis Benjamin Stein, Orlando Auciello and Maria J. Arellano-Jimenez; The University of Texas at Dallas, United States

Fungal mycelium has been recently promoted as an environmentally sustainable natural material to potentially replace a wide range of materials commonly used today in various technologies, including nano-porous scaffolds for biological cell cultivation, wound dressings, electrical circuit boards, biosensors, substitute leather, building materials and medical bandages. The feasibility of transforming mycelium into carbon-based materials for various nanotechnologies has been previously demonstrated using a Microwave Assisted Pyrolysis (MAP) process, involving microwave (MW) energy to heat polar water molecules contained in biomass, in controlled environments, either directly or via the addition of microwave absorbers such as activated carbon, whereby the natural chitin in the mycelium is carbonized to produce carbon allotropes like biochar or activated carbon in solid or powder form. This abstract describes breakthrough materials science that relates to Nanomaterials, Soft Materials and Biomaterials, and Structural and Functional Materials topics at the MRS Fall meeting 2022. The materials science to be presented relates to research performed by our group developing a transformation of mycelium into a unique nanoscale carbon-based material via a new fast and low-cost pyrolysis process produced in a plasma-reactor integrated into a commonly available kitchen microwave oven. In the novel microwave plasma pyrolysis (MPP) process described in this abstract, the microwave energy is directed to a low pressure (<10 Torr) gaseous environment of Ar gas, flown into a sealed circular quartz tube inside the microwave oven, containing residual atmospheric N_2 and O_2. At the low 10 Torr pressure, the MW power, directed at the flowing gas, induces the formation of a plasma containing Ar^+, N^+, O^+ ions, and Ar^0, N^0, O^0 neutral atoms, and free electrons, all acting on the mycelium biomass, inducing physical / chemical transformations. The data to be presented reveals that the MPP process transform the mycelium into a "myco-diamond" matrix with a unique ultrananocrystalline diamond (UNCD) nanostructure (3-5 nm grains) inserted into macro, micro, and nanoscale structures. The UNCD structure produced by the MPP process is identical to a transformational UNCD coating (3-5 nm grains), previously developed by Auciello's group using patented MPCVD and HFCVD growth processes. Verification of the MPP-induced transformation of mycelium into UNCD was performed via complementary materials analysis techniques including Raman spectroscopy, for chemical analysis, Scanning Electron Microscopy (SEM), to determine the myco-diamond surface morphology, High Resolution Transmission Electron Microscopy (HRTEM), to confirm UNCD nanostructure, and X-Ray Diffraction (XRD) to confirm diamond structure. All analysis techniques confirmed the formation of UNCD, identical to UNCD coatings previously grown by MPCVD and HFCVD processes[1]. The MPP process represents a scalable and low-cost method of producing UNCD nanomaterials derived from renewable biological sources. O. Auciello, J. J. Alcantar-Peña, E. de Obaldia, Ch. 1-Book, **"**Ultrananocrystalline Diamond Coatings for New Generation High-Tech and Medical Devices", O. Auciello (Ed.), Cambridge, July 2022.

Non-Stoichiometry of Indium Oxide Thin Films—The Role of the Pulsed Deposition Method Magdalena Nistor; NILPRP - National Institute for Laser, Plasma and Radiation Physics, Romania

Pulsed electron beam deposition (PED) is now a well-established method to grow oxide thin films, superlattices or heterostructures on rigid or flexible substrates for applications in energy, optoelectronics and photovoltaics [1]. PED has features in common with the pulsed laser deposition but uses a pulsed electron beam instead of a laser beam for ablating a material and formation a plasma plume that mediates the growth of thin films. Apart from this classic aspect, PED, when operated at low oxygen pressure controls oxygen incorporation and hence the stoichiometry of oxide films, leading to the growth of oxygen-deficient metastable phases that cannot be obtained in bulk form [2]. We report on the non-stoichiometry (cation-anion ratio) of indium oxide thin films in relation to structure, optoelectronic properties and plasma parameters. The effect of ablation plasma on the film properties was investigated by ion probes. In the indium oxide films with a high level of non-stoichiometry the phase separation occurs with the formation of metal clusters embedded in a stoichiometric crystalline oxide matrix. The metal clusters induce very specific transport properties; otherwise the films are still non-degenerate or degenerate semiconductors. By controlling the growth and plasma parameters, the properties of nanocomposite oxide films could be tailored from transparent and insulating films to absorbing and metallic films for energy applications, nonvolatile data storage devices and nonlinear optical devices. [1] M. Nistor et al., Appl. Surf. Sci. **563**, 150287 (2021); [2] M Nistor, et al., Appl. Surf. Sci. **307**, 455 (2014)

Plasma Technologies for the Creation of Tailorable Biosignalling Interfaces for Cell Culture Materials, Porous 3D Scaffolds and Micro/Nanoparticles Marcela Bilek, Clara T. Tran, Aaron Gilmour, Behnam Akhavan, Laura Haidar, Rashi Walia, Kanako Sato, Xuege A. Feng, Shelley Wickham, Anna Waterhouse, Giselle Yeo and Stuart Fraser; Univ of Sydney, Australia

Modern biomedical research and clinical practice rely on a wide range of materials formed into complex structures to provide suitable environments for cells and tissues. These materials range from metals and glasses to plastics and hydrogels. Constraints on mechanical and optical properties required for particular in-vivo and in-vitro applications are usually not compatible with providing the optimum biological microenvironments for the interfacing cell

types.

Here we describe rapid, wet-chemistry-free, plasma-based approaches that utilize environmentally-friendly ionized gases to activate a range of materials and structures for spontaneous, reagent-free, covalent functionalization with bioactive molecules. Molecules that can be immobilized whilst retaining their functions include but are not limited to oligonucleotides, enzymes, peptides, aptamers, cytokines, antibodies, cell-adhesion extra-cellular matrix molecules and histological dyes. Their immobilization occurs via surface-embedded radicals that are created by energetic ions from the ionized gas bombarding the materials' surfaces prior to contact with the biomolecules [1]. Typical time scales of cell cultures necessitate covalent tethering because physical bonding would be susceptible to exchange with biomolecules from the culture media and robust spatial patterning of the molecules is required to replicate physiologically relevant structures.

This presentation will examine the fundamental science and process adaptions that enable such surface modifications to be applied to the internal surfaces of multi-well plates, complex, porous materials and micro/nanostructures whilst retaining favorable optical properties. Strategies to pattern immobilized molecules on the surfaces will be examined. Applications enabling biological studies of the response of individual cells to proteins on a sub-cellular scale [3], and the preparation of multi-functionalizable nanoparticles [4] will be discussed. The surface embedded radicals are shown to enable polymerization of hydrogels from thus activated surfaces [5] and control of the density and orientation of surface-immobilized bioactive peptides through pH variations and/or the application of external electric fields during the immobilization [6].

Carbon Decarbonase—Plasma-Electrified Nanocarbon Processes for Zero-Carbon World Kostya (. Ostrikov[1], Wei-Hung Chiang[2], Zheng Bo[3], Holger Kersten[4], Igor Denysenko[5], Volker Brueser[6] and Liming Dai[7]; [1]QUT, Australia; [2]National Taiwan University of Science and Technology, Taiwan; [3]Zhejiang University, China; [4]University of Kiel, Germany; [5]Kharkiv Karazin National University, Ukraine; [6]INP Greifswald, Germany; [7]University of New South Wales, Australia

This presentation focuses on the applications of plasma nanoscienice and nanotechnology to produce functional solid nanocarbon materials, liquid fuels and chemicals, and value-added gaseous products through the plasma-enabled conversion of carbon-rich precursors. These plasma-enabled processes are pursued for the development of clean energy and sustainable green chemistry solutions to achieve zero-carbon-emissions industrial processes and help decarbonize the way we live more broadly. Uisng the analogy with natural enzymes where naming conventions include their function, and also the "-ase“ ending, here we introduce a concept of "carbon decarbonase“. This concept implies the production of value-added carbon products typically from carbon-rich waste (in solid, liquid of gaseous forms). These waste-derived carbon products in turn present interesting advanced functional properties which help achieve the global goals of decarbonozing the world, set by the recent UN sustainability programs and climate-change meetings. These carbon-based functional "decarbonases“ include water desalination and purification membranes, advanced structures for energy conversion in its various forms, electrocatalytic and photocatalytic processes for energy and environmental applications, electrode materials for next-generation energy storage materials and several others. These applications are ultimately aimed for decarbonising the main greenhouse gas emissions generating industries. Radically new approaches are needed to achieve these challenging goals, and one of the viable solutions is beased on electrification of the production of materials, chemicals, and fuels. Selected case studies will discuss the utilization of the *re-carbon – de-carbon – up-carbon* sustainable cycle in the production of advanced carbon nanomaterials which can perform as "decarbonases“. To this end, we apply the innovative P2X (Power-to-X) approach, where X denotes the many products that can be fabricated using clean and renewable power P, including plasma-electrified power. We discuss several possibilities to utilize the plasma-power (plasma-P in P2X equation), paying particular attention to highly-efficient processes and technologies based on low-temperature plasmas, including low-pressure and atmospheric-pressure plasma discharges. Applications of plasmas to produce selected health, biomedical, and hygiene products using the highlighted approaches are discussed as well. Support from the Alexander von Humboldt Foundation through the Humboldt Award Program, the Australian Research Council, Centre for Materials Science, Centre for Clean Energy Technologies and Practices, and Centre for Waste-free-World is kindly appreciated.

Nonthermal Plasma-Sustained CO_2 Methanation Over Ru-Based Multi-Metallic Catalysts Chunyuan Zhan[1], Shuya Xu[1], Hyun-Ha Kim[2] and Tomohiro Nozaki[1]; [1]Tokyo Institute of Technology, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

As a future low-carbon technology with minimum CO_2 emission, synthetic methane formation from CO_2, known as methanation or Sabatier reaction, is being highlighted ($CO_2 + 4H_2 = CH_4 + 2H_2O$; DH = -165 kJ/mol). Methanation is an exothermic reaction and the low-temperature condition is favored thermodynamically to achieve high CH_4 selectivity. Meantime, room temperature operation is obviously impossible kinetically: Catalyst temperature needs to increase up to 300-400 °C so that methanation reaction occurs at a high reaction rate while maintaining high selectivity. If catalyst activity is excellent, catalyst temperature reaches up to 500 C, creating a detrimental hotspot at the reactor inlet: high-performance catalyst would conflict with the low-temperature operation and high CH_4 selectivity and yield may not be realized. In order to optimize reaction conditions, high CH_4 selectivity, and yield, nonthermal plasma (NTP) was applied to heterogeneous catalytic reactions. NTP activates CO_2 and H_2 which promotes methanation at 100 C, while heat generation by methanation cooperatively promotes radical-enhance methanation at an elevated temperature of around 300 C. As a result, CH_4 yield achieved 100 % without an external heating source. NTP-catalyst interfacial reaction is the primary key to the reaction enhancement, while unique heat and mass transfer pray a unique role in the methanation reaction at high yield.
This study focuses on the nonthermal plasma effect on CO_2 methanation over Ru-based multi-metallic catalyst using dielectric barrier discharge (DBD). To this end, CO_2 conversion behaviors in a packed-bed DBD reactor at 30 kPa with catalyst temperature between 150 °C and 400 °C were investigated. Two types of catalysts were studied: First, La(3wt%)-Ni(11wt%)/Al_2O_3 catalyst was studied as a control catalyst. Second, this catalyst was modified by adding Ru(1wt%) in order to promote hydrogen spillover which is the key step for CH_4 synthesis at high yield [1]. The total flow rate was 1200 cm^3/min (at STP*) and dielectric barrier discharge (DBD) was applied at 30 W which corresponds to the specific energy input of 0.38 eV/molecule. H_2/CO_2 ratio was varied from 2 to 10.
Ru-modified catalyst yielded CH_4 selectivity and CO_2 conversion of 100%, respectively at 300 °C: CH_4 yield reached the thermodynamic equilibrium. In contrast, without Ru modification, CH_4 yield was 30% with 60% CH_4 selectivity at 350 °C. Moreover, there is no reaction promotion by DBD without Ru at all [2]. Obviously, Ru promotes hydrogen spillover that promotes CO_2 conversion and CH_4 selectivity simultaneously. More importantly, the catalytic performance of Ru-modified catalyst is further improved by superposing DBD.
The tentative reaction pathway is as follows. CO_2 and H_2 are dissociated on Ru and Ni respectively, while Ru also provides H adsorption sites that spill over hydrogen to nearby Ni sites. CO_2 is directly reduced to CO, followed by C or CH_xO formation and then hydrogenated to form CH_4. Additionally, CO

is obtained from formate (HCOO) through prior generation of bicarbonate (HCO_3) while the Ru-support interface and Lanthanum (La) make contributions to this. Our previous study showed that La provides reactive cites which form carbonate species when CO_2 is activated by DBD [3]. Carbonate further reacts with surface hydrogen when Ru is co-exist nearby La and Ni. HAADF-STEM analysis support such mechanism because Ru, Ni, and La are well dispersed and overlapped on Al_2O_3 support. We are performing *in situ* infrared absorption spectroscopy which reveals a transient behavior of surface species under the presence of DBD. More detailed mechanistic insight is presented in the symposium.
* STP: Standard Temperature and Pressure (25 °C and 101 kPa).

Surface Morphology Refinement and Laves Phase Control of Inconel 718 During Plasma Arc Additive Manufacturing by Alternating Magnetic Field Yi Zheng; Shanghai Key Laboratory of Materials Laser Processing and Modification, School of Materials Science and Engineering, Shanghai Jiao Tong University, China

Improving formability and mechanical properties has always been one of the challenges in the field of additive manufacturing (AM) of nickel-based superalloys. In this work, the effect of a coaxially coupled alternating magnetic field (AMF) on surface morphology and mechanical properties of plasma arc additive manufactured Inconel 718 deposit were investigated. The exploratory experiments involve two aspects: (i) the effect of different AMF parameter on the morphology and grain structure of the single-pass bead was explored and (ii) an appropriate AMF (30Hz, 12mt) parameter was selected for the fabrication of a 20-layer Inconel 718 thin-walled deposit. Results show that the electromagnetic stirring promoted grain refinement of the single-pass bead, and the finest grains were achieved with AMF of 12mt and 30Hz. The Lorentz force induced by AMF strongly changes the flow behavior of the plasma jet and the molten pool, suppressing the tendency of the liquid metal in the molten pool to flow down on the two side face of deposit, which in turn remarkable improved the surface accuracy of the thin-walled deposit. Furthermore, the electromagnetic stirring induced by AMF can effectively enhance the convection between the dendrites, which could not only contribute to the formation of finer dendrites but also alleviates the enrichment of the elements (i.e., Nb and Mo) at solid-liquid interface and inhibits the precipitation of Laves phase. The smallest primary dendritic arm spacing (~13 μm) and lowest Laves phases area fraction (3.12%) were witnessed in the bottom region of the AMF-assisted deposit. The mechanical test confirmed that the microhardness of the deposit was moderately improved and the tensile properties were slightly enhanced compared with the counterpart without AMF. This paper provides guidelines for tailoring the microstructure and the mechanical properties of Inconel 718 via AMF, indicating the significant application potential of AMF for the arc-based AM process.

9:15 PM SF03.12.04
Electrical Explosion as a Methodology for One-Step Preparation of Nano-Materials with Particular Structure and Composition Chen Li[1], Ruoyu Han[1], Yuchen Cao[1], Qifan Li[2] and Ming Gao[3]; [1]Beijing Institute of Technology, China; [2]University of Electronic Science and Technology of China, China; [3]Shenzhen Institute of Advanced Technology, Chinese Academy of Sciences, China

Electrical explosion, characterized by ultrafast heating ($dT/dt \sim 10^{11}$ K/s) and quenching (10^{10} K/s) rates of the sample, is a powerful tool for synthesizing nanomaterials, including pure metal, alloy and metallic compounds and composites. This method is highly productive (200 g/h or more) and provides high-quality powders with particle size less than 100 nm; moreover, μm/mm-thick coating or film can be synthesized within a short period (μs/ms timescale). Benefitted from the simple and inexpensive device as well as the great efficient, it provides desirable possibility for industrial production. Micromorphology, microstructure and functionality should be most concerned in nanomaterials filed. Researches including our works show that the produced products characteristics is prominently influenced by the explosive behaviors and dynamic process of wires. For example, the thermal instability (e.g. stratification) in discharge process who causes the discrepant parameters of density and temperature will leads to the inhomogeneous nanoparticle size. Sufficient plasma process maintains the exploded products at a high temperature and promotes the growth process after nucleation, as a result, average particle size increases. Different breakdown modes, like surficial or internal, lead to distinctive energy deposition mechanism (Joule heating for surface breakdown and heat transport/radiation for internal) and result in relatively dispersive nanoparticles or agglomerated particle-clusters, respectively. Except nanoparticles produced by exploding wire itself, the accompanied effect, like strong shockwaves and high-speed expanded metallic products (~ km/s), is valuable in layered materials exfoliation and surface decoration. Exploding a copper wire in a graphite powder-contained tube (polymethyl methacrylate-PMMA), the strong impact of pressure and thermal metal turbulence effectively exfoliate graphite into thin nanosheets, and copper vapor quenches and nucleates on the surface of the nanosheets forming homogeneous nanoparticles (＜100 nm). A novel structure of metallic elements decorated-thin nanosheets based composite is synthesized. Moreover, other layered materials (e.g., black phosphorus and bismuth selenide) can also be exfoliated and decorated by this method. To sum up, whatever use exploding wire as the source for nanomaterials production or as a tool for materials treatment due to its high-pressure and temperature attributions, explosive behaviors and dynamic process are the most substantial influenced elements. Further investigating on the physical mechanisms can give a significative guidance on practical application.

SESSION SF03.13: On-Demand Presentation

Plasma Assisted *In Situ* Synthesis of Nanodiamonds for Functional Textiles Karan Chandrakar; Indian Institute of Technology Delhi, India

Carbonaceous material is abundant in nature, and its nanostructures have drawn interest due to their unique features. The conventional synthesis of these nanostructures is a time-consuming procedure that necessitates the utilization of high temperature and pressure. In this study, the utilization of atmospheric pressure low-temperature plasma for *in-situ* production of carbon nanostructures on polyester fabric surface was investigated.
The nanostructures formed due to the *in-situ* plasma synthesis from carbon precursor (alcohol) were characterized by HRTEM-Saed patterns and Raman spectra which confirmed the formation of crystals of nanodiamonds. The surface modification was found to significantly enhance the functional properties, such as wettability and flame retardancy, of the polyester fabric, which were also wash durable. FTIR and Raman spectroscopies indicated the existence of interactive forces between the insitu formed nanodiamonds and the polyester surface. This research presents a revolutionary method for in-situ functionalization of textiles by carbon nanodiamonds that does not compromise the intrinsic qualities of the material used for various functional applications.
Key words : Carbon nanostructures, Nanodiamond, Polyester

Dislocation, Disconnection, Disclination, Step and Facet Associated with Twinning in Metals and Minerals Jian Wang; University of Nebraska--Lincoln, United States

Due to the small shear vector associated with twinning, deformation twining is often activated in crystalline materials, especially for metals with low symmetry or low stack fault energy and minerals with large lattice constant. Nucleation, propagation and thickening of deformation twins are accomplished through gliding of twinning dislocations associated with atomic shuffles. Twinning dislocation has both dislocation character and step character. It is generally observed that twinning dislocations pile up to form coherency gliding disclination, step and even facet during twinning. The topological model demonstrates that such terraced interfaces, with coherency strains accommodated by arrays of dislocations and disconnections, can migrate without long-range diffusion. In this lecture, our objective is to concentrate on defects relevant to interface motion, and these exhibit dislocation, disclination, or step character, or some combination thereof. We take twinning in hcp metals as many defect examples. The definition of shuffles within the topological model is presented. The concept of anisotropic kinetics for twinning disconnections has recently been elucidated.

Analysis of Grain Boundary (GB) Structure and Dislocation-GB Interactions Using Unsupervised Machine Learning Nithin Mathew, Avanish Mishra, Sumit Suresh, Khanh Dang, Saryu Fensin and Edward Kober; Los Alamos National Laboratory, United States

Dislocation-Grain Boundary (GB) interactions play an important role in determining the mechanical response of structural materials. This interaction is strongly influenced by GB structure, especially in the presence of GB dislocations. Many methods have been proposed for characterization of GB structure using structural/polyhedral units, which have been applied to both minimum energy and metastable structures. We will present a method to characterize GB structure using a complete and symmetry-adapted set of atomic environment descriptors, namely the Strain functional descriptors (SFD), in conjunction with unsupervised machine learning methods such as Gaussian Mixture Models (GMM), Principal Component Analysis (PCA) and t-distributed Stochastic Neighbor Embedding (t-SNE). Structural units are identified for GBs, reducing thousands (~5000) of metastable states to six different classes. The physical insights derived from SFDs are used to isolate the distribution of deformed/undeformed atomic environments from these six classes at GB. The variation in the atomic arrangement at GB is further examined by developing a similarity metric to delineate GB regions into ‘most similar’ or ‘most dissimilar’ with respect to the undeformed lattice. Dislocation-GB interactions are analyzed using these classes and the similarity metric. Dislocation-GB interaction sites

with higher similarity (to undeformed lattice) results in transmission across the GB, whereas the lower similarity region leads to dislocation pinning/absorption due to local reconstructions. In addition, identified classes and the similarity metric are shown to be good descriptors for developing supervised machine learning models of GB properties.

9:30 AM SF04.01.04
Towards Quantum-Accurate Modeling of Polycrystalline Grain Boundary Environments Malik Wagih and Christopher A. Schuh; Massachusetts Institute of Technology, United States

The properties of grain boundaries (e.g., diffusion, mobility, and solute segregation) are strongly dependent on the array of the local atomic environments present at the boundary. Therefore, to fully understand the structure-property relationships for grain boundaries, it is essential to study grain boundaries with atomic resolution. However, the most important general low-symmetry grain boundaries are inaccessible to quantum mechanical simulation methods. As a result, researchers tend to focus on high-symmetry coincident site lattice (CSL) grain boundaries in bicrystals, which are accessible to quantum methods, as opposed to the more complex polycrystalline grain boundaries. In this talk, using solute segregation for illustration, we will discuss the shortcomings of using CSL grain boundaries as a general model for grain boundary environments. In addition, we will discuss our recently developed algorithmic framework that can be used to study grain boundary local atomic environments in polycrystals with quantum accuracy. Using this framework, we are able to directly compute from quantum methods the full spectrum of solute segregation energies in polycrystals, and to build a comprehensive segregation database across the alloy space.

Grain Boundary-Dislocation Interaction Simulations Designed to Allow Transmission David E. Page[1], David T. Fullwood[1], Robert Wagoner[2] and Eric R. Homer[1]; [1]Brigham Young Univ, United States; [2]The Ohio State University, United States

The advance of experimental and simulation tools have advanced our ability to examine grain boundary (GB)-dislocation interactions in greater numbers and detail. These interactions underpin the well-known Hall-Petch relationship, which still lacks understanding of just how each individual GB-dislocation interaction contributes to the overall material response. Predicting the types of GB-dislocation interactions that can occur remains a challenge because the conditions for each can be so complex and unique. We designed a specific set of simulations to address these challenges and account for the variability that is inherent in these types of interactions. The simulations are limited to [112] tilt boundaries in FCC Ni, such that slip plane and slip direction alignment are maximized for transmission. Additionally, it is well-known that GBs can assume different atomic configurations, so we examined 3 different atomic structures for each GB. We present the results of these simulations and the corresponding GB-dislocation interactions. Interestingly, despite the attempts to maximize transmission in these simulations, only 4 of the 27 simulations show direct transmission. Another 5 simulations have dislocation nucleation at another site, somewhat removed from the site of impact. The remaining simulations demonstrate absorption of the dislocation with no indications of transmission or nucleation of any kind. These results are discussed in the context of the literature and the impact it could have on how we may wish to consider GB-dislocation interactions in general.

11:00 AM *SF04.02.02
Grain Boundary Dislocation Interaction Using Atomistic Modeling Saryu Fensin, Sumit Suresh, Khanh Dang, Nithin Mathew and Avanish Mishra; Los Alamos National Laboratory, United States

A material's ability to accommodate stress induced through mechanical loads is dependent on the ease with which dislocations (line defects) can move through the microstructure to relieve accumulated stress. Grain boundaries (GBs) are the largest impediment to this motion – this is true to some extent regardless of the grain size. The GB structure defines whether a dislocation can transmit across a GB, be partially absorbed at the GB, or glide along the GB and re-emit, altering the GB structure. Our recent MD results suggest that Dislocation grain Boundary interactions (DiGBi) are sensitive to GB structure as characterized by structural units that make up the GB. This work shows that altering the GB structure by changing the GB plane, causes changes in the structural units which alters GB interactions with dislocation loops. However, outstanding questions remain about DiGBi as a function of changes in the local atomic arrangements of GBs. This talk will show examples highlighting the affect of altering grain boundary structure on interaction with dislocations.

11:30 AM SF04.02.03
Calculations of Grain Boundaries with a Parametrized Embedded Atom Method Interatomic Potential Yasir Mahmood[1], Murray Daw[1], Michael Chandross[2] and Fadi Abdeljawad[1]; [1]Clemson University, United States; [2]Sandia National Laboratories, United States

Atomic simulations based on inter-atomic potentials offer a powerful tool for a fundamental understanding of materials processes and properties. The conventional approach for devising an interatomic potential is fitting a set of functions to basic properties obtained from experiments or density functional theory calculations, or both, and using this fit to explore more complex properties. Recently, Daw & Chandross [1] have introduced a comparatively simple parametric functional form based of the Embedded Atom Method for FCC metals. This model takes an inside-out approach, allowing us to generically explore the dependencies of complex properties on the function parameters, and then determining the parameter space that corresponds to a real element. Due to the generic nature of this approach, the model is referred to as EAM-X. In this work, we explore FCC grain boundary (GB) properties in this EAM-X parameter space. We use a representative set of [001] and [110] symmetric tilt, [111] symmetric twist, and [001] asymmetric tilt boundaries. We find that the GB energy can be factored neatly into two parts: one that depends on the boundary parameters evaluated at a chosen reference point in the parameter space, the other being a smooth function of the EAM-X parameters. Generally, the second factor correlates very well with the shear moduli, confirming earlier observations by Holm, Olmsted and Foiles [2], and Foiles [3]. On the whole, our approach provides future avenues to rapidly explore trends in GB properties for a wide range of FCC metals.

11:45 AM SF04.02.04
Development of Strain Functionals for Physics Informed Machine Learning of Grain Boundary Structures Edward M. Kober[1], Avanish Mishra[1], Colin M. Adams[2] and Nithin Mathew[1]; [1]Los Alamos National Laboratory, United States; [2]Arete, United States

The analysis of molecular dynamics simulations of the deformation of metals and the validation of potential functions used in these simulations compared require a robust set of descriptors that can identify a wide variety of crystal and defect structures. The use of strain functionals descriptors for characterizing such arbitrarily ordered atomistic structures is demonstrated here for use in conjunction with machine learning applications. This approach is derived using using a Taylor series expansion of the geometry of the local atomic neighborhood, ensuring both numerical convergence and a direct relationship to physical properties. They are reduced to a minimal non-redundant set using closure relationships from angular momentum / spherical tensor properties. The resulting functionals naturally describe the deformations in terms of simple physical concepts: measuring how tetrahedral or cubic a geometry is, how much shear or trigonal deformation is present. This formulation cleanly maps onto other entities that are described by tensor formulations: strain, stress, elasticity, and other physical properties. Using these as a basis facilitates the development of physically-informed models from machine-learning applications. Here, the method is extended out to sixth order, which is necessary to fully distinguish all possible crystallographic symmetries. The approach has been extended to the analysis of vector (velocities, forces) and tensor (stress, strain) fields as well. Applications of the method to the characterization of grain boundaries will be shown.

SESSION SF04.03: Grain Boundaries and Interfaces III
Session Chairs: Saryu Fensin and Nithin Mathew
Tuesday Afternoon, November 29, 2022
Sheraton, 3rd Floor, Berkeley

1:30 PM *SF04.03.01
On the Effect of 3D Grain Boundary Orientation on Slip Transfer and Fracture in Ti Eugenia Nieto[1,2], Eshan Ganju[3], Nikhilesh Chawla[3] and Javier Llorca[2,1]; [1]IMDEA Materials Institute, Spain; [2]Technical University of Madrid, Spain; [3]Purdue University, United States

Grain boundaries play a crucial role during plastic deformation of polycrystals, acting as physical barriers that hinder dislocation motion and potential sites for damage nucleation and fracture. Their influence is more severe in metals with hexagonal closed-packed lattice because of the limited number of available slip systems as well as the large differences in the critical resolved shear stresses to active dislocation slip, which difficult the accommodation of plastic deformation in the microstructure. Thus, it is important to develop robust geometrical criteria to assess whether slip transfer/blocking will occur at a given grain boundary and what is the influence of grain boundary orientation on the nucleation of cracks. Most of the experimental information available to this end has been obtained by means of slip trace analysis and high-resolution digital image correlation (HR-DIC) on the surface of deformed specimens in which the grain orientation was determined by electron backscatter diffraction (EBSD). However, these results lack information about the grain boundary orientation perpendicular to the surface, which is known to play a significant role to control slip transfer/blocking as well as damage nucleation at grain boundaries.

In this talk, the mechanisms of slip transfer and blocking are analyzed in commercially pure Ti thin foils subjected to uniaxial tensile loading. The microstructure of the polycrystal was characterized by means of laboratory diffraction contrast tomography (LabDCT) to obtain information about the crystallographic orientation of the grains as well as about the grain boundary geometry on the specimen surface and through the thickness. The samples presented a strong basal texture typical of cold rolled thin foils, with a bimodal distribution of grain boundary misorientation angles with either very little or highly disoriented grains. After tensile deformation, a thorough slip transfer/blocking analysis was performed in more than 300 grain boundaries via slip trace analysis coupled with HR-DIC in selected areas. The strain concentrations around grain boundary areas captured by HRDIC allowed to uniquely identify slip blocking/transfer events while the slip traces observed on the surface of the sample were correlated with the crystal orientation of the grains to determine the active slip system. In addition, intergranular cracks were identified at grain boundaries and triple junctions as well as transgranular cracks parallel to the active slip systems.

The information on the deformation and damage nucleation mechanisms was combined with the full 3D information of the microstructure provided by LabDCT to assess the influence of the 3D grain boundary orientation slip transfer and damage at grain boundaries. Different metrics based on geometrical factors (grain boundary misorientation, Luster-Morris parameter, residual Burgers vector, LRB factor) and/or driving forces (critical resolved shear stresses for slip and/or twinning) were employed to assess the likelihood of slip transfer/blocking and fracture across grain boundaries. These results provide novel information to understand the effect of grain boundaries in polycrystal deformation and to simulate their influence on the mechanical behavior.

2:00 PM *SF04.03.02
Slip Transmission Across Three-Dimensional Crystalline Interfaces Irene J. Beyerlein[1], Shuozhi Xu[1], Justin Cheng[2] and Nathan Mara[2]; [1]University of California, Santa Barbara, United States; [2]University of Minnesota, United States

Even after their introduction some decades ago, metallic nanostructured, multi-phase composites have continued to draw world-wide interest due to their exceptionally high strength and hardness and outstanding tolerance to extreme conditions, such as elevated temperatures, irradiation, and high-rate impact. The combination makes them an exciting class of materials for meeting the demands of future applications, such as nuclear power reactors, propulsion systems, and microelectromechanical devices. At present, however, they are not suitable for long-time service due to insufficient toughness and a greater tendency to develop shear localizations than their more coarsely structured counterparts. A unique and important feature of these materials is the physical dominance of biphase interfaces, the atomically thick boundary between the dissimilar phases in the composite. The deformation response of the biphase interface and interactions with moving dislocations can have a profound effect on overall material behavior, suggesting the appealing potential to control its localization tendencies via design of the interface itself. In this talk, we will focus on the behavior of nanolayered nanocomposites made with extraordinarily “thick” interfaces under mechanical deformation. We will discuss efforts to characterize and design the morphology, size, and chemistry of the interface, especially in its third dimension (normal to the interface plane). Results from a model developed to simulate the dynamic interactions of

individual dislocations and these 3D interfaces under applied stress will be presented. The talk will share our findings to date, which indicate that both the macroscopic and microscopic responses are sensitive to interface thickness and through-thickness chemical gradients. We will conclude with a discussion on the intriguing possibility to design 3D thick interfaces to attenuate shear concentrations and postpone instabilities without sacrificing strength.

2:30 PM SF04.03.03
Extracting Relative Grain Boundary Energies from Triple Junction Geometry in Nanocrystalline Thin Films—Effect of Film Geometry on Interfacial Equilibrium Matthew J. Patrick[1], Gregory S. Rohrer[2], Ooraphan Chirayutthanasak[3], Sutatch Ratanaphan[3], Eric R. Homer[4], Gus L. Hart[4], Yekaterina Epshteyn[5] and Katayun Barmak[1]; [1]Columbia University, United States; [2]Carnegie Mellon University, United States; [3]King Mongkut's University of Technology, Thailand; [4]Brigham Young University, United States; [5]The University of Utah, United States

Grain boundary character distributions (GBCD) and relative grain boundary energy distributions (GBED) are routinely calculated from 3D serial-section electron backscatter diffraction (EBSD) data from microcrystalline bulk samples, and are consistently found to be inversely correlated. The GBEDs are calculated based on triple junction geometry and the assumption of force balance via the Herring condition. For nanocrystalline thin films, precession electron diffraction (PED) has proven an effective method to measure the GBCD, but the GBED has not been reconstructed. In the work reported here, we adapt the established energy reconstruction method to PED data from films with columnar grain structures, where serial sectioning is not required to determine boundary inclination. For a 40 nm-thick, sputter-deposited, nanocrystalline tungsten film, the relative GBED obtained by this method does not correlate to grain boundary energies which are interpolated with Read-Shockley-Wolf (RSW) functions from molecular dynamics calculations. Furthermore, while the boundary populations in this data-set have been previously demonstrated to show both an inverse log-linear correlation with the RSW-calculated energies and a clear correlation to the GBCD of comparable microcrystalline bcc materials, the populations of boundaries show no inverse relationship to the relative energies obtained here. This failure indicated that the assumed Herring condition does not successfully relate triple junction geometry and boundary energy in this system, and thus cannot be used to extract relative boundary energies. This film had not experienced grain growth, however, and so its structure may reflect a metastable state. To address this, a set of aluminum samples were also examined: a film in its as-deposited state and after 30 and 150 minutes at 400°C. Here, the film experiences significant grain growth, with equivalent circle diameter of mean area increasing by more than 40% after 150 minutes of annealing. Still, when the relative energies are reconstructed from the data-set the inverse relationship with population is not recovered, even when accounting for certain boundaries (i.e. coherent twins) which are not likely perpendicular to the plane of the film. When compared to aluminum grain boundary energies recently calculated with molecular dynamics, the populations show an obvious inverse trend with energy, in line with the previously reported correlation of the nanocrystalline GBCD to the bulk microcrystalline results. The failure of the energy reconstruction model to reproduce the expected trends likely implies that the assumed conventional Herring condition of force balance is not an appropriate avenue for energy extraction in thin films, indicating that the Herring equation does not fully specify the geometry at triple junctions in these systems. While boundary character follows well established thermodynamic expectations, this result points to other factors, including those related to thin film geometry, which must play a significant role in determining triple junction geometry in these spatially constrained systems.

Hydrogen Trapping at Grain Boundaries and Embrittlement in High-Strength Al-Alloys Dierk R. Raabe, Huan Zhao and Baptiste Gault; Max Planck Institute for Iron Research, Germany

High-strength Al-alloys help reduce the weight of automobiles, but they are susceptible to environmental degradation. Hydrogen (H) embrittlement is often pointed as the main culprit, however, the mechanisms underpinning failure are elusive: atomic-scale analysis of H inside an alloy remains a challenge, and this prevents deploying alloy design strategies to enhance the materials' durability. Here we successfully performed near-atomic scale analysis of H trapped in second-phase particles and at grain boundaries in a high-strength 7xxx Al-alloy. We used these observations to guide atomistic *ab-initio* calculations which show that the co-segregation of alloying elements and H favours grain boundary decohesion, while the strong partitioning of H into the second-phases removes solute H from the matrix, hence preventing H-embrittlement. Our insights further advance the mechanistic understanding of H-assisted embrittlement in Al-alloys, emphasizing the role of H-traps in retarding cracking and guiding new alloy design (1).

4:00 PM DISCUSSION TIME

4:15 PM *SF04.04.03
Tracking Grain Boundary Microstates via Microscopy and Deep Learning Emily Hopkins[1], Ryan Jacobs[2], Priyam Patki[3], Kevin Field[3], Dane Morgan[2], Jaime Marian[4], David Srolovitz[5,6] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]University of Wisconsin–Madison, United States; [3]University of Michigan–Ann Arbor, United States; [4]University of California, Los Angeles, United States; [5]The Hong Kong University, Hong Kong; [6]University of Pennsylvania, United States

Achieving radiation tolerance in crystalline materials will require a thorough understanding of defect evolution and corresponding material responses to ion bombardment. Tailoring grain boundaries to behave as enhanced defect sinks poses a potential solution toward the development of more radiation tolerant materials; however, critical nuances illustrating the microstructural response of grain boundaries under irradiation have yet to be explained. In particular, the relationship between GB structural states and their effect on the rate of defect absorption is unclear. In this study, we utilize automated object detection models of in situ TEM experiments to offer new insight into transient GB states and analyze cyclic absorption behavior. By providing an indicator of changes in GB absorption mechanisms and recognizing GB absorption responses in real time, we move closer to explaining GB metastability with the onset of radiation damage.

Plasticity Mechanisms in Laser Processed Al-Si Alloys with Heterogeneous Microstructures Amit Misra[1] and Jian Wang[2]; [1]University of Michigan–Ann Arbor, United States; [2]University of Nebraska–Lincoln, United States

A range of heterogeneous Al-Si microstructures, comprising of nanoscale Al-Si eutectic domains with nanotwinned Si fibers and sub-micron-scale primary Al, with or without Si nano-precipitates, were fabricated by processing as-cast Al-20wt.%Si alloy using laser rapid solidification. *In situ* tensile testing in a scanning electron microscope demonstrated high tensile strength, ≈600 MPa, and ductility, ≈10%, and high strain hardening rate, ≈7 GPa. Microstructural characterization revealed the plastic co-deformation mechanisms between soft Al grains and the surrounding relatively harder nanoscale Al-Si eutectic. The progression of plasticity in nanoscale Al-Si eutectic with increasing applied strain is accommodated by dislocation plasticity in the nano-Al channels and cracking in Si nanofibers. The propagation of nano-cracks is suppressed by surrounding Al, retaining good ductility of the sample. Cross-sectional scanning/transmission electron microscopy of nanoindents revealed a transition in morphology from high aspect ratio nano-fibrous Si to short nano-fibrous Si, preferentially located along triple junctions of the dynamically recovered sub-grains in Al. Molecular dynamics simulations of the interaction of glide dislocations in Al with the flat Si/Al interfaces revealed climb and cross-slip mechanisms but no direct slip transmission into Si. The role of the heterogeneous Al–Si microstructure in enhancing strain hardening rate and resulting in plasticity in micro-tensile sample even after fracture of nanoscale Si fibers is discussed by integrating experimental characterization with atomistic simulations and dislocation theory. This research is supported by DOE, Office of Science, Office of Basic Energy Sciences.

Interfaces Induced Extra Strain Hardening in Additive Manufactured Laminated Steels Zhi Li[1] and Huajian Gao[2,1]; [1]Agency for Science, Technology and Research, Singapore; [2]Nanyang Technological University, Singapore

Metallic alloys with heterogeneous microstructure have demonstrated superior mechanical properties, including high strength, extra work hardening and high ductility. By manipulating the thermal stability and inducing site-specific recrystallization in metal additive manufacturing, laminated 316L steels have been recently printed with various lamella structures and phase compositions, demonstrating extra strain hardening and high ultimate strength under tensile loading. We present a theoretical and numerical study on the flow behavior of the laminated structure by considering the strengthening effects of the interface affected zone. It is shown collectively from the experiments and simulations that extra back stress is developed in the interface affected zone during the deformation process, and the magnitude of this extra back stress changes with the lamella structure. Our work provides new understandings of the deformation mechanism in the heterogeneous alloys and demonstrates the potential of engineering the interfaces for enhanced mechanical properties.

Kinetically-Driven Microstructure and Mechanical Properties of 3D Micro-Architected Metal Alloys Formed via Hydrogel Infusion Additive Manufacturing (HIAM) Thomas Tran, Rebecca Gallivan and Julia R. Greer; California Institute of Technology, United States

Hydrogel infusion-based additive manufacturing (HIAM) to create 3D micro-architected metals is unique in its absence of melt pool solidification. By nucleating and growing parent oxide phases and subsequently reducing them, HIAM provides a kinetically-driven pathway for forming boundaries in polycrystalline metal microarchitectures. Using EBSD and TEM analysis, we characterize these boundaries, defects, and other microstructural features within Cu, Ni, and Cu-Ni alloys produced by this technique over a span of thermal treatment conditions. These metals and alloys exhibit anomalous nanoindentation hardnesses, exceeding predictions of the classical Hall-Petch relation by at least 30%, which we postulate to be due to the present networks of high-angle grain boundaries, annealing twin boundaries, and higher-order coincident site lattice (CSL) boundaries. We explore the role of formed boundaries by conducting site-specific compression experiments on nano- and micropillars carved from individual grains -- as well as spanning specific boundaries --, isolating the contribution of each type of boundary to plasticity in HIAM-produced metals. We present a phenomenological framework that accounts for the contribution of special boundaries to global mechanical properties, which helps inform HIAM as a novel means to create 3D-architected metals and alloys with non-equilibrium microstructures and compositions.

Phase-Field Modeling of Grain Growth in Thin Films on Planar and Non-Planar Substrates Ahmad Nadeem, Hwanwook Lee, Muhammad H. Ali, Kiran Raj and Kwon Yongwoo; Hongik University, Soeul, Korea (the Republic of)

The phase-field technique is the most effective for modeling and simulating microstructure evolution, such as grain formation in a polysilicon channel of V-NAND flash memory. It estimates the development of grain boundaries in areas with excessive free energy. The material system should evolve in such a way that the total free energy, which is the driving factor for grain growth, is minimized, resulting in a smaller grain boundary. Process engineers put a lot of emphasis on grain size since it is strongly connected to effective material properties. We adopt phase-field method to simulate the microstructure evolution during the post-annealing to crystallize as-deposited amorphous films in the semiconductor processing. This process is called solid-phase crystallization. Initially, nucleation occurs and then grain growth follows. Our main interest is studying how the final grain size is determined. The dependence on nucleation density, nucleation site location, film thickness, and annealing temperature is primarily investigated. The sheet resistance and conductivity of the polycrystalline films derived from phase-field modeling are also calculated. Nonplanar films are also being studied because the designs of cutting-edge nanodevices, such as multi-bridge channel field effect transistor (MBC-FET) in sub 3nm nodes, 3D-NAND flash memory, and so on, are becoming more three-dimensional. Accordingly, the grain formation in geometrically confined structures is becoming of great interest. In this work, we demonstrate our phase-field simulation on thin films for which we developed our in-house C++ code and present our simulation results.

9:45 AM SF04.05.05
Regularized Anisotropic Motion-By-Curvature in Phase-Field Theory Thomas Philippe; Condensed Matter Physics Group, Ecole polytechnique, France

The kinetic equation for anisotropic motion-by curvature, largely used to model the dynamics of grain boundaries and interfaces, is ill-posed when the surface energy is strongly anisotropic. In this case, corners or edges are present on the Wulff shape, which span a range of missing orientations. In the sharp-interface problem the surface energy is augmented with a curvature-dependent term that rounds the corners and regularizes the dynamic equations. This introduces a new length scale in the problem, the corner size. In phase-field theory, an approximation of the Willmore energy is often added to regularize the model. We discuss the convergence of the Allen-Cahn version of the regularized phase-field model toward the sharp-interface theory for

strongly anisotropic motion-by-curvature, in two and three dimensions, for large corner size with respect to interface thickness. We also study the opposite limit, for corner size smaller than the interface width, and show that the shape of corners differs from the sharp-interface picture. However, we find that the phase transition at the interface is preserved and presents the same properties than the classical problem. This demonstrates that regularization also operates in the intermediate regime, i.e. for corner size and interface width of same order, that is numerically more attractive and allows for simulations in three-dimensions. As an illustration, we investigate the dynamics of the faceting instability, when initially unstable surfaces decompose into stable facets. Finally, we study nucleation of crystal surfaces in a two-phase system.

Predicting Variants During Phase Transformation and Twinning in BCC Microstructures During Deformation and Unloading Avinash M. Dongare and Avanish Mishra; University of Connecticut, United States

The deformation behavior of BCC metal microstructures at high pressures has contributions from dislocation slip, deformation twinning, and phase transformation. While deformation twinning is a common mode of deformation in BCC metals at high pressures, Fe-based microstructures also demonstrate a BCC → HCP phase transformation when deformed above a threshold pressure of ~13 GPa. Recent studies have demonstrated the BCC à HCP à BCC phase transformation can result in a distribution of twins in the bcc microstructure. This distribution of twins is attributed to the selection of HCP phase variants during compression and their stability and reverse transformations during unloading. Understanding and predicting the role of microstructure and stress-states on these variant selections during deformation and their stability and reverse transformation behavior during unloading is important The current efforts to investigate variant selections in BCC metals are largely limited to real-time *in situ* x-ray diffraction (XRD) and for single-crystal (sc) systems. In addition, the interpretations of the plasticity contributions from diffractograms are non-trivial, especially when multiple modes of deformation may be operating. Molecular dynamics (MD) simulations can successfully capture various deformation modes in metals and complement experiments using simulated diffractograms at various stages of evolution. This talk will discuss the use of virtual XRD to characterize the variant selections and their plasticity contributions during plastic deformation. The simulations investigate the role of BCC microstructure and loading stress-states on variant selections during phase transformation and twinning in BCC Fe microstructures as predicted using MD simulations. In addition, the simulations investigate the stability and the reverse transformation behavior of the variants during unloading. The simulations are able to unravel the role of variant selection and transformation that renders a distribution of twin boundaries in unloaded microstructures. The characterization of the phase/twin variants is based on a newly developed virtual texture analysis (VirTex) algorithm that enables the creation of EBSD maps of the simulated microstructures to compare with experimental EBSD maps. In addition, the capabilities and limitations of virtual x-ray diffraction (XRD) on the simulated microstructures to characterize the phase/twin variants will be presented.

11:00 AM *SF04.06.02
Solute Partitioning Behavior within Nanocrystalline Grain Boundaries Gregory B. Thompson[1], Xuyang Zhou[1,2], Reza Kamachali[3], Jonathan Priedeman[1], Dierk R. Raabe[2], Brad L. Boyce[4] and Blythe G. Clark[4]; [1]University of Alabama, United States; [2]MPIE, Germany; [3]Federal Institute for Materials Research and Testing (BAM), Germany; [4]Sandia National Laboratories, United States

Spinodal decomposition is often described as a 'barrier-free' transformation. Unlike nucleation and growth, where defects play a dominate role in the nucleation of the secondary phase, such defects are largely considered inconsequential to this continuous phase transformation. At the nanoscale, where a high density of planar defects exists, their presence can have a profound influence on the temporal evolution of this phase transformation. In this presentation, the phase separation of a Pt(Au) nanocrystalline alloy is characterized using a correlative method of electron diffraction and atom probe. A competition between interfacial segregation to the grain boundaries and spinodal decomposition is observed. A density-based phase field model for the grain boundary character's influence on the Gibbsian free energy is used to elucidate this evolution. Finally, how the Au solute within the grain boundary regulates faceting is discussed.

11:30 AM SF04.06.03
Phase-Field Modeling of Solid-State Metathesis Reactions Guanglong Huang[1], David Montiel[1], Rebecca D. McAuliffe[2], Gabriel M. Veith[2] and Katsuyo Thornton[1]; [1]University of Michigan, United States; [2]Oak Ridge National Laboratory, United States

To fully understand the process of phase transformation, it is important to follow the evolution of the system in detail, including those occurring at interfaces. This is particularly true in solid-state metathesis (SSM) reactions, where multiple chemical species with different charge states interact in a complex manner. However, temporal and spatial resolutions available in experiments are often limited, posing a challenge to construct a full picture of the process. In this presentation, we will discuss an integrated experimental-modeling effort to address this issue. We propose a phase-field model to simulate the evolution of ionic concentrations (in terms of mole fractions) and phase fractions in SSM reactions. The evolution of ionic concentrations is obtained via the reduction of a free energy, including a free energy landscape that has local minima located at the compositions of products. We utilize two Lagrange multipliers to impose constraints on the sum of mole fractions and of electroneutrality. Using this model, we study the effect of different reaction pathways (e.g., bulk diffusion, grain boundary diffusion and surface diffusion), as well as the effect of the mobility of each ion on the reaction dynamics. We then demonstrate the capability of the model by applying it to simulate a thin-film reaction for the synthesis of FeS_2. The values of the thickness and roughness of the interface between two precursors are determined based on X-ray reflectivity measurements. We set the mobilities of ions based on the diffusivities suggested by the experiment. The simulated diffusion behavior is in qualitative agreement with the experiment. In addition, the simulation predicts a nonplanar evolution of phases, which was not initially expected.

11:45 AM SF04.06.04
Coupling Reversion and Partial Recrystallization for Hetero-Structured Metastable Microstructural Design Shaolou Wei and Cem Tasan; Massachusetts Institute of Technology, United States

Achieving a desirable strength-ductility synergy in metallic alloys indispensably relies on the understanding and control of crystalline defects and the

interplay involved therein. An effective pathway to approach this is to activate plastic strain-induced martensitic transformation because of the salient strain hardenability resulting from massive dislocation-phase boundary interactions. Provided the appreciable attempts to maximize the mechanical benefits of such a displacive transformation, microstructural design concepts based on its complementary part, *i.e.* martensite reversion via thermal annealing appear rather scant. Here we present a microstructural design strategy by combing plastic strain-induced epsilon-martensite reversion and partial recrystallization. We will show that by exploiting the displacive nature of epsilon-martensite reversion to promote strength, and by activating partial recrystallization to balance ductility, a feasible pathway to overcome the rule-of-mixture bound can be paved. Through *in situ* tensile tests under synchrotron X-ray diffraction and post-mortem electron channeling contrast imaging (ECCI) characterization, we underpin the dominant role of mechanical faulting throughout the entire strain hardening process. Assessments of individual strengthening mechanisms will also be presented to shed a bit more quantitative light on the heterogeneous microstructures by design.

1:30 PM *SF04.07.01
The Austenite/Martensite Interface Structure, Kinetics, Resulting Transformation Strain—Theory and Experiment William A. Curtin[1], F. Maresca[2], E. Polatidis[3], M. Smid[3] and H. Van Swygenhoven[3]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]U. Groningen, Netherlands; [3]Paul Scherrer Institute, Switzerland

In next-generation high-strength/high-toughness steels, the austenite/martensite (fcc/bcc) interface is the dominant microstructural feature controlling important properties. In spite of decades of research, the fundamental structure, mechanism of motion, and transformation strain due to this interface have remained uncertain. Here, an atomistic fcc-bcc iron interface is constructed that completely matches experimental observations and reveals a defect structure differing from longstanding theory assumptions while also violating conditions believed essential for a glissile interface. Based on this interface, we develop a new crystallographic double-shear theory of lath martensites that provides predictions in near-perfect agreement with both simulations and experiments. In a classic Fe-Ni-Mn alloy, we then use in-situ high resolution digital image correlation to measure the transformation strain and confirm the parameter-free theory [1]. The theory predicts increasing the fcc/bcc lattice parameter ratio increases the transformation strain, which is validated with literature data and then provides a new path for developing tougher high-strength steels.

Multiscale Simulations of Interfacial Effects in High Entropy Alloys Diana Farkas; Virginia Tech, United States

This presentation will address the multiplicity of possible interfacial structures in compositionally complex alloys and the possible effects on the material mechanical response. Atomistic simulation techniques with model empirical potentials are used to study the effects of compositional complexity on grain boundary structures and dislocation behavior under applied strain. A multiscale technique is utilized to study the fracture response of these alloys.

4:00 PM *SF04.08.02
Computational Studies of Interfaces in High Entropy Ceramics: Chemical Ordering, Structure and Stability Donald Brenner[1], Sam Diagle[1], Belicia Castillo[1], Simon Divilov[2], Hagen Eckert[2], Stefano Curtarolo[2], Jon-Paul Maria[3], Douglas Wolfe[3], Eva Zurek[4], Cormac Toher[5] and William Fahrenholtz[6]; [1]North Carolina State University, United States; [2]Duke University, United States; [3]The Pennsylvania State University, United States; [4]University at Buffalo, The State University of New York, United States; [5]The University of Texas at Dallas, United States; [6]Missouri University of Science and Technology, United States

It is well established in conventional alloys that stresses at grain boundaries, free surfaces, dislocations and related defects can attract solute atoms and in some cases induce ordering. In high-entropy ceramics, configurational entropy makes a relatively large contribution to the free energy (and hence stability) compared to ceramics with fewer components. Using first principles calculations and analytic modeling, we have been exploring whether interfaces and defects in high-entropy carbides induce similar chemical ordering, and if this ordering changes the interfacial stability and mechanical properties. Of particular interest are energies to form twins, whether ordering around dislocations increases (or decreases) the barrier for motion, and the effects of ordering on grain boundary energy, decohesion, and inter- versus trans-granular fracture.

4:30 PM SF04.08.04
Slip Behavior at Grain Boundaries Assessed with Nanoindentation Hardness TaNbTiV Refractory High Entropy Alloy Thomas R. Bieler and Eugenia Nieto; Michigan State University, United States

Preparation of refractory high entropy alloys by melt solidification led to dendritic segregation, which provides different compositions that can be used to assess the mechanical properties as a function of composition using nanoindentation arrays. EBSD orientation maps combined with backscattered electron images show that each grain consists of its own dendrite, and grain boundaries are usually along inter-dendritic zones. Hardness values track with local composition, with softer values in Ta dendrite cores and harder values in the interdendritic regions, but hardness also depended on grain orientation and grain boundaries. Relatively few indents exhibited obvious shear bands, which were usually correlated with {112} slip planes, and more often observed in the softer high-Ta dendrite cores. AFM characterization of selected indents on grain boundaries suggests uniform deformation on both sides of the

boundary such that quantifying effects related to slip transfer is difficult.

SF04.09.02
Effect of Elemental Segregation on Resistance of Grain Boundary Migration in High-Entropy Alloys Kohei Shiotani, Tomoaki Niiyama and Tomotsugu Shimokawa; Kanazawa University, Japan

High-entropy alloys (HEAs), which are solid solution materials obtained by mixing five or more than five elements with near equimolar fractions, have attracted significant attention because of their unique mechanical properties. Grain boundary (GB) migration velocity of some HEAs has been reported to be slower than that of conventional alloys; however, the origin of the slow GB migration is not yet fully understood. For dilute alloys, conventional theory and recent atomistic simulations have shown that dynamic GB segregation increases the driving force required for the GB migration; therefore, it is important to elucidate conditions under which dynamic GB segregation occurs in HEAs and its mechanism. In this study, we systematically investigate the dynamic GB segregation phenomena in HEAs byperforming molecular dynamics simulations of GB migration under various deformation conditions for equimolar and non-equimolar HEA models.
As model alloys, we use $(FeNiCrCo)_{1-x}Cu_x$, where the concentration of Cu is changed in the range of x = 0-1 and the other four elements are kept equimolar fractions each other. In this HEA model, Cu tends to segregate to GBs. The analysis models are bicrystal with a Σ17 tilt-GB. At the initial atomic configuration, five kinds of elements are randomly distributed on the bicrystal lattice sites. By applying shear deformation at various constant strain rates and 80 % of the melting temperature, we investigate the strain rate dependence of the resistance of GB migration caused by the dynamic GB segregation. The velocity of GB migration is proportional to the shear strain rate based on the shear-coupling theory.
First, through the analyses with the equimolar HEA (x = 0.2), it is found that the resistance of GB migration reaches the maximum at the GB migration velocity of 1 m/s. At velocities slower than 1 m/s, GB segregation by Cu can be observed, but at velocities faster than 1 m/s, the GB segregation is hardly observed. Calculation of the diffusion coefficient for Cu within the GBs shows that Cu can follow the moving GBs by GB diffusion. These suggest that the dynamic GB segregation increases the resistance of the GB migration and the drag capacity of Cu determines the GB migration velocity at the maximum driving force. Next, through the analyses with the non-equimolar HEAs, the resistance reaches the maximum at the Cu concentration of x = 0.6, where the difference in Cu concentration in the matrix and GB during the GB migration shows almost the maximum value. This indicates that different Cu concentrations in the matrix and the GB increases the resistance of GB migration. The results suggest that designing for diffusion capacity and tendency of GB segregation can produce HEAs that exhibit better mechanical properties.

8:30 AM *SF04.10.01
Tuning Nanocrystals and Nanocomposites by Doping and Interface Modification Daniel Kiener, Michael Wurmshuber, Michael Burtscher, Klemens Schmuck and Markus Alfreider; Montanuniversity Leoben, Austria

In order to accomplish a resource conserving future for our planet, it is inevitable to increase material performance. This requires on the one hand to design ever stronger materials to increase the load bearing capability of the materials employed in increasingly harsher environments. On the other hand, safety considerations also necessitate a certain ductility and fracture toughness in order to prevent fatal overload failure upon critical operation events. Furthermore, reuse and circular material use concepts also suggest to advance from overly complex alloying strategies back to lean alloying or even just minor doping additions.
To respond to these demands, we designed nanocrystalline W-based materials and nanocomposite based on the thermodynamically insoluble pairing of W with Cu. Starting from powders as initial input materials before refining to the bulk nanostructured material using severe plastic deformation, it remains a trivial task to vary the fraction of strong vs. ductile phase or to add minor amounts of doping elements, such as C, B, Hf of Re, to modify the material or interface conditions. The selection of these doping elements was guided by thermodynamic considerations and ab initio computations of interface properties.
Based on a comprehensive microstructural examination and micromechanical experiments, we will discuss how interface segregation engineering and microstructural design allow to adjust strength, ductility and fracture toughness of nanostructured and nanocomposite materials.

9:00 AM SF04.10.02
Spectrum of Grain Boundary Segregation Vibrational Entropy in Dilute Ni(Pd) Polycrystals Nutth Tuchinda and Christopher A. Schuh; Massachusetts Institute of Technology, United States

Understanding vibrational entropy of grain boundary segregation is important to understand the equilibrium state at finite temperatures. While the recent works have shown the importance of treating the grain boundary network as a collective of sites with varying atomic environments, progress in quantifying the distributions of segregation vibrational entropy is still limited to only a few systems for small coincident site lattice (CSL) boundaries. Here we apply a variant of the harmonic approximation to quantify the spectrum of vibrational entropy of grain boundary segregation in a Ni(Pd) polycrystalline system. The results show a strong correlation between 0-K segregation energy and vibrational entropy in agreement with previously reported results from small CSL boundaries using Monte Carlo simulations. The spectrum can be used with the established spectral thermodynamic framework to predict equilibrium solute content at finite temperatures, enabling a pathway to model interfacial segregation in polycrystalline materials at finite temperatures.

9:15 AM SF04.10.03

Grain-Boundary Solute Segregation and Associated Shear Localization Mechanisms in Random FCC Ag, BCC Nb and HCP Zr Polycrystals
Frederic Sansoz, Tara Nenninger and Eve-Audrey Picard; The University of Vermont, United States

Different segregation types in nanocrystalline alloys have been described in the literature as being either homogeneous or heterogeneous, which differently impacts their mechanical properties. In heterogeneous segregation, solute atoms are clustered along some grain boundaries (GBs), while other GB regions remain solute-free, as evidenced with Ni segregation in nanocrystalline Ag. This talk presents our recent efforts to better understand solute segregation and interaction within random GB networks, with particular focus on heterogeneous Ni segregation in different FCC, BCC and HCP alloys, and their roles on plastic deformation mechanisms such as shear localization. Using hybrid MC/MD, we simulated and analyzed solute segregation in random Ag, Al, Nb and Zr polycrystals, each with same solute content of 4 at.% Ni. A spectrum of segregation configurations from fully heterogeneous to fully homogeneous is revealed. Second, a fast algorithm based on atomic-scale GB segregation energy spectra was developed and applied to quantify the alloy tendency for GB solute clustering in both symmetric GBs and random GBs of polycrystals. This presentation will underscore the importance of solute interactions in profoundly altering segregation and mechanical behavior in stable nanocrystalline alloys.

9:30 AM SF04.10.04
An Accelerated Approach to Learn the Solute-Solute Interaction Spectra in Grain Boundaries Thomas Matson and Christopher A. Schuh; Massachusetts Institute of Technology, United States

Recent progress in understanding the thermodynamic stabilization of nanocrystalline alloys via grain boundary solute segregation has revealed the need for spectral information which captures the full distribution of grain boundary environments. Our recently developed accelerated framework, which predicts segregation energy spectra from the local atomic environments at the grain boundary, has made spectral information accessible even with ab-initio methods. However, this framework has only been applied in the dilute limit, and does not yet account for the spectral nature of solute-solute interactions. In this talk, we review our recent development of an atomistic, physically motivated method to measure the full spectrum of grain boundary solute interactions, and discuss a case study on the results of this method for a general polycrystal of Al(Mg). Additionally, we present a modified version of our accelerated framework, which uses the Smooth Overlap of Atomic Positions (SOAP) to construct descriptors for specific nearest neighbor pairs, and demonstrate its use for multiple binary alloys, including Al(Mg), Pt(Au), and Ag(Cu), using existing interatomic potentials.

9:45 AM SF04.10.05
The Grain Boundary Solute Drag Hypersurface—Insights from Theoretical and Machine Learning Studies Malek Alkayyali and Fadi Abdeljawad; Clemson University, United States

Nearly all functional and structural materials are polycrystalline systems, they are composed of crystalline grains that are separated by grain boundaries (GBs). It is well established that GBs play a critical role in a wide range of phenomena during materials processing or under service conditions. Of particular interest is GB migration and associated grain growth, as these processes control many crystal-size-dependent properties. Recent experimental studies have demonstrated stagnant grain coarsening due to GB solute segregation. However, most studies are focused on the thermodynamic aspect of solute segregation, and the role of GB solute drag remains poorly understood. The interaction of migrating GBs with elemental species influences GB dynamics, where the GB solute atmosphere exerts a drag, resisting GB migration. Herein, we present a solute drag model in concentrated alloys that accounts for solute-solute interactions in both the bulk and GBs and captures experimentally observed effects such as asymmetrical and multi-layer segregation. Our analysis suggests a self-similar behavior for the solute drag-GB velocity curves. Further, it is shown that the magnitude of GB solute drag is a function of bulk and interface alloy thermodynamics parameters, solute transport coefficients, and driving force; the GB solute drag is a hypersurface. Simulation data obtained using our mathematical model are used to train an artificial neural network (ANN) model to predict the solute drag hypersurface. Our results are used to explain experimental observations of sluggish grain growth in a wide range of metallic alloys. Moreover, the trained ANN shows the role of the recently observed asymmetric GB solute segregation in solute drag. In broad terms, our model provides avenues to explore the role of solute drag in GB dynamical processes.

From Slip Localization to Crack Formation at (0001) Twist Grain Boundaries in Ti Alloys Subjected to Dwell-Fatigue and Fatigue Loadings Cyril Lavogiez[1], Patrick Villechaise[1], Jean-Charles Stinville[2], Fulin Wang[3], Marie-Agathe Charpagne[2], Meghan G. Emigh[3], Tresa M. Pollock[3], Valery Valle[1] and Samuel Hemery[1]; [1]Institut Pprime, France; [2]University of Illinois at Urbana-Champaign, United States; [3]University of California Santa Barbara, United States

Titanium components employed in the aerospace industry generally experience fatigue loadings during in-service operation. Intense research efforts were put into the understanding of crack formation mechanisms to enable accurate prediction of the fatigue performance as well as microstructure optimization. However, literature review reveals an intricate situation owing to the competition between different mechanisms. In this presentation, a brief overview of microstructural features found at crack initiation sites in a variety of alloys with different microstructures and loading conditions will be reported first. Based on collected data, the occurrence of a single crack nucleation mechanism involving (0001) twist grain boundaries will be discussed and a criterion to identify candidates for crack initiation will be proposed. Details of the mechanism governing crack nucleation will then be described. Characteristics of these critical grain boundaries, including potential composition heterogeneities, were studied using TEM. In addition, their role in the early slip activity was investigated with a statistical significance using a combination of in situ tensile testing with high resolution DIC, EBSD and TEM. The transition from localized plasticity to crack formation at (0001) twist grain boundaries will finally be discussed in light of these results.

***In Situ* Nanomechanical Testing to Understand the Role of Grain Boundary Structure in Materials** Nan Li[1], Dongyue Xie[1], Saryu Fensin[1], Abigail Hunter[1], Darby Luscher[1], Muh-Jang Chen[2] and Mohammed A. Zikry[2]; [1]Los Alamos National Laboratory, United States; [2]North Carolina State University, United States

Grain boundary is one of the most important planar defects in materials. Correlated mechanical response under loading leads to localized strain accumulation and structural changes in the vicinity of the boundary. This can determine whether dislocations can nucleate, transmit, or just be blocked at the boundary. In order to understand this process, we have performed in situ pillar compression in a scanning electron microscope coupled with electron backscatter diffraction scanning. The bicrystalline pillars, with the chosen boundary in the middle, are prepared in a shape of rectangular cuboid. During the uniaxial compression, the indentation has been paused at different strains to perform the electron backscatter diffraction scanning. Depending on the boundary structure, various interactions with dislocations at the boundary are captured. Correlated with the electron backscatter diffraction mapping at different strain states, we are able to quantify the lattice rotation and local strain tensor along the loading axial. Such information has helped us to better understand the mechanical role of grain boundaries and provided a unique validation for the modeling at both atomic and mesoscales.

11:30 AM SF04.11.03
Plastic Strain Inhomogeneity in (α+β) Titanium Alloys—A Focused *In Situ* Exploration of Transformed β-Colonies Shaolou Wei[1], John Foltz[2], Luis Ruiz-Aparicio[2] and Cem Tasan[1]; [1]Massachusetts Institute of Technology, United States; [2]ATI Specialty Materials, United States

(α+β) titanium alloys demonstrate diverse microstructural combinations that enable fruitful pathways to engineer the macroscopic load-bearing performances. The microscopic deformation mechanisms leading to plastic strain inhomogeneity are, on the other hand, rather complex and deemed detailed considerations. Transformed β-colonies are one such example. Exhibiting a Burgers orientation relationship (BOR) between the BCC-structured retained β-phase (β_r) and the HCP-structured transformed β-phase (β_t), the transformed β-colonies have triggered appreciable interest in correlating slip activation and its crystallographic properties that can be relevant in microstructural design. By studying a Ti-Al-V-Fe-Sn alloy via integrated *in situ* SEM-based DIC, *in situ* synchrotron X-ray diffraction, and crystallographic theory, this presentation aims to address three fundamental aspects of the transformed β-colonies: (1) What is the critical factor that dominates plastic strain accommodation in different β_t variants? (2) What are the characteristics of plastic strain partitioning between β_r and β_t phases? (3) How does the BOR contribute to slip transferability across the β_r/β_t boundaries? Broader implications for cooperative and heterogeneous plastic deformation and their roles in damage initiation will also be discussed.

11:45 AM SF04.11.04
Microstructural Inelastic Deformation and Fracture Modes in Crystalline Materials Muh-Jang Chen[1], Dongyue Xie[2], Saryu Fensin[2], Nan Li[2] and Mohammed A. Zikry[1]; [1]North Carolina State University, United States; [2]Los Alamos National Laboratory, United States

Interrelated aspects of thermo-mechanical behavior with a specific focus on microstructural characteristics, such as partial and total dislocations densities and grain-boundary (GB) that span the nano to the micro, and how these characteristics affect failure modes, such as fracture nucleation in crystalline materials, will be presented. Recently developed methodologies have been used for a detailed analysis of fracture nucleation and the accurate characterization of intergranular and transgranular crack growth. Criteria for dislocation-density mechanisms and immobilization are directly related to interactions with GB ledges and propagating cracks in polycrystalline aggregates. The effects of interfaces, such as GB blockage, dislocation-density motion, and pileups on fracture nucleation will be discussed. The predictions are validated with micropillar compression experiments and provide further understanding of how defects, such as partial and total dislocation-densities, affect failure nucleation and intergranular and transgranular fracture.

Predicting Slip Transfer from Atomistic to Microscale—Methodology, Mechanisms and Applications Liming Xiong; Iowa State University, United States

Engineering alloys are usually heterogeneous and contain a high density of interfaces such as stacking faults, grain boundaries (GBs), and phase boundaries (PBs). When subjected to plastic deformation, the overall performance of these materials is largely dictated by the interaction between the dislocation-mediated slip and those interfaces. Due to the length-scale limitation, a fully atomistic model usually can only accommodate a few dislocations without considering much material microstructure complexities. In contrast, our concurrent atomistic-continuum (CAC) approach unifies the atomistic and continuum description of materials. It can accommodate the long-range dislocation slip and the atomically structured interfaces all within one model. Here we will present our recent development of an adaptive CAC for predicting slip transfer in plastically deformed polycrystalline alloys with its grain size spanning from nanometers to micrometers. The slip-interface reaction-induced complex internal stress as well as its contributions to the subsequent structure changes, such as lattice rotation, twinning (nucleation, growth, variant selection), and phase transformation, will be all characterized from the bottom up. The obtained results will be then informed into a local stress- or couple stress-based slip transfer metrics. An implementation of such metrics in higher length scale models, such as crystal plasticity finite element, dislocation dynamics, or phase field models, will significantly improve their predictive capability. This in turn, will lead to an atomistic-to-macroscale computational platform that can be used for predicting the microstructure evolutions in a variety of engineering materials exposed to extreme stress, corrosive, irradiations, and even a combination of them.

9:30 PM *SF04.12.02
Investigation of Near Grain Boundary Gradient Zones Using HRDIC and HREBSD David T. Fullwood[1], Tristan Russell[2,1], Ryan Sperry[1], Landon Hansen[3,1], Guowei Zhou[4], Ehsan Taghipour[5] and Robert Wagoner[5]; [1]Brigham Young University, United States; [2]Los Alamos National Laboratory, United States; [3]Kitty Hawk Technologies, United States; [4]Shanghai Jiao Tong University, China; [5]The Ohio State University, United States

It is well known that deformation behavior in polycrystalline materials is modified significantly in the region of grain boundaries (GBs), in comparison to the response at the center of grains. This study observes various aspects of deformation response in FCC nickel and BCC tantalum using high-resolution digital image correlation (HRDIC) and high-resolution electron backscatter diffraction (HREBSD). Contrasting behavior is observed in terms of slip band nucleation and propagation, modification to active slip systems near GBs, strain and orientation gradients and geometrically necessary dislocation (GND) distributions, and transmission across GBs. Correlations between local microstructural features and deformation response in the near-boundary gradient zones are analyzed. The insights are used to assess the performance of crystal plasticity type models and inform the next generation of simulation approaches.

10:00 PM SF04.12.03
Development of a Systematic and Efficient Method for Searching for the Most Stable Grain Boundary Structures—A Method Based on Non-Identical Termination Combination Yuki Hata[1], Yaoshu Xie[2], Kiyou Shibata[1,2] and Teruyasu Mizoguchi[1,2]; [1]Grad. Sch. of Eng., the Univ of Tokyo, Japan; [2]IIS, the Univ, of Tokyo, Japan

The rich diversity of grain boundaries (GBs) can affect macroscopic properties of entire material in various situations. Determining GB structures as systematically and as rapidly as possible is the first step toward understanding the properties of materials with GBs. Currently, a common method for determining the GB structure is a sequential grid search of rigid body translation (RBT), which is computationally expensive. Therefore, there is a need to develop a systematic and efficient method to search for the most stable GB structures.
The GBs are generally considered to be complex and have random structures, but it is known that characteristic structures (structural unit) appear on some GBs [1][2]. In this study, we have found that the structural units of the most stable GBs are naturally reproduced in a comprehensive combination set of GB plane terminations without considering the variation in RBT. Since the number of GB plane terminations is limited systematically by the crystal geometry, it may be possible to reduce the number of candidates for searching the most stable GB structures by focusing only on non-identical GB plane terminations. Based on this assumption, here we propose a new method for searching the most stable GB structures based on the non-identical GB plane terminations.

We chose symmetric tilt GBs with three rotational axes of [100], [110], and [111] in fcc Cu and bcc Mo as our research targets. Based on coincident site lattice theory, 170 GBs with Σ less than 100 were selected. First, relaxation calculations have been performed based on conventional brute-force RBT grid searching method. Then, in the same way, the relaxation calculations have been performed only on structures with non-identical end-face (termination) combinations among them. The most stable GB' s energies and computational cost obtained by these two methods were compared. In addition, we have taken one GB with Σ> 100 (Σ157[001](-11 6 0)), which generally requires a large amount of computational cost to determine the most stable GB structure, as an example and evaluated utility of our new method. The relaxation calculations were performed with the LAMMPS code [3] and GB model were made by Interface Master [4].

For almost all of the 170 GBs, the most stable GB structures obtained from the structures screened by focusing on the combination of non-identical GB plane terminations have shown agreement with those obtained from the conventional brute-force calculations with high accuracy.
We have also found that the number of the screened structures, with which is necessary to obtain the most stable GB, decreases down to several times value of Σ. For example, our method can find the most stable structure of Σ157[001](-11 6 0)ΣGB with only 1/120th the number of candidate structures of the conventional brute-force calculations. This result indicates that the selection of the candidate structures based on the GB plane termination is closely related to the conditions for the most stable GB structures and can be applied to the fast determination of GB structures. This result indicates that the generated structures by changing the GB plane termination are sufficient enough to determine the most stable GB structures.

These results suggest that the GB plane termination plays an important role in determining whether GB structures of single-element crystals become the most stable or not. To determine the most stable structure of GBs systematically and efficiently, it would be effective to focus on the combination of non-identical terminations. We are now applying this method to other GBs such as twist GBs and GBs in oxides.

Integration of Experimentation and Modeling in Heterogeneous Microstructures by Precision Nanocrystallization Mark Atwater and Joby M. Anthony III; Liberty University, United States

Heterogeneous microstructures offer a complementary approach to balance strength and ductility. In their various forms, regions of nanoscale grains provide strengthening to regions of coarser grains in which dislocation mediated plasticity is maintained. These interfaces result in hetero-deformation induced (HDI) hardening, which causes a back stress in the coarse-grained regions and forward stress in the nanoscale regions. These unique microstructures require multi-scale modeling to fully capture the interactions, and they are often challenging to control experimentally. We have developed methods to precisely induce local deformation hardening in materials, such that modeling can be accurately validated. Characterizing the behavior and interaction of grain boundaries and dislocations is vital to predict mechanical properties and performance of the selected material. Many historical and novel material behavior modeling techniques validate the application of some algorithm or implemented codes against physical experiments, but uncertainty in predicting material behavior increases if the modeling technique does not well capture many features of mechanical performance that may arise from complex microstructures. Integrated Computational Materials Engineering (ICME) is a physics-based modeling paradigm to characterize a material's properties to predict its performance for some boundary conditions which may vary drastically with time. At the electronic and atomistic length scales, ICME relies on Density Functional Theory (DFT) to characterize the quantum mechanics interactions between electrons and Modified Embedded Atom Method (MEAM) interatomic potentials to characterize how a unit cell of material interacts with its neighbors given so much strain. The change in microstructure can then be examined by Dislocation Dynamics (DD), which relies on the formulated MEAM potential and dislocation velocity quantified at the lower length scales. Again, the ability of DD to characterize interactions between dislocations and grain boundaries is only as good as the techniques at the lower length scales. DD simulations and later Finite Element Analysis (FEA), is also only as confident as the data is for the MEAM potentials and dislocation velocity. These multiscale factors in the development of a computational framework and the real-world performance of heterogeneous microstructures created through precision nanocrystallization will be discussed.

Study of Pseudomorphically Transformed bcc Mg in Mg/Nb Multilayer Nanocomposites Under Extreme Conditions Sid Pathak[1], Manish Jain[2], Nathan Mara[3], Irene J. Beyerlein[4], Marko Knezevic[5] and Johann Michler[6]; [1]Iowa State University of Science and Technology, United States; [2]University of

Nevada, Reno, United States; [3]University of Minnesota Twin Cities, United States; [4]University of California at Santa Barbara, United States; [5]University of New Hampshire, United States; [6]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

In recent years two-phase nanolayered composites with individual layer thicknesses varying from 200-300nm down to 1-2 nm have been the subject of intensive study because of their unusual physical, chemical and mechanical properties. For example, with decreasing layer thicknesses (down to nanometer length scales) the mechanical response of these nanocomposites becomes increasingly interface dominated, and they exhibit ultrahigh strengths approaching the theoretical limit for ideal crystals. Moreover if the constituent phases present large differences in strength, elastic modulus and ductility, these multilayers give rise to new possibilities for the deformation mechanisms and properties of the composite as a whole. In this work we explore the possibility of synthesizing multilayered composites where one constituent phase has a low ductility, with a final goal of enhancing both the strength and ductility of the system.

Using physical vapor deposition (PVD) techniques we synthesized a hexagonal close-packed (HCP) – body-centered cubic (BCC) Mg-Nb system (where twinning in Mg leads to its lack of ductility), over a range of layer thicknesses ranging from 5 nm to 200 nm. We investigated the structure of the hitherto-unknown bcc Mg phase in the Mg/Nb multilayer nanocomposite under high pressures in a diamond anvil cell experiment using synchrotron radiation x-ray diffraction (XRD). We utilize a suite of small scale testing techniques to evaluate the deformation mechanisms in these nanocomposites that involve both compressive loading scenarios such as (a) high throughput nanoindentation testing, to more-specialized FIB-fabricated (b) micro-pillar compression, and (c) micro-tensile tests. The mechanical data obtained from these tests are correlated with the structure information at complementary length scales using techniques such as XRD, SEM, and TEM. The use of such diverse testing technologies allows a detailed characterization of the structure-property correlations at each length scale of interest; ranging from the response of each individual interface within the laminate to properties of the ensemble.

The specialized testing techniques such as FIB-fabricated micro-pillar compression and micro-tensile experiments are used to characterize the anisotropic response of the nanolayered composite, with interfaces oriented either normal, parallel and oblique (45^{o}) to the compression axis. Each of these configurations generate unique mechanical information: thus while compressions and tensions normal and parallel to the interface are important for a complete understanding of the anisotropy of properties and size-related effects, the tests with the interfaces loaded obliquely provide a measure of interfacial shear strength. Ductility and fracture toughness at the micrometer level are investigated using *in-situ* observations inside an SEM coupled with a micro-tensile geometry. Tests repeated as a function of layer thickness and interface orientations provide us with valuable information regarding the Mg-X interface character.

We have also extended our techniques to measuring the strain rate sensitivity (SRS) of the Mg-X nanocomposites using *in situ* strain rate jump experiments conducted under both indentation and micro-compression/micro-tensile loading scenarios. Elevated temperature measurements are especially important, since the SRS for nano-(bcc)Mg is expected to differ from its nano-(hcp)Mg counterpart as a function of temperature from which activation energies/volumes for deformation mechanisms can be extracted. Results from these tests were analyzed in terms of the measured activation energies and activation volumes from sub-micrometer sized Mg/Nb multilayer nanocomposites. These findings reveal an alternative solution to obtaining lightweight metals critical needed for future energy efficiency and fuel savings.

10:30 AM *SF05.01.01
Intrinsic Defects and Charge-Carrier Localisation in Metal Halide Semiconductors Laura Herz; University of Oxford, United Kingdom

Metal halide semiconductors have emerged as attractive materials for solar cells with power-conversion efficiencies now exceeding 25%. However,

challenges and opportunities remain relating to material microstructure, defect formation, ionic migration and toxicity.

We show that $FAPbI_3$ perovskite, which has recently been implemented in highly efficient solar cells, can exhibit a peculiar structural defect that leads to intrinsic quantum confinement of charge carriers, apparent through surprising oscillatory features in the absorption spectrum.[1] By determining the threshold film thickness at which the amplitude of the peaks is appreciably decreased, and through ab initio simulations of the absorption features, we have estimated the length scale of confinement to be 10–20 nm. Such domains may result from δ_H-phase barriers or ferroelectric effects and, depending on application, may be either detrimental (e.g. to charge extraction in solar cells) or advantageous (e.g. to light emitting devices). We further show[2] that such nanoscale electronic effects can be controlled through partial replacement of the FA cation with Cs. We find that Cs-cation exchange causes a weakening of quantum confinement in the perovskite, arising from changes in the bandstructure, the length scale of confinement, or the presence of δ_H-phase electronic barriers. We further observe photon emission from quantum-confined regions, highlighting their potential usefulness to light-emitting devices and single-photon sources.[2] Overall, these structural defects present a new and intriguing quantum electronic phenomenon in a nominally bulk semiconductor, offering intrinsic nanoscale optoelectronic properties without necessitating cumbersome additional processing steps.

We further report on ultrafast charge-carrier self-trapping in lead-free silver-bismuth semiconductors[3-5] which promise lower toxicity and potentially higher barriers against ion migration than their more prominent lead-halide counterparts. We examined the evolution of photoexcited charge carriers in the double perovskite $Cs_2AgBiBr_6$ using a combination of temperature-dependent photoluminescence, absorption and optical pump−terahertz probe spectroscopy.[3] We observe rapid decays in terahertz photoconductivity transients that reveal an ultrafast, barrier-free localization of free carriers on the time scale of 1.0 ps to an intrinsic self-trapped small polaronic state. We further demonstrate the novel lead-free semiconductor Cu_2AgBiI_6 which exhibits several advantages over $Cs_2AgBiBr_6$, namely a low exciton binding energy of ~29 meV and a lower and direct band gap near 2.1 eV,[4,5] making it a significantly more attractive lead-free material for photovoltaic applications. However, charge carriers in Cu_2AgBiI_6 are found to exhibit similarly strong charge-lattice interactions[5] to those in $Cs_2AgBiBr_6$, suggesting a link with the presence of AgBi. The presence of such self-trapping therefore emerges as a serious challenge for this class of materials.

11:00 AM *SF05.01.02
Visualising and Mitigating Problematic Defects in Halide Perovskite Photovoltaic Absorbers Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites are exciting materials showing high performance in photovoltaic devices, among other device platforms. This performance is in part due to the fact that many of the defects in halide perovskites appear to be electronically benign. However, there are still deep traps in halide perovskites that limit performance and need addressing.

Here, I will outline work where we have characterised deep trap states in halide perovskite absorber materials. We find that there are small nanoscale clusters of impurity phases including hexagonal polytypes that have high defect densities leading to deep trap states. Furthermore, these defective sites are where photo-instability pathways are seeded, realising a fundamental link between carrier traps and device stability. I will outline how managing these particularly problematic defects – through passivation and material composition control – will be key to further pushing device performance and stability.

11:30 AM *SF05.01.03
Tailored Interfaces in Metal Halide Perovskites for Efficient Charrier Transfer Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Perovskite solar cells promise to yield efficiencies beyond 30% by further improving the quality of the materials and devices. Electronic defect passivation and suppression of detrimental charge-carrier recombination at the different device interfaces has been used as a strategy to achieve high performance perovskite solar cells. However, the mechanisms that allow for carriers to be transferred across these interfaces are still unknown. In this presentation, I will discuss the role of crystal surface structural defects on optoelectronic properties of lead halide perovskites through synchrotron-based techniques. The importance of interfaces and their contribution to detrimental recombination will also be discussed.

SESSION SF05.02: Harvesting Defects in Multifunctional Oxides

1:30 PM *SF05.02.01
Structure and Properties of Low Dimensional Epitaxial Oxides; Interfaces and Superlattices Gertjan Koster; University of Twente, Netherlands

In complex oxide materials the occurrence of ferroelectric, ferromagnetic or other properties are for the most part determined by the detailed oxygen coordination of metal cations. More specifically, in the case of perovskite-type materials ABO_3, where A and B are metal cations, by the BO_6 octahedral orientations and rotations. At interfaces in epitaxial oxide hetero structures, for example magnetic junctions or capacitive structures, this oxygen sub-lattice is found to be different from its bulk counterpart.
I will briefly introduce the current status of the often used technique to fabricate epitaxial layers, ‘atomically controlled PLD’, as well as give a few examples of oxygen sub-lattice and interface engineering achieved by controlled thin film parameters such as, composition, digital thickness variation, polar discontinuous interfaces or the insertion of oxide buffer layers that influence the perovskite-type BO_6 sub-lattice or related structures. I will further elaborate on the effects of such thin film parameters on the structure and properties of various model systems that have been subsequently studied by *in situ*

characterization techniques, high resolution scanning transmission electron microscopy or other spectroscopic techniques (XAS, RIXS, PNR etc.). More practically, often-encountered problems due to dead-layer effects, which normally hamper many functional devices, could be identified.

2:00 PM *SF05.02.02
Growth of Oxide Thin Films on Different Natures of Substrates for Various Electronic and Medical Applications Wilfrid Prellier; CRISMAT Laboratory, France

Transition metal oxides often having a perovskite structure form a wide and technologically important class of compounds. In these systems, ferroelectric, ferromagnetic, ferroelastic, or even orbital and charge orderings can develop and eventually coexist. These orderings can be tuned by external electric, magnetic, or stress field, and the cross-couplings between them enable important multifunctional properties, such as piezoelectricity, or magneto-elasticity. In spite of the large number of observations and promise of epitaxial oxide thin films, most of the investigations have been focused on films on low-index commercially-available single-crystal substrates, which have limited the scope of the study, and the applications. Here, we will present how oxide thins films can be grown on different types of substrates including polycrystalline substrates, and glass templates. Examples will given to show different applications that can be utilized for medical or electronics.

2:30 PM SF05.02.03
Atomic Scale Structure and Electronic Structure of Defects at Misfit Dislocations in CeO_2/MgO Heterostructure Pratik P. Dholabhai; Rochester Institute of Technology, United States

Among the numerous functionalities of mismatched oxide heterostructures and thin films, one of their most promising energy applications is in solid oxide fuel cell (SOFC) electrolytes. Epitaxial growth of oxide thin films on substrates above critical thickness result in the formation of misfit dislocations. These functional extended defects influence key material properties of thin film SOFC electrolytes. Nevertheless, fundamental understanding of the atomic scale structure and electronic structure of misfit dislocations and their intricate interaction with mobile oxygen vacancies at functional oxide interfaces is lacking. In this work, first principles density functional theory was used to elucidate the atomic scale structure and electronic structure of misfit dislocations for experimentally observed epitaxy in CeO_2/MgO heterostructure. Rotation of CeO_2 thin film is uncovered as one potential mechanism eliminating the surface dipole, which results in experimentally observed epitaxy. In Gd-doped CeO_2 thin film, thermodynamic stability and electronic structure of oxygen vacancies in the neighborhood of misfit dislocations will be contrasted against their behavior in the bulk and at surfaces. Changes in the electronic density of states and interface electronic charge transfer due to defect formation in the vicinity of misfit dislocations and their impact on ionic transport will be discussed. Present results are instrumental in understanding the intricate interplay between misfit dislocations, dopants, and oxygen vacancies and their ultimate impact on ionic transport in thin film SOFC electrolytes.

We acknowledge support from NSF CAREER Award DMR-2042311.

2:45 PM SF05.02.04
Oxygen Vacancies in High Entropy Perovskite Oxides—A Computational Study about Local Ordering, Distortion and Redox Activity Boyuan Xu[1], Stephan Lany[2], Jiyun Park[1], Dawei Zhang[3], Xingbo Liu[4], Jian Luo[3] and Yue Qi[1]; [1]Brown University, United States; [2]National Renewable Energy Laboratory, United States; [3]University of California, San Diego, United States; [4]West Virginia University, United States

High entropy perovskite oxides (HEPOs), typically consist of four or more elements fully mixed at {A} or/and {B} sites in ABO_3 perovskite lattices. Mixing multiple cations can reach a significant configurational entropy that offers a wide, unexplored new compositional space with vast tunability to meet challenging requirements of real applications. One of applications is the two-step solar thermochemical hydrogen generation (STCH) techniques, in which HEPOs are believed to provide higher redox capacities, longer durability and lower reduction temperature.

Multiple cation mixing introduces new computational challenges, such as composition design rule for higher hydrogen yield, strategy to sample and analyze possible configurations, and nonstoichiometry prediction for HEPO system with spread oxygen vacancy formation energies. In this research, density functional theory (DFT) is combined with Metropolis Monte Carlo method (DFT-MC) to efficiently sample the possible cation configurations and discover the role of each {B} site elements on oxygen vacancy formation. $(La_{0.8}Sr_{0.2})\{MnFeCoAl\}O_3$ (LS_MFCA) was simulated first as one of the materials that shows good STCH performance. Cation positions or magnetic moment exchanged configurations were used in the DFT-MC simulations at 1600 K (reduction temperature in STCH process), and more than 2600 bulk, 3000 vacancy configurations that gave rise stable energies in MC simulations were saved for further analysis.

The neutral oxygen vacancy formation energy in LS_MFCA is sensitive to {B} site element type, charge state, local ordering and structural distortion. The oxidation state determined by magnetic moments shows that the charge states on {MnFeCoAl} are Mn^{4+}, Fe^{3+}, Co^{3+}, and Al^{3+} and Co^{3+} is the predominant redox active element, which agrees with the in-situ X-ray photoelectron spectroscopy (XPS) observations. Cation mixing causes local lattice distortion. Cation Bond Valence Sum (BVS) descriptor analysis shows that Co-O bonds in bulk LS_MFCA structures are much more stretched (weakened) than Mn-O and Al-O bonds, while Fe-O bonds are slightly compressed (strengthened). Since the oxygen vacancy formation causes volume expansion in many oxides, the stretched bonds will lower the vacancy formation energy near Co. Among the saved structures, the configurations of the two B-cations connected to the oxygen (or vacancy) were analyzed for possible {B} site preference or local ordering. The elemental combination of the {B} pairs connecting to oxygen in the bulk LS_MFCA is close to random, but more than 80% of the {B} pairs connecting to oxygen vacancy contains Co. This means the local excess space due to Co^{3+}-O bond stretching outpaced the tendency to generate vacancies near Mn^{4+}, leading to the oxygen vacancy generation favoring Co site.

Ferroelastic Domain Walls in $BiFeO_3$ as Memristive Networks J. Rieck[1,2], D. Cipollini[2,1], M. Salverda[1], C.P. Quinteros[1,3], L.R.B. Schomaker[2,1] and Beatriz Noheda[1,2]; [1]University of Groningen, Netherlands; [2]Cognigron - Groningen Cognitive Systems and Materials Center, Netherlands; [3]ECyT-UNSAM, CONICET, Argentina

Domain walls of ferroic oxides have been extensively investigated as functional defects. In particular, ferroelastic domain walls of ferroelectric oxide perovskites have shown enhanced conductivity with respect to the insulating domains. Memristive behaviour has also been demonstrated in these nanoscale objects. However, until now, these properties have been measured on individual domain walls with current flowing between electrodes located at the bottom and top of the thin film samples. Here we show that lateral current flow from wall to wall is also possible in these materials, therefore allowing information transfer through the domain wall network and making these systems promising for brain-inspired applications.

Spatially Resolved Electrical Analysis of Epitaxial Defect-Stabilized Hafnium Oxide Thin Films Niclas Schmidt[1], Silvia Karthäuser[1], Nico Kaiser[2], Tobias Vogel[2], Eszter Piros[2], Lambert Alff[2], Regina Dittmann[1] and Rainer Waser[1]; [1]Forschungszentrum Jülich GmbH, Peter-Grünberg-Institut 7 (PGI-7), Germany; [2]Advanced Thin Film Technology Division, Institute of Materials Science, TU Darmstadt, Germany

Hafnium oxide (HfO_2) is a transition metal oxide which receives great research interest due to its compatibility with complementary metal-oxide-semiconductor (CMOS) technology, as well as its ferroelectric and memristive properties. One key to improve the performance of hafnium oxide based non-volatile resistive random access memory (ReRAM) devices is specifically tuning the electronic properties. Here, the precise engineering of defects, such as doping with other transition metals or the variation of the oxygen content, plays a major role. The objective is to improve the formation and disruption of a conductive filament by diffusion of oxygen vacancies in valence change mechanism (VCM) type of ReRAM devices. Scanning probe techniques, such as conductive atomic force microscopy (c-AFM), are powerful tools to investigate the switching behavior and electronic properties at the surface of transition metal oxides with highest local precision.[1]
The purpose of this study is to identify filament locations on the nanoscale and to examine their minimal size with respect to the sample stoichiometry of hafnium oxide thin films. The hafnium oxide samples with varying oxygen content were grown by molecular beam epitaxy (MBE) on c-cut sapphire substrates with an intermediate TiN layer acting as bottom electrode. The oxygen flow during evaporation was varied to grow a series of samples, starting from stoichiometric, monoclinic HfO_2 and going to substoichiometric, highly oxygen deficient HfO_{2-x}, where a low-temperature cubic phase could be identified.[2] Subsequently, the samples were analyzed without breaking the vacuum by c-AFM and scanning tunneling microscopy/spectroscopy (STM/S). The RMS surface roughness of the hafnium oxide films, which have a thickness of 10nm, is about 1nm or less, measured by c-AFM. By performing a series of conductivity maps, a gradual increase in conductivity of the hafnium oxide layer with decreasing oxygen content and increasing amount of the substoichiometric cubic phase can be determined. The onset behavior of the conductivity for each case of the different oxygen deficiencies has a similar appearance. In particular, while the first conductive pathways are identified along grain boundaries and expand with increasing bias voltage, distinct grains show a gradual onset behavior in a voltage range of about 1V. Analogous to the onset of the general conductivity, the forming behavior of grains is likewise dependent on the mean oxygen vacancy content defined by the growth process. Moreover, the switching behavior for the different stoichiometries is analyzed with one focus on the smallest switchable structure. For a more profound perception of the electronic properties around the Fermi level, the most conductive samples are investigated by STS. Thereby, the target is the identification of possible in-gap states caused by introduced defects.[3]

Growth of High-Crystalline α-Ga_2O_3 Thin Films on Sapphire Substrates Using Template Engineering for High Voltage α-Ga_2O_3 Power Devices Byoungsoo Kim, Duyoung Yang, Yongjo Park and Ho Won Jang; Seoul National University, Korea (the Republic of)

With the rapid expansion of the industry, the demand for high-efficiency and durable power semiconductors in harsh conditions such as high temperature and high voltage has increased. Gallium oxide (Ga_2O_3) is a potential material for next-generation power devices, with a bandgap energy of 4.8-5.3 eV, which is higher than Si, SiC, and GaN. Ga_2O_3, especially corundum structured α-Ga_2O_3, has gotten a lot of interest among Ga_2O_3 phases, owing to its special characteristics such as epitaxial growth on a cheap sapphire substrate and the presence of p-type materials with the same crystal structure. However, the mismatch of the lattice and thermal expansion coefficients between α-Ga_2O_3 and sapphire, however, causes a high density of threading dislocations (TDs) and cracks in films. High-density TDs act as leakage current paths within the device, reducing efficiency and limiting lifetime. Solving these problems is essential for the development of high-performance devices based on α-Ga_2O_3.
Herein, we proposed the template engineering for the high-quality and strain-free α-Ga_2O_3 films by adopting the compositionally graded α-$(Al_xGa_{1-x})_2O_3$ layers and a thin sapphire nano-membrane.
In the first chapter, compositionally graded α-$(Al_xGa_{1-x})_2O_3$ layers are adopted to reduce threading dislocations for high-quality epitaxial α-Ga_2O_3 films. the evolution of strain relaxation and the inclination of threading dislocations in graded α-$(Al_xGa_{1-x})_2O_3$ layers are confirmed by reciprocal space mapping (RSM) and transmission electron microscopy (TEM). Through RSM and TEM studies, we confirmed that compressive strain enhances the inclination of dislocations, and therefore, the dislocations merge and annihilate in the graded α-$(Al_xGa_{1-x})_2O_3$ layers. The calculated density of threading dislocations in α-Ga_2O_3 films with a graded a-$(Al_xGa_{1-x})_2O_3$ buffer layer is reduced by 64.9% compared with that of α-Ga_2O_3 films deposited directly grown on a bare sapphire substrate. Furthermore, a fabricated lateral-structure Schottky diode reveals enhanced breakdown voltages and forward current density due to the improved crystalline quality by using the graded α-$(Al_xGa_{1-x})_2O_3$ buffer layer.
In the second chapter, the properties of the α-Ga_2O_3 thin films selectively grown on the thin substrates, stripe patterned sapphire nanomembrane, were investigated. First, the microstructure of α-Ga_2O_3 was investigated about the pattern direction, leading to the conclusion that it is preferable to construct the pattern in the [100] direction for device development. The thin substrate absorbed the stress applied to the thin film due to the strain partitioning effect, resulting in a 13.6% drop in misfit edge dislocation density of α-Ga_2O_3 and an 18.7% decrease in the 104 FWHM value of the XRD ω-rocking curve. The thin film's stress was analyzed using reciprocal space mapping, and it was proven that the thin substrate was responsible for the highest stress reduction of 51.6%, due to the strain partitioning effect.
This work will pave the way for high-quality α-Ga_2O_3 growth and its related application development, with follow-up research predicted to lead to the advancement of high-performance power devices.

Fabrication and Characterization of IrO_x Nanosheets for Methane Sensors Tatsuki Umeda, Takahisa Tanaka and Ken Uchida; The University of Tokyo, Japan

Introduction
CH_4 is a greenhouse gas that throughs the second largest impact on global warming after CO_2, and it is essential to develop a technology to continuously monitor CH_4 emissions [1]. Recently, it has been reported that C-H bond of CH_4 can be cleaved at the IrO_2(110) surface in an ultrahigh vacuum [2]. However, the reaction has only been verified in ultrahigh vacuum, and it has not yet been clarified whether the C-H cleavage reaction by IrO_2 occurs in the standard atmosphere or whether this reaction can be applied to CH_4 resistive sensors.
In this study, IrO_x nanosheets with IrO_2(110) were fabricated using reactive sputtering system and examined their resistive response to CH_4 in dry air. The impacts of film deposition conditions on the sensor response were also investigated.

Experimental Method
To fabricate IrO_x-based CH_4 sensors, reactive sputtering system (Target: Iridium, Base pressure: 5×10^{-3} Pa, RF power: 80 W, Substrate temperature: as-is)

was used. IrO_x nanosheets of approximately 30 nm and 5 nm in thickness were deposited on 1-μm-thick thermal oxide (SiO_2) films on Si substrates. The chamber pressure during the deposition process was 0.67 Pa, and the flow ratio of O_2 against the total flow of 20 sccm was set to 10, 20, or 40%. After IrO_x deposition, the films were annealed process at 500°C for 30 min in an O_2 atmosphere. X-ray diffraction (XRD) and X-ray reflectivity (XRR) measurements were performed to 30-nm-thick IrO_x nanosheets. On the 5-nm-thick IrO_x nanosheets, 50-nm-thick Au electrodes were deposited, and the electrode pattern was formed by a metal shadow mask. The fabricated sensors were initialized by exposing to dry air for 5 minutes at 200°C. The sensing evaluation sequence is as follows. The sensors are 1) exposed to dry air with 50-ppm CH_4 for 1 minute, and then 2) exposed to dry air without CH_4 for 3 minutes. The sensor characteristics were evaluated at 200°C by repeating 1) and 2) twice. The sensor responses ($\Delta R/R_0$) were evaluated as the ratio of resistance change ($\Delta R = R\text{-}R_0$) due to the target gas (CH_4) with respect to the initial resistance (R_0), where R_0 is the initial sensor resistance.

Results and Discussion
In XRD 2θ-θ measurements of IrO_x nanosheets after O_2 annealing, the peak from IrO_2 (110) was observed, regardless of the O_2 flow ratio. The broadening of the IrO_2(110) peak width indicates that the size of the IrO_2 microcrystals decreased with an increase in the O_2 flow ratio. XRR measurements of the nanosheets showed that the density of IrO_x nanosheets decreased as the O_2 flow ratio increased, implying that the nanosheets became sparser. Nanosheets made with a 10% O_2 flow ratio showed no sensor response at 200°C, whereas the sensor was responded to CH_4 at 200°C for the nanosheets made with 20 and 40% O_2 flow ratio, where the size of IrO_2 grains and density of IrO_x films were smaller than the 10% counterpart. This suggests that the size of IrO_2 crystals and/or the voids in the IrO_x nanosheets affected the sensor response to CH_4. In the previous study, it has been reported that CH_4 is oxidized by the bridging O atoms (O_{br}) on coordinatively unsaturated IrO_2 (110) surface and is desorbed as CO or CO_2 [3]. Thus, we consider that the oxidation reaction and resultant desorption of CH_4 and O_{br} led to the increase in resistance because the hopping transfer of electrons between the microcrystals was more difficult due to increased gaps between microcrystals. Therefore, it is expected that the sensor response to CH_4 can be increased by fabricating IrO_x nanosheets with narrower gaps between the microcrystals.

Functional Silicon Oxide Nanolayers for Temperature Sensing on 4H-SiC Gernot Fleckl; TU Wien, Austria

Silicon Carbide's (SiC) physical properties make it an excellent candidate for high performance applications in harsh environments. Especially its large bandgap of ~3.25 eV, high electric breakdown field of 3 MV/cm and a high thermal conductivity represent outstanding material properties which qualify SiC for power electronics and high operating temperatures. The materials oxidizability to silicon oxide (SiO_2) is a major advantage in comparison to other large bandgap materials, like GaN. SiO_2 is favored as it is a well-known material in both, electrical properties and fabrication. Still, there are major drawbacks of device stability and charge carrier mobility due to insufficient oxidation at the interface between SiO_2 and SiC. Furthermore, the growth rates of thermal SiO_2 on SiC are rather low in comparison to silicon (Si), even at high temperatures of 1000°C and above. Therefore, the dry thermal oxidation of SiC is an ineffective method and not suited for device fabrication in semiconductor foundries.
The aim of the work was to find new approaches to overcome these drawbacks. Therefore, an implantation dominated oxidation method was introduced, able to fabricate SiO_2-nanolayers. Unlike originally expected, an unprecedented property of the fabricated SiO_2-layers occurred: the materials polarization characteristic is strongly dependent on its temperature. The effect is fully reversible after cooling down to room temperature with minor hysteresis effects. The materials new property appears to related with a defect induction into the SiO_2-layer, caused by the novel, implantation dominated fabrication method. The materials behavior is highly functional with many possible applications but its most obvious in temperature sensing. The devices were calibrated by an allocation of extracted permittivities to temperatures in range between 300 K to 575 K. To gain information about the sensing accuracy, 30 randomly chosen temperatures within the calibration range were approached and capacity-over-frequency spectra recorded. By an interpolation of the calibration curve, each from capacity-over frequency spectra extracted permittivity can be dedicated to a certain temperature.
The sensor concept is based on a simple MOS capacitor, incorporating the functional SiO_2-layer as dielectric material. The bulk materials high thermal conductivity of 280 $Wm^{-1}K^{-1}$ makes 4H-SiC an excellent candidate as a carrier for a functional material for temperature sensing. Any change in temperature on its surface is quickly conducted to the functional SiO_2-layer, changing its polarization immediately. By this work not only a novel and simple temperature sensor concept is introduced but a functional SiO_2-based dielectric material.

SESSION SF05.03: Harvesting Functional Defects in Halide Perovskites II

High Photoluminescence Quantum Yield Downconversion in Ytterbium-Doped Metal Halide Perovskites Minh N. Tran, Iver J. Cleveland, Joseph R. Geniesse, Yukun Liu, Seda Sarp and Eray S. Aydil; New York University (NYU) Tandon School of Engineering, United States

Redshifting the solar spectrum received by a solar cell with an overlayer that creates two near-infrared (NIR) photons from each ultraviolet (UV) and blue photon via quantum cutting can increase their power conversion efficiencies while reducing their degradation by UV light and heating. Yb-doped $CsPb(Cl_{1-x}Br_x)_3$ ($x<0.65$) has emerged as a potential quantum cutting material for this application because the Yb^{3+} emission via $^2F_{5/2} \rightarrow {}^2F_{7/2}$ electronic transition at 1.24 eV is close to the bandgap of silicon (~ 1.1 eV) and photoluminescence quantum yields (PLQY) approaching 200% (2 NIR photons per UV photon) has been demonstrated in colloidal dispersions, and thin films synthesized using solution-based approaches.[1] These films, however, exhibit significant sub-bandgap absorption. We are using physical vapor deposition (PVD), specifically evaporation, as an alternative for depositing films with high PLQY and low sub-bandgap absorption. We explore the PVD of thin Yb-doped $CsPb(Cl_{1-x}Br_x)_3$ ($x<0.65$) and Yb-doped lead-free double perovskite films (e.g., Cs_2AgBiX_6 with B = Bi, In, Sb and X=Cl, Br) via co-deposition from metal halide precursors. Yb is doped into the host halide perovskite, which absorbs in the UV and visible regions of the electromagnetic spectrum and then transfers energy to two Yb^{3+}, exciting them from the $^2F_{7/2}$ ground state to the $^2F_{5/2}$ state. The excited Yb^{3+} emits NIR photons at ~1.24 eV upon relaxation. In this scenario, the two Yb^{3+} that receive the energy must be close to each other and likely also to a defect that captures the exciton. A likely candidate is a charge-compensated defect complex involving three corner-connected PbX_6

octahedra where one octahedron has a Pb vacancy (V_{Pb}), and two neighboring octahedra have Yb^{3+} ions that substitute in Pb^{2+} lattice sites (Yb_{Pb}).[2] PLQY from PVD $CsPb(Cl_{1-x}Br_x)_3$ depends strongly on the annealing environment implicating surfaces and their importance in achieving quantum cutting and PLQY. To replace Pb and contrast $CsPb(Cl_{1-x}Br_x)_3$ with a material where Pb is heterosubstituted to form a double perovskite, we deposited Yb-doped $Cs_2AgBiBr_6$ films using PVD. Yb^{3+} ions substitute into the double perovskite structure of $Cs_2AgBiBr_6$, specifically the $AgBr_6^{5-}$ and/or $BiBr_6^{3-}$ octahedra. Robust, reproducible, and stable PLQY as high as 95% are achieved with $Cs_2AgBiBr_6$ films doped with 8% Yb. This high PLQY indicates facile and efficient energy transfer from the perovskite host, $Cs_2AgBiBr_6$, to Yb, making $Cs_2AgBiBr_6$ the most promising lead-free down-conversion material.[3] However, downconversion is achieved even when the excitation energy is less than ~2.5 eV, indicating that the mechanism is not via quantum cutting. It is interesting to note that Yb^{3+} substitution into neither Ag^+ nor Bi^{3+} lattice positions has the potential to form a defect like Yb_{Pb}- V_{Pb} - Yb_{Pb} in $CsPb(Cl_{1-x}Br_x)_3$. PLQY of Yb-doped $Cs_2AgBiBr_6$ thin films synthesized via physical vapor deposition depends strongly on how the substrate temperature changes during the deposition because it determines the amount of Bi incorporated into the film. Yb-doped $Cs_2AgBiBr_6$ films with PLQY as high as 95% are obtained only with excess $BiBr_3$ and by ramping substrate temperature during the deposition. Ramping the substrate temperature reduces $BiBr_3$ loss from the film by promoting reactions that form $Cs_2AgBiBr_6$.

Defect Management Through Additive Engineering and Light Soaking in Sn-Based Perovskite Solar Cells and LEDs Ivan Mora-Sero; Universitat Jaume I, Spain

Halide perovskite solar cells have revolutionized the photovoltaic field in the last decade. In a decade of intensive research it has been a huge improvement in the performance of these devices, however, the two main drawbacks of this system, the use of hazardous Pb and the long term stability, still to be open questions that have not been fully addressed. The photoconversion performance of perovskite solar cells containing alternative metals to Pb is significantly lower than the reported for devices containing Pb, where Sn-based perovskite solar cells is the alternative reporting higher photovoltaic performance close to 14%. Nevertheless, Sn-based perovskite solar cells exhibit a long term stability lower than their Pb containing counterparts, making stability their main problem. In this talk, we highlight how the use of proper additives and light soaking for defect engineering can increase significantly the stability of formamidinium tin iodide ($FASnI_3$) solar cells, and discuss about the different mechanism affecting this stability, beyond the oxidation of Sn^{2+}, and how they can be countered. Effect in Sn-based perovskite LEDs will be also analyzed.

9:30 AM SF05.03.03
Physical Vapor Deposition of Yb-doped Double Perovskite Halide $Cs_2AgIn(Br, Cl)_3$ Yukun Liu, Iver J. Cleveland, Minh N. Tran and Eray S. Aydil; Tandon School of Engineering, New York University, United States

Inorganic double perovskite halides $A_2B^+B^{3+}X_6$ (A = Cs, Rb, B^+ = Ag, Na, B^{3+} = In, Sb, etc. and X = Br, Cl) have been receiving attention as an alternative to the extensively studied $APbX_3$ because of their potential to eliminate Pb while preserving some of their attractive optical and electronic properties. For instance, downconversion and nearly perfect quantum cutting with photoluminescence quantum yields (PLQY) approaching 200% have been achieved with Yb-doped $CsPb(Cl, Br)_3$,[1] but the search for an as efficient perovskite without Pb continues. Quantum cutting down conversion phosphors are receiving increasing attention, as overlayers for solar cells, owing to their capacity of red-shifting photons from sunlight to those of lower energies and enhancing the efficiencies of solar cells by reducing charge recombination and energy losses as hot carriers relax to band edges. Yb^{3+} stands out among rare earth metals as an ideal downconverter because it can emit at ~1.25 eV, just above the bandgap of 1.1 eV of crystalline silicon, and can potentially quantum cut one incoming photon in the UV range to two NIR photons when embedded in a host with bandgap > 2.5 eV. We have been exploring double all inorganic halide perovskites as a host for Yb^{3+}. $A_2B^+B^{3+}X_6$ structure has been reported to be stable to heat, moisture, and exposure to light.[2] Specifically, we use physical vapor deposition (PVD) as a solvent-free, ligand-free technique with precise control over parameters such as film thicknesses and composition and as a synthesis technique that can overcome limitations such as poor precursor solubilities in solvents. This talk will cover the physical vapor deposition of undoped and Yb-doped $Cs_2AgSbBr_6$ and $Cs_2AgInCl_6$ thin films as well as undoped $Cs_2AgInBr_6$. The latter, $Cs_2AgInBr_6$, has been difficult to synthesize using other methods. We show that while cubic $Cs_2AgInBr_6$ can be formed at high temperatures, it appears to be unstable at room temperature, ultimately decomposing into more stable products such as $Cs_3In_2Br_9$, Cs_2AgBr_3, $CsAgBr_2$, $InBr_3$ and AgBr, likely depending on local composition. Specifically, co-deposited precursors CsBr, AgBr, and $InBr_3$ react at and above ~100 ºC to form cubic $Cs_2AgInBr_6$. This structure remains stable long enough to be studied when cooled down to room temperature. However, it ultimately decomposes. In contrast, $Cs_2AgInCl_6$ can be formed via codeposition of the precursors easily and is stable. XRD confirmed the formation of $Cs_2AgInCl_6$, which can be doped with Yb up to 12% without impurity phases. So far, NIR PLQY values of 28.1% have been achieved when doped with 4% of Yb. The major obstacle in depositing $Cs_2AgSbBr_6$ lay in the volatility of the Sb precursor, $SbBr_3$. PLQY values could be improved to ~14% either by increasing the amount of $SbBr_3$ flux or adopting a sandwich deposition structure where $SbBr_3$ is placed between two layers of CsBr and co-deposited CsBr, AgBr and $YbBr_3$. In contrast, $Cs_2AgInCl_6$ could be deposited and formed easily owing to the higher evaporation temperature of $InCl_3$. These films could be doped with Yb by coevaporating $YbCl_3$ with the other precursors. Achieving high PLQY requires annealing at 300 ºC for 1 hour. .

Understanding Defect Driven Phase Transitions in Correlated Quantum Materials with Quantum Monte Carlo Paul R. Kent, Jaron T. Krogel and Panchapakesan Ganesh; Oak Ridge National Laboratory, United States

One of the most promising routes for manipulating the properties of correlated solids for technological applications is through control of defects, doping, and stoichiometry. However, the mechanisms that drive the electronic and magnetic transitions in these materials and the specific role of defects not fully understood. For example, the perovskite SrCoO3 is a ferromagnetic metal, while the oxygen-deficient (n-doped) brownmillerite SrCoO2.5 is an antiferromagnetic insulator. The challenge in predicting and understanding these behaviors from the intricate couplings of charge, spin, orbital, and lattice degrees of freedom. These challenge standard modeling approaches, requiring either significant empiricism or adoption of new methodologies to make progress. Here we outline our use of the highly accurate ab initio quantum Monte Carlo (QMC) approach to address these challenges. To control computational costs, we have developed a protocol of using QMC results to validate more scalable approaches via magnetic moments, charge densities, and thermodynamic properties. We present results for bulk and heterostructures of VO2[1,2], our model for how doping controls the metal-insulator transition in the correlated-perovskites[3], and the role of defects in the $MnBi_2Te_4$ system following this protocol.

This work was supported by the U.S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division, as part of the Computational Materials Sciences Program and Center for Predictive Simulation of Functional Materials.

10:45 AM SF05.04.02
Mutlicrystalline Informatics—A Methodology to Realize High-Performance Multicrystalline Materials Noritaka Usami[1], Yutaka Ohno[2], Hiroaki Kudo[1], Kentaro Kutsukake[3], Takuto Kojima[1] and Tatsuya Yokoi[1]; [1]Nagoya University, Japan; [2]Tohoku University, Japan; [3]RIKEN, Japan

We introduce our methodology, “multicrystalline informatics”, which integrates experiments, theory, computation, and machine learning to establish a universal guideline to maximize the macroscopic performance of multicrystalline materials by controlling microstructures and reducing crystal defects. We employ silicon as a model material and prepare various helpful machine learning tools for efficient materials development.

A realistic three-dimensional multicrystalline model of a silicon ingot for solar cells grown by directional solidification was obtained by integrating grain segmentation and orientation prediction by a machine learning model using multidimensional optical images of silicon wafers. The region of the interest was selected to contain the generation point of dislocation clusters as evidenced by photoluminescence images to reveal the spatial distribution of crystal defects. Finite element stress analysis was performed on the three-dimensional model by referring to the temperature distribution during crystal growth obtained from the simulation. The analysis results indicated that dislocations were generated along the main slip system where the greatest shear stress was applied. As for the experimental approach, multiscale structural analysis including transmission electron microscopy clarified that dislocations were generated from a curved Σ3 grain boundary with stepped microscopic {111} facets. It seems that high shear stress at the step edge would be responsible for the generation of dislocations.

As an alternative approach to access the underlying mechanism of the generation of dislocations, we attempt to apply image translation methods such as generative adversarial networks to obtain the likelihood distribution of dislocations generation from optical images or other processed images. By considering various models employing different images as a pseudo color input image, combining a grain boundary image and two optical images with different illumination angles showed a realistic output image. This indicates that a grain boundary network and crystal orientations play an essential role in the generation of dislocations. A further study to apply explainable artificial intelligence may help clarify the physics behind the phenomena.

11:00 AM SF05.04.04
High-Throughput Search for Defect-Based Qubits for Quantum Information Science Applications Yihuang Xiong[1], Diana Dahliah[2], Céline Bourgois[2,1], Sinead M. Griffin[3,3], Alp Sipahigil[4] and Geoffroy Hautier[1,2]; [1]Dartmouth College, United States; [2]Université Catholique de Louvain, Belgium; [3]Lawrence Berkeley National Laboratory, United States; [4]University of California, Berkeley, United States

Silicon is an attractive platform for implementing solid-state qubits due to the mature process technology and commercial compatibility. The color centers in silicon have seen a resurgence of interest in quantum information science, including the T-center and Se^+. [1,2] Using first-principles methods, we performed a high-throughput search for charged defects in silicon for qubit applications. By evaluating the thermodynamic, electronic, and optical properties, we suggest possible candidates that are promising for quantum defects and shed light on their electronic structures and potential excitation mechanism compared to the other well-known systems (e.g., NV– center in diamond).

***sp3*-Doped (6,5) Single-Walled Carbon Nanotubes as a New Class of Materials for Spin Qubit Technology** Kasidet Jing Trerayapiwat[1], Jia-Shiang Chen[2], Xuedan Ma[2,3] and Sahar Sharifzadeh[1,1]; [1]Boston University, United States; [2]Argonne National Laboratory, United States; [3]The University of Chicago, United States

Single-walled carbon nanotubes (SWCNTs) doped with *sp3* defects are a promising class of optoelectronic materials with bright tunable photoluminescence and localized spin density. We study a series of *sp3* defects within (6,5) SWCNT that result in one single unpaired spin within the bandgap of the tube and show, using experimental and computational techniques, that this spin has a decoherence time competitive with molecular spin qubits. Density functional theory (DFT) studies indicate that an unpaired spin localizes around the defect site. We simulate dephasing of the localized spin by considering spin-nuclear spin bath interactions as the main source of decoherence at low temperature. We apply the cluster correlation expansion method with a pure-dephasing spin Hamiltonian to doped SWCNT in presence of solvent molecules at near 0 K and estimate the magnitude of the intrinsic dephasing time (T2). Combined with other decoherence mechanisms based on empirical parameters, we calculate a real dephasing time in good agreement with measured Hahn spin echo T2 and suggest a way to further improve dephasing time.

First-Principles Study of the Stark Effect of the NV Center Louis Alaerts and Geoffroy Hautier; Dartmouth College, United States

The NV center is a defect found in diamond and consists of a nitrogen substitution and a adjacent vacancy. It is arguably the most studied defect thanks to its particular electronic structure which leads to several important quantum technology applications such as solid-state qubit or in quantum sensing. In particular, the spin-conserving optical transition from the $^3A_2$ state to the ^3E state at 1.945eV plays an important role in all the aforementioned applications. This optical transition is accompanied with a change of dipole moment. Applying an electric field will therefore change the energy difference between the two levels, a phenomenon well-known and called the Stark effect. The Stark shift is detrimental for quantum emitters as fluctuation of the local field will cause spectral diffusion. It is therefore important to quantify this effect with precision.

In this poster, we present the results of our density functional theory calculation on the NV center. We use several methods to compute the dipole moment of the $^3A_2$ ground-state and the ^3E excited-state such as the modern theory of polarization or electric field calculation. We then compare the different methods used with experimental results.

SESSION SF05.05: Harvesting Functional Defects in Energy Materials I
Session Chairs: Panchapakesan Ganesh and Yiyang Li
Tuesday Afternoon, November 29, 2022
Sheraton, 3rd Floor, Gardner A/B

1:30 PM *SF05.05.01
Defects and Design in Energy Materials Matthew Rosseinsky; University of Liverpool, United Kingdom

The presence of defects is essential for many functional properties of materials. For example, segregation of substitutional defects to domain boundaries in nanostructured self-assembled composites can be harnessed to control the stability and performance of solid oxide and proton conducting fuel cell cathodes (*Advanced Materials Interfaces* 9, 2102131, 2022; *J. Mater. Chem. A*, 2022, 10, 2559). However, materials design approaches have predominantly focussed on perfectly ordered average structures, because of the challenges associated with disorder. Focussing on low thermal conductivity *(Science* 373, 1017-1022, 2021), we show how average structure prediction coupled with machine learning affords outperforming materials with defect elimination through formation of aperiodic structural motifs (*Angewandte Chemie-International Edition.* 2021, 60, 2–11). This emphasises the future scope to build in functional defects by design.

Tuning Surface Acidity—Novel Strategy for Recovery of Degraded Oxygen Exchange Kientics in Mixed Conducting Oxides Han Gil Seo, Anna F. Staerz, Dennis Kim, James LeBeau and Harry Tuller; Massachusetts Institute of Technology, United States

The performance and viability of applications ranging from energy conversion and storage devices (solid oxide fuel/electrolyser cells (SOFCs/SOECs), permeation membranes, batteries), and sensors are presently limited by performance degradation due to impurity poisoning, for example in SOFCs, due to chromia and silica impurities coming from metal interconnects and furnace refractories respectively. We recently showed that the oxygen surface exchange kinetic (k_{chem}) values of the mixed conducting oxide, $Pr_{0.1}Ce_{0.9}O_{2-\delta}$ (PCO), can be systematically varied by over 6 orders of manitude by infiltrating the surface with binary oxides ranging from strongly acidic to strongly basic. Basic lithia increased k_{chem} by nearly 1,000 times over that of pristine PCO, while acidic silica depressed k_{chem} by nearly the same factor with variations in k_{chem} attributed to the induced relative accumulation or depletion of surface electrons. With this insight, we hypothesized that surface acidity could be used not only to predict the effect of a single additive on oxygen exchange, but also to recover the oxygen exchange degraded by acidic additives.
Here, we demonstrate that a drastic depression in the oxygen exchange kinetics of PCO induced by infiltration of acidic binary additives (*e.g.* chromia and silica in this work), can be fully recovered by subsequent infiltration of basic additives (*e.g.* lithia and calcia). Electrical conductivity relaxation measurements on porous PCO specimens were used to examine the impact of serial infiltration of basic additives on the degraded exchange rate of oxygen. In parallel, the electrochemical performance of screen-printed PCO symmetric cells (cathode|electrolyte|cathode) with serial infiltration of basic additives were further assessed by electrochemical impedance spectroscopy in terms of area-specific resistance with similar trends observed. Surface microstructures of the respective infiltrated specimens were examined by scanning transmission electron microscopy with electron energy loss spectroscopy to characterize the chemical nature and distribution of the additives.

Structural Contribution of Fe-Enhanced Oxygen Evolution Electrocatalysis in Nickel Oxides Tae Gyu Yun, Jumi Bak and Sung-Yoon Chung; Korea Institute of Science and Technology, Korea (the Republic of)

Controlling electronic states is crucial in electrocatalysis because it controls charge transfer behavior, which is crucial for improving catalytic reaction efficiency. While many complex oxides have been subjected to a variety of chemical changes to cause a change in electronic states at catalytically active sites, there have been few studies to investigate the impact of local crystal structures on electronic states under the same composition. Here we compare the electrocatalysis of the oxygen evolution reaction (OER) between amorphous and crystalline perovskite nickelates in a thin film when Fe is added as an active site. The enhancement of OER activity by Fe in amorphous films with a random atom configuration is found to be insensitive to the Fe doping method. In crystalline films, on the other hand, an order of magnitude change in OER activity is induced, which is substantially influenced by the resultant structure variation during doping. For extremely high activity, theoretical studies consistently show a significant rise in the density of Fe 3*d* states beneath the Fermi level. Our findings show that the atomic-scale structure of crystalline oxide catalysts is an important factor to consider when trying to understand how to improve OER catalysis.

Interaction and Transformation of Defects in Energy Materials Andrej Singer; Cornell University, United States

Non-equilibrium defects often dictate macroscopic functional properties of materials. In energy materials, dislocations and planar defects significantly modify reversibility and kinetics. Nevertheless, transient imperfections briefly appearing during ionic transport have been challenging to capture, limiting understanding of their life cycle and impact. I will present our recent operando x-ray nanoimaging results, where we track the dynamics of metastable defects within alkaline ion intercalation hosts and proton conducting ceramics. In intercalation oxides, three-dimensional coherent X-ray imaging reveals

the transformation and self-healing of a metastable domain boundary, glissile dislocation loop, and stacking faults. In proton conducting ceramics, an abundant defect activity is observed, culminating in the cracking of individual grains. The presence of high dimensional defects in energy materials observed with operando nanoimaging suggest their abundance and highlights the importance of defect engineering for developing next-generation energy solutions.

3:30 PM SF05.05.05
Shifting and Breaking Scaling Relations at Transition Metal Telluride Edges for Selective Electrochemical CO_2 Reduction Courtney Brea and Guoxiang Hu; Queens College, CUNY, United States

The electrochemical reduction of CO_2 (CO_2RR) to hydrocarbons and alcohols provides a means to solve problems pertaining to fossil energy shortages and environmental pollution. However, developing electrode catalysts that can perform this transformation with a low overpotential and a high product selectivity remains a challenge. Two-dimensional (2D) transition metal dichalcogenides (TMDCs) have emerged as promising catalysts for the CO_2RR, where primarily the edges are responsible for the catalytic activity. Herein by using first-principles density functional theory (DFT), we study 48 TMDC edges with six different chemical compositions (MX_2, M = Mo, W; X = S, Se, Te). By plotting their phase diagrams, we provide guidelines on the synthesis conditions for the edges. Furthermore, by computing the binding energies of key reaction intermediates, we find that the linear scaling relations can be broken by the edge reconstruction and shifted by the chemical composition. Specifically, compared with sulfide and selenide edges, more telluride edges show similar affinity to Cu towards the reaction intermediates. The computed free-energy diagrams show that certain reconstructed telluride edges exhibit high catalytic activity and selectivity for CO_2 reduction to CH_3OH and CH_4. These insights help pave the way for efficient and selective electrochemical CO_2RR on transition metal tellurides.

3:45 PM SF05.05.06
Charge Density Manipulation by Transition Metal Heteroatoms on Tungsten Trioxide for Photocatalytic CO_2 Reduction Chih-Yang Huang[1,2,1], Ying-Ren Lai[1], Kuei-Hsien Chen[2] and Li-Chyong Chen[1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

In the past decades, the greenhouse gases and renewable energy topics have attracted attention because of the expeditious climate change. Photocatalytic (PC) CO_2 reduction into value-added molecules can be a potential method to address the abovementioned problems. However, PC CO_2 reduction suffers from the low production rate, which contributed to low surface electron density. That is electron-rich surface is essential for superior catalytic activity. Engineering the surface defects such as point defects is an effective way to manipulate the local electronic structure and activate the inert surface. Point defect can be introduced by doping heteroatoms and the generation of vacancies. In the field of catalysis, heteroatom doping or single-atom catalysts (SACs) is a rapidly developing approach due to its unique electronic properties to boost catalytic performances. Although most studies on the SACs have used highly active noble metals, their high cost limits their utilization for industry applications. So, we choose transition metals with the 3*d* electronic configuration (i.e., Cr, Fe, and Ni atoms) as the candidate heteroatoms. However, the influences of transition metal heteroatom doping on charge density distribution haven't been clearly studied yet. Herein, we theoretically predict and experimentally confirm the heteroatom-assisted charge density re-distribution on the surface of tungsten trioxide (WO_3).Density functional theory (DFT) calculations show that the anchored transition metals play a role as electron contributors to the neighbor atoms. Synchrotron-based x-ray absorption near-edge structure (XANES) and Fourier transform extended x ray absorption fine structure (FT EXAFS) are performed to prove the presence of single atoms thereon the WO_3 surface. Further, the x-ray photoelectron spectroscopy (XPS) technique is used to find the direction and amount of transferred charge. Finally, the PC CO_2 reduction yields also unveil that the production rate is proportional to the amount of transferred (donated) electron. This study provides insights into the correlation between CO_2 conversion and the surface charge distribution, implying the significance of the surface charge density in the field of catalysis.

4:00 PM SF05.05.07
Metallurgical Alloying Enables Supersaturated Cu Solid Solution for Efficient CO_2-to-ethanol Electroconversion Ji Yong Kim[1], Heh Sang Ahn[1], Dae-Hyun Nam[2], Eun Soo Park[1] and Young-Chang Joo[1]; [1]Seoul National University, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Converting CO_2 into value-added chemicals through electrocatalysis not only utilizes the CO_2 to achieve net negative carbon emission, but also enables long-term storage of intermittent renewable electricity. There has been a great interest in electrochemical CO_2 reduction reaction (CO_2RR) to produce liquid fuels which has high energy density. In light of the progress, energy efficiency and reaction rate for C_{2+} products have been largely improved, especially for ethylene (C_2H_4) production. However, the development of electrocatalysts that efficiently produce ethanol (C_2H_5OH), another C_2 product which is one of the most essential organic chemical, has been retarded. To enhance C_2H_5OH productivity, heteroatom alloying and defective sites have been known to be effective by promoting preferential binding with reaction intermediates and lower an energy barrier of rate-determining step. Herein, we developed alloy catalysts in which Cu sites were evenly dispersed in Ag lattice over a thermodynamic immiscibility for efficient C_2H_5OH production. For precise microstructural control, alloying and chemical de-alloying strategies were adopted which were scalable for porous electrode. Removing sacrificial metal through the de-alloying formed defect sites such as vacancy in the catalysts which were effective to enhance the affinity to the reaction intermediate. Microstructural optimization was judiciously carried out based on metallurgical considerations in the perspective of composition and undercooling. Cu catalysts from eutectic composition and rapid quenching acquired high porosity and the undercoordinated sites after the de-alloying, enabling robust CO_2-to-C_{2+} products electroconversion at the Faradaic efficiency (FE) of 80.1±1.6% and partial current density of -127.7±30.3 mA/cm^2 using membrane electrode assembly (MEA) reactor in a neutral electrolyte. Main products of the de-alloyed Cu was C_2H_4. Thereafter, introduction of the heteroatom (Ag) to the Cu catalysts was conducted to steer the catalysis toward C_2H_5OH production. Elemental distribution of Ag conformed to the immiscibility at initial addition of heteroatoms. However, it was noteworthy that non-equilibrium alloying exploiting large undercooling enabled dissolution of Cu in Ag_2Al phase overcoming the immiscibility. After removing Al, supersaturated solid solution of Ag-Cu alloy was fabricated. Well-defined crystal structure and even distribution of Cu sites significantly facilitated C_2H_5OH formation rather than C_2H_4, achieving the maximum selectivity of 40.4±2.4% and full cell energy efficiency of 14.4%. The relative productivity of C_2H_5OH to C_2H_4 was widely controlled within the range of 0.1 to 1.9. Our metallurgical alloying strategy not only extended the range of alloy catalysts beyond thermodynamic immiscibility, but also highlighted the modifications of microstructure and atomic configuration for efficient production of liquid chemicals from CO_2.

4:15 PM SF05.05.08
Designing a Highly Active and Selective Defect-Rich g-C_3N_4 Photocatalyst for CO_2RR: Experimental and Theoretical Insights Mahmoud K. Hussien[1,2], Amr Sabbah[1], M. Karen Qorbani[3], Heng-Liang Wu[3], Ming-Chang Lin[2], Li-Chyong Chen[3] and Kuei-Hsien Chen[1,3]; [1]Academia Sinica, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan; [3]National Taiwan University, Taiwan

Photocatalytic CO_2 reduction into valuable chemicals and fuels is a promising approach to alleviate the global energy and environmental crises. Recently, achieving high catalytic activity and selectivity using single-material photocatalyst in the absence of any sacrificial electron donor, photosensitizer, or cocatalyst has become a major challenge in the photocatalysis research field. It is far more challenging to produce outstanding catalytic performance from a naturally abundant, metal-free photocatalyst using an environmentally benign approach. Recently, graphitic carbon nitride (g-C_3N_4) has attracted great

attention as a metal-free photocatalyst due to its medium band gap, low cost, and high chemical stability. Unfortunately, the low specific surface area, poor visible light-harvesting ability, slow charge interjection rate, and fast charge carrier recombination limit the practical application of pristine g-C_3N_4 in photocatalytic applications. Among the variety of modification strategies, defect engineering has been demonstrated as a viable strategy for modifying the optical, structural, and electronic features of g-C_3N_4 for improved photocatalytic performance. Prior research has mostly focused on the modification of g-C_3N_4 with a single specific defect. Unfortunately, a single defect can not simultaneously solve all the shortcomings of g-C_3N_4. Herein, a novel green method is developed to prepare a functionalized nanoporous nonmetal-doped g-C_3N_4. The newly designed defect-rich g-C_3N_4 has excellent photocatalytic performance in the gas-phase CO_2 reduction reaction (CO_2RR) with nearly 100% selectivity towards carbon monoxide (CO) production. In-depth mechanistic and theoretical studies were performed to provide a detailed mechanism of CO_2RR. Besides, temperature-dependent and intensity-dependent photoluminescence (PL) measurements were investigated to understand the exciton dissociation mechanism. DFT calculations supported by synchrotron-based X-ray absorption near-edge spectroscopy (XANES) analysis were utilized to determine the active site towards CO_2RR. The results show that the numerous-defect modification technique prolongs the visible light absorption, increases the surface area, improves the adsorption capacity, decreases the charge recombination rate, and promotes the exciton dissociation of the modified g-C_3N_4. This study provides a new energy-efficient route for the engineering of graphitic carbon nitride for photocatalytic applications. Besides, it presents a deeper understanding of the role of each type of the defect in the outstanding photocatalytic performance of the modified g-C_3N_4

SF05.06.01
Effects of Fe Species on the Surface of TiO_2 Nanostructures and Their Influence on Photocatalytic CO_2 Reduction Waldir J. Avansi[1], Paulo Henrique Eleuterio Falsetti[1], Gelson Thiago dos Santos Tavares da Silva[2] and Caue Ribeiro[2]; [1]University de Sao Carlos, Brazil; [2]Embrapa, Brazil

In the last decades, global energy demand for fossil fuels has resulted in increased CO_2 emission in the atmosphere, leading to several negative impacts on the environment[1-3]. Among the various methods studied to overcome this problem, the photocatalytic conversion of CO_2 into solar fuels (CH_4, HCO_2H, CH_2O and CH_3OH) using semiconductors has been considered a promising technology[1-3]. Titanium dioxide (TiO_2), which has several advantages when applied in heterogeneous photocatalysis, have been extensively studied for the photocatalytic conversion of CO_2[1-4]. As a matter of fact, different modification techniques have been employed to improve the efficiency of TiO_2 in this process, such as surface modifications, doping of metals and non-metals, and so on[1-4]. Thus, the aim of this work is to evaluate the effects of Fe on the photocatalytic CO_2 reduction of different TiO_2 morphologies. The different TiO_2 morphologies were obtained by the synthesis route proposed by Mendonça et al. through a hydrothermal reaction by changing the pH of the reaction medium[5]. TiO_2 decoration was performed using an impregnation method adapted from Xie et al.[4] Different proportions of Fe were evaluated (0.2, 0.8 and 1.6 % of mass). For comparison purposes, the same process was performed using commercial TiO_2 anatase. XRD measurements revealed that all samples exhibited TiO_2 anatase crystalline phase, while EDS results confirmed the presence of Fe and the absence of contaminants in the samples. DRS UV-Vis showed a tendency of band gap energy (Eg) decrease related to the increase in the amount of Fe in all studied samples. Electron microscopy revealed that the as-synthesized samples had a faceted - TiO_2 morphology regardless of the presence of Fe. XPS results confirmed the presence of different Fe species (FeOOH and Fe_2O_3) in the samples, with a strong interaction between Ti and loaded Fe. The photocatalytic CO_2 conversion results showed that the studied samples successfully converted CO_2 into CO and CH_4. The higher amount of Fe (1.6 % of Fe) on TiO_2 nanocrystals led to a better performance in the production of CH_4. The improved photocatalytic performance can be attributed to faceted TiO_2 nanocrystals and the efficient electron transfer due to the presence of Fe species on their surface.

SF05.06.02
Sn/Sb Segregation Effect at Polycrystalline Hematite Interfaces Flavio L. De Souza[1,2]; [1]Brazilian Nanotechnology National Laboratory, Brazil; [2]University Federal-ABC, Brazil

The effect of atomic structure modification in hematite has become a key factor for the rational design of the highly efficient system. Herein, this study describes the segregation effects of Sn and Sb-dopants on both solid-solid (grain boundaries) and solid-liquid interfaces (surfaces) of polycrystalline hematite. From an experimental point of view, the proper sintering process allows freezing of a state of electronic defects, in which the electrical properties of hematite are controlled by the grain boundary and Sn or Sb segregation. Impedance spectroscopy and dc conductivity measurements show that current flows through preferential pathways associated with Sn or Sb segregation that occurs at the grain boundary, leading to a decrease in grain-boundary resistance. By employing the ab initio approach, the potential barrier reduction was observed on polycrystalline interfaces due to the dopant, which causes an increase in the inter-grain electron transport. Concomitantly, the dopants' segregation on hematite surfaces results in a decrease in the oxygen vacancy formation energy. Such vacancies lead to the experimentally observed rise of the flat band potential. The comprehension of the electronic effects of dopants on both types of interfaces has important implications to explain the experimental results, also enabling the control and design of interfaces for different higher-efficiency applications.

SF05.06.03
Construction of Long-Range EAM-Type Interatomic Interaction Model for Dynamical Analyses on Long-Periodic Polytypism Shinya Ogane[1], Kazumasa Tsutsui[2] and Koji Moriguchi[1]; [1]Tohoku University, Japan; [2]Nippon Steel, Japan

Many crystalline compounds are composed of one or more structural units. When these units can be stacked in different ways to form stable or metastable phases, the resulting phases are known as polytypes [1]. Among these polytypes, the crystalline systems composed of close-packed (CP) layers have especially attracted attention on their fundamental and technological properties for many years. The material engineering demand for polytype phase control is diverse [2-4]. However, the scientific control of the polytype phase is still incomplete in the field of practical materials engineering and predicting polytype phase stability for a material has also been a long-standing issue in condensed matter physics and/or materials science. This is because the polytype control technology has many uncertainties since the polytype formation mechanism has yet been physically unsolved.
To provide a useful theoretical tool in this situation, we have constructed EAM-type potentials that can be applied to atomic-level dynamical analyses on long-period polytypism. In this study, the metallic lanthanum (La) system has been selected as a prototype system analyzing the dynamical processes of polytype formations for the following reasons; (i) the ground state for pure La is the 4H structure which is the simplest long-periodic polytype, (ii) La has the phase stability in both 4H and 3C phases below 583K [6], and (iii) it is, therefore, expected that the phase transition phenomena including 4H and/or 3C polytype structures can be investigated by the molecular dynamical (MD) studies such as crystal growth kinetic simulations.
We have recently presented a theoretical consideration on the CP polytype total energetics using the geometrical analysis on the correlation between interlayer interactions and interatomic ones [7]. These results suggest that short-range interactions are not enough to describe the CP polytype energetics and provide significant insights for creating interatomic models successfully showing the polytypes other than 3C and 2H structures as a ground state. We have succeeded in constructing an EAM-type potential that mimics the energetics of metallic La based on the first-principles calculations [8]. The following three procedures are found to be essentially important for deriving an interatomic interaction model with the 4H structure as the ground state; (i) The cutoff radius should be set to have a relatively longer distance (three or more interlayer distances in the 4H stacking). (ii) The equations of state for the energetics of 2H, 3C, and 4H structures need to be reproduced as accurately as possible. (iii) The adiabatic potential along important transition paths among crystal structures such as the Bain path for the bcc-fcc transition must be exactly considered [9,10].
We have calculated the Generalized stacking fault energy (GSFE) surface for some CP structures using the present potential constructed. Both unstable stacking fault and stable fault energies for La are much lower than ones for Al calculated by another EAM-type potential [11]. Therefore, La has low energy barrier required for forming stacking defects, and polytype formations can easily appear. The presentation of the day will also discuss other basic properties, the transferability for the potential constructed, and some of the dynamical phenomena by the MD analyses.

SF05.06.04
Effect of Embedding Cavities into Reduced Graphene Oxide-coated Micropillar on Boiling Heat Transfer Enhancement Maroosol Yun[1], Geehong Choi[2], Donghwi Lee[3], Beom Seok Kim[4] and Hyung Hee Cho[1]; [1]Yonsei University, Korea (the Republic of); [2]Hyundai Steel Co. Ltd, Korea (the Republic of); [3]Jeonbuk National University, Korea (the Republic of); [4]Seoul National University of Science and Technology, Korea (the Republic of)

As cooling capacity demands for systems of high heat flux, i.e. data storage center, nuclear fusion reactor, and computer chip cooling, continuously grows, boiling heat transfer with phase change could be a favorable method since it utilizes latent heat, which allows smaller superheat of system. Critical heat flux (CHF), which indicates the maximum cooling capacity can be obtained by fully developed nucleate boiling, is determined by vapor film formation on the heated surface. If the vapor film covers the entire heated surface, an abrupt increase in wall temperature is observed as the thermal conductivity of the vapor film is a few orders of magnitude smaller than that of liquid-phase working fluid. To delay the formation of vapor film, bubble coalescence should be prevented to supply sufficient, fresh working fluid. The merging of adjacent bubbles can be suppressed by controlling bubble characteristics. Nanoparticle coating with graphene/graphene-oxide could generate smaller bubbles compared to the plain surface, by offering a myriad of micro-sized cavities which promote bubble nucleation. However, bubble coalescence still occurs with high heat flux conditions. To ensure liquid paths with high thermal load, the location of bubbles should be considered. Here, we propose reduced graphene oxide (rGO)-coated patterned surfaces with micropillar array and microcavities to pattern nucleation sites, thus, to suppress bubble coalescence observed in our previous work, rGO coated micropillar. The rGO-coated nucleation pattern surfaces were prepared by stepwise methods of deep reactive ion etching (DRIE) and nanofluid boiling with 0.0005 wt% rGO solution. Micropillars are made to be 20 um in height, 4 um in diameter, and 20 um in pitch, respectively, and square cavities' width is 200 um, and 1 mm in pitch, respectively. Fabricated surfaces of micropillar only, cavity embedded surface were evaluated by deionized (DI) water pool boiling experiment. The experimental conditions are the saturated temperature of DI water at atmospheric pressure. Experimental surfaces of Plain, rGO-coated micropillar, rGO-coated cavity embedded surface recorded 89 W/cm2, 224 W/cm2, and 261 W/cm2 in CHF and 20.4 kW/m2K, 74.3 kW/m2K, and 85.8 kW/m2K in maximum heat transfer coefficient, respectively. CHF and HTC records confirm that the nucleation pattern surface exhibits superior heat transfer performance to the rGO-coated micropillar surface. Bubble visualization results show that rGO-coated nucleation pattern surfaces have separated bubble departure with the presence of cavities, while bubbles merge laterally with the high heat flux on the rGO-coated micropillar surface. Thus, the CHF and HTC are heightened for the cavity-embedded case owing to the suppressed bubble merger on the heated surface. Bubble images which are taken at 50 W/cm2 heat flux show liquid paths between the cavity pattern on the cavity embedded surface. This means the working fluid could imbibe through the microstructures; thus, bubble coalescence can be effectively suppressed, delaying the CHF. The notable improvement on CHF and HTC in the rGO-coated nucleation pattern surfaces indicates cavity embedment for bubble merger resistance can be a powerful design for nanoparticle-coated surfaces, allowing 320% increased HTC compared to the plain surfaces. This study will be helpful for designing nanoparticle-coated surfaces for enhanced boiling heat transfer on cooling systems for high heat flux devices like heat exchangers and fusion reactors.

SF05.06.05
Defect Dominated Hierarchical Ti-Metal-Organic Frameworks via a Linker Competitive Coordination Strategy for Toluene Removal Jin Jie and

Jong Hyeok Park; Yonsei University, Korea (the Republic of)

As relatively new porous materials, metal-organic frameworks (MOFs) have become attractive materials for many applications, especially for gas adsorption and photocatalysis, due to their high function tunability, porosity, and crystallinity. Recently, impressive improvements and achievements have been reported thanks to the numerous effort on improving the performance of MOFs in those two aspects. Representatively, the construction of the hierarchical pore in microporous MOFs can overcome the micropore blockage to improve the diffusion of the large molecules and the accessibility of their active sites. However, most of the methods to control the formation of hierarchically porous MOF have focused on the crystal growth steps, topology structure design, or post-treatment, few approaches regarding the nucleation process have been adapted due to its random fluctuation and difficulty to predict.
Herein, we proposed a novel linker competitive coordination strategy based on the electronegativity difference of two kinds of organic linkers (H2BDC and NH2-H2BDC) to tailor the pore size of the Ti-MOF (MIL-125). The different electronegativity can determine the nucleation rate of those linkers. By simply controlling the feed ratio of these two organic linkers, a series of Ti-MOFs with continuously tunable hierarchical porosity is directly obtained as evidenced by the DFT pore size distribution and N_2 sorption isotherms. Besides, we also demonstrated that the missing-linker defect is created during this process and plays dominated role in the construction of the hierarchical pore.
The demonstration of toluene removal shows that the competitive coordination strategy not only contributes to wide pore size distribution to enhance the adsorption performance of toluene but also endows good charge separation ability to facilitate photocatalytic performance. Finally, the toluene removal efficiency of optimal Ti-MOF with mixed organic linkers of a 1:1 molar ratio is 2.14 times and 1.88 times of the pristine MIL-125 and MIL-125(NH2), respectively.
In conclusion, we constructed a hierarchically porous MIL-125 with tailored pore size via a simple linker competitive coordination strategy and verified the superiority of the hierarchical pore structure by evaluating the adsorption and photocatalytic performance of as-obtained Ti-MOFs for toluene mineralization. Given that this approach is a one-pot method and shows some merits, such as low cost, controllable pore size distribution, without impurity, and avoiding additional post-treatment processes, it can be a new prospect to optimize the porosity of Ti-MOF for various heterogeneous catalysis applications.

Enhancing BH_{max} Through Control of Functional Defects in Ferromagnetic τ Mn-Al Using Equal Channel Angular Extrusion and Ti Addition
Thomas Keller, Ian Baker and Geoffroy Hautier; Dartmouth College, United States

Manganese-Aluminum permanent magnet alloys are a promising alternative to rare-earth permanent magnets (REPMs), due to their advantages of lower raw material cost, more robust global supply chains, and higher corrosion resistance. The ferromagnetic Mn-Al τ phase is a metastable ordered L10 structure that is of particular interest to applications such as electric car motors and direct drive wind turbine generators. The maximum energy product (BH_{max}) of the τ phase is strongly dependent on the microstructure of the permanent magnet. Twins and antiphase boundaries (APBs) have been shown to lower BH_{max} while dislocations and refined grain size have been shown to improve coercivity (H_c) and BH_{max}. Equal channel angular extrusion (ECAE) is a technique for imparting high strain into a material without changing its cross-sectional area. The high amount of strain is demonstrated to introduce high defect density into the bulk. In this study, we employ ECAE for the purpose of improving the coercivity of $Mn_{54}Al_{46}$ bulk ingots, using crystalline defects as pinning sites to inhibit magnetic domain motion. Using ECAE, coercivity is shown to increase from 95 kA/m to over 183 kA/m, without any loss to the saturation magnetization (M_s). This results in a BH_{max} improvement from 8.6 kJ/m^3 to 20.9 kJ/m^3. We investigate the microstructure to understand which defects affect the increase in H_c and why they do not diminish M_s of the ordered τ structure. Furthermore, we substitute Ti for Al to improve BH_{max}, as Ti is anticipated to energetically favor APBs to the bulk τ phase. In this way, we demonstrate how the addition of 1 at.% Ti for Al in a $Mn_{54}Al_{45}Ti_1$ alloy improves τ phase BH_{max} to 11.5 kJ/m^3 when annealed without ECAE. We investigate the microstructure to confirm if Ti suppresses APB formation and the effect of Ti addition on other defects.

Synthesis of $PtSe_2$ Nanoparticles and the Se Vacancy Defect Formation ($PtSe_x$) Towards Hydrogen Evolution Reaction Victor S. Lemos[1], Carolina P. Torres[1], Isabela J. Vieira[1,2], Edson R. Leite[1,3], Adalberto Fazzio[1] and João B. Souza Junior[1,2]; [1]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil; [2]Universidade Estadual de Campinas (Unicamp), Brazil; [3]Universidade Federal de São Carlos (UFSCar), Brazil

The hydrogen evolution reaction (HER) has been a topic of interest. Like other gas evolution reactions, the HER needs an overpotential, and catalyst engineering aims to maximize the process's effectiveness. The best catalysts for the HER are the Pt catalysts, but due to their high cost and rarity are not viable candidates.[1] New studies show a lot of promising catalysts for the HER, among them are the transition metal dichalcogenides (TMDCs), which can be obtained as a 2D nanostructure, and a lot of effort is being made to improve these materials. The $PtSe_2$, is a TMDC that shows high potential due to its high catalytic and conductivity properties.[2] Many paths exist to induce defects on the surface of materials[3]. Our focus is on a new method of synthesis of $PtSe_2$ nanoparticles through the selenization of previously synthesized Pt nanoparticles. The selenization process was performed in a closed alumina reactor with an excess of Se in the presence of Pt nanoparticles. At higher temperatures, Se becomes liquid and the selenization reaction occurs. The excess of Se was removed by solubilization in trioctylphosphine (TOP) and centrifugation. First, Pt nanoparticles were synthesized using 90 mg of $Pt(acac)_2$, 10 mL of oleylamine, and 1 mL of oleic acid in a three-neck round bottom flask with a condenser attached to a Schlenk line. The system is heated to 80 °C under vacuum and constant stirring for complete precursor solubilization. Then, under N_2 atmosphere, the temperature was raised to 250°C for 60 min for precursor decomposition, particle nucleation, and growth. The products are isolated by centrifugation, washed with acetone, and dispersed in hexane. Excess Se is added to the mixture of Pt nanoparticles and heated to 400 °C for 120 min. To remove the Se byproduct, TOP was added to the final reaction product, kept under stirring for 2 hours, and washed with hexane several times followed by centrifugation. To induce defects into $PtSe_2$ nanoparticles, the $PtSe_2$ was dispersed in 1 mL of hexane and 1.6 mL of butyl-lithium hexane solution was added under magnetic stirring, followed by 10 min in ultrasonic bath. The dispersion was washed with hexane. To see the changes in the structure of the $PtSe_2$ the material was characterized by High-Resolution Transmission Electron Microscopy (HRTEM) and EDS chemical analysis. The images of the $PtSe_2$ revealed few-layered ordered flakes (~5.1 Å between layers) with high crystallinity. After the lithium treatment, the defects were visible in the flakes that look like broken structures with small regions of atomic ordering. Energy Dispersive X-ray Spectroscopy (EDS) showed that the Pt/Se ratio decreased from 2 for ordered $PtSe_2$ to 1.5 after intercalation. EDS indicated that Se vacancies are induced in the structure ($PtSe_x$), which was corroborated by X-ray Photoelectron Spectroscopy (XPS) results. The new $PtSe_x$ structure presented huge shifts in Raman Spectroscopy of 40 cm^{-1}, and E_g/A_{1g} peak intensity inversion and a new peak appeared at a lower energy of spectrum due to the defects. After confirming the defects, we made preliminary catalytic tests, resulting in an overpotential of 145 mV (measured at 10 mA cm^{-2}) for the $PtSe_x$ nanoparticles. We hope that future improvement in $PtSe_x$ defect engineering and catalyst optimization in the electrode could lead to an even better HER performance.

First-Principles Study of Photocatalytic Activity of Amorphous TiO_2 Surface Motoyasu Kato, Tomoyuki Tamura and Mitsuhiro Honda; Nagoya Institute of Technology, Japan

TiO_2 is a typical photocatalytic material that is relatively inexpensive and highly safe, and has been actively studied to improve its performance for wider range of applications. One of our group reported that the formation of an amorphous structure on TiO_2 surface increased the reaction rate by about 13 times compared to the anatase surfaces. However, its high catalytic activity was reduced when the amorphous surface was scraped by etching. Therefore, it is considered that the control of the amorphous surface is the key of improving the catalytic activity.
STEM-EELS has been widely used in recent years to observe nanoscale atomic-arrangements and electronic structures with high spatial resolution.In particular, ELNES (electron energy-loss near-edge structures) is able to provide sensitive information on chemical bonding, valence states and coordination. We observed amorphous surfaces of TiO_2 samples with high photocatalytic activity using the atomic-resolution electron microscope (JEOL ARM-200F @Nitech), and found that spectra for the surface region were significantly different from those for bulk region. In this study, we identify amorphous surface structures that contribute to improve the catalytic activity using first-principles calculations, combining with electron-microscopy observations.
Amorphous surface models were generated by quenching from the melt using classical MD method and subsequent relaxation using first-principles method with VASP code [1]. Ti *L*-edge ELNES were simulated for those models with QMAS code [2]. We found that Ti *L*-edge ELNES for 4-coordinated Ti in the amorphous surface region are in good agreement with experimental results. In addition, in order to clarify the origin of the high photocatalytic activity of the amorphous surface, we investigated the chemical reaction between 4-coordinated Ti and adsorbed molecules. Our results suggest that oxygen defects in the amorphous surface contribute to the improvement of photocatalytic activity.

Ionic Control of Emergent Physical Phenomena in Epitaxial Oxide Thin Films Hyeon Han and Stuart S. Parkin; Max Planck Institute, Germany

Iontronics is an emerging science and technology that shows fascinating physical phenomena, particularly in oxide thin films controlled by ionic motion and arrangement. The most significant impact of iontronics is that iontronic devices enable us to control exotic physical properties, such as insulator-metal transitions, emergent superconductivity, and tunable magnetism, which are extremely difficult or even impossible with conventional field-effect-transistors. Here, we show how the oxygen vacancy channels (OVCs) in brownmillerite $SrCoO_{2.5}$ thin films can be manipulated via ionic gating (IG). In addition, we demonstrate the epitaxial growth of single-domain *T*-Nb_2O_5 thin films, for the first time, critically with the ion channels oriented perpendicular to the film's surface. We show that the insertion of just a small amount of Li via IG results in a colossal insulator to metal transition with almost eleven orders of magnitude decrease in resistivity. In situ experiments, in conjunction with theoretical calculations, reveal a series of transitions between distinct crystal and electronic structures as the Li content is systematically increased. These include hidden phases that have not previously been identified. Furthermore, by replacing the conventional Au gate electrode with Li-containing gate electrodes, tunable and low voltage operation via Li-chemical potential control is demonstrated. Finally, we present a new concept to tailor octahedral distortion, magnetism, and anomalous Hall effect in ferromagnetic $SrRuO_3$ thin films via hydrogenation. These findings open a new path towards the exploration of hidden phases and the development of novel electrochemically controlled electronic devices.

9:30 AM SF05.07.02
Influence of Humidity Level on Synaptic Behaviour of Redox Transistors with Proton Defects Enhanced Electrochemical Reaction Lingli Liu, Putu Andhita Dananjaya and Wen Siang Lew; Nanyang Technological University, Singapore

Biologically-inspired neuromorphic computing systems are attractive for next-generation computing technologies. This non-conventional computing approach offers processing parallelism, cognitive capability and boasts high energy efficiency. In recent years, the redox transistor has emerged as a potential candidate for artificial synaptic devices that can concurrently execute signal transmission and memory operations. In this work, a complementary metal-oxide semiconductor-compatible redox transistor with a highly linear weight update is presented. The synaptic weight represented by the channel conductance is modulated under an electrochemical reaction followed by electric field-driven ion migrations in and out of the channel. This electrochemical reaction involved in such device operation is known to correlate strongly with humidity. However, available studies which specifically address this humidity aspect are still limited. We investigate the humidity-sensitive pre-oxidation process of the pristine W channel required to initiate the switching operation, which can be attributed to the proton defects-enhanced electrochemical process. Under the bipolar pulse scheme, the gradual oxidation of W derived from the progressive activation of the proton transport channels is observed. Performances of the redox transistor under different moisture levels are presented, i.e., pre-oxidation and potentiation/depression. Excellent endurance performance with more than 256 k synaptic weight updates can be obtained. Furthermore, a handwritten digit recognition accuracy of more than 90% is achieved in a 4-layer neural network simulation. Overall, it is concluded that the as-presented redox transistor is a promising candidate for realizing hardware implementation of the artificial neural network.

9:45 AM SF05.07.03
Tunable Ion Hopping in Tantalum Oxide Resistive Switching Memory by Zirconium Doping Young-Woong Song and Jang-Yeon Kwon; Yonsei University, Korea (the Republic of)

Artificial intelligence (AI) has received great attention for powerful performance over broad areas. However, conventional devices are unsuitable for multiply-accumulate operation (MAC), which is essential for the artificial neural network. This due to limitations in the architecture and device physics. In this context, in-memory computing technology is emerging. There have been numerous reports on establishing neural network with next generation memory devices, [1] but only few are fully hardware implemented due to imperfections of the devices. [2] Although resistive switching memory (RRAM) based on binary oxides is a promising candidate, it suffers from critical drawbacks: Stochastic switching process, sudden formation or rupture of conducting path. Inconsistent ionic motion in the switching medium is assumed to be related with the unreliable performance of the devices. Metal cation

doping of binary oxides can facilitate or regulate the resistive switching process, by forming additional bonds with oxygen. We adopted doping as a method for tuning analog switching properties of RRAMs and studying the switching principles towards further understanding.
We found that zirconium (Zr) doping effectively suppress sudden changes of cell conductance, which can be highly related with ionic hopping modulation. RRAM based on mixture of tantalum oxide (TaO_x) and Zr as a metal cation dopant was fabricated. We specified switching type of our devices to be filamentary, as local conducting paths with nanometer scale dimension were observed by conductive atomic force spectroscopy. The thickness of the switching medium is ~ 40 nm, confirmed by AFM. TaO_x RRAM exhibited gradual current hysteresis along voltage sweep of 0 ~ 5 ~ 0 V, resistance modulated from high resistance state (HRS) of 10 pA to low resistance state (LRS) of 5 nA, determined at 0.3 V read voltage. When voltage sweep of 0 ~ -5 ~ 0 V is applied, the devices return to HRS, showing bipolar resistive switching behavior.
Doping concentrations of Zr in TaO_x is observed to be from 3.79 ~ 7.25 at %, determined by X-ray photoelectron spectroscopy. TaO_x RRAMs with 0, 3.57, 5.35 at % Zr doping concentrations exhibited similar HRS of 10 ~ 16 pA, whereas LRS significantly decreased (0 % : 5.78 nA, 3.57 % : 907 pA, 5.35 % : 283 pA). It is expected that Zr doping does not influence the intrinsic resistance of the cell, but takes role in the resistive switching process, regulating ionic hopping and formation of conducting filament. Incorporation of Zr in the TaO_x lead to multiple bonding with oxygen, where oxygen vacancies are the constituent of the conducting path.
For artificial neural network applications, analog resistive switching properties of the devices were investigated by voltage pulse scheme. Zr doped TaO_x RRAMs exhibit gradual potentiation and depression of 200 conductance levels switching window within 0.1 ~ 1.4 nA. Gradual conductance modulation for 200 states is hardly achieved in previously reported RRAMs. [3] The devices exhibit low power consumption of micro-Watts, which is comparable to previously reported RRAMs.
In conclusion, we realized in-memory computing unit with Zr doped TaO_x RRAM that meets two criteria, superior analog switching properties and simple cell structure. Metal cation doping of resistive switching memory opened a new method to study switching phenomena and proved the higher potential towards hardware implementation of neural network and AI.

Defining Properties via Material Microstructure—Defect and Strain Engineering Approaches for Developing Ferroelectric AlScN John Wellington-Johnson, Jialin / James Wang, Azadeh Ansari, Lauren M. Garten and Nazek El-Atab; Georgia Institute of Technology, United States

AlN has long been used as a low loss piezoelectric material but only recently has it emerged that with the addition of scandium $Al_xSc_{1-x}N$ also becomes ferroelectric [2] AlScN has a high electromechanical coupling coefficient (k^2), low loss tangent, and high piezoelectric coefficient (d_{33} AlScN ~ 44 pC/N), along with a large polarization [3]. Unfortunately, the electric fields needed to reorient the polarization, the coercive field, of AlScN is near the breakdown strength of the material, reducing the reliability and viability for memory or electronics applications [3]. Strain engineering approaches can be used to lower the ***coercive field (E_c),*** reducing the energy needed to switch the ferroelectric dipole, because strain favors the layered hexagonal structure. Furthermore, defect engineering can enhance piezoelectric properties and manifest ferroelectric properties.

This talk details the development the impact of strain, defects, and doping on the ferroelectric and piezoelectric response of AlScN thin films. $Al_xSc_{1-x}N$ thin films are fabricated on a range of different substrates using DC and RF sputtering techniques with varying N2:Ar gas ratios, from 350 - 400 degrees C. X-ray photoelectron spectroscopy (XPS) studies show changes in Sc target power influence not only the concentration of Sc in the microstructure but also the crystalline quality. The impact of Sc on the lattice is further corroborated through X-Ray Diffraction (XRD) studies which show a structural shift towards as a function of increased Sc, up to $Sc_{0.4}$. Phase formation beginning at 350 degrees C, but enhanced crystalline orientation begins above 400 degrees C. Ferroelectric, piezoelectric, and dielectric measurements are used to track the impact of microstructure and composition on the ferroelectric and dielectric response. Polarization-electric field loops with defining hysteretic ferroelectric shapes and observations of coercive field shifts up to 30V away from the breakdown voltage are presented. The impact of defects on breakdown strength will be discussed. Piezoresponse force microscopy and First-Order Reversal Curve (FORC) measurements demonstrate the domain kinetics across microstructures; CV and PUND measurements illustrate film quality, and further characterize the contributing and shifting electrical responses. Overall, this work provides insight into the impact of film microstructure on the ferroelectric response as a function of doping, strain, and defect concentration.

Low-Current and High Temperature Nonvolatile Analog Memory Through the Electrochemical Control of Point Defects Yiyang Li and Thomas Defferriere; University of Michigan, United States

Modern machine learning and artificial intelligence workflows consume vast amounts of energy due to the need to move massive quantities of data between memory and processor. Analog, in-memory computing can be much more energy efficient by simultaneously acting as both memory and processor. In-memory computing has been limited by the lack of an analog nonvolatile memory with reliable switching and low-current and voltage operations.
In this work, we show how electrochemical random access memory (ECRAM) can fulfill this needed. Inspired from a battery, ECRAM electrochemically shuttles oxygen vacancy point defects between two transition metal oxides with a solid electrolyte sandwich. The oxygen vacancy concentration is able to deterministically control the analog resistance states, just as how the state of charge of a battery is a reproducible analog value. Whereas earlier ECRAM devices based on lithium ions and protons would rapidly lose state (self-discharge) when scaled to nanosized dimensions, our solid-state, oxygen-based ECRAM is not only nonvolatile at room temperature, but can also switch and retain state at 200C, well above the operating temperature of any solid-state memory. ECRAM's ability to electrochemically move point defects within solids provide new approaches for both analog and high-temperature memory.

11:00 AM SF05.07.07

Visible Light Induced Negative Photo Conduction in Wide Bandgap Oxides Based Memristor for Nonvolatile Opto-Electronic Memory and Photo Sensing Dayanand Kumar, Lana Joharji and Nazek El-Atab; King Abdullah University of Science and Technology, Saudi Arabia

The photo sensor based on wide bandgap oxides relies on the phenomenon of defect generated negative photoconductivity in memristors. Wide bandgap oxides naturally are unresponsive to low energy light, particularly in the visible regime and higher wavelengths owing to their large bandgap energies. Due to the bandgap energy being larger than the energy of the photons in the visible range, they are transparent to visible light and the visible photons are incapable of causing photocarrier generation within the oxide and are therefore naturally photo unresponsive. This has restricted the use of oxide based photosensors to rely on other lower bandgap materials for a photo response or to be restricted strictly to the higher energy ultraviolet band.
However, in the phenomenon studied in this work, through electrically generated defect states within the oxide, it is possible to sensitize wide bandgap oxides to respond to visible light regimes. This is accomplished due to the defect generation creating sub-bandgap states in the forbidden gap which can respond to visible energy photons. The mechanism has been theorized to work as follows; when the oxide system is electrically stressed beyond the breakdown field, the lattice oxygen bonds are severed. If this is done in a constrained manner by means of a current compliance to prevent catastrophic breakdown, the effect is reversible and results in a change in the resistive state of the device and is termed soft breakdown. Such a phenomenon is widely used in memristive devices. During this breakdown, the lattice bonds are broken, and the oxygen is displaced as ions into the interstitial spaces as a metastable vacancy-ion equilibrium. The ions do not naturally recombine with the vacancy and restore the lattice of the oxide as there is an energy barrier that prevents this. However, such an energy may be supplied by means of optical illumination which can cause the vacancy-ion pairs to recombine and return the pristine state of the oxide consequently resulting in a resistance increase in the system. When optical energy greater than the bandgap of the defect state to the conduction band is provided to such a system, a vacancy trap state electron may be excited to the conduction band, resulting in a positive charging of the vacancy state. This creates an electrostatic force between the positively charged vacancy and the negatively charged interstitial ion resulting in a recombination of the two and reformation of the oxide.
In this work, we present a novel bilayer ITO/SiO_2/HfO_x/Pt memristor for optoelectronic nonvolatile memory storage and photo sensing. The device demonstrates good photo sensing characteristics in terms of highly stable endurance at least 200 (electrical SET/optical RESET) cycles for blue light (intensity:10 mW/cm2, wavelength: 405 nm) and excellent retention (10^5 s) without any disruption. These features of the memristive device would allow us to produce either an optoelectronic nonvolatile memory for data storage or photo sensing in single memristive cell.

11:15 AM SF05.07.08
Electrochemical Control of Resistance States in Metal Oxide Bilayer Stack Thomas Defferriere[1], Baoming Wang[1], John Rozen[2], Takashi Ando[2], Frances M. Ross[1] and Harry Tuller[1]; [1]Massachusetts Institute of Technology, United States; [2]IBM T.J. Watson Research Center, United States

Electrochemical control of metal oxide based devices has emerged recently as an attractive approach to achieving reprogrammable microelectronic devices that move beyond simple semiconductor device physics principles. The operational concept of such devices relies on the shuttling of ionic species from an ionic conducting oxide towards either an active interface or active oxide layer where a chemical reaction or exchange of ionic species occurs, changing the functional properties of that layer. Devices exhibiting electronic/magnetic/optical and thermal switching have been demonstrated to offer unique advantages over their more traditional electronic counterparts. For example, electronic switching devices, either in two-terminal device configurations typical of memristive devices or three-terminal configurations akin to a transistor device, have the ability to directly emulate neuronal behavior potentially leading to more efficient neuromorphic computational hardware. Beyond purely electronic applications, the advantages of using ionic species to modulate the functional properties of metal oxides (mechanical, ferroelectric, magnetic, optical, and thermal) offer unique perspectives to redesign traditional applications considering the ubiquitous use of these metal oxide materials for their functional properties.

While electrochemically gated microelectronic devices have been demonstrated in many materials systems, open questions still remain about how to best optimize their device performance. While ionic mobility within and interfacial ion transfer between the two solid layers are key device parameters, little reliable information exists regarding these key parameters given the predominantly electronic character of metal oxide material near room temperature. Such knowledge is vital for mastering overall device performance such as speed, retention, and predictability. To address these challenges, we have investigated the reversible exchange of ions between two adjacent solid oxide layers.

Specifically, we have measured the reversible ionic transport and interfacial transfer kinetics in a thin film bilayer oxide system based on a $Pr_xCe_{1-x}O_2$/$La_{2-x}Ce_xCuO_4$ stack that uses model materials for which the defect chemical and transport properties have already been carefully characterized. These materials offer high ionic mobilities and can accommodate large levels of non-stoichiometry. By studying the characteristics of our devices with a combination of electrochemical impedance spectroscopy and potentiostatic measurements, we demonstrate the ability to reversibly modulate the bilayer device resistance near room temperature and isolate the resistance contributions of both layers as a function of the total device resistive state. We show that these changes can be directly correlated with the respective materials' defect chemistries, typically investigated at elevated temperatures under varying gas atmospheres. Dynamic current-voltage studies enable us to separate the rate-limiting kinetics related to the defect mobilities and the interfacial exchange kinetics of the system. The findings in this work can be expected to aid in developing material selection and design criteria for similar bilayer systems, and be used to achieve faster resistance switching speeds, larger resistance switching ranges, and longer device retentions.

SESSION SF05.08: Harvesting Functional Defects in Energy Materials II
Session Chairs: Hui Xiong and Hua Zhou
Wednesday Afternoon, November 30, 2022

1:30 PM *SF05.08.01
Electrochemically-induced Amorphous to Crystalline Transformation in Niobium Oxide Electrodes for Lithium-Ion Batteries Pete Barnes[1,2], Yuxing Zuo[3], Kiev Dixon[1], Dewen Hou[1], Sungsik Lee[4], Justin Connell[4], Hua Zhou[4], Yuzi Liu[4], Paul H. Davis[2], Olivia Maryon[1], Shyue Ping Ong[3] and Hui Xiong[1]; [1]Boise State University, United States; [2]Idaho National Laboratory, United States; [3]University of California, San Diego, United States; [4]Argonne National Laboratory, United States

Intercalation-type metal oxide electrodes are promising negative electrode materials for safe and stable operation of rechargeable lithium-ion batteries due to the reduced risk of Li plating at low voltages. Nevertheless, lower energy and power density along with cycling instability remain a bottleneck for their implementation, especially for desirable fast charging applications. Recent studies have shown enhanced electrochemical charge storage in metal oxide electrodes that contain intentional structural defects (e.g., vacancies and interstitials). In this talk, we will discuss an electrochemically driven amorphous-to-crystalline (a-to-c) transformation in a nanoporous Nb_2O_5 material for Li-ion storage. Through integrated experimental and computational study, we

elucidated the mechanism of multi-electron transfer reaction in the a-to-c Nb2O5 electrode as well as its enhanced kinetics for Li-ion batteries.

2:00 PM SF05.08.02
Dynamics of Defects in 2-D MnO2 During Charge-Discharge Cycling Scott T. Misture; Alfred University, United States

MnO_2 in its many forms has attractive properties for a wide range of applications from catalysis to charge storage. 2-D MnO_2 nanosheets demonstrate an interesting response to reduction of Mn^{4+} to Mn^{3+}, where Jahn-Teller distorted Mn^{3+} is displaced out of the plane of the nanosheet forming a "surface Frenkel" defect. We find that introducing this unusual defect results in dramatic improvements in the electrochemical charge storage capacity as well as the catalytic activity for many reactions. Specimens were prepared via exfoliation of nominally defect-free KxMnO2 crystals and by electrodeposition to enable studies of a range of Mn3+ defect content. The talk centers on the application of advanced materials characterization tools for study of complex nanoscale 2-D oxides. In-situ and in-operando studies using high energy X-ray diffraction, X-ray pair distribution functions, EXAFS/XANES and Raman spectroscopy will be discussed. We show that linking electrochemical measurements to local structure characterization results enables us to understand the mechanisms by which charging occurs in supercapacitor electrodes. It is clear that the Mn3+ defects are not altered during electrochemical cycling but that they dramatically alter the electronic band structure, yielding large improvements in charge transfer resistance. Further detailed PDF and Raman studies show that partial nanoscale conversion to tunnel-form MnO2 is a primary degradation mechanism that lowers capacitance compared to the layered MnO2.

2:15 PM SF05.08.03
Resisting Dendrites in Lithium Batteries, One Pinhole at a Time Solomon Oyakhire, Wenbo Zhang, Yi Cui and Stacey F. Bent; Stanford University, United States

For humanity to successfully transition from fossil fuels, the mismatch in the demand and supply of renewable energy must be addressed by reliable, high energy storage systems. One promising energy storage system is the lithium metal battery (LMB), owing to the high gravimetric capacity of lithium (3860 mAh/g). The potential gain in volumetric and gravimetric energy density offered by LMBs could usurp today's lithium-ion battery technology and revolutionize energy storage. However, the lifetime of LMBs is hindered by morphological instabilities experienced during the electrodeposition of lithium.

Modifications of the solid electrolyte interphase (SEI) and electrolyte are the most common strategies for improving lithium metal morphology. However, electrolyte and SEI engineering are often tedious, based on trial and error, and insufficient for enhancing lithium electrodeposition. Here, we demonstrate a new, alternative strategy for controlling lithium metal morphology and improving electrochemical performance that is independent of the electrolyte and SEI. By modifying the current collector with atomic layer deposited (ALD) thin films of ZnO, SnO_2, and Al_2O_3, we show that lithium deposits atop, rather than beneath, the thin films, resulting in changes in lithium morphology and battery performance that are strongly dependent on the electrical resistance of the ALD films. The results show that low resistance copper modification films like SnO_2 and ZnO provide numerous sites for lithium nucleation and promote the formation of high surface area (fast electrolyte consuming) lithium deposits, while the highly resistive Al_2O_3-modified copper reduces the available sites for lithium nucleation and promotes the formation of low surface area (slow electrolyte consuming) clusters of lithium deposits.

We propose and demonstrate the first recorded mechanism for the connection between electrical resistance and lithium growth - we propose that, in resistive substrates, lithium metal nucleates atop only pinhole or defect sites, then grows laterally by the radial diffusion of lithium ions from the electrolyte. We prove this mechanism analytically, using diffusion controlled current equations, and experimentally by introducing patterned pinholes into a resistive, pinhole-free substrate. We generalize the concept of resistance-controlled morphology and demonstrate high battery performance in three distinct classes of electrolytes, culminating in anode-free pouch cells that retain 60% of their initial discharge capacity after 100 cycles. This work presents a new approach for understanding the electrodeposition of lithium and tuning the performance of lithium metal batteries.

Ionic Transport in Natural Phyllosilicates Giyeok Lee[1], Gunyoung Heo[1], Mirella S. Santos[2] and Aloysius Soon[1]; [1]Yonsei University, Korea (the Republic of); [2]École normale supérieure (ENS) de Lyon, France

Electrochemical ion-insertion in anisotropic solids is conventionally important for high-performance energy harvesting systems and understanding the underlying coupled ion-electron transfer mechanism, transportation of guest ions, and the redox of these anisotropic solids are of utmost importance for the engineering of these energy harvesting systems [1]. Natural clay minerals (e.g., in the class of phyllosilicates) show great promise as anisotropic host solids for these applications but are still poorly understood and a clear atomistic picture of the underlying mechanisms is still missing. Especially, the direct relationship between the efficiency of energy conversion (e.g., from the salinity gradient between the sea water and saline water) and the layer charge of clay minerals is insufficient to design the clay-based energy materials, which can play a critical role in maximizing efficiency. In this work, using vermiculite as an archetypical but promising layered host material [2], we construct different supercell models with varying 3+/4+ ion ratios in the tetrahedral layers and examine the role of interlayer surface charges on ionic transport via first-principles derived machine-learning potential enabled molecular dynamics simulations [3]. Through this study, we will provide a first-step understanding of the underlying atomistic design rules in natural clay materials for energy applications, which has the potential to establish itself as design rules for efficient vermiculite-based energy material.

New Fast Oxygen Ion Conductor Perrierite-Type Oxide $La_4Mn_5Si_4O_{22+\delta}$ Discovered by Harnessing the Materials Project and High-Throughput Computation Jun Meng, Md Sariful Sheikh, Ryan Jacobs and Dane Morgan; University of Wisconsin–Madison, United States

Oxygen-ion conducting materials are important for a variety of applications such as solid-oxide fuel cells, gas sensors, catalysts, and oxygen separation membranes. Applications typically utilize oxygen-active materials operating at high temperatures (e.g. ≈800 °C for fuel cells). The key issue that limited industrial applicability is the high operating temperature which results in high system cost, materials degradation, and slow start-up and shutdown cycles. Development of alternative electrolyte/electrodes materials with good oxygen ionic conductivity at low temperature (room temperature-400 °C) is of great interest. However, fast oxygen conductor materials are concentrated in only a handful of materials structure families such as perovskite, fluorite, manganite, melilite, scheelite, and apatite. Hence, it is critical to find new materials which transport oxygen ion efficiently at low temperatures.
In this work, we developed a high-throughput computational screening of the 33,975 oxide materials from the Materials Project database and discovered the new structure family of interstitial oxygen diffuser based on perrierite-type oxide $La_4Mn_5Si_4O_{22}$ (LMSO). We used a hierarchy of screening criteria including the geometric free space, thermodynamic stability, synthesizability, redox-active elements, diffusion pathways, ab initio calculated defect

formation energy and diffusion barrier. Our screening has yielded several material families to date, among which LMSO was selected for investigation with higher-level DFT hybrid functional calculations and experimental ionic conductivity measurements. Interstitial oxygen formation energy and migration energy were studied by Density Function Theory (DFT) calculations with SCAN functional. The formation energy of interstitial oxygen is -0.11 eV at a concentration of 2.3% under air condition, indicating that LMSO is oxygen hyperstoichiometric with an expected composition of $La_4Mn_5Si_4O_{22+0.5}$ in air. Oxygen ion diffusion pathways and energetics were studied by ab initio Molecular Dynamic (AIMD) simulation, showing migration pathways along the connected sorosilicate Si_2O_7 groups through an interstitial mechanism. The migration barrier is predicted as 0.45 eV and 0.69 eV based on AIMD simulation and the Climbing Image-Nudged Elastic Band (CI-NEB) calculation, respectively. The diffusivity of oxygen ion is calculated to be 10^{-5} cm^2/s and the ionic conductivity is 0.1 S/cm at 800 °C. The above computational predictions have been verified by experimental investigations. The existence of interstitial oxygen ($\delta \sim + 0.5$) is validated by the Electron Probe Micro-analyzer (EPMA) and iodometric titration method, and the ionic conductivity is measured as 0.11 S/cm at 800 °C, consistent with the computational results. Experimental studies show that LMSO has mixed electronic and oxygen ionic conduction, indicating that LMSO is a very promising oxygen active material for numerous applications.

4:00 PM SF05.08.06
Surface-Based Post-Synthesis Manipulation of Defects in Metal Oxides using Liquid Water Heonjae Jeong, Nabiel Abuyazid, Elif Ertekin and Edmund Seebauer; Univ of Illinois, United States

Lowered chemical coordination at metal oxide surfaces facilitates the creation of interstitial atoms that would not otherwise form in the bulk. For example, clean surfaces of ZnO and TiO_2 create interstitials of oxygen (O_i) [1,2] from adsorbed O atoms with energy barriers near or below roughly 1 eV. The atomic configurations for interstitial injection resemble those for site hopping in the bulk, with barriers only slightly higher. The modest hopping barriers of O_i in oxides, coupled with those for injection, make clean surfaces likely pathways for populating the nearby bulk with O_i near room temperature, thereby accessing a regime wherein kinetic rather than thermodynamic effects dominate defect behavior and opening new possibilities for functional defect manipulation. Post-synthesis regulation of defects such as vacancies becomes possible near room temperature, together with formation of new types of complexes. Here we show by isotopic self-diffusion measurements combined with first-principles calculations by density functional theory (DFT) that poison-free oxide surfaces inject O_i when contacted with liquid water near room temperature. For single-crystal oxides of zinc, titanium and gallium, O_i penetrates to depths ranging between 20 nm and 2 μm. This O_i almost certainly eliminates oxygen vacancies within the penetration depth, and probably forms stable complexes with hydrogen interstitials that neutralize their action as adventitious donors. The results point the way toward uses in photocatalysis, photoelectrochemistry, renewable energy production and storage, and advanced electronics that could benefit from such manipulation.

Fundamental Understanding of a Defect Density and Catalytic Activity for Methane Combustion Using Colloidally Engineered Pd Nanoparticles Jinwon Oh and Matteo Cargnello; Stanford University, United States

Recently, defect engineering has been widely used in catalysis study to enhance catalytic activity. Defect sites in nanomaterials have a high energy state due to their unsaturated coordination or strain effects. Therefore, these sites have different absorption/desorption energy of reactant/intermediate molecules than those without defects, and the difference potentially affects the activity of catalysts. Among various types of defects, planar defects such as stacking fault, grain boundary, and twin boundary have been highly studied in the field of catalysis due to their stability during a reaction. There are various ways to introduce defects in catalysts, but those methods often inevitably introduce changes in the size or shape of nanoparticles which also have the potential to affect the catalytic activity. However, to address the direct correlation between the defect density and intrinsic activity of catalyst materials, it is required to control and exclude the change in other variables than defect densities, including the size and shape of nanoparticles. Therefore, the method to control defect density in nanoparticles while minimizing the change of other variables is highly required.
Here we chose a Pd nanoparticle catalyst for methane combustion reaction as a model system. We vary the amount of phosphorous in Pd nanoparticles using wet chemical synthesis to modify defect density in nanoparticles without changing other factors such as shape and size. Firstly, we synthesize well-defined colloidal Pd nanoparticles and expose them to phosphorous sources to introduce a phosphorous into a Pd crystal structure. Next, nanoparticles are exposed to an oxygen environment to extract phosphorous. Structural rearrangement is expected to occur at this step due to the diffusion of phosphorous atoms, resulting in defects forming. Using this method, we successfully synthesize Pd nanoparticles with different defect densities and compare their intrinsic activity for the methane combustion reaction. Finally, we confirm that Pd nanoparticles with a high density of defects show higher intrinsic activity for this reaction. This study provides a way to introduce defects in nanoparticles and fundamental insights for the correlation between a defect density and activity.

Spatially Resolved Defect Formations in Metal Halide Perovskites Jonghee Yang[1], Diana K. LaFollette[2], Benjamin Lawrie[3], Anton V. Ievlev[3], Juan Pablo Correa Baena[2] and Mahshid Ahmadi[1]; [1]University of Tennessee, Knoxville, United States; [2]Georgia Institute of Technology, United States; [3]Oak Ridge National Laboratory, United States

Metal halide perovskites (MHPs) are currently leading materials towards high-performance optoelectronics. Despite today's scientific renaissance of the MHPs, a key constraint hesitating one-step towards their realization is stability. There are several challenges which must be overcome to improve the stability of MHP devices. One of these challenges is the understanding and control of their defect chemistry. Conventional spectroscopy faces serious obstacles to investigate defects in MHPs. In this talk, I will discuss a combination of spatially-resolved chemical and spectroscopic analysis, including time-of-flight secondary-ion mass spectroscopy (ToF-SIMS), cathodoluminescence (CL) spectroscopy and conductive atomic force microscopy (c-AFM) to systematically explore the fate of defects in MHP systems [1-3]. Our observations provide key features that must be considered towards development of

MHP optoelectronics, which guarantees excellent performances and longevities.

Selective Amorphization of Oxide Surface by Introducing Hydrogen Impurity Seohan Kim[1] and Joonho Bang[2]; [1]Uppsala University, Sweden; [2]Gyeongsang National University, Korea (the Republic of)

The oxide semiconductors have been widely used in various electronic devices such as flat panel displays and solar cells. Especially, crystalline oxide semiconductors are attracting industrial interest due to their high electron mobility that arises from the well-aligned periodic array of the constituent elements. However, the rough surface morphology resulting from the grain growth triggers severe drawbacks in their thin-film applications. In this study, we demonstrate a surface amorphization of the oxide semiconductor thin film by introducing hydrogen gas during the deposition process. The surface of the crystalline In–Sn–O thin film is selectively amorphized, allowing for smooth surface morphology without any degradation of the electrical properties. In addition, the progressive surface amorphization offers the tunability of the work function, leading to the improved power conversion efficiency of the thin-film solar cell. The present study provides a tractable way to achieve the smooth surface of the crystalline thin films.

Electronic Properties and Migration Dynamics of (Functional) Defects in Heterogeneous Metal-Halide Perovskites from First Principles Linn Leppert; University of Twente, Netherlands

Halide double perovskites are an emerging class of photoactive materials with considerable structural and electronic diversity [1,2, 3] and reliable stability towards heat and moisture under ambient conditions. However, in contrast to ABX_3 perovskites like $CH_3NH_3PbI_3$, most halide double perovskites have comparably large band gaps and exhibit signatures of strongly bound and self-trapped excitons [4, 5]. In the first part of this talk, I will show how the band gap of $Cs_2AgBiBr_6$ can be dramatically altered by dilute alloying with symmetry-matched impurities leading to significantly reduced band gaps while preserving long carrier lifetimes [6]. I will also discuss the challenges that first principles numerical modelling techniques face for accurately describing defects in this chemically and electronically diverse family of materials [7].

In the second part of my talk, I will focus on the migration dynamics of halide vacancies in $CsPbBr_3$. Migration of halide vacancies is one of the primary sources of phase segregation and material degradation in lead-halide perovskites. We use first principles density functional theory to compare migration energy barriers and paths of bromine vacancies in the bulk and at a surface of $CsPbBr_3$. We find that surfaces facilitate bromine vacancy migration due to their soft structure that allows for bond length variations larger than in the bulk. Our calculations also demonstrate that this effect can be mitigated by lattice-matched passivation with alkali halide salts [9].

Ion-Gated Transistors Based on Metal Oxides—From Electronics to Iontronics and Li-Iontronics Clara Santato; Ecole Polytechnique de Montreal, Canada

Ion-gated transistors (IGTs) employ ionic gating media (e.g. ionic liquids, polymer electrolytes, aqueous saline solutions) to modulate the density of the charge carriers in the transistor channel. The high capacitance featured by IGTs permits, among others, to use them in the study of insulator-to-metal transitions. Considering IGT-based technologies, not only IGTs operate at voltages as low as 0.1-1 V but they can also feature mechanical flexibility, printability and easy integration with chemo- and bio-sensing platforms.
Metal oxides are transistor channel materials interesting for their processability in air, at low temperature. They also constitute the basis for battery cathode materials in lithium-ion batteries.
In this contribution, we will discuss the opportunity IGTs offer to be employed as in situ diagnosis tools to evaluate the state of health of Li-ion batteries from the point of view of the evolution of the electronic properties of the battery cathodes (e.g. charge carrier density, electronic charge carrier mobility) as a function of the electrode (lithiation and de-lithiation) cycling conditions.

10:45 AM SF05.09.06
Giant & Controllable Photoplasticity and Photoelasticity in Compound Semiconductors Jiahao Dong[1], Yifei Li[1], Yuying Zhou[2], Alan Schwartzman[1], Haowei Xu[1], Bilal Azhar[3], Joseph W. Bennett[4], Ju Li[1,1] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]Chinese Academy of Sciences, China; [3]Cornell University, United States; [4]University of Maryland Baltimore County, United States

We show that the wide-band gap compound semiconductors ZnO, CdS, and ZnS feature large photo-plastic and photo-elastic effects that are mediated by point defects. We measure the mechanical properties of single crystals (ZnO and CdS) and ceramics (ZnS) using nanoindentation, and we find that elasticity and plasticity vary strongly with moderate illumination. For instance, the elastic stiffness of CdS can increase by 20% due to blue illumination of intensity 1.4 mW/cm^2. Above-band-gap illumination (*e.g.* UV light) has the strongest effect, and the relative effect of sub-band gap illumination varies between samples – a clear sign of defect-mediated processes. We show giant optomechanical effects can be tuned by materials processing and varying point defect concentration. The photo-plastic effect can be understood by a long-established theory of charged dislocation motion. The photo-elastic effect requires a new theoretical framework. Using density functional theory (DFT), we find that the point defect ionization is accompanied by large lattice

distortions and large changes in elastic constants in both CdS and ZnS. DFT predicts a large photoelastic effect, on the order of 5% for realistic point defect concentration. Our results update the longstanding but lesser-studied field of semiconductor optomechanics, and suggest interesting applications.

11:00 AM SF05.09.07
Hot Electron Enhanced Defect Diffusion in Semiconductors Under Laser Irradiation Yifan Yao and Andre Schleife; University of Illinois, Urbana Champaign, United States

Precise manipulation of defect diffusion is important for cutting-edge applications in the semiconductor industry and quantum computing. Thermal annealing is the major technique to increase defect mobility, which becomes challenging in manufacturing at atomic-scale precision as the entire sample is elevated to a high temperature. Recently, our group predicts that under proton irradiation, hot electrons localized near oxygen vacancies in MgO reduce the migration barrier, providing an alternative route to increase defect mobility. Similarly, such hot electron distributions are expected to be achieved under laser irradiation but require a detailed understanding of coupled laser-electron-ion interactions. In this work, we employ a combination of first-principles methods to quantitatively describe multi-temporal dynamics triggered by external laser irradiation. We first use the time-dependent density functional theory to investigate the excited electron dynamics. By tuning the laser parameters, we achieve a hot electron distribution that is similar to the one predicted to reduce the migration barrier of oxygen vacancies by 0.94 eV under proton irradiation. Then, to quantify the number of excited oxygen vacancies, we examine the hot electron lifetime accounting for the electron-electron and electron-phonon scattering. Finally, we reveal that the oxygen vacancy diffusion mediated by laser-induced hot electrons can be increased by10^5 at 900 K for the largest experimentally available oxygen vacancy concentration of 10^{18} cm^{-3}. Such enhancement at this defect concentration is 2 orders of magnitude greater compared to proton irradiation due to the high vacancy excitation rate under laser irradiation. Also, while laser and ion irradiation differ in their beam precision of the affected sample region, both enable higher accuracy of defect manipulation than annealing the entire sample. Moreover, we expect this mechanism is applicable to intrinsic or extrinsic defects in other wide bandgap semiconductors with defect-related states located within the bandgap. Therefore, we explore the enhanced gallium vacancy diffusion in GaN and the debonding of carbon divacancy in diamonds for their vital importance in semiconductor electronics and quantum computing.

SESSION SF05.10: Understanding Functional Defects by Advanced Characterizations and Manipulations
Session Chairs: Rama Vasudevan and Yuanyuan Zhou
Thursday Afternoon, December 1, 2022
Sheraton, 3rd Floor, Gardner A/B

1:30 PM *SF05.10.01
Nanoscale Volumetric Mapping of Functional Properties at Microstructural Interfaces and Defects Luis Ortiz[1], Karla Del Cid-Ledezma[1], Jackson Kaszas[1], Ramamoorthy Ramesh[2], Yuanyuan Zhou[3] and Bryan D. Huey[1]; [1]University of Connecticut, United States; [2]University of California, Berkeley, United States; [3]Hong Kong Baptist University, Hong Kong

Real world capacitors, transistors, solar cells, and other devices are increasingly 3 dimensional in response to persistent demands for smaller footprints and improved energy efficiency. Microstructural features such as epitaxial interfaces, grain boundaries, composition gradients, and strain fields—whether engineered, or unavoidably resulting from fabrication constraints—are correspondingly increasingly important. In order to elucidate the influence of such traditional defects on local and even emergent properties, Tomographic Atomic Force Microscopy (TAFM) has been developed and applied for through-thickness nanoscale property mapping. Examples of normal and lateral strain effects for monolithic films, 2d heterostructures, and 3d nanocomposites are demonstrated for ferroelectrics, dielectrics, and multiferroics. Differential photoconduction at grains and grain boundaries in halide perovskite solar cells is also identified, including incorporating carrier selective architectures to directly identify any charge-dependent preferential networks. Such novel volumetric mapping of nanoscale properties is crucial for optimizing future devices.

2:00 PM *SF05.10.02
***In Situ* Investigation of Point Defects in Functional Materials Using Advanced Electron Probes** Alejandra Guedeja-Marron[1], Francisco Fernandez-Canizares[1], Gabriel Sanchez-Santolino[1], Juan I. Beltran[1], Paolo Perna[2], Lucas Perez[1] and Maria Varela[1]; [1]Universidad Complutense de Madrid, Spain; [2]IMDEA Nanociencia, Spain

Harnessing relevant behaviors in multifunctional materials relies, now more than ever, on understanding and controlling the properties and responses of relevant point defects. The success of aberration correction in the electron microscope, in fact, has allowed electron probes to bear on this task with atomic resolution in real space and with single atom sensitivity both in imaging and spectroscopy. Recent years have also witnessed the development of specimen holders that allow modifying samples in-situ. The effects of external stimuli, such as temperature or bias, can be now explored at the flick of a switch. We are now perfectly poised to explore the presence and responses of point defects to externally applied driving forces that mimic operando conditions of future devices in detail. This talk will review examples of in-situ investigations of point defects in the scanning transmission electron microscope (STEM) in materials of interest for fields as diverse as spintronics or energy. An example can be found in the study of single Bi dopants in Cu nanowires with very low doping levels. These are very interesting systems due to the spin Hall effect associated with the presence of Bi. However, the dopant size and the presence of defects such as grain boundaries may promote Bi segregation when the temperature is raised or electric polarization is applied, which may affect the electrical performance of future devices based on these wires. Density-functional theory calculations show that for Bi doping levels below 1% the most stable dopant configuration is sitting within a Cu lattice site. Larger doping levels result in a distribution of different types of defects, being the subtitutional ones the less prone to react to temperatures of a few hundred degrees C. Other point defects of interest in functional materials are vacancies. We will again combine theory, experiment and simulation to quantify and detect small concentrations of O vacancies in complex oxides. Simulations show that virtual detector optimization in 4D-STEM techniques can, in fact, lead to vacancy detection for vacancy compositions below 0.7%. Experiments including in-situ reduction processes will also be discussed. Acknowledgements: Financial support form Spanish MICINN/FEDER RTI2018-097895-B-C43 and RTI2018-099054-J-I00 is acknowledged.

Dephasing Dynamics of Local Vibrational Modes in Diamond Defects Detected Using Perturbed Free Induction Decay Terng Junn Keat, Daniel J. Coxon, Michael Staniforth, Vasilios G. Stavros, Mark E. Newton and James Lloyd-Hughes; University of Warwick, United Kingdom

Infrared pump-probe spectroscopy is a powerful technique used to measure the population lifetime time T_1 and the total dephasing time T_2 of vibrational energy state transitions in many functional defects. Measuring T_2 provides valuable insight into interactions between the defect of interest and its local

lattice environment. However, the standard method of extracting T_2 from equilibrium spectra uses a Voigt function fit that is often unreliable due to a large number of fit parameters and sensitivity to data quality. Perturbed free induction decay (PFID) appears in some pump-probe measurements and counter-intuitively appears at negative time delays [1]. While often ignored in vibrational energy state transition measurements, the PFID can provide useful information about the system under study. Here we present the use of PFID as a method to 1) reliably measure the dephasing times T_2 across different defect environments and for different vibrational modes and 2) predict higher energy state transitions that cannot be observed using equilibrium measurements such as Fourier Transform Infrared (FTIR) Spectroscopy.
We carry out infrared pump-probe measurements on the N_3VH diamond defect, which exhibits both stretch mode (S) and bend mode (B) vibrational energy transitions. This was done on a set of diamonds with different origins, all containing the N_3VH to explore its dephasing dynamics across different diamond lattice environments. The B mode transitions all gave $T_2 = 2.8 \pm 0.1$ ps, whereas the S mode transitions gave a faster $T_2 < 1.7$ ps and were also sample dependent. The faster dephasing given by S mode vibrations suggests that it provides a stronger coupling to crystal lattice phonons compared to the B mode vibrations. We find that S mode vibrations are also sensitive to strain in the local lattice through measuring defect concentrations in each sample.
We then present a numerical model of the PFID signal, building on previous work by Yan et al. [2]. Simulating the PFID signal based on our energy level model of the N_3VH defect and the extracted T_2 shows excellent agreement with experimental data. This demonstrates the feasibility of using PFID to directly measure dephasing lifetimes.
We further carry out an infrared pump-probe measurement on the 3237 cm^{-1} absorption feature which originates from an unknown diamond defect to uncover any possible coupling between this vibrational mode and the N_3VH defect. While no transient absorption change was observed at positive time delays, a PFID signal was detected at negative delays. Analysis of this PFID signal suggested a transition involving a higher energy state, which was then found at 3030 cm^{-1}. This opens up the possibility of using PFID signals in infrared pump-probe spectroscopy to predict higher-lying energy state transitions in previously unknown defects.

2:45 PM BREAK

3:15 PM *SF05.10.04
Structural Defects in Thin Films of Complex Oxide Materials Investigated by AC-STEM Nuria Bagues[1,1], Louise Colfer[2], Elahe Farghadany[3], Michael Schmidt[2], Robert E. Williams[1], Alp Sehirlioglu[3], Lynette Keeney[2] and David McComb[1,1]; [1]The Ohio State University, United States; [2]University College Cork, Ireland; [3]Case Western Reserve University, United States

Correlating defect structure and functionality through direct observation using aberration corrected electron microscopy offers a unique opportunity for functionalized, thin-film deposited nanostructures; specifically, in the case of defects originating during thin film grown processes and relaxation mechanisms. An example of such defects are misfit dislocations or twins that affect local physical properties in epitaxial thin films of complex oxides [1, 2]. Characterizing these structural defects is critical to understanding their effect on functionality, and often requires the use of complex and complementary methods. Aberration corrected scanning transmission electron microscopy (AC-STEM) provides an unparalleled method to observe and identify the crystallographic and compositional variations on the atomistic scale occurring from non-ideal deposition parameters and resulting in defects that could compromise the local physical properties. Indeed, characterizing and describing functional defect provides a potent tool for optimizing properties and predicting materials for future energy and electronic applications.

For this talk, we combine AC-STEM imaging and spectroscopy techniques to investigate structural defects and interfaces in thin films of complex oxides. Two systems of complex oxides with structural defects will be presented: (1) a multiferroic, the Aurivillius phase, $Bi_6Ti_xFe_yMn_zO_{18}$ (B6TFMO), which exhibits desired properties at room-temperature, and (2) an ionic conductor (Nd,Li)TiO_3 (NLTO). Various AC-STEM methods, such as high-angle annular dark-field (HAADF)-STEM and integrated differential phase contrast (iDPC)-STEM imaging, as well as electron energy loss spectroscopy (EELS) - spectrum imaging (SI) are used to characterize the defect structures in these systems. Combining the imaging and spectroscopy analysis, the influence of interfaces and defects on the local chemistry and physical behavior will be discussed, shedding light on the possibilities and limitations of these defects on functionality.

3:45 PM *SF05.10.05
Characterizing and Exploiting Topological and Point Defects in Ferroelectric Thin Films—Optimizing Electromechanical Response and Investigating Energy Landscapes with Automated Experiments Kyle P. Kelley[1], A. Borisevich[1], A.N. Morozvska[2], V. Sharma[3], J.C. Yang[4], Panchapakesan Ganesh[1], Stephen Jesse[1], Sergei V. Kalinin[3] and Rama K. Vasudevan[1]; [1]Oak Ridge National Laboratory, United States; [2]National Academy of Sciences of Ukraine, Ukraine; [3]The University of Tennessee, Knoxville, United States; [4]National Cheng Kung University, Taiwan

The static and dynamic properties of ferroelectric thin films are heavily impacted by the presence and distribution of both point- and topological defects. Harnessing and controlling these factors has been critical to improving the dielectric and electromechanical properties of ferroelectric thin films [1,2]. However, many of the mechanisms that associate functional properties with changes to material properties are still difficult to pinpoint, and their effects at the nanoscale are still poorly understood in many cases [3].

In this talk, we will discuss our work on studying and characterizing both point- and topological defects in ferroelectric thin films. First, we explore the ability to dynamically modify the electromechanical response of defective $BaTiO_3$ thin films [4], via injection of vacancies in ultra-high vacuum environments by the scanning probe tip. Multiple lines of evidence from detailed piezoresponse force spectroscopy and atomic resolution imaging via scanning transmission electron microscopy are used to measure the local structure and functionality of these films. A strong environmental dependence on the local dynamics is found on the piezoresponse as a function of field cycling. These measurements are corroborated by thermodynamic, first-principles and reactive force field calculations, which point towards a mechanism of increased electromechanical response engendered by dynamic injection of vacancies in the scanning probe volume.

At the same time, topological defects such as domain walls and vortices can also be critical to understanding and modifying the dielectric and piezoelectric properties of thin films [5]. We discuss a newly developed automated experiment framework that explores the interplay between grain boundaries, domain switching, and domain wall de-pinning, to attempt to quantitatively measure the impact of local domain structure and longer-range elastic fields on the dynamics of topological defects in a model $PbTiO_3$ thin film grain boundary. Preliminary reinforcement learning methodologies to optimize the domain

wall geometries will be discussed. This work was supported by the Center for Nanophase Materials Sciences (CNMS), which is a US Department of Energy, office of Science User Facility at Oak Ridge National Laboratory.

Operando Investigation of the Gas Sensing Mechanisms in SnO_2, Sn_3O_4 and SnO Nanomaterials Pedro H. Suman[1,2], Benjamin Junker[2], Udo Weimar[2], Nicolae Barsan[2] and Marcelo Orlandi[1]; [1]São Paulo State University (UNESP), Brazil; [2]University of Tübingen, Germany

Semiconducting metal oxides (SMOx) have been the most used sensing materials for detecting multiple gaseous compounds over the last decades. However, fundamental questions concerning the surface reactions responsible for their performance still need further comprehension. In this context, operando techniques can provide insights into surface chemistry and electronic properties of chemoresistive gas sensors in working conditions. Here, a phenomenological study of the sensing mechanism of single-crystalline SnO_2, Sn_3O_4, and SnO nanobelts is presented by using operando Diffuse Reflectance Infrared Fourier Transform (DRIFT) spectroscopy. DRIFT spectra and DC resistance measurements were recorded simultaneously in the presence of multiple target gases, including H_2, CO, NO_2, ethanol, and acetone, at 200ºC and 300ºC. The influence of water vapor adsorption in the background atmosphere was also analyzed. This study allowed the real-time monitoring and identification of the adsorbed species on the surface of the sensing layer and their impact on the output electrical signals in each experimental condition. Based on the results, detection mechanisms were proposed for these tin oxide nanostructures with different oxygen stoichiometries. The results are particularly interesting for Sn_3O_4 and SnO materials, which are less studied than SnO_2.

Smart Additive and Interface Engineering to Achieve Perovskite Solar Cells with High Efficiency and Stability, and Efficient Capturing of Degraded Pb-Containing By-Products Alex K. Jen[1,2]; [1]City University of Hong Kong, Hong Kong; [2]University of Washington, United States

Minimizing energy loss and improving stability are the key aspects to transcend the current limitations on the performance of perovskite photovoltaics (PVSC). Our recent study combining additive and interface engineering to dramatically improve the efficiency and long-term operational stability of the PVSCs. By introducing a non-volatile additive functioning both as crystallization modulator and defects passivator, high power conversion efficiency and stability can be achieved simultaneously. In addition, innovative methods have also been developed to efficiently trap decomposed Pb-containing by-products for solving the very challenging environmental issue in PVSCs for facilitating their commercialization.

This talk is divided into two parts: (1) Progress of achieving the highest efficiency (24.8%) in inverted planar junction perovskite solar cells (PVSCs) through smart interface engineering using 0D, 1D, and 2D perovskites; (2) Demonstration of simultaneously achieving high PCE, excellent operational stability, and the ability to capture degraded Pb-containing by-products using efficient and very low cost cation exchange resins and sulphonated graphene aerogels for PVSC encapsulation

8:30 AM *SF05.11.02

Inactive Secondary Phase Stabilizes Perovskite for Efficient Solar Cells Jingbi You; Chinese Academy of Sciences, China

In halide perovskite solar cells, the formation of a secondary phase of excess lead iodide has little effect on power conversion efficiencies (PCEs), but can be detrimental to device stability and lead to large hysteresis effects in voltage sweeps. We converted lead iodide into inactive secondary phase, which effectively stabilizes the perovskite. We obtained a certified PCE of 25.6% for $FAPbI_3$ perovskite solar cells based on this strategy. Devices retained 96% of their original PCE values after 1000 hours shelf storage and 80% after 500 hours of thermal stability testing at 85 Celsius .

High Efficiency Tin Perovskite Solar Cells Zhijun Ning; ShanghaiTech University, China

The development of high performance lead free perovskite solar cells (PSCs) is important to address the environmental concern of heavy metal lead. In recent years, tin perovskite solar cell (TPSCs) is developing quickly and emerging as a promising candidate for high efficiency lead free PSCs. Meanwhile, the narrow bandgap of tin perovskite solar cells enables it potential to be used for the fabrication of tandem solar cells. In this presentation, I will summarize recent work of our group about tin perovskite solar cells, including the introduction of low-dimensional structure, crystal growth kinetic control to manipulate its nanostructure and orientation, as well as device structural engineering to reduce interface carriers recombination. Based on these efforts, the highest efficiency of tin perovskite solar cells is up to 14.6% that is certified in an independent agency. In addition, the fabrication of low dimensional inorganic tin perovskite solar cells will be introduced, as well as the construction of bilayer structure on film surface to reduce carriers recombination.

9:30 AM SF05.11.04

X-Ray Ptychographic Tomography of Morphological Defects in Metal Halide Perovskites Yalan Zhang[1], Mingwei Hao[1], Hua Zhou[2], Junjing Deng[2] and Yuanyuan Zhou[1]; [1]Hong Kong Baptist University, Hong Kong; [2]Argonne National Laboratory, United States

Perovskite-based solar cells (PSCs) are considered a disruptive photovoltaic technology with their power conversion efficiency rapidly climbing to certified 25.7%. To exploit its maximum potential, the microstructure and morphological defects of metal halide perovskites (MHPs) must be fully characterized, understood, and then tailored. Recently, X-ray ptychography has emerged as a new imaging technique that can combine advantages of coherent X-ray diffractive imaging and conventional scanning transmission X-ray microscopy techniques. With the latest development, it can achieve 3D tomography of materials structures with a high resolution of sub-10 nm while it may cause little damage on soft material samples compared to another characterization tool. Here I will present our recent achievement leveraging X-ray ptychographic imaging to characterize MHPs, revealing various 3D structural defects fully or partially buried underneath the surface. We demonstrate X-ray ptychography as a new, powerful, non-intrusive characterization method for illuminating the complete microstructure of perovskites for energy applications.

Spin Dynamics of Low Sodium Type-II Silicon Clathrates Joseph Briggs[1], Yinan Liu[1], Ahmad A. A. Majid[1], Justin Johnson[2], P. Craig Taylor[1], Meenakshi Singh[1], Reuben T. Collins[1] and Carolyn A. Koh[1]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

In this work we examine the relaxation and coherence times of Na in silicon clathrate thin films for potential use in quantum applications. Diamond silicon (d-Si) is under active investigation as a quantum material motivated to a large extent by the depth of knowledge surrounding this material and its dominant position in microelectronics. Type II silicon clathrate represents an interesting alternative Si crystal structure. This cage-like inclusionary compound is made up of a silicon lattice with interstitial "guests" such as sodium situated inside the cages. The Na atoms, which are decoupled from the lattice, act as shallow donor atoms and are potential qubits. In addition, unlike d-Si, type II Si clathrate has a direct or quasi-direct bandgap which may allow easier optical access to Na electronic states which makes it of interest as a potential material for microelectronics, LEDs, and solar cell applications.
Most reported studies of silicon clathrate have utilized powders. Powders, however, are not the preferred form factor for optoelectronic studies or transport measurements and the measurements reported here use low Na content, type II Si clathrate films. To synthesize these materials, a two-step procedure adapted from powder synthesis has been developed. First, sodium is evaporated from a crucible and diffused into a silicon wafer under an inert gas atmosphere to form NaSi. The wafer is then annealed under vacuum to thermally decompose the film into clathrate. The clathrate films are then characterized through a variety of techniques including x-ray diffraction, Raman spectroscopy, scanning electron microscopy, photoluminescence, and, of particular importance to this study, continuous wave and pulsed electron paramagnetic resonance (EPR). EPR gives insight into the electronic properties of the Na donors and their placement and interactions within the silicon cages. The naturally occurring Na isotope, ^{23}Na, has nuclear spin 3/2 with the EPR spectrum exhibiting four hyperfine lines associated with the interaction of the electronic and nuclear spins. Hyperfine features associated with Na atoms in neighboring cages and clustered Na are also observed as well as a dangling bond signature indicative of a minority phase of disordered Si. Pulsed-EPR spectra clearly exhibit spin echo signals with T1 times in the microsecond regime at temperatures near 10K. By probing the spin echo's of specific Na hyperfine interactions, we have gained insight into the relaxation and coherence times of electron spins bound to the Na of low Na doped type-II silicon clathrates. The effects of various parameters (i.e. temperature, pulse duration, magnetic field center) on the relaxation and coherence times are also explored. Results of this work provide new understanding of the spin properties of Na in Si clathrates and provides useful insights into the potential use of Na in Si clathrate as a qubit material. This work was supported by National Science Foundation award #2114569.

Exploiting Functional Defects in Epitaxial Oxide Thin Films for Giant Piezoelectricity and Synaptic Electronics Huajun Liu; Institute of Materials Research and Engineering, A*STAR, Singapore, Singapore

Transition metal oxide thin films exhibit many interesting properties, including superconductivity, ferroelectricity, piezoelectricity and electrochemical activities for energy applications. Defects, such as oxygen vacancies, have long been known to be detrimental to certain functional properties of oxide thin films. However, by properly designing and controlled synthesis, the defects can be beneficial and even greatly improve the functional properties.
In this talk, I will discuss our recent work on the giant piezoelectricity and memristive behaviour induced by antisite defects in $NaNbO_3$ (NNO) epitaxial thin films. Through precise control of Na deficiency, Nb atoms occupy vacant Na positions and form the Nb_{Na} antisite defects in NNO films. These antisite defects self-assembled to form vertical nanopillar structures. Such nanopillar regions with local structural and polar heterogeneity give rise to giant piezoelectric coefficients while maintain a high Curie temperature (Science, 369, 292, 2020). The antisite defects also induce resistive switching behaviour and tunable resistance states by electric field. The NNO film based devices exhibit synaptic plasticity under applied electrical pulses, promising for the application in neuromorphic computing.

Controlling Defect-Assisted Nonradiative Recombination in Halide Perovskites Chris G. Van de Walle; University of California, Santa Barbara, United States

Halide perovskites offer impressively high solar conversion efficiencies and are being considered for applications as light emitters. These materials are often called "defect tolerant", but we show that the impact of point defects on device efficiency has not been properly assessed to date. We have performed comprehensive studies for the prototypical hybrid perovskite $MAPbI_3$ [MA=(CH_3NH_3)], as well as for other halide perovskites. To achieve accurate and reliable results, our first-principles calculations are based on hybrid density functional theory with spin-orbit coupling included [1]. Rigorous calculations of nonradiative recombination coefficients show the limitations of the widely adopted rule that only defects with charge-state transition levels deep in the

band gap can be efficient nonradiative recombination centers. We demonstrate that the position of the level does not directly determine the capture rates, due to strong lattice coupling and anharmonicity in the halide perovskites [2]. Our results clearly show that (1) point defects can indeed be present in relevant concentrations in the halide perovskites and (2) some of these point defects lead to nonradiative recombination rates that are just as high as in conventional semiconductors. We therefore conclude it is incorrect to call the halide perovskites "defect tolerant". A more relevant distinction, compared to conventional semiconductors, is that halide perovskites with modest defect densities can be grown using low-cost deposition techniques.
For $MAPbI_3$ the results indicate that iodine interstitials are most harmful, and hence iodine-rich synthesis conditions should be avoided. Experimental reports have indicated, however, that iodine-poor conditions are also detrimental. We explain this puzzle by demonstrating that iodine-poor conditions lead to formation of hydrogen vacancies on the MA molecule, which act as very efficient nonradiative recombination centers [3]. By contrast, hydrogen vacancies are not a problem in $FAPbI_3$ [$FA=CH(NH_2)_2$], rationalizing why FA is essential for realizing high efficiency in hybrid perovskites. Our findings also indicate the advantages of avoiding the organic cation altogether [4]. We show that the common belief that the organic cation suppresses defect-assisted nonradiative recombination is unfounded. Our study suggests that all-inorganic halide perovskites hold great promise for high-efficiency optoelectronic applications.

High Throughput Optical Measurements and Machine Learning Analysis of Hybrid Perovskites Abigail Hering, Meghna Srivastava and Marina S. Leite; University of California, Davis, United States

Hybrid organic-inorganic perovskites are an emerging class of materials for energy-efficient devices. Intriguingly, their high density of defects has not prevented this material from presenting nearly optimal optical properties for light-absorbing and -emitting application. A primary challenge to commercialize optoelectronics based on hybrid perovskites lies on the lack of material stability. To advance the understanding of the role of environmental stressors in the optical behavior of perovskites, we implement high-throughput steady-state environmental photoluminescence (PL) while exposing the samples to distinct levels of temperature and relative humidity. Then, we use these measurements to compare the performance of linear regression, Echo State Network (ESN), and Auto-Regressive Integrated Moving Average with eXogenous regressors (ARIMAX) machine learning algorithms when predicting the PL response of perovskites with variable chemical composition. While linear regression is not adequate to forecast PL (with average normalized root mean square error, NRMSE, >20%), both ESN and ARIMAX enable reliable predictions, with NRMSE < 16% and 8%, respectively. Overall, our results indicate the promise of machine learning to accelerate the development of stable perovskites. Further, the paradigm presented here can be extended to other perovskites families.

11:45 AM SF05.12.03
Halide Perovskite Mem-Emitter for Analog Salience Processing Si En T. Ng; Nanyang Technological University, Singapore

To sense is the ability to extract critical information from the environment. However, in a realistic scenario, we are often exposed to a myriad of stimuli at the same time. To effectively scan across them, the objects in the image can be processed based on their saliencies and a set of regulatory equations. Since these differential equations are dependent on inputs from the near history, processing them sequentially with digital computers (physically separated memory and processing units) would be very inefficient. Analog computing in modern applications is revisited for its efficient use of resources (power and footprint). To emulate the neuronal processes in analog fashion, the three device functionalities required are the interconnectivity, distinct wavelengths and the temporal dependencies of the transmission. In contrast to electrical physical wiring, higher levels of interconnectivity can be achieved by emitter-based systems processing information with light as the transmission medium. Here, we fabricated a mem-emitter (memory emitter) device comprising of an organic emitter and a perovskite emitter. The mem-emitter device has dual distinct emission wavelengths. Initially, the red organic emitter is first activated due to the small recombination zone spatially located at the organic emitter layer. However, with repeated electrical pulsing, ionic drift in the halide perovskite layer results in the widening of the recombination zone, enabling the green perovskite layer to emit. As a result, the emission spectra from the device not only depends on the present input but also the operational history of the device as well. We first studied the widening of the recombination zone; both the electroluminescence and photoluminescence spectra of the bilayer stack are compared. Interestingly, the photoluminescence spectra did not exhibit any emission from the red organic emitter. This highly suggests that the color change is not due to reabsorption but a spatial shift in recombination zone. Furthermore, we have optimized the pulse operation conditions for the mem-emitter device, achieving a dynamic gain of 470% in the green emission. Finally, we showcase two use cases of our mem-emitter device in analog temporal processing. Firstly, the temporally dependent green emission represents the self-inhibitory process in a salience processing network. For the first time, with a physical circuit comprising of mem-emitters and photodiodes, we managed to emulate inhibition of return - a key adaptive functionality in salience processing. Secondly, we utilize an array of mem-emitter devices as a physical salience heatmap display for the first time. With optimized pulse schemes, our mem-emitter array is capable of encoding analog salience values into distinct emissive colors – red, orange and green. With its dynamic temporal memory, the proposed dual wavelength mem-emitter device offers significant advantages in efficient salience processing with fewer components and smaller energy consumption.

12:00 PM SF05.12.05
Atomistic Solution to the Doping Bottleneck in Compound Semiconductors Olivier C. Gagné; Carnegie Institution for Science, United States

Activation and tuning of the useful properties of semiconductors intended for photovoltaic, electronic, electrochemical and other applications hinges on their successful release of charge carriers, a process typically achieved in appreciable quantity via substitutional incorporation of foreign ions into the host crystal structure. As it stands, the rate-limiting step in designing efficient semiconductors is the identification of the most viable dopant ions to achieve n- and/or p-type conductivity – a process severely clouded by our incomplete understanding of chemical bonding behavior in solids. Today, doping studies rely exclusively on resource-intensive first-principles calculations, with little chemical guidance available to computationalists on where to focus their resources. An atomistic understanding of the factors underlying ion substitutions in solids would provide such guidance, and would further enable rapid calculations to be made for host/dopant combinations prior to their synthesis in lieu of expanding costly resources in low-return compositional spaces.

Three major factors underlie doping difficulties in semiconductors: [1] dopant insolubility, [2] dopant un-ionizability, and [3] dopant compensation. Factor [3] is terminal whereby formation of compensated defects is caused by the charge carrier itself, and not the identity of the dopant. However, difficulties associated with factors [1] and [2] may be circumvented via appropriate dopant selection, whose ease of substitution in the host crystal structure dictates dopant level depth in the band structure. Factors known to influence dopant level depth include similarities in atomic orbital energies, size of the

substituting ions, and local bonding geometry – all of which amenable to guidance via an adequate, systematized understanding of crystal-chemical behavior.

By and large, the primary reason underlying our inability to model ion substitution in solids (and therefore semiconductor doping) has been our collective failure to systematically describe, rationalize and quantify pairwise chemical bonding behavior across the periodic table of elements. We recently remediated to this problem via wide-scale analysis of chemical bonding in solids in the form of bond-length dispersion analyses. Results were reported for cations bonded to O^{2-} and N^{3-},[1] covering 177,446 reliable bond lengths hand-picked from 9210 crystal-structure refinements for oxides, and 6,770 bond lengths from 720 crystal-structure refinements for nitrides; equivalent analysis for cations bonded to S^{2-}, Se^{2-} and Te^{2-} is underway. These data were subsequently used to identify and quantify structural, electronic and/or bond-topological mechanisms underlying anomalous bonding behavior across the periodic table.

Having quantified the most elusive of crystal-chemical variables for the very first time, i.e. chemical bonding behavior, we successfully developed an atomistic model of ion substitution which instantaneously and quantitatively predicts solubility limits between ion configurations at ambient conditions. Our model quantitatively reproduces doping profiles for all popular compound semiconductors (e.g. III-V, II-VI semiconductors), and can further make instantaneous predictions for the doping of ternary, quaternary and higher-dimensional systems. Thus, our model resolves the doping bottleneck in compound semiconductors while enabling the pursuit of complex, bespoke semiconductor design with bulk properties adapted to end-user needs.

8:00 AM *SF05.13.01
Atomic Site HAADF-STEM and EELS of Complex Oxides Thin Films—The Role of Oxygen Vacancies Regina Ciancio; CNR-IOM, Italy

Complex oxides are fascinating systems which host a vast array of unique phenomena, such as high temperature (and unconventional) superconductivity, ‘colossal’ magnetoresistance, all forms of magnetism and ferroelectricity, as well as (quantum) phase transitions and couplings between these states. The recent years have witnessed considerable achievements in the ability to grow thin film heterostructures of these materials with atomic precision. With this level of control, the electrostatic boundary conditions at oxide surfaces and interfaces can be used to form new electronic phases or novel low-dimensional states at the interfaces inaccessible in bulk oxides. Oxygen vacancies play crucial roles in determining the physical properties of metal oxides and controlling and manipulating the defect structure provides a degree of freedom for harvesting and tailoring the functional properties of oxides. This is the case of anatase titanium dioxide TiO_2, where the formation of oxygen vacancies has been proved to effectively tune the amount of Ti3+ ions [1-2] and to extend the photoresponse of TiO_2 from the UV towards the visible-light region [3].
The correlation between the functional and atomic scale properties requires a detailed analysis by local probe techniques with advanced capabilities, allowing the accurate determination of the atomic positions, the chemical composition and the electronic state with atomic resolution. In this regard, aberration-corrected STEM and the possibility to couple STEM imaging (in Z-contrast or Annular Bright Field) and EELS spectroscopy enables to determine the chemistry, crystal and electronic structure of new materials locally, with atomic resolution, and often in a quantitative way by the smart combination of imaging and spectroscopy.
This lecture will review the themendous impact of having access to atomic resolution HAADF-STEM, complemented by spectroscopic analysis, atomistic calculations and multislice simulation of atomic resolution STEM in oxide thin films. The case of anatase TiO_2 thin films will be described, where oxygen vacancies are observed to form arrays of ordered superstructures with varying oxygen content which reflect into a Ti^{3+}/Ti^{4+} mixed population [4]. The combination of atomically resolved STEM-EELS along with extensive atomistic and multislice simulations lead to the validation of a new model for the defect structures in anatase that excludes the typical shear-plane structures, like the Ti_nO_{2n-x} Magnéli phases, which are commonly claimed to occur in titanium dioxide. The relevant case of $La_{0.7}Sr_{0.3}MnO_3$ thin films will also be discussed where the evidence of a structural shift of Mn ions correlated with the reduction of Mn valence state is found to be correlated with the preferential formation of oxygen vacancies at the interface with the substrate [5].
In both the cases, the identification of secondary structures as well as the determination of the intrinsic structure of oxygen defects is a crucial step to improve the functionalities of such material systems and to open up new options to engineer devices with targeted properties.

8:30 AM *SF05.13.03
Effect of Polaron Formation on Optical and Carrier Transport Properties of Transition Metal Oxides as Photoelectrodes from First-Principles Calculations Yuan Ping; University of California Santa Cruz, United States

Transition metal oxides are promising photoelectrode materials for solar-to-fuel conversion applications.However, their performance is limited by the low carrier mobility due to theformation of small polarons. Recent experimental studies have shown improved carrier mobility andconductivity by atomic doping; however the underlying mechanism is not understood. A fundamentalatomistic-level understanding of the effects on small polaron transport is

critical to future material design withhigh conductivity. In this talk, we will discuss the effect of small polaron formation on optical and carriertransport properties of transition metal oxides from first-principles calculations.First, we resolve the conflicting findings that have been reported on the optical gap of a well-known catalysis Co_3O_4 as an example[1]. We confirm that the formation of small hole polarons significantly influences the optical absorption spectra and introduces extra spectroscopic signature below the intrinsic band gap, leadingto a 0.8 eV transition that is often misinterpreted as the band edge that defines the fundamental gap.

Then we discuss the formation of small polarons' effect on carrier concentration, by resolving the controversyof nature of "shallow" or "deep" impurities of intrinsic oxygen vacancies in $BiVO_4$ as an example[2], i.e. how tounify different experiments with the correct definition of ionization energy in polaronic oxides. We furtherdiscuss why certain dopants can have very low optimal concentrations (or very early doping bottleneck) inpolaronic oxides such as Fe_2O_3, through a novel "electric-multipole" clustering between dopants andpolarons[3]. These multipoles can be very stable at room temperature and are difficult to fully ionize comparedto separate dopants, and thus they are detrimental to carrier concentration improvement. This allows us to uncover mysteries of the doping bottleneck in hematite and provide guidance for optimizing doping and carrier conductivity in polaronic oxides toward highly efficient energy conversion applications. In addition, we show the importance of synthesis condition such as synthesis temperature and oxygen partial pressure on dopantand polaron concentrations, and how to optimize the synthesis condition based on theoretical predictions[4].

At the end, we show different theoretical models for polaron mobility calculations from a macroscopic dielectriccontinuum picture with an example of spin polarons in CuO[5] and a microscopic polaron hopping picture bycombining generalized Landau-Zener theory and kinetic Monte-Carlo samplings for doped oxides[6]. Our first-principles calculations provide important insights and suggest design principles for optimal optical andtransport properties of polaronic oxides.

Understanding Extrinsic and Intrinsic Anisotropic Heat Transport in Crystalline Materials Yee Kan Koh; National University of Singapore, Singapore

Although thermal transport in cubic crystals is isotropic, thermal transport could be highly anisotropic, depending on crystallographic orientations. The anisotropy in thermal transport could originate from either intrinsic (e.g., crystal structures) and extrinsic (e.g., defects) factors. In this talk, I will present

our recent works that advance the fundamental understanding of intrinsic and extrinsic anisotropy in thermal transport in crystalline materials. I will first discuss the anisotropy thermal transport in single-crystal InN films induced by dislocations. I will report strong thermal transport anisotropy governed by highly oriented threading dislocation arrays along the cross-plane direction in micron-thick, single-crystal indium nitride (InN) films. We find that the cross-plane thermal conductivity is more than tenfold higher than the in-plane thermal conductivity at 80 K when the dislocation density is on the order of ~3×10^{10} cm^{-2}. This large anisotropy is not predicted by the conventional models. With enhanced understanding of dislocation-phonon interactions, our results open new regimes for tailoring anisotropic thermal transport with line defects, and will facilitate novel methods for directed heat dissipation in thermal management of diverse device applications. Then, I will discuss the intrinsic thermal transport anisotropy in layered, two-dimensional (2D) crystals such as black phosphorus (BP) and $MoTe_2$. We find that the anisotropy in the cross-plane direction behaves differently from the anisotropy in the in-plane directions. We find that, contradictory to common beliefs, anisotropy in the heat capacity and relaxation times also contribute significantly to the overall anisotropy in thermal transport. We will discuss the origin of the anisotropy in more details in the talk.

11:00 AM SF06.01.02
Chemical States and Bandgap Energy of Thin and Ultra-Thin Titanium Nitride Thin Films Manosi Roy[1], Kaushik Sarkar[1], Jacob Som[1], Abiodun Odusanya[1], Mark A. Pfeifer[2], Darrah Dare[2], Valentin Craciun[3] and Dhananjay Kumar[1]; [1]North Carolina A & T State University, United States; [2]Cornell University, United States; [3]National Institution for Laser, Plasma and Radiation Physics, Romania

Singly crystalline titanium nitride (TiN) and partially oxidized titanium nitride ($TiNO_x$) thin films have been grown in a rock-salt structure on sapphire substrates using high vacuum conditions during pulsed laser deposition (PLD). The film thickness was varied in the length scale from a few unit cells to several unit cells. X-ray photoelectron spectroscopy (XPS) analysis has shown that oxygen content of the $TiNO_x$ films increases with film thickness (or deposition time), which in turn, affects the exposure time of the ablated materials to the residual oxygen in the deposition chamber (the source of TiN oxidation). The lattice constant of the $TiNO_x$ films, measured using XRD, is found to increase with the oxygen content in the film that is validated by the density functional theory (DFT) calculations. The lattice constant increase is explained using enhanced electrostatic repulsion between O^{2-} orbitals in the absence of vacant Ti^{3+} sites; in order to maintain charge neutrality within the lattice, one Ti^{3+} cation vacancy is created for every three substitutions of N^{3-} ions by O^{2-} ions. We have observed an asymmetric 'V' shape variation in the optical bandgap as a function of film thickness. The bandgap values decreased from 3.89 eV to 3.30 eV as the film thickness increased from 1.5 nm to 4 nm and then increased from the minimum of 3.30 eV to 3.87 eV as the film thickness increased from 4 nm to 30 nm. The bandgap variation following the left arm of the V-curve is attributed to the quantum confinement effect, while the variation of the bandgap following the right arm of the V-curve is believed to be associated with the increased defects density of the Ti^{3+} cations that is caused by the charge imbalance in the $TiNO_x$ lattice due to partial substitution of N^{3-} by O^{2-} ions.

Thermal Characterisation of Nanoscale Wide Bandgap Transistors Martin Kuball and James W Pomeroy; University of Bristol, United Kingdom

Wide bandgap RF and power electronic devices are needed to meet future efficiency and performance requirements, providing ultra-high areal power densities. "Conventional" wide bandgap transistors, with 100's nm sized channel hot spots, are already thermal limited, driving the development of new thermal management solutions such as GaN-on-diamond . However, the thermal dissipation problem is now being amplified by the development of scaled devices, such as finFETs, SLCFETs, nanowire transistors, etc., where channel sizes and layer thicknesses are less than the bulk phonon mean free path, which suppresses thermal conductivity, increasing thermal resistance. Bulk thermal properties can no longer be assumed for <100's nm-sized structures, making thermal simulation results more uncertain; this is also true for thin films and superlattices. We examine two case studies: SLCFETs (RF switches) and thin-GaN HEMTs, which deliver improved electrical performance, but have thermal dissipation trade-offs. We use a combination of Raman nanoparticle thermometry, thermoreflectance and thermal simulation to illustrate how feature sizes influence thermal dissipation and how structures can be thermally optimised. We discuss how peak temperatures in highly scaled devices cannot be measured directly with existing optical thermography techniques and the critical need for nanoscale thermal imaging, motivating the development of super-resolution quantum-dot thermal imaging (QTI), to beat the diffraction limit.

Quantifying the Effects of Disorder on Mobility of Nitride Semiconductors Robert Makin, Krystal R. York, Andrew S. Messecar and Steven Durbin; Western Michigan University, United States

Measuring the degree of disorder within crystalline samples began in the early 1930s with Bragg and Williams, who developed the order parameter S—which ranges from 0 (disordered) to 1 (ordered)—to quantify the degree of disorder in binary metal alloys. Recently, we have extended their x-ray diffraction based methodology to measure S from Raman spectra, reflection high-energy electron diffraction patterns (RHEED) and electron microscopy images. Quantifying the degree of disorder in samples allows for relationships to be uncovered between the order parameter and property of materials. In fact, for system-level properties that are dominated by pair-wise interactions, it can be shown using cluster expansion theory in combination with spin modeling that these properties have a linear dependence on S^2. Recently, we have experimentally verified this relationship holds for band gaps of semiconductors ranging from 2D to heterovalent ternary materials. Here, we demonstrate that the mobility of electrons in nitride semiconductors also exhibits a linear relationship with S^2.

Samples of undoped GaN, Mg-doped InN and Zn-doped InN were grown by plasma-assisted molecular beam epitaxy, and their degree of ordering was measured using both RHEED patterns and SEM images. For GaN, samples were grown in compositions ranging from Ga-rich to N-rich; all of these samples were determined to be n-type from Hall effect measurements. The electron mobility of the samples was observed to increase linearly with decreasing value of S. The largest range of order parameters and mobilities was obtained for nominally stoichiometric samples, where mobilities varied linearly from 138 $cm^2/(Vs)$ to 5 $cm^2/(Vs)$ for S^2 values between 0.113 and 0.332, respectively. For Mg-doped InN, samples were grown with Mg concentrations ranging from 1×10^{16} to 1×10^{20} cm^{-3} and all samples were confirmed to be n-type by variable magnetic field Hall effect measurements. Similar to undoped GaN, these samples all exhibited a linear increase in the electron mobility with decreasing S of the sample. The largest range of order parameters was obtained for doping concentrations on the order of 1×10^{17} cm^{-3}, where measured electron mobilities ranged from 295 $cm^2/(Vs)$ to 16 $cm^2/(Vs)$ for S^2 values between 0.064 and 0.221, respectively. For Zn-doped InN, samples were grown with Zn concentrations ranging from 1×10^{15} to 1×10^{16} cm^{-3} and all samples were determined to be n-type. Like the GaN and Mg-doped InN samples, the Zn-doped InN samples all showed an increase in electron mobility with decreasing S value. The largest range of order parameters was obtained for doping concentrations on the order of 1×10^{15} cm^{-3}, where measured electron mobilities varied linearly between 700 $cm^2/(Vs)$ and 48 $cm^2/(Vs)$ for S^2 values between 0.008 and 0.202, respectively.

These experimentally-verified linear relationships between disorder and electron mobilities for each material, as well as the trends observed among these materials, can be physically understood through the lens of structural motifs (nearest neighbor bonding environments of the atoms in the lattice) and the dependence of the different motif types on the degree of disorder within the lattice. Importantly, these results present a possible pathway to increase the mobility of nitride semiconductors through the control of the degree of disorder in the materials, and present a framework for investigating similar relationships between disorder and mobility in other semiconductor systems.

SESSION SF06.02: Alloys and Amorphous Materials
Session Chairs: Valentino Cooper and Lucas Lindsay
Monday Afternoon, November 28, 2022
Sheraton, 3rd Floor, Fairfax A/B

1:30 PM *SF06.02.01
Nanoscale Phase Transitions in Amorphous Materials Under Swift Heavy Ion Irradiation Flyura Djurabekova[1], Aleksi A. Leino[1], Henrique Vazquez[1] and Patrick Kluth[2]; [1]University of Helsinki, Finland; [2]The Australian National University, Australia

Analyzing the behaviour of amorphous materials under swift heavy ion irradiation by means of molecular dynamics simulations, we have discovered unexpectedly fast phase transition processes that take place on a nanoscale in the regions affected by the passing ion. The behavior is characteristic to a specific combination of pressure and temperature that may appear in the wake of a swift heavy ion passing through the material. We relate this behavior to the strong tetrahedral network in Si-based materials that also explains rich polyamorphism in these materials. We determine that the fine structure of the track is composed of two distinct amorphous phases that result from the different pressure levels in the core and in the shell during solidifiation. The mechanism involving ultrafast nanoscale phase transitions sheds the light on the origin of the core-shell fine structure observed in a-SiO2 and a-Si3N4, as well as the dense core in a-Si.
On the other hand, in amorphous Ge fast phase transitions under swift heavy ion irradiation lead to nanoporosity that displays a peculiar self-organisation process. Low-density solid to high-density liquid transtions lead to formation of initially almost randomly distributed pores which grow with ion fluence and eventually self-organize in well-separated layers parallel to the sample surface. This self-organisation mechanism depends on the ion energy, thickness of the amorphous Ge layer and the angle of ion incidence and is potentially caused by the fragmentation of ion tracks into segments of characteristic length. Using molecular dynamics simulations we investigate the process of pore formation and the mechanisms leading to self-organization of the pores in a layered structure.

2:00 PM SF06.02.02
Enhancement of Critical Current Density and Strong Vortex Pinning in High Entropy Alloy Superconductor $Ta_{1/6}Nb_{2/6}Hf_{1/6}Zr_{1/6}Ti_{1/6}$ Synthesized by Spark Plasma Sintering Jin Hee Kim[1], Rahmatul Hidayati[1], Soon-Gil Jung[2], Yusuff A. Salawu[3], Heon-Jung Kim[3], Jae Hyun Yun[1] and Jong-Soo Rhyee[1]; [1]Kyung Hee University, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Daegu University, Korea (the Republic of)

We synthesized the high entropy alloy (HEA) $Ta_{1/6}Nb_{2/6}Hf_{1/6}Zr_{1/6}Ti_{1/6}$ compound by planetary ball milling and the spark plasma sintering (SPS) method. The sintered HEA sample had a BCC crystal structure with small amount of secondary phases. The superconducting phase transition is observed in the electrical resistivity ($T_c \sim 7.8$ K) and magnetic susceptibility ($T_c \sim 7.6$ K) measurements, and the T_c was similar to that of an arc-melted sample. The zero-temperature limit of the upper critical magnetic fields $H_{c2}(0) = 10.5$ T and coherence length $\xi = 5.66$ nm were slightly decreased or comparable to the arc-melted HEA sample ($H_{c2}(0) = 12.05$ T and $\xi = 5.23$ nm). The field-dependent isothermal magnetization hysteresis M(H) exhibited the typical type-2 superconducting behavior with magnetic flux avalanches in the low magnetic field region. The calculated critical current densities were significantly increased by 286 % ($J_c = 32{,}606$ A cm^{-2} at 2 K) ~ 687 % ($J_c = 73{,}200$ A cm^{-2} at 4 K) compared to the arc-melted HEA sample ($J_c = 11{,}401$ A cm^{-2} at T = 2 K). The enhanced J_c of the sintered HEA sample is caused by enhancement of the pinning force due to point pinning as well as surface pinning effects. The vortex relaxation mea- surements showed stable remanent magnetization for over 10,000 s after magnetic fields were turned off, which is unlike conventional sueprconducting vortex relaxation behavior. The strong pinning force in the SPS sintered $Ta_{1/6}Nb_{2/6}Hf_{1/6}Zr_{1/6}Ti_{1/6}$ compound is beneficial for practical applications because of the significantly enhanced critical current density J_c with stable remanent magnetization $M_{rem}(t)$.

2:15 PM SF06.02.03
Designing Electronic and Magnetic Order with Compositional Disorder T. Zac Ward[1], Elbio Dagotto[1,2] and Alessandro R. Mazza[1,2]; [1]Oak Ridge National Laboratory, United States; [2]The University of Tennessee, Knoxville, United States

In this talk, we will discuss developments in entropy-assisted synthesis that are allowing never before possible levels of parameter disorder to be hosted on positionally ordered single crystal lattices. We will present recent results on single crystal high entropy correlated oxides showing how compositional complexity can be used to drive novel tunability of charge and spin orderings.
Substitutional doping is a cornerstone of experimental approaches used to explore mechanistic responses to changes in the charge, orbital, lattice, and spin contributions of strongly correlated and quantum materials. The energy scales of these parameters can have near degeneracies, which means that minute extrinsic shifts to untargeted values, as with ion size variance, must also be considered. However, even well diluted disordering from doping can play an important or even dominating role in the emergence of macroscopic behaviors, such as, high Tc superconductivity, magnetic texture, scalable non-fermi liquid responses, and metal-insulator transitions. Synthesis of crystalline systems that host broad parameter disorder is exceptionally challenging, since traditional substitutional doping routes are dominated by formation enthalpy. This means that increasing substitution on a single sublattice-site beyond a few percent often results in the formation of unintended secondary phase formations or compensating vacancy creation. Thus, while substitutional doping may give a direct route to accessing fundamental parameter tunability in computational approaches, enthalpic effects during synthesis drive element clustering which limits mixing and reduces the number of desired composite microstates that exist in well-mixed regions.

2:30 PM SF06.02.04
Predicting Short-Range Ordering/Clustering Kinetics in Binary FCC Solid Solution Alloys Using a Mean-Field Method Anas Abu-Odeh[1], Blas Uberuaga[2] and Mark Asta[1,3]; [1]UC Berkeley, United States; [2]Los Alamos National Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States

At equilibrium, disordered solid solution alloys will have some level of short-range ordering (SRO) or clustering (SRC). SRO/SRC has been experimentally shown to affect the mechanical properties of concentrated FCC and HCP solid solution alloys through the rise of planar slip, and atomistic simulations have shown an effect on dislocation behavior for FCC, HCP, and BCC solid solution alloys due to the presence of a diffuse anti-phase boundary. While the presence of SRO/SRC in solid solutions is thermodynamically expected, it is unclear how long of an annealing time is required to reach the equilibrium SRO/SRC state of an alloy. Previous experimental resistivity and diffuse intensity measurements of binary alloys undergoing

isothermal annealing have shown that the SRO/SRC relaxation times of these alloys span many orders of magnitude and depend on the material system, alloy composition, and temperature. The ability to predict these relaxation times can facilitate designing experiments dependent on SRO/SRC. Kinetic Monte Carlo (kMC) simulations provide an avenue for these predictions but are dependent on parameterizing vacancy transition state energies sampled from a sufficient variety of chemical environments. In the absence of a reliable interatomic potential, this would require many expensive density-functional theory (DFT) calculations. A quicker alternative method that circumvents these calculations would be desirable. Using interactions parameterized by embedded atom method descriptions of Cu-Au and Cu-Ni, which exhibit SRO and SRC, respectively, we compare relaxation kinetics modeled through kMC as well as a mean-field method (MFM). This method estimates the decay rate of concentration waves in a stable solid solution and requires two simple inputs: a mobility factor related to interdiffusion, and a reciprocal space dependent SRO/SRC diffuse intensity. This latter input is readily obtained from canonical Monte Carlo (cMC) simulations at equilibrium. We find that the relaxation times of real space SRO/SRC and regions of enhanced SRO/SRC diffuse intensity obtained from the MFM agree to within an order of magnitude to those obtained from kMC. It is also able to capture the unique transient behavior of SRC present in Cu-Ni. These results suggest that the MFM allows for order of magnitude estimates for experimental design of SRO/SRC and can also be connected to current theories of SRO/SRC strengthening. While the mobility parameter in this study was obtained from kMC, for a general binary alloy, this parameter can be obtained from mobility databases fit to experiments. Obtaining diffuse intensity information would require cMC simulations parameterized by an interatomic potential or DFT but would not require vacancy transition state calculations. The success of the MFM for these binary systems suggests that extensions of this method to SRO/SRC kinetics in multicomponent systems may also be a satisfactory alternative to kMC.

2:45 PM SF06.02.05
Computational Study on Atomic Arrangements of CuZn Alloy Determining Ethylene and Ethanol Selectivity Deokgi Hong[1], Yeji Baek[2], Hakhyeon Song[2], Sungwoo Lee[1], Young-Chang Joo[1], Jihun Oh[2] and Gun-Do Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Electrochemical CO_2 reduction reaction (CO_2RR) is a promising route to alleviate the problems of global warming and realize the carbon neutral cycle. Selectivity control in CO_2RR over Cu-based catalyst is an important issue for multicarbon product generation. Especially, C_2 products like ethylene and ethanol has high economic efficiency and energy density. Among various approaches to enhance the C_2 product selectivity of Cu-based catalyst, alloying is promising method. The alloy atoms added to the Cu lattice modify the reaction mechanism by diversifying the structure of the active site and changing the electronic structure. However, the complex atomic structure of the active sites on the Cu-based alloy surface impedes our understanding on the origin of enhanced C_2 product selectivity. Therefore, it is necessary to understand the effect of atomic arrangement on C_2 product selectivity of Cu-based alloys. Our group synthesized CuZn alloys with different Zn compositions and conducted electrochemical measurements to investigate the effect of atomic arrangement on the C_2 product selectivity of CuZn alloys. [1] We controlled the phase of the CuZn alloys to exclude other factors affecting the C_2 product selectivity, except for the atomic arrangement. All alloy samples exhibited random solid solution properties. It was observed that the ratio of ethanol production to ethylene production increased as the atomic composition of Zn increased from 10% to 33%. DFT calculations were performed to understand the change in C_2 product selectivity according to Zn composition and the effect of atomic arrangement on C_2 product selectivity. We classified the atomic arrangement on the CuZn alloy surface into three types of Cu-rich, Zn-rich and Cu-Zn interfacial sites and calculated the free energy change of CO_2RR on the three types of sites. Then we compared the energy changes at the step where the reaction pathways for ethanol production and ethylene production branched. As a result, it was confirmed that ethanol production was more dominant at Cu-Zn interface sites and ethylene production was more dominant at Cu-rich sites. Therefore, as the Zn content increased, the ratio of Cu-Zn interfacial sites increased, and accordingly, the ratio of ethanol production to ethylene production increased.
This study contributes to understanding the effect of local atomic arrangement in CuZn alloys on C_2 product selectivity and provides insight into the prediction of catalytic performance of disordered metal lattices.

Disorder Driven Relaxor Ferrorelectrics—A Computational Design Strategy Valentino R. Cooper; Oak Ridge National Laboratory, United States

High entropy, multi-component metal alloys, have superior mechanical properties and high radiation tolerances; which are, in part, driven by configurational entropy. Recently, an oxide analogue comprised of MgO, CoO, NiO, CuO and ZnO was synthesized; exhibiting a truly entropy-stabilized, reversible phase transition from a multiphase material to a single rock salt-ordered phase above 850-900°C. This entropy-driven stabilization may engender many unique properties, such as high melting temperatures, radiation resistance and other anomalous responses. Here, we discuss a design strategy for the prediction of synthesizable disordered oxides. Our effort employs first principles studies of 2-component oxides to develop design rules based on the relationship between pairwise enthalpies of formation, $\triangle H$, and configurational entropy of the disordered material. A similar chemical identity-to-$\triangle H$ map was previously explored using the class of high entropy alloys, where the stability of multicomponent metal alloys was correlated to the enthalpy of mixing of binary and ternary compounds. Here, the focus will be on the exploration and discovery of synthesizable entropy-stabilized Ba-based perovskites that rely on configurational disorder to foster relaxor ferroelectric behavior.
This work was supported by the U.S. D.O.E., Office of Science, BES, MSED using resources at NERSC and OLCF.

4:00 PM SF06.02.07
Effect of Elemental Segregration in High-Entropy Alloys on Materials Transport Properties Kai H. Nordlund, Jesper Byggmästar, Flyura Djurabekova, Fredric Granberg and Filip Tuomisto; University of Helsinki, Finland

High-entropy alloys are considered to exhibit so called sluggish diffusion, which may at least partly explain many of their unusual macroscopic properties. However, the origins of this effect remain unclear, in part because the atom-level modelling of dynamic processes in an alloy with 5 or more elements is very challenging. To improve on this, we have recently developed a machine-learning interatomic potential for the 5-element refractory metal high-entropy alloy VNbTaMoW [1]. Using such potentials, it is possible to use molecular dynamics and Metropolis Monte Carlo simulations to examine elemental segregation effects of defects and dislocations in a true high entropy alloy. The simulation results and associated positron annihilation experiments [2] show major elemental segregation effects in the intermediate atomic environment around both vacancy- and interstitial-like defects in high entropy alloys. The defect migration is then strongly affected by this segregation. This implies that the point defect migration cannot be treated in the traditional manner of a certain defect type having a well-defined migration energy.

4:15 PM SF06.02.08
Atomistic Modeling of Surface Segregation Driven by Defect Transport in Binary Alloy Guofeng Wang and Siming Zhang; University of Pittsburgh, United States

Surface segregation process in binary alloys results in the surface layers with their own set of composition and structure different from the bulk ones, which serves as an important model system to advance understanding of interface dynamics in nanoscale systems for future materials design. Moreover, surface segregation affects greatly the catalytic, friction, and anti-corrosion properties of binary alloys. In this study, we applied the first-principles density functional theory computational method to predict the surface segregation profiles as related the transport of different vacancies in binary alloy nanostructures.

(1) For Cu20Au80 random solid solution alloy, our computation reveals that structural defect, i.e., surface steps, could induce compositional and structural evolution in the subsurface of a Cu(Au) solid solution and lead to a stacked sequence of Cu-Au ordered phases in the subsurface. The presence of a monatomic step at the surface induces the formation of an antiphase boundary that extends from the surface step to deeper layers by maintaining the same composition profile associated with each terrace.

(2) For ordered Cu3Au (100) surface, we modelled an adatom process underlying transient surface segregation dynamics through the temperature-change-driven creation and annihilation of thermal vacancies in the bulk and the resulting bulk-surface mass exchanges. Our computational results indicate that the lower vacancy formation energy for Cu than Au in Cu3Au results in more bulk thermal vacancies of Cu with the increase in temperature, for which the excess Cu atoms are expelled onto the surface as adatoms that aggregate as Cu-rich clusters. Decreasing temperature drives more Cu adatoms than Au adatoms back to the bulk, thereby making the adatoms Au rich.

(3) Using the example of Pt85Fe15 alloy nanoparticles (NPs), we modelled the composition-dependent ordering processes on the single-particle level. Our results reveal that ordering transformations are controlled by the vacancy-assisted diffusion of Pt and Fe atoms in the nanoparticles. In Pt85Fe15 nanoparticles, Fe is predicted to be the fast-migrating species; the inward diffusion of surface Fe and outward diffusion of core Fe atoms lead to this particular structure of the $Pt_{85}Fe_{15}$ NPs of an outermost Pt shell, a Pt_3Fe $L1_2$ ordered phase underneath, and an inner Pt-enriched core.

Title: Role of Sn Concentration in the Amorphous-to-Crystalline Transition of the Mixed Oxide SnO_2/TiO_2 Pritha Biswas, Tamara Koledin, Melissa K. Santala and Janet Tate; Oregon State University, United States

Although rutile titania is the thermodynamically stable phase at a high temperature in the bulk, stabilization of this polymorph at a lower temperature with a high surface-to-volume ratio remains an elusive target in the field of catalysis and low-temperature gas sensing. Stabilization of rutile TiO_2 by isostructural alloying with the isovalent dopant Sn is one of the most established methods[1,2] among the variety of doping routes. We describe the deposition of metal Sn between two amorphous TiO_2 layers and show that rutile TiO_2 results upon annealing at 500 °C once the Sn:Ti ratio exceeds a critical value. Below that value, anatase TiO_2 is formed. Phase identification and corresponding morphologies of the different phases of the SnO_x/TiO_y system with different percentages of Sn have been characterized by x-ray diffraction (XRD), transmission electron microscopy (TEM), scanning electron microscopy (SEM), and Raman spectroscopy. Initial ex-situ XRD and Raman measurements at different stages of oxide formation indicate that the rutile phase forms directly from the amorphous precursor and that the transformation is not a polymorphic anatase-to-rutile transition. Based upon the layered geometry of the SnO_2/TiO_2 mixture, we propose that the incorporation of Sn between two amorphous TiO_2 layers changes the *amorphous precursor* of TiO_2 by scavenging oxygen from the TiO_6 octahedra that then form an oxygen-deficient environment with short-range order, which ultimately stabilizes the rutile polymorph of TiO_2.[3]

Zeta Potentials and NMR—Probing Ion-Surface Interactions in an Inhomogeneous Solid-Liquid Media Using Nuclear Magnetic Resonance Ruth Zlanseu Tan[1,2], Vincent Sarou-Kanian[1] and Michael Deschamps[2,1]; [1]CNRS, France; [2]University of Orleans, France

The accurate description of interface phenomena in solid-liquid heterogeneous media is a common issue in many scientific fields[1,2,3]. Whatever the domain, the main question remains : how much do we know about the interaction between the surface of a solid and the molecules and ions of the liquid phase ? In this work, we are specifically interested in individual ion-surface interactions and we managed to probe them using Nuclear Magnetic Resonance (NMR). NMR is a well-known characterisation method for probing local structure around spin bearing atoms, as well as their dynamics at the nanometer scale through relaxation at high fields. These features make it a suitable tool to differentiate ions according to their location (interface or bulk?) and dynamics in such media (slow or fast motion?), in solid-liquid mixtures with relatively low amounts of liquids.
Oxides powders (TiO_2 and Al_2O_3) were mixed with aqueous electrolytes containing several types of ions (NO_3^-, NH_4^+, Br^-, Na^+, Li^+, Rb^+, Cs^+), with quadrupolar spins that are observable in NMR, in the 0.1 M - 2 M concentration range. NMR longitudinal relaxation times (T_1) and signal areas measurements allowed us to indirectly characterize the quadrupolar interactions at the solid-liquid interface and to observe pH sensitive ion-surface interactions, which can be correlated with zeta-potential measurements. Moreover, competitions between ions can be characterized *in situ* by NMR and we showed that a complex picture emerges when solutions with two cations are in contact with the solid surface.

Thermal Transport in Micro-to-Nanoscale Systems Affected by Volumetric and Surface Disorder—A First-Principles Study Navaneetha Krishnan Ravichandran; Indian Institute of Science, India

In nanoscale crystalline semiconductor films and wires, where the surface area-to-volume ratio is large, phonon scattering at surface disorder affects heat transport, particularly at low temperatures. In a previous study, we experimentally extracted the phonon specularity parameter, which quantifies the relative extent of specular-to-diffuse scattering of phonons at a rough surface, using transient grating measurements of lengthscale-dependent thermal conductivities in sub-micron thick silicon films [1]. We showed that, in our silicon films, phonons with wavelengths shorter than 8 nm undergo partial specular reflection at the boundaries, resulting in significant reduction in the thermal conductivity of these films compared to bulk silicon. In the first part of this talk, I will describe our recent computational effort to describe this additional thermal resistance due to phonon-boundary scattering in nanoscale wires and films made from III-V compounds and other low-dimensional materials, informed by the aforementioned experimentally extracted phonon specularity parameter.

In chemically grown bulk crystals, volumetric disorder such as substitutional defects and vacancies are often present in significant concentrations. Phonon scattering with defects in these crystals cause additional resistance to heat flow, apart from the anharmonicity-driven intrinsic phonon-phonon scattering. In the second part of this talk, I will describe our group's ongoing effort to study the relative importance of phonon-phonon and phonon-defect scattering in modulating the thermal conductivity of compound semiconductors at different defect concentrations and temperatures, using our in-house unified first-principles computational framework [2].

Utilizing Order-Disorder Phase Transitions for Solid-State Cooling: From Thermodynamics to Devices Adam H. Slavney, Jinyoung Seo, Vidhya M. Dev and Jarad A. Mason; Harvard University, United States

Vapor-compression air conditioning is a technology which is essential to modern life. However, the established hydrofluorocarbon refrigerants central to this technology are potent greenhouse gases—one to five thousand times more effective than CO_2. The unintentional release of these refrigerants to the atmosphere during air conditioner installation, maintenance, and disposal is currently responsible for ca. 4% of planetwide global warming and is expected to rise to 10% of all warming by 2050. To eliminate this source of atmospheric emissions, we are developing solid-state barocaloric materials which can serve as direct replacements for hydrofluorocarbons in air conditioners and other heat-pump applications. We have recently discovered a promising new family of barocalorics: layered halide perovskites with long alkyl ammonium tails. These materials undergo solid-solid, order-disorder transitions within the alkyl sublattice which are analogous to the melting of simple *n*-alkanes, albeit confined to two dimensions by the layered perovskite structure. Layered perovskite transitions occur near ambient temperature and with high transition entropies making them able to adsorb and release significant amounts of heat in the temperature range relevant for indoor cooling. Additionally, these phase transitions show low hysteresis, and the transition temperatures are highly sensitive to pressure. This combination of properties enables layered perovskites to realize efficient barocaloric cooling with a pressure swing of 200 bar or less—a range achievable with standard hydraulic systems—whereas prior barocaloric systems require pressures above 1000 bar to realize measurable cooling. To demonstrate this in practice, we have designed and constructed a custom barocaloric prototype device and achieved efficient barocaloric cooling at pressures at and below 200 bar for the first time. I will discuss our current progress, ongoing challenges, and future directions of this work.

Water/Zirconia Interfacial Behavior—Water Adsorption and H^+ Subsurface Diffusion Saul Perez Beltran[1], Pablo Gargano[2,3], Mariano Forti[2], Gustavo Emilio Ramirez Caballero[4], Gerardo H Rubiolo[2,5], Perla B. Balbuena[1] and Paula R. Alonso[2]; [1]Texas A&M, United States; [2]Comisión Nacional de Energía Atómica, Argentina; [3]Universidad Nacional de San Martín, Argentina; [4]Universidad Industrial de Santander, Colombia; [5]Consejo Nacional de Investigaciones Científicas y Técnicas (CONICET), Argentina

We evaluated the interfacial behavior between water and zirconia using a computational approach based on density functional theory (DFT), ab-initio molecular dynamics (AIMD) and constrained molecular dynamics (c-AIMD). ZrO_2 crystallites improve corrosion resistance in Zr-Nb alloys by hindering H^+ diffusion, which is essential to ensuring the safe operation of heavy water reactors.[1] Among the different ZrO_2 polymorphs, monoclinic ZrO2 (m-ZrO2) is the most naturally occurring form at low pressure[2]. Meanwhile, the high-pressure cubic ZrO_2 (c-ZrO2) grows from $Zr(OH)_4$ decomposition and in radiated Ce-doped tetragonal ZrO2 materials;[3, 4] its occurrence has been reported via transmission electron microscopy (TEM) in Zr-based alloyed fuel clads for light-water reactors and Zr surfaces.[5-9]
We studied dissociative water adsorption on pristine and defective c-ZrO_2(111) and m-ZrO_2([endif]-->11) surfaces using the DFT engine Vienna ab-initio simulation package (VASP, version 5.4.0).[10] The surface defects studied included an oxygen vacancy, interstitial oxygen, and substitutional Ta and Nb.[2, 11-13] The first step involved the surfaces' optimization via DFT in a vacuum. Then, we added water molecules into the simulation cell and ran AIMD simulations for about ten ps intervals at 300, 900 and 1500K. These calculations showed dissociative water adsorption even at 300 K, with the adsorption of H+ and OH- groups in surface oxygen and Zr atoms. The presence of defects led to a surface reconstruction in some cases and favored the water dissociation. Moreover, an interfacial oxygen exchange occurred at 1500 K.
For the second part of this work, we studied the H+ subsurface diffusion via c-AIMD calculations. The outermost surface layers showed the highest energy barrier, with some exceptions due to defects. However, the inner layers showed a lower energy barrier for the H+ diffusion, which was most evident between the second and third layers; the more buried the layer, the lower the energy change. The presence of defects showed a lowered energy barrier in some cases, which led us to believe that surface defects trigger material failure. We elucidated the H^+ diffusion mechanism in each case.

Effect of Positional and Energetic Disorder on Charge Transport in Nanocrystal Quantum Dot Thin Films Yunhua Xing, Nuri A. Yazdani, Weyde Lin, Maksym Yarema, Raphael Zahn, Vanessa Wood and Simon Wintersteller; IfE, D-ITET, ETHZ, Switzerland

Understanding and controlling mobility disorders in self-assembled nanocrystal (NC) solids is crucial for accelerating development for NC solids-based electronics [1]. Especially, Ccompared to energetic disorder, the impact of positional disorder on charge carrier transport is less studied due the challenges of experimentally controlling the films has not yet been clarified due to its diversity and complexity. We present In this work, we seek to fill the knowledge gap by demonstrating an approach to systematically investigate different types of disorder and their impact on charge transport in NC solids [2]. We computationally construct and quantify the artificial NC thin films containing different types of realistic disorders. By applying density functional theory (DFT) parameterized Kinetic Monte Carlo (KMC) simulations, we extract statistics to quantify the probe effective carrier mobility and origins of the understand charge transport behavior at an “artificial atomic (NC)” level. We demonstrate that the impact of positional disorder on charge transport depends on the type of disorder and how it affects the spacing between neighboring NCs. We found that certain disorders that shorten inter-NC distances can enhance the carrier transport, while random packing of NCs and energetic disorder due to a distribution of NC sizes decreases mobility 2- to 4-fold. We further demonstrate how electric field impacts the charge transport in disordered NC thin films. Finally, we address the detrimental impact of deep electronic trap states on carrier mobility, particularly at low electric field and when the films are otherwise highly ordered. Overall, we show that our approach can be a power tool to investigate charge transport in NC-solid-based devices. And Bbased on our results, we suggest what to prioritize in terms of synthesis and thin film fabrication in the future development of NC devices.

Interfacial and Bulk Defect Resolution Using Machine-Learning Augmented Ultrafast Diffraction Mingda Li; Massachusetts Institute of Technology, United States

Materials defects are ubiquitous and play a key role in materials’ functional properties. However, there has been a lack of non-contact, non-destructive defect quantification tools to resolve complex defect profiles when multiple types of defects are present. Here we introduce an alternative approach for defect quantification, using the fact the phonons – major heat carriers in insulators and semiconductors – are sensitive to defect scattering: phonon-frequency-resolved relaxation time and transmittance are known to contain direct and quantitative knowledge of materials’ bulk and interfacial defect structures. However, frequency-resolve phonon relaxation and transmittance are long considered not measurable. We design an integrate theoretical-experimental-machine-learning framework to extract such quantities by using machine-learning to analyze time-resolved diffraction patterns: ultrafast diffraction offers high-dimensional data in time-momentum space where phonon thermal transport is reflected on the atomic vibrations and thereby diffraction intensities, and scientific machine learning is used to solve an inverse thermal transport problem and extract those frequency-resolved phonon transport with significantly increased reliability[1]. We anticipate the work representing an alternative pathway for non-contact, quantitative defect resolution.

Tuning the Properties of Thin Metal Films via Disorder Alessandro Troglia[1] and Roland Bliem[1,2]; [1]Advanced Research Center for Nanolithography, Netherlands; [2]University of Amsterdam, Netherlands

Crystalline order is typically considered a prerequisite for an ideal material. Disorder is thus commonly perceived as detrimental, even though it is a key advantage in important classes of materials. Structural disorder in amorphous alloys, for example, benefits various macroscopic properties, such as hardness or corrosion resistance, leading to an excellent performance as coatings, barrier layers, catalysts, or in advanced electronics [1]. So rather than distracting and detracting from perfection, structural disorder can serve as an ideal design parameter for new corrosion-resistant, hard, and selectively reactive alloys.
Typically, crystallinity and amorphicity in alloys are connected to specific stoichiometries, making the effects of structure and composition difficult to disentangle. In the present work we make use of pulsed laser deposition (PLD) to prepare crystalline and amorphous alloy layers of identical composition by growing thin films under two very different types of conditions, close to and far from equilibrium. We study the structural, mechanical, and electronic properties as well as the surface chemistry of polycrystalline and amorphous films for two selected alloys: CuZr and HfMoNbTiZr. CuZr is a model system for metallic glasses with composition-dependent glass-forming ability [2], whereas the high-entropy alloy (HEA) HfMoNbTiZr has exclusively been observed in its crystalline form [3].
In contrast to literature results, HfMoNbTiZr films grown with PLD at room temperature show no sign of crystallinity in grazing-incidence X-ray diffraction (GI-XRD) and transmission electron microscopy (TEM). Even an increase of the deposition temperature to 700°C is insufficient to induce crystallization, which starts at 900°C. The liquid-like diffraction features of the amorphous films shift to higher diffraction angles and decrease in width with increasing deposition temperature. This indicates that a lower-energy glassy structure is formed for high-temperature growth. It further suggests that the packing density in amorphous HEA thin films is tuneable, which could be of interest for their applications as energy storage medium [4]. The remarkable thermal stability of the amorphous phase and its facile formation highlight the potential of complex alloys for high-temperature applications requiring structural stability.
For CuZr, on the other hand, smaller variations in temperature are sufficient to induce crystallization. Room-temperature PLD leads to amorphous layers according to GI-XRD, while films of the same composition are polycrystalline when deposited at 500°C. Raman spectroscopy measurements show no discernible features for the amorphous layers while broad but distinct modes related to Cu and Zr oxides are observed for polycrystalline films. The effect

of disorder on the surface chemical properties of CuZr was measured using X-ray photoelectron spectroscopy (XPS) by comparing as-grown and air-exposed CuZr films. The XPS results show a remarkable preference in the surface oxidation of the Cu species. Cu is fully metallic for the amorphous film whereas both oxide and hydroxide components are observed for the crystalline layer.
Our results demonstrate that the level of structural disorder in thin alloy films can be tuned from polycrystalline to fully amorphous using PLD. This structural disorder significantly influences the surface reactivity and oxidation resistance of the model compound CuZr.

11:00 AM SF06.03.08
Correlation of Oxygen Nonstoichiometry on Chemical Expansion in LCCO Thin Films Hendrik Wulfmeier[1,2], Dhyan Kohlmann[1], Thomas Defferriere[2], Harry Tuller[2] and Holger Fritze[1]; [1]Clausthal University of Technology, Germany; [2]Massachusetts Institute of Technology, United States

Mixed electronic/ionic conductors (MIECs) are of great technological interest with applications, for example, in solid oxide fuel cells (SOFCs). Reduction of operation temperatures is needed both for extended life and reduced costs, but this increases the demand for more electrocatalytically active electrodes. The MIEC layer compound lanthanum cerium cuprate ($La_{1-x}Ce_xCuO_{4+\delta}$, LCCO) shows promise in this regard given relatively high electronic conductivities at reduced temperatures [1], as well as the ability to accommodate both oxygen excess and deficiency, the latter making it an attractive candidate for both the SOFC cathode and anode [2], and thus a promising material for reversible SOFCs. In this work, oxygen nonstoichiometry in LCCO thin films is characterized in the temperature range of 500 to 700 °C. The determination of the oxygen nonstoichiometry in thin films is a challenging task, especially at elevated temperatures. Piezoelectric nanobalances, based on catangasite (CTGS, $Ca_3TaGa_3Si_2O_{14}$) single crystals, were applied to monitor changes in δ in these thin oxide films [3] reaching values of up to $\delta = -0.118$ at e.g. 600 °C and $\log(p_{O2}) = -13$.
Changing oxygen content in LCCO films, for positive or negative values of δ, results in chemical expansion that can lead to stresses resulting in cracks and malfunction. In the case of thin films this chemical expansion occurs mainly perpendicular to the substrate. In lateral direction of the substrate, mechanical stress is generated leading to substrate bending. The surface near film expansion is characterized by X-ray diffraction under temperature and p_{O2} variation. We characterize the overall thin-film expansion of LCCO films deposited on single crystalline yttria stabilized zirconia (YSZ) substrates acting as oxygen pumping cells by high-temperature laser-Doppler vibrometry (LDV) [4]. An applied voltage results in an oxygen activity which corresponds to an effective oxygen partial pressure and can be calculated via the Nernst relation. When a sinusoidal excitation voltage is applied to the cell, the reversible *breathing* of the LCCO film can be detected via LDV. If the excitation frequency is low enough, a quasi-stationary state is reached. At 500 °C and an excitation frequency of 100 µHz, positive and negative voltages of +/– 0.5 V correspond to oxygen activities of $\log(a_{O2}) = -10$ and +10, respectively. In both cases thin-film expansion of only a few nm, results in total displacements (i.e. thin-film expansion plus substrate bending) of 64 nm and 239 nm respectively.

Understanding the Structure-Dielectric Property Relationships of $(Ba_{0.8}Ca_{0.2})TiO_3$-$Bi(Mg_{0.5}Ti_{0.5})O_3$ Perovskites Colin Freeman and Derek Sinclair; University of Sheffield, United Kingdom

There is a constant search for new functional ceramics particularly in the improvement of their dielectric properties such as higher temperature operating ranges. In the last two decades a particularly exciting set of materials have been identified based around a mix of a $BaTiO_3$ with an Bi perovskite such as $BiScO_3$, $Bi(Mg_{0.5}Ti_{0.5})O_3$ and $Bi(Zn_{0.5}Ti_{0.5})O_3$ [1-4]. These materials produce a relatively flat permittivity-temperature profile at high temperatures. Structurally, these materials appear pseudo-cubic but detailed investigations have highlighted structural variation over the length-scale viewed [5]. This couples with localised atomic relaxations[6-7] and potential chemical inhomogeneity [8]. Collectively this makes a highly disordered material that demonstrates complex mixing behaviour and properties. Understanding the structure-property relationships present are vital to understand for designing future materials in this area.

We present a set of atomic-level simulations to examine the structure, thermodynamics, and dielectric properties of $(Ba_{0.8}Ca_{0.2})TiO_3$-$Bi(Mg_{0.5}Ti_{0.5})O_3$ perovskites. By examining thousands of atomic configurations we are able to comment on the mixing properties and demonstrate that the solid-solution is non-ideal and only specific configurations can form at higher $Bi(Mg_{0.5}Ti_{0.5})O_3$ content. We identify the main structural relaxations that take place in the structure connect this to the dielectric properties of the materials by examining the polarisation of the system. Our analysis allows us to link the material disorder with disrupting ferroelectric domains linking to the flat permittivity profiles reported.

Exploring Phonons Across the Order-Disorder Barocaloric Phase Transition in Adamantane Bernet Meijer[1], Richard Dixey[1], Robin Perry[2], Anthony Phillips[1] and Helen C. Walker[3]; [1]Queen Mary University London, United Kingdom; [2]University College London, United Kingdom; [3]Rutherford Appleton Laboratory, United Kingdom

For years the scientific community has widely followed the maxim that structure dictates functionality and disorder is something to be avoided as far as possible. Those using inelastic neutron scattering (INS) to study phonons have therefore restricted themselves to near perfect crystalline material, sweeping any evidence of disorder under the carpet, using the argument that it is too difficult to analyse data from disordered systems and that simulations are beyond the scope of current computational power. However, it is now quite clear that computational physics has made more than enough progress to build both random and correlated disorder into phonon simulations [1,2]. It is therefore time for INS experimentalists to exploit these developments and finally explore the phonon spectrum of "real" functional materials with inherent disorder in order to determine their thermal properties.
Adamantane is a molecular crystal built up from near spherical molecules that undergoes an order-disorder transition between a low temperature ordered phase and a dynamically disordered phase at room temperature. This disorder between two possible orientations arises from the centroid of each molecule being a crystallographic centre of symmetry, even though the molecules themselves are not centrosymmetric, and neutron total scattering has revealed that there is no correlation between these orientations [3]. Our current interest in adamantane stems from the phase transition being associated with a large change in entropy, and a large change in volume, such that the phase transition can be driven by the application of pressure. This makes adamantane an example of a barocaloric, materials offering technological application potential for environmentally friendly refrigeration.
We have measured the phonon spectrum in both phases of single crystal adamantane as a function of temperature and hydrostatic pressure on the LET direct geometry neutron spectrometer at ISIS. The spectra in the low temperature phase are well reproduced by combining the output from GULP with Euphonic, a python package which calculates phonon bandstructures, density of states and INS intensities from force constants [4]. In the high temperature phase, the INS data show a significant broadening of the phonon branches. We will compare this with the results of simulations based on a supercell lattice dynamical approach [2] to treat the rotational disorder explicitly.

Exploring the Potential Energy Surface to Describe Phonon-Defect Scattering Georg Madsen; TU Wien, Austria

Defects play an important role in engineering the electronic properties of semiconductor materials. At the same time they can strongly influence the phonon scattering processes and thereby the thermal conductivity. In the talk, I will highlights both the need for a global exploration of the potential energy surface (PES) governing the competing defect structures and how the details of the regions surrounding the defect atoms can changes the scattering strength by orders of magnitude. I will discuss approaching this juxtaposition by a combination of a evolutionary strategy and machine learned force fields. The approach is based on modifying the covariance matrix adaption evolution strategy (CMA-ES) to suit the specific problem of point defects. I will furthermore introduce a fully differentiable neural network force field that can be trained both on energies and forces and it can accelerate both the PES exploration and the calculation of force constants.

Unravelling the Impact of Disorder on the Electronic Properties Of Mixed-Metal Chalcohalides Adair Nicolson[1], Kazuki Morita[2], Seán R. Kavanagh[1,2], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom

Mixed-metal mixed-anion systems have seen a significant rise in interest as 'perovskite-inspired materials' as are expected to combine the excellent stability seen in metal chalcogenide solar cells with the well-known performance of hybrid halide perovskite solar cells.[1]

$Sn_2SbS_2I_3$ is a promising solution-processed photovoltaic absorber having achieved efficiency above 4% in initial devices.[2] Theoretical work predicts that the material family of $A_2BCh_2X_3$ mixed-metal chalcohalides could also be ferroelectric, with $Sn_2SbS_2I_3$ having strong lattice polarization and large dielectric constants.[3]

However, this family has not been rigorously explored resulting in confusion in the literature regarding the structure of these materials, with some works observing disorder in room temperature crystals.[4] Without a proper description of the structure, prediction of the electronic properties cannot be accurately performed. Understanding the extent of the disorder in these systems is of key importance due to its tendency to quench favourable properties such as macroscopic polarisation.

Using Density Functional Theory, Cluster expansion and Monte Carlo techniques, we have systematically examined the cation disorder in $Sn_2SbS_2I_3$ for the first time and will discuss its likely impact on the potential for this material family to produce ferroelectric and photovoltaic devices.[5]

Influence of Defects on Thermal and Electrical Transport G. J. Snyder; Northwestern University, United States

Defects, such as point defects (impurity, vacancies or interstial atoms) are well known to impede thermal and electrical transport in materials by scattering electrons and phonons. This is perhaps best documented in the study of thermoelectric materials where it is important to reduce phonon thermal conductivity without disrupting the electrical conductivity.
In semiconductors (such as thermoelectrics) or insulators, the electrical transport is determined by the defects. To make a n-type or p-type semiconductor we typically use point defects to introduce a slight valence imbalance that leads to excess electrons or holes. Often intrinsic defects such as vacancies, interstials or antisite defects, provide the necessary carriers to make the semiconductor conducting. Most materials, however, require extrinsic dopants to be a good conductor and intrinsic defects often only make it more difficult. Sometimes intrinsic defects are so prevalent they are *killer defects* that prevent any dopant from making the material n-type or p-type. By understanding that atomic chemical potentials influence defect energy and also define regions in phase diagrams we can use *phase boundary mapping* to explore all the possible thermodynamic defect states of a material to avoid killer defects. The most dramatic demonstration of this is the discovery of high performance thermoelectric Mg_3Sb_2 which only occurs in Mg-rich Mg_3Sb_2 where Mg-vacancies are suppressed.
Point defects are also well known to reduce thermal conductivity in solid solution alloys. Although the random distribution of atoms is essential to scatter phonons, the simple analytic theory explains why thermal conductivity is not simply correlated to entropy in high entropy alloys. For a full spectrum engineering of phonon scattering from lower dimension defects, such as line defects (dislocations) and planar defects (grain boundaries) must also be used and better understood. The phonon scattering of dislocations is much less studied. However, from simple dimensionality arguments it can be shown that the T^2 temperature dependence observed in polycrystalline materials probably arises from periodic dislocation arrays. This mechanism provides a simple replacement for the commonly used diffuse mismatch model that is more physical as it predicts that low energy, low angle grain boundaries scatter phonons less than high energy, high angle grain boundaries.

***Ab Initio* Models of Orientational Order and Phase Transitions in Hybrid Piezoelectric Materials** Kasper Tolborg and Aron Walsh; Imperial College London, United Kingdom

Piezoelectric materials interconverting electrical and mechanical energy find applications in diverse areas as sensors, actuators, and high precision motors. Current state-of-the-art piezoelectric materials are made from lead-based ceramics, which pose significant environmental issues and precludes design of biocompatible devices. Recent progress in molecular and hybrid organic-inorganic piezoelectric materials have led to discovery of new materials with properties rivalling the lead-based ceramics, and with the additional prospects of being solution processable, flexible, and potentially biocompatible [1,2]. However, conventional computational methods fail to predict their large piezoelectric response [3], and pertinent phase transitions to disordered, centrosymmetric phases appear near or above room temperature, which may hamper their practical applications. Thus, proper computational modelling of this materials class must include nanoscale effects for response properties, and entropic effects to phase stability [4].

Here, we present the development of ab initio models for the ordering of dipolar molecules in hybrid piezoelectric materials. Based on model Hamiltonians fitted to density functional theory (DFT) data and Monte Carlo simulations, we predict and rationalise the order-disorder phase transitions in these materials. We show that a model Hamiltonian based on internal energies calculated from DFT fails to quantitatively reproduce phase transition temperatures, whereas inclusion of vibrational free energy effects improves the agreement with experiment significantly. This highlights the importance of vibrational entropy in describing phase stability for a materials class seemingly driven by configurational entropy.

Besides prediction of phase stability, our model Hamiltonian also provide insights into the strong piezoelectric response, which has been reported to be influenced by metastable phases [3].

Accelerated Densification in Nanocrystalline Ni Challenges Organic Burn-Off Yannick Naunheim and Christopher A. Schuh; MIT, United States

Nanocrystalline metals are high defect-density materials due to the numerous grain boundaries and interfaces that provide rapid-diffusion kinetics as compared to their polycrystalline counterparts. In this talk, we present a set of Ni-base powders and alloys that are produced via sintering of high-energy ball milled powders. Due to the large plastic deformation, the powders are nanocrystalline and the consolidation is accelerated by structural refinement. Some alloys are further out of chemical equilibrium through mechanical alloying and supersaturation with an immiscible solute. These highly-driven powders evolve during a sintering cycle and undergo a kinetically accelerated phase-evolution leading to low-temperature onset of densification.
In some of the sintered powders, the fast consolidation can compete with organic burn-off, which is a new challenge to additive manufacturing, such as for binder jetting. We will discuss strategies to address the competition between rapid consolidation and organic volatilization.

Optimized Lithography-Free Fabrication of Sub-100 nm Nb_2O_5 Nanotube Films as Negative Supercapacitor Electrodes—Tuned Oxygen Vacancies and Cationic Intercalation Nageh K. Allam, Doha M. Sayed and Kholoud E. Abousalem; American University in Cairo, Egypt

The direct growth of sub-100 nm thin-film metal oxides has witnessed a sustained interest as a superlative approach for the fabrication of smart energy storage platforms. Herein, sub-100 nm Zr-doped orthorhombic Nb_2O_5 nanotube films are synthesized directly on the Nb-Zr substrate and tested as negative supercapacitor electrode materials. To boost the pseudocapacitive performance of the fabricated films, supplement Nb^{4+} active sites (defects) are subtly induced into the metal oxide lattice, resulting in a 13% improvement in the diffusion current at 100 m V/s over that of the defect-free counterpart. The defective sub-100 nm film (H-NbZr) exhibits areal and volumetric capacitances of 6.8 mF/cm^2 and 758.3 F/cm^3, respectively. The presence of oxygen-deficient states enhances the intrinsic conductivity of the thin film, resulting in a reduction in the band gap energy from 3.25 to 2.5 eV. The assembled supercapacitor device made of nitrogen-doped activated carbon (N-AC) and H-NbZr (N-AC//H-NbZr) is able to retain 93, 83, 78, and 66% of its first cycle capacitance after 1000, 2000, 3000, and 4500 successive charge/discharge cycles, respectively. An eminent energy record of approximately 0.77 µW h/cm^2

at a power of 0.9 mW/cm^2 is achieved at 1 mA/cm^2 with superb capability.

Computational and Characterization Methods to Quantify Chemical Ordering in Compositionally Complex Alloys Anne Barnett[1], Daniel Foley[1], Elaf Anber[1], Yevgeny Shlafstein[1,2], Peng Yi[1], Michael L. Falk[1] and Mitra L. Taheri[1]; [1]Johns Hopkins University, United States; [2]Columbia University, United States

Non-uniform, chemically complex alloy landscapes are challenging to fully characterize. Difficulty arises in confirming the ordering mechanisms, in quantitatively describing order, and in rigorously relating such order to experimental measurement of reciprocal space lattices patterns. Precession Electron Diffraction (PED) can extract quantitative ordering information in metallic systems, including slight changes in ordering that occur at high spatial resolution, but there remains a need for more evidence of local behavior. Focusing on binary and ternary alloys, hybrid Monte-Carlo/Molecular Dynamics simulations were performed to generate experimentally comparable models to compliment conclusions about the ordering signatures previously found using PED. To assign a value to systems with varied degrees of disorder, the Warren-Cowley parameter was used to quantify chemical short-range order by considering pairwise bonding tendencies in these systems. This parameter is well-defined mathematically but does not directly provide any physical interpretation. We use the Warren-Cowley parameter to benchmark the chemical state of systems generated both experimentally and computationally. Modeling results, experimental PED patterns, and SRO parameters illustrate the benefits of a combined methodology to facilitate quantification of systems with intermediate levels of disorder. This analysis also provides important information about the local nature of chemical ordering in highly complex, metallic systems.

SF06.05.02
Enhanced Photocatalytic Performance of Transition Metal-Doped CeO_2 Nanoparticles Jeong-Woo Nam[1], Jeong Min Ha[1], Youngsoo Kim[1], Hangil Lee[2] and Young-Sang Youn[1]; [1]Yeongnam University, Korea (the Republic of); [2]Sookmyung Women's University, Korea (the Republic of)

Since CeO_2 nanoparticle is widely used as photocatalyst, many researchers have tried to improve the photocatalytic activity of CeO_2 nanoparticles by transition metal ion doping. It is well known that photocatalytic activity is related to oxygen vacancies on nanoparticles. In this study, CeO_2 nanoparticles doped with Cr (Cr@CeO_x) or Fe (Fe@CeO_x) were prepared to check the enhanced photocatalytic activity by increasing oxygen vacancies compared to CeO_2 nanoparticles.
The change in the crystal structure for all the samples was identified by the X-Ray diffraction (XRD), in which all the XRD patterns correspond to typical cubic-structure of CeO_2. In Raman spectra, a prominent band at ~467 cm^{-1} by the F_{2g} Raman active mode in cubic-structure of CeO_2 and a D band at around 250 and 600 cm^{-1} appearing as its oxygen vacancies are observed. In particular, the F_{2g} peak of Cr@CeO_x and Fe@CeO_x is shifted to a slightly lower wavenumber, resulting from the increase in oxygen vacancies due to CeO_2 lattice distortion by dopants. Therefore, for all the CeO_2 nanoparticles, the characteristic cubic-structure is reserved with the change in the amount of oxygen vacancies.
In addition, the local electronic structures in the unoccupied state regions of the transition metal-doped CeO_2 nanoparticles were compared with the those of CeO_2 nanoparticles using X-Ray absorption spectroscopy (XAS). Based on the ratio of the 4f and 5d-e_g peaks related to oxygen vacancies in the O K-edge spectra, we verified that oxygen vacancies increase by transition metal ion doping.
Finally, we examined the photocatalytic degradation(PCD) rates of 5-hydroxymethylfurfural in the presence of each CeO_2 samples. With PCD results, we confirmed that the transition metal-doped CeO_2 show the excellent PCD efficiency compared to CeO_2.

SF06.05.03
Physical Unclonable Function from Disordered Silane-Based Self-Assembled Monolayers Subin Lee, Juhyung Seo and Hocheon Yoo; Gachon University, Korea (the Republic of)

As the quantity of the information increases, it is crucial to implement low-power operation devices. Here, we present physical unclonable function devices using two self-assembled monolayer (SAM) materials, octadecyl trichlorosilane (ODTS) and 1H,1H,2H,2H-Perfluorooctyltriethoxysilane (PFOTES), which have different chain lengths, terminal functional groups, and dipoles. The surface was treated by UV-ozone before the SAM coating process to make it hydrophilic on a p-doped Si substrate. The current value at zero voltage bias was evaluated to utilize the electrical characteristics of the electrical characteristics of the different SAMs on the p-doped Si substrate without an external electric field. The current values of the device-to-device were dispersed based on a specific current. We performed atomic force microscope (AFM), Kelvin probe force microscopy (KPFM), Raman spectroscopy, X-ray photoelectron spectroscopy, contact angle, and ultraviolet-visible spectroscopy to analyze the mixed SAM structure and its electrical properties. We verified the current dispersion caused by dipole affection, not the physical accumulation of SAM materials through the AFM and KPFM patterns of Z-phase and potential on the device surface. Compared to the median value each security key, higher value is defined as the state '1' whereas lower value is defined as the state '0'. The uniqueness and security were evaluated by the 50~66 % of uniformity and 41.1~52.9 % of inter-HD.

SF06.05.06
Synthesis of Self-Modified Black $BaTiO_{3-x}$ Nanoparticles and Effect of Oxygen Vacancy for the Expansion of Piezocatalytic Application Myeongjun Ji, Jeong Hyun Kim, Cheol-hui Ryu and Young-In Lee; Seoul National University of Sciecne and Technology, United States

Piezocatalysis has been considered a promising green and sustainable technology because of its ability to promote the passive conversion of natural mechanical energy into electrochemical energy. Among various piezoelectric materials, barium titanate ($BaTiO_3$) nanoparticles have been actively studied as a piezocatalyst due to their non-toxicity, physicochemical stability, and high piezoelectric potential. However, the low carrier concentration of $BaTiO_3$ is a significant drawback that limits their applicability as piezocatalyst only in ultrasonic systems, which can thermally excite $BaTiO_3$ via cavitation. Although the ultrasonic system can simultaneously supply thermal energy for the generation of carriers and high pressure as the driving force for chemical reactions, this system requires bulky, and expensive facilities that result in space constraints. Therefore, a novel strategy that can overcome the limitation of material is still necessary for the development of a high-performance piezocatalyst that convert the various natural low mechanical energy.
Self-modification is a useful technique to modulate the electrochemical properties of oxide materials via the introduction of atomic defects such as oxygen

vacancies and/or low valence metal ions. However, only a few reports on the synthesis of self-modified black $BaTiO_{3-x}$ are available, and investigations on the piezocatalyst performance of black $BaTiO_{3-x}$ nanoparticles have not yet been reported. Moreover, the conventional synthesis methods of black metal oxides depend on the post-treatment methods to form the atomic vacancies. Since these methods require complicated and prolonged processes that are inappropriate for practical application, it is still necessary to develop facile and versatile synthesis methods for the synthesis of black metal oxide.
In this study, the self-modified black $BaTiO_{3-x}$ nanoparticles were successfully synthesized by a simple solid-state reaction using defective raw materials in a reducing atmosphere. From these results, the initial atomic defects in raw material were demonstrated as the critical factor to determine the size and defect concentration of final products. Therefore, the synthesis mechanism of black $BaTiO_{3-x}$ was systematically investigated in terms of the initial defect concentration of raw material. In order to study the effect of atomic defects on piezocatalytic performance, the piezocatalytic performance of self-modified $BaTiO_{3-x}$ nanoparticles was evaluated under an ultrasonic system and stirring system compared with commercial white $BaTiO_3$ nanoparticles. The piezocatalytic performance of self-modified $BaTiO_{3-x}$ nanoparticles showed a higher degradation efficiency of about 4.28 times than white $BaTiO_3$ under the stirring system, and the effect of self-modification was clearly identified. This study demonstrated a pioneering strategy that can promote the practical applications of $BaTiO_3$ as a piezocatalyst in an environment that requires low energy harvesting.

SF06.05.07
Implications of Water Intercalation in Graphene-Based Biomedical Devices Long Term Performance Elena del Corro[1], Marta D. Fernández[1], Anton Guimera[2], Xavier Illa[3] and Jose A. Garrido[1]; [1]ICN2, Spain; [2]CNM, Spain; [3]CIBER, Spain

Due to its aspect ratio, i.e. large surface exposure for a minimal thickness, events occurring at the graphene interface are of crucial interest, especially for its application in sensing devices, where differently supported graphene is in direct contact with the atmosphere or even with aqueous electrolyte containing ions and molecules of different nature. Among the existing variety of interfacial events associated to graphene, water intercalation between graphene and the supporting material, its mechanism and implications, needs to be fully understood. Water intercalation in graphene causes decoupling from the substrate, which may derive in desirable effects such as doping or strain release. However, such decoupling can also, compromise the stability and, thus, the lifetime of the graphene electronic devices.
Me and my group develop new technologies based on graphene for neuro-medical applications, where the durability of the neural probes is a required aspect, especially for chronic implants. In this work we aim to address water intercalation phenomena in our graphene technology, by combining simultaneous electrical characterization with *in-operando* Raman spectroscopy and Kelvin Probe Force microscopy.

Besides possible water residual confined between graphene and the substrate at the moment of the transfer (wet), we aim to evaluate the entrance of water during the device characterization in aqueous electrolyte. To this end, two possible routes for the water to enter are evaluated: graphene point defects and graphene edges. Graphene based solution field effect transistors (gSGFETs) have been fabricated on Si/SiO_2 substrates with different width to length ratios and the graphene channel has been passivated (SU8 and polyimide) using different configurations, protecting all or some of the graphene edges. Additionally, UVO treatment is used to generate vacancies in the graphene honeycomb that could act as additional routes for the water penetration.

Electrical and electrochemical characterization of the devices will be combined with Raman spectroscopy that accounts for graphene-substrate decoupling through the energy of the 2D phonon, and KPFM to obtain the graphene work function which is substrate dependent (water versus silicon, in this case). Aging agents such as high temperature will be used to mimic chronic operando conditions and study the effect of water intercalation .

This work aims to provide valuable information that will help in the development of new fabrication protocols designed for minimizing water intercalation events, thus extending the lifetime of our technology in its operational environment.

SF06.05.08
Computational Investigation of Short-Range Order Suppression in High-Entropy Disordered Rocksalt Cathode Materials Alexander Squires[1,2] and David O. Scanlon[2,3]; [1]University College London, United Kingdom; [2]Faraday Institution, United Kingdom; [3]Thomas Young Centre, United Kingdom

Disordered rock salt cathode materials are perceived as excellent candidates for application as future lithium-ion cathode materials enabling chemistries beyond commercial Ni-Mn-Cotechnologies [1]. Suppressing short-range order (SRO) in disordered rocksalt cathode materials is crucial to maximizing their performance. Disordered rocksalt cathodes can possess long-range “0-TM” percolation networks, which allow for fast and facile lithium diffusion, ensuring a good rate capability and high capacity [2]. SRO is typically associated with reduced connectivity of these 0-TM networks [3]. Alloying many transition metals together across the cation sublattice in a rocksalt structure, creating so-called high entropy rocksalts, has been proposed as a method for minimizing SRO [4, 5]. This approach is expected to improve Li transport through the bulk by suppressing the formation of a single dominant SRO type by increasing competition between a larger number of transition metal species [6]. While the high-entropy cathode concept has been shown to have initial promise, typically studies on these materials have not gone far beyond “proof of concept” stages, identifying optimal compositions remains an open question. When designing new energy materials which contain many component elements, working within sustainability and cost constraints becomes even more important. Many transition metals with favorable electrochemical properties are subject to high and volatile prices, with supply chain issues, precluding their use of truly sustainable cost-effective energy storage technologies [7]. Taken together, this poses an exciting design challenge in identifying low-cost, high-entropy rocksalt compositions which can remain insensitive to market fluctuations and supply chain issues, while retaining excellent electrochemical performance. In this work, we use cluster-expansion parameterized Monte Carlo simulations to examine the connectivity of the Lipercolation network when varying the number and concentration of different transition metals. We then assess the electrochemical properties and stability of these systems using first-principles approaches. Also included in our cathode design is an analysis of time-series data for the cost and availability of the component elements to ensure that not only are any proposed compositions excellent candidate cathode materials but also should represent cost-effective potential future cathodes.

SF06.05.10

Tailoring Resistive Switching in Cerium Oxide Films by Grain Boundary Engineering Hongyi Dou[1], Markus Hellenbrand[2], Ming Xiao[2], Zedong Hu[1], Aiping Chen[3], Judith L. MacManus-Driscoll[2], Quanxi Jia[4] and Haiyan Wang[1]; [1]Purdue University, United States; [2]University of Cambridge, United Kingdom; [3]Los Alamos National Laboratory, United States; [4]University at Buffalo, The State University of New York, United States

Resistive random-access memory, in particular valence change memory made of transition metal oxides, has great potential for applications in next-generation memories and neuromorphic computing. In valence change memory, the different resistance states are realized by the drift and migration of oxygen vacancies under different electrical fields. Defect engineering methods utilizing defect-defect interaction in tuning the concentration and transport of the oxygen vacancies have been studied extensively. Despite the efforts on investigating the impact of single extended defects, such as dislocations and grain boundaries, studies of the collective contribution of grain boundaries in different grain morphologies are still missing. Here, three different grain morphologies: “network”, “scaffold”, and “island” are realized in CeO_2 by simply tuning the growth temperature to investigate the impact of grain morphologies on resistive switching performance. Under the same oxidizing environment during growth, the devices with the three grain morphologies demonstrated vastly different resistive switching behaviors. The experimental results show the best overall resistive switching performance in the “scaffold” structure, where the vertical grain boundaries extended through the film helps with proper oxygen vacancy concentration as well as oxygen vacancy migration under external bias. The coexistence of both interfacial and filamentary switching modes found only in the devices with the “scaffold” structure further confirms its contribution. In contrast, the “network” (“island”) structure results in excessive (insufficient) oxygen vacancy concentration and oxygen vacancy migration paths. The research provides guidance for grain boundary engineering of the oxide switching material to tune the resistive switching performances for memory and neuromorphic computing applications.

SF06.05.11
Investigation of Thermal Stress Effects During Annealing of HfO_2 Thin Film Using Molecular Dynamics Simulations Kiran Raj and Kwon Yongwoo; Hongik University, Korea (the Republic of)

Hafnia is the major high-k dielectric material in mainstream semiconductor devices in logic and memory. Recent three-dimensional device structures require a few nanometers-thick conformal films on nonplanar substrates. Representative examples are gate oxide in multi-bridge channel field effect transistor (MBC-FET) for next-generation complementary metal-oxide-semiconductor (CMOS) technology and blocking oxide in vertical-NAND flash memory. Such thin high-k dielectric film is vulnerable to thermal stress generated by Joule heating during the switching operations. Also, the thermal stress may result in defect formation at the nanoscale, which may further give rise to leakage current issues. Moreover, the presence of intrinsic residual stress resulting from the fabrication process has been found to cause the failure of thin films by cracking or delamination. We employ molecular dynamics simulations using LAMMPS to investigate the effect of the thermal stress during the annealing of amorphous hafnia and silica-made thin films. The amorphous structures are modeled using the Charge-Optimized Many-Body (COMB) potential that facilitates variable charge by allowing charge exchange between the constituent atoms. In this study, we report the deformation/fracture behavior of the thin films at various annealing temperatures. Our study may provide insights into the thermal issues prevalent in thin films owing to the high-temperature gradient during the operation or fabrication and also address the ways to alleviate such undesirable deformation behavior.

SESSION SF06.06: Novel Structural and Functional Behaviors

8:45 AM *SF06.06.01
Multinary Chalcogenides: a Fruitful Playground for Property Tuning via Cation Substitution Lilia Woods; University of South Florida, United States

Multinary chalcogenides offer a vast selection of materials with diverse properties due to flexibility of structure, morphology, composition, doping, and other factors. By employing a hierarchical strategy based on cross-cation substitution we can build complex ternary and quaternary systems starting with simpler II-VI binary materials. Within this fruitful approach, I_2-II-IV-VI_4, I-II_2-III-VI_4, and I-III-IV-VI_4 classes of materials can be obtained. While I_2-II-IV-VI_4 has been extensively explored in the past, I-II_2-III-VI_4 and I-III-IV-VI_4 systems are much less studied. In this presentation, we present first principles simulations to examine the structural diversity of these newer classes of materials. Several metastable phases that are also dynamically stable, are found for I-II_2-III-VI_4. Compositions from the I-III-IV-VI_4 class are also studied showing highly defective chalcopyrite-like structures among others. Simulations for the electronic and phonon properties are also conducted, which help us find common features and mechanisms that limit the transport in these materials. Given the inherently low thermal conductivity, electronic property tuning possibilities, and earth-abundant constituents in many compositions, these materials are examined in the context of thermoelectricity as potential candidates for environmentally friendly energy conversion devices.

Support from the US National Science Foundation under Grant No. DMR-1748188 is acknowledged.

9:15 AM SF06.06.02
Quantifying Long- and Short-Range Cationic Disorder in $(Ag_xCu_{1-x})_2ZnSnSe_4$-Based Kesterite Lattice Shaham Quadir[1], Mohammad Qorbani[1], Amr Sabbah[2], Kuei-Hsien Chen[2] and Li-Chyong Chen[1]; [1]National Taiwan University, Taiwan; [2]Academia Sinica, Taiwan

Research on earth-abundant and non-toxic kesterite-based $Cu_2ZnSn(S,Se)_4$ (CZTS/Se) solar cells has recently drawn significant attention in the photovoltaic sector. However, the large open-circuit voltage deficit ($V_{OC,def}$) issue in CZTS/Se solar cell remains unsolved even after a decade of research and prospects. This study focuses on investigating the fundamental limitations of CZTSe solar cells, in particular the large V_{OC} deficit. One of the reasons that substantially impairs the photovoltaic (PV) performance of CZTSe is the occurrence of intrinsic point/cluster defects. Understanding the nature of and controlling cation disorder remains a crucial challenge for improving the PV performances. Herein, a cation substitution method has been introduced to control and passivate the defect states in the bandgap of CZTSe by incorporating Ag. Different x values of $(Ag_xCu_{1-x})_2ZnSnSe_4$ (ACZTSe) materials were synthesized to provide a comprehensive understanding of defect states for ACZTSe. To determine the relationships among cation disorder, defect concentration, overall long-range crystallographic order, and local atomic-scale structure for $(Ag_xCu_{1-x})_2ZnSnSe_4$ (ACZTSe) material, the combination of neutron diffraction and synchrotron-based x-ray absorption techniques are implemented. The joint Rietveld refinement technique is used to quantify the concentration of defects in Ag-alloyed stoichiometric and non-stoichiometric $Cu_2ZnSnSe_4$ (CZTSe) powder samples. As the main outcome, the cation distribution was determined to quantify the intrinsic point defects. This directly shows that Ag effectively inhibits the high concentration of the deep Cu_{Zn}

antisite and promotes shallower defects such as Cu-vacancy (V_{Cu}), which is important for improved photovoltaic performance. Moreover, we studied the atomic-scale structure of ACZTSe as a function of composition using x-ray absorption spectroscopy (XAS). X-ray absorption near-edge structure (XANES) and extended X-ray fine structure (EXAFS) analyses of the nearest neighbor shell have been performed by the simultaneous fitting of all K-edges to determine oxidation states, charge transfer mechanism (reflecting the occupancy of electronic states at/near the probed element) and structural parameters, respectively. Temperature-dependent photoluminescence has been performed to understand the defect states inside the bandgap. Finally, the combination of these techniques provided new structural insight, useful for controlling disorder in kesterite-based materials. This information can be applied in diverse energy-related applications such as solar cells, photoelectrochemical water splitting, thermoelectrics, optoelectronics, and advanced Li-ion batteries.

9:30 AM SF06.06.04
Structural Dynamics of Solid Ionic Conductors Roman Korobko, Rituraj Sharma, Thomas M. Brenner and Omer Yaffe; Weizmann Inst of Science, Israel

Solid ionic conductors are commonly crystalline compounds in which electric current is carried by charged atoms. Since the current requires a mass transfer of the conducting ions, the rest of the atoms presumably remain in place to maintain a crystallographic structure. In this presentation, I will show how the structural dynamics influence the properties of selected solid ionic conductors, change local structure and symmetry, and thus contribute to the ionic conductivity.
Our research group uses a state-of-art custom-built Raman spectroscopy system to study structural dynamics and anharmonic effects. By applying modern experimental and computational techniques, we can detect relaxational and anharmonic motions of the ions, which were previously considered immobile. These discoveries contribute to a deeper understanding of the basic ionic conductivity mechanism of some important materials in the field of solid-state electrochemistry.

9:45 AM SF06.06.05
Polaronic States and Their Impact on Charge Carrier Mobility in Lithium Titanium Oxide Battery Electrodes Matthias Kick[1], Cristina Grosu[1], Christoph Scheurer[2] and Harald Oberhofer[3]; [1]Massachusetts Institute of Technology, United States; [2]FHI Berlin, Germany; [3]University Bayreuth, Germany

Lithium-ion batteries are without a doubt a key technology in the coming energy revolution. It is thus surprising that one of the more prevalent Li battery anode materials, reduced lithium titanium oxide (LTO, $Li_4Ti_5O_{12}$), is still poorly understood on a microscopic level. While recent theoretical and experimental evidence suggests that a polaron hopping mechanism is responsible for the increased electronic conductivity of reduced LTO (compared to pristine LTO), no such explanation exists for the concurrent improvements to the ionic mobility. In this computational study, we show that the presence of polaronic Ti^{3+} centers leads to a significant lowering of Li hopping barriers in both bulk and surface reduced LTO. In agreement with experimental observations our results also suggests that polaron formation upon lithiation of LTO leads to a similar reduction of barrier heights. Further, to gauge polaronic charge mobility, we compute the relative stabilities of different localization patterns and estimate polaron hopping barrier heights. Altogether, our analysis hints at a correlated movement of Li ions and polarons, highlighting LTO's potential for rational defect engineering.

Liquid-Like Mass Transport, Without Melting, In Solid Metallic Films via Ultrafast Laser Enhancement of Point Defect Diffusion Abdul R. Ansari, Ben Torralva and Steven M. Yalisove; University of Michigan, United States

Ultrashort laser pulses (150 fs) at fluences below that needed to melt a material excite electrons into unoccupied states for brief moments of time significantly weakening bonding for possibly as long as 10 nanoseconds. The ions drift with their room-temperature velocity and create transient lattice disorder. Approximately 1-2% of the atoms in the high velocity tail of the Boltzmann distribution will have sufficient energy to create a Frenkel pair. Repeated irradiation leads to an accumulation of point defects and vastly increases (12 to 20 orders of magnitude) mass transport via an ultrafast laser enhanced diffusion mechanism.
Our previous work with semiconductors has demonstrated that repeated exposures of a gallium arsenide (GaAS) surface to ultrashort laser pulses leads to the generation followed by enhanced diffusion of point defects. The defects diffuse to the surface and their accumulation leads to morphological changes that are observed as Laser Induced Periodic Surface Structures (LIPSS). We have shown that high spatial frequency LIPSS (HSFL) are formed while irradiating GaAs with 1000 pulses. The diffusion process is electronically driven and occurs on timescales shorter than 10 ns, the time it takes for a majority of the excited carriers to equilibrate after irradiation. This suggests that the ultrafast laser enhanced diffusion coefficient is increased by up to 20 orders of magnitude over the room temperature value. This is the same order of magnitude value as diffusion in a melt. Hence we observe liquid-like mass transport while remaining in the solid phase.
This talk will show that a similar process can also work in metals, leading to atomic scale mixing from defect- and disorder-driven departures from a perfect lattice. We set out to study this mixing with ultrashort laser irradiation using fluences below that needed to melt a material in a single exposure. We chose a well studied system (Ni/W) that offers the promise of thermally stable nanostructured materials previously grown with electrochemical methods [1].
Alternating film stacks of Ni and W were deposited onto a glass substrate by magnetron sputter deposition. A working gas pressure of 2 mTorr and 3 mTorr was used for growing the Ni and W, respectively. A 100 nm Ni film was first deposited on the glass substrate as a heat sink. 12 alternating layers of Ni and W were then deposited on the heat sink such that a layer of W was present on the surface. The Ni layers were 2.5 nm and the W layers were 1.5 nm thick so that the layers are an average of 27 at% W. Multiple pulses from a Ti:Sapphire laser with $\lambda = 780$ nm and pulse duration $t = 150$ fs were used to irradiate the surface of the stack, on the W layer.
We will present scanning electron micrographs showing that irradiating the alternating film stack with 1,000 pulses leads to the formation of HSFL on the surface of the films. Using transmission electron microscopy, we will show that the HSFL is composed of the top 6 layers, meaning that the laser affected the material to a depth of only ~12 nm below the surface. Furthermore, we will show with x-ray dispersive spectroscopy that the layers are mixed. This solid-state mass transport enhancement process will be discussed in the context of ultrashort lattice disordering, bond softening, diffusion and defect generation mechanisms.

Defect-driven Biocidal Enhancement of Cuprous Oxide Brian Lejeune, Xiaoyu Zhang, Su Sun, Julia Hines, Ashlyn Reilly, Heather Clark and Laura Lewis; Northeastern Univ, United States

Non-stoichiometric metal-oxides are known for their enabling roles in energy conversion and storage devices, sensors and catalysts, among other

applications. Indeed, the compound $Cu_{2-d}O$ (cuprous oxide or cuprite), which is copper-deficient in its native state, has been documented as a contact-kill antimicrobial material; however the origins of its biocidal effectiveness are not well understood. To this end, it is of interest to investigate how cuprite's antipathogenic character scales with the density of copper vacancies; these defects are hypothesized to donate highly elevated local electrical potential that disrupts cell membranes and/or virus protein shells. In this work, commercial cuprous oxide powder (99.99%) was processed using high-energy cryomechanical milling to amplify lattice disorder and was subsequently incorporated into coatings. Coatings made from these processed powders demonstrate a self-sterilizing response to *E. coli* bacteria that is 4x (400%) faster than coatings made from unprocessed powder. No viable bacteria (> 99.999% (5-log10) reduction) are detected in bioassays performed after two hours of exposure of *E. coli* to coatings of processed cuprous oxide, while a greater than 99% bacterial reduction is achieved within 30 minutes of exposure. Further, these coatings are hydrophobic and need no external energy input to activate their contact-kill capability. The upregulated antibacterial response of the processed powders is positively correlated with extensive induced crystallographic disorder and microstrain in the Cu_2O lattice, and is accompanied by color changes that are consistent with an increased semiconducting bandgap energy. Electron microscopy reveals that cryomilled powder consists of well-crystallized nanoscale regions enmeshed within a highly lattice-defective particle matrix. These results highlight avenues for further enhancement of the antipathogenic capability of this abundant, inexpensive, robust and easily handled metal-oxide powder for wider deployment in contact-kill surfaces.

Funding Acknowledgement: This work was conducted at Northeastern University under the auspices of NSF DMR Grant #2029194 (for determination of fundamental materials aspects) and DEVCOM Soldier Center Contract Agreement W911QY-19-9-0011 (for experiments related to preparation of coatings).

Ionic Peltier Effect in Liquid Electrolytes Zhe Cheng, Arghya Patra, Beniamin Zahiri, Paul Braun and David Cahill; University of Illinois at Urbana-Champaign, United States

The Seebeck effect in ionic thermoelectric (i-TE) materials has been extensively studied recently because Seebeck coefficients in i-TE materials are found to be orders of magnitude higher than their counterparts in electronic thermoelectric materials. However, the reverse phenomenon of the Seebeck effect, namely the Peltier effect, remains unexplored in i-TE materials partly due to the experimental difficulty in thermal measurements. Here, we report the first experimental observation of the ionic Peltier effect at the lithium metal-liquid electrolyte interfaces ($LiPF_6$ and LiTFSI) by developing an ultra-sensitive differential temperature metrology (10 uK temperature resolution). By sandwiching liquid electrolytes between two lithium metal plates to form a coin cell, we can measure the Peltier heat generated in the ionic systems quantitatively by measuring the temperature difference of the two sides of the coin cell with an applied electrical current. To make the effect of the parasitic Joule-heating negligible in the measurements, small electrical currents (mA-scale) are applied because Peltier heat is proportional to current while Joule-heating is proportional to the square of current. The results show that the observed Peltier heat strongly depends on the types and concentrations of electrolytes dissolved in the supporting solvents. Our work sheds light on the thermoelectric effects with ions as the energy carriers, and will impact energy conversion and storage applications such as ionic thermoelectric materials and batteries.

11:15 AM SF06.06.10
Obtaining the Charge Carrier Diffusion Length in Disordered Semiconductors from Photoconductivity Transients Hannes Hempel, Markus Schleuning, Moritz Kölbach, Fatwa F. Abdi, Roel van de Krol, Klaus Schwarzburg, Rainer Eichberger and Dennis Friedrich; Helmholtz Zentrum Berlin, Germany

Long diffusion lengths of photo-excited charge carriers are crucial for high power conversion efficiencies of photoelectrochemical and photovoltaic devices. In ordered materials, the diffusion length is usually determined from the product of charge carrier lifetime and mobility, which both can be measured by time-resolved photoconductance measurements.
However, in disordered or defect-rich materials effects such as (multiple-)trapping, carrier localization and polaron formation can lead to time-varying mobilities and lifetimes that are not accounted for in the conventional analysis.
Therefore, here, a generalized analysis is presented that is valid for time-dependent mobilities and time-dependent lifetimes. It determines the diffusion length directly from the integral of a photoconductivity transient, regardless of the nature of carrier relaxation.
This approach is presented on amorphous silicon, a prototype of disordered materials, and $BiVO_4$, one of the most studied photoanode materials for solar water splitting. To this end, photoconductivity transients are measured from 100 fs to 100 µs by the combination of time-resolved terahertz (TRTS) and microwave spectroscopy (TRMC). Our generalized analysis allows monitoring the temporal evolution of the charge carrier displacement, which converges for both materials after ~100 ns to a diffusion length of a few tens of nanometers. For $BiVO_4$, the obtained diffusion length is significantly shorter than the typical thin film thickness, which rationalizes the photocurrent loss in the corresponding photoelectrochemical device.
Our novel analysis significantly simplifies the determination of the diffusion length and will allow a robust comparison between material classes subject to different relaxation processes.

11:30 AM SF06.06.11
Mechanism Elucidation of Resistance Relaxation Phenomenon in Pt/Nb-doped $SrTiO_3$ Junctions for AI Applications Hayato Nakamura, Hiromasa Aoki, Hiroyuki Kai and Kentaro Kinoshita; Tokyo University of Science, Japan

Resistive switching (RS) devices of a Schottky junctions consisting of a doped wide bandgap oxide such as $SrTiO_3$ (STO) and a high work function metal such as Pt have been the subject of considerable interest in terms of both non-volatile and volatile resistance relaxation nature. When used as general non-volatile memory, the continuously tunable write/erase characteristics are advantageous for multibit application [1]. In this sense, resistance state retention characteristics are important and improving resistance volatility is crucial. On the other hand, when used in new computational paradigm for the breakthrough of von Neumann-type computing, controllability of resistance relaxation phenomenon is critically important. It has been reported that the resistance relaxation phenomenon after RS in Pt/Nb(0.5 wt%)-doped STO can be used to mimic synaptic plasticity for AI applications [2]. The development of nanoscale devices with this neuromorphic functionality is the basis for hardware implementation of artificial neural networks. For practical application, details of the resistive relaxation phenomenon is required to be understood. Schottky parameters (SPs) such as barrier height (SBH) and depletion width (W_D) can be determined by combining current-voltage (*I-V*) and capacitance-voltage (*C-V*) measurements. To date, this has been conducted only for two extreme states, high-resistance states (HRS) and low-resistance states (LRS) [3]. Changes in SPs with subsequent resistance relaxation have not been reported.
In this study, sequential *I-V* and *C-V* measurements of a Pt/Nb:STO junction were performed on the same junction to extract time evolution of SPs during the relaxation. This is the first report on the time dependence of SPs as a function of resistance during the relaxation. *I-V* and *C-V* measurements were performed by the 2-terminal method using a semiconductor parameter analyzer and impedance analyzer, respectively. Since the resistance value changes logarithmically after RS, the switching unit was used to instantly switch to the circuit for *C-V* measurements after setting the junction to HRS or LRS using the circuit for *I-V* measurements.
The relaxation phenomenon until 1000 s after RS was sequentially captured. All SPs such as SBH and W_D linearly depend on the logarithm of time as the change in resistance during the relaxation was. After setting to LRS, SBH was estimated to be changed from 0.57 to 0.63 eV and from 0.81 to 0.87 eV by

the *I-V* and *C-V* measurement, respectively, showing an increase of 0.06 eV independently of measurement methods. Furthermore, the ideal factor *n* of the Schottky barrier was also decreased from 3.2 to 2.9 with increasing SBH. Considering the time dependence of *n*, the donor concentration (N_D) decreased from 7.5×10^{19} cm^{-3} to 6.5×10^{19} cm^{-3} and W_D increased from 19.0 nm to 20.8 nm after LRS. This change is considered to be caused by the trapping of electrons in the defects, which were once de-trapped by the application of forward bias to set the device to LRS. The revealed continuous change in the SPs suggests that resistance relaxation is brought about by electron trapping/de-trapping to/from oxygen defects rather than oxygen vacancy diffusion that likely gives discontinuity. This is consistent with the result of impedance spectroscopy measurement that no peak was observed in imaginary part of the dielectric constant for the frequency range of 10 Hz-5 MHz.
The present study showed that time dependent SPs of metal/oxide junctions undergoing relaxation can be obtained by the simple method. We are now investigating the time dependence of SPs on doping concentration, electrode type, etc., to establish a method to control the relaxation characteristics of Pt/Nb:STO junction for AI applications.

1:30 PM *SF06.07.01
Phonon Quasiparticle Breakdown and Novel Excitations in Strongly Disordered Solids Olivier Delaire; Duke University, United States

A deeper understanding atomic motions in solids is needed to refine microscopic theories of transport and thermodynamics, in order to design improved materials. In particular, the behavior of phonons in crystalline materials is key to rationalize numerous functional properties, ranging from thermoelectrics for cooling or waste-heat harvesting to multiferroics and phase-change materials for information processing, or superionics for solid batteries. Yet, textbook models of lattice dynamics fall short in crystalline systems featuring disorder, which disrupts translational periodicity and conventional phonon band structures. For instance, alloying may result in resonance modes that lack the propagation of conventional phonons [1,2], and spontaneous nanostructures associated with structural instabilities and sublattice disordering can lead to strong phonon scattering and glassy thermal transport [3,4]. In addition, weak bonding and strong anharmonicity can yield large vibrational amplitudes [5] and even thermally driven ionic delocalization that can lead to atomic dynamics intermediate between those of crystalline solids and those of liquids [6,7]. I will describe our combined use of state-of-the-art neutron and x-ray scattering techniques together with first-principles and machine-learning augmented simulations to probe the complex atomic structure and dynamics of disordered materials. Deviations from long-range crystalline order are probed through diffuse scattering measurements while inelastic neutron/x-ray scattering reveals both the spatial and temporal correlations of atomic motions. We rationalize our experimental data using our large-scale simulations based on surrogate neural-net force-fields trained against ab-initio data with machine learning. This integrated approach provides insights into the effect of disorder on phonons and points to descriptors that could enable future materials design.

2:00 PM *SF06.07.02
Energy Transport at Organic-Inorganic Interfaces of Nanocrystals Suspended in Solvents or Assembled into Solid Superlattices Jonathan A. Malen[1], Alexander Christodoulides[1], Yuxing Liang[1], Zhongyong Wang[2], Benjamin Diroll[3], Richard Schaller[3] and Robert Wang[4]; [1]Carnegie Mellon University, United States; [2]University of Michigan–Ann Arbor, United States; [3]Argonne National Laboratory, United States; [4]Arizona State University, United States

Nanocrystals in solution or assembled into solids have numerous potential applications in electronics, optoelectronics, and biomedical engineering. Hard/soft interfaces at the core/ligand, ligand/ligand, and ligand/solvent create a complex and uncharted vibrational landscape for thermal energy transport that will influence their technological feasibility. Here we show that core/ligand bonding sites and ligand/ligand interdigitation can significantly impact energy transport at these interfaces. In the case of nanocrystal suspensions we use infrared pump, electronic probe spectroscopy to probe energy transport from CdSe nanocrystals into the surrounding solvent. The IR pump pulse excites vibrations of one or few ligands per nanocrystal and the energy moves into the nanocrystal and solvent in parallel, allowing this method to uniquely isolate thermal conductances at the core/ligand and ligand/solvent interface. Preliminary analyses suggest that core/ligand conductances are 5-10 times higher than ligand/solvent conductances and are insensitive to grafting density, perhaps because a sparse set of strong binding sites dominates thermal conductance. In the case of nanocrystal assemblies we report thermal transport and mechanical measurements on single-domain colloidal PbS nanocrystal superlattices that have long-range order as well as measurements on nanocrystal films that are comparatively disordered. Over a nanocrystal diameter range of 3.0−6.1 nm, we observe that the superlattices have thermal conductivities

and Young's moduli that are up to ~3 times higher than those of the corresponding films. Our measurements and computational modeling indicate that stronger ligand−ligand interactions due to enhanced ligand interdigitation and alignment in nanocrystal superlattices account for the improved thermal transport and mechanical properties.

2:30 PM BREAK

SESSION SF06.08: Nuclear Materials
Session Chairs: Cody Dennett and Michael Manley

3:30 PM SF06.08.01
Nanoscale Mechanisms for Reducing Thermal Boundary Resistance via Ion Bombardment Thomas W. Pfeifer[1], Henry Aller[2], Eric Hoglund[1], Ethan A. Scott[3], John A. Tomko[1], Habib Ahmad[4], Ashutosh Giri[5], Alan Doolittle[4], Khalid Hattar[3], Alan McGaughey[2] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Carnegie Mellon University, United States; [3]Sandia National Laboratories, United States; [4]Georgia Institute of Technology, United States; [5]University of Rhode Island, United States

Given the role of interfaces as the limiting thermal resistance within devices, methods for the reduction of thermal boundary resistance (TBR) are desired. Similarly, with ion bombardment as a prominent method for the doping of semiconductors, the influence of the defects resulting from ion irradiation must be explored.
We present an experimental and computational study wherein we investigate the TBR across defected / pristine crystalline-crystalline interfaces. Experimentally, we use Time Domain Thermoreflectance to measure the TBR across an aluminum / gallium nitride (GaN) interface, where the GaN has been bombarded with various doses of carbon, nitrogen, and gallium ions.
Computationally, we explore a Silicon / Heavy Silicon toy system in which we introduce void / interstitial defect pairs.
We observe a decrease in TBR through the introduction of these defects, both
experimentally and in our simulations. We theorize that this TBR reduction is due to enhanced scattering within the defected material, which serves to assist the transfer of energy between different vibrational populations. This enhancement occurs between bulk and interfacial modes in addition to across the interface, suggesting that the TBR can be engineered by manipulating
just a single material involved. We also note the presence of slight deformation of the lattice between defects, amplifying the effects from relatively-sparse ion-induced defects.

3:45 PM SF06.08.02
Atypical Phonon Scattering by the Fission Products in Thorium Dioxide Linu Malakkal[1], Ankita Katre[2], Shuxiang Zhou[1], Chao Jiang[1], David Hurley[1], Chris Marianetti[3] and Marat Khafizov[4]; [1]Idaho National Laboratory, United States; [2]SP Pune University, India; [3]Columbia University, United States; [4]The Ohio State University, United States

This work presents the first principles calculations of the lattice thermal conductivity degradation due to point defects in thorium dioxide using an iterative solution of the Pierels-Boltzmann transport equation. We have used the advanced non-perturbative Green's function methodology to compute the phonon-point defect scattering rates that consider the local distortion around the point defect, including the mass difference changes, interatomic force constants, and structural relaxation near the point defects. The point defects considered in this work include a single vacancy of thorium and oxygen, single substitutions of xenon krypton, zirconium, and iodine in the thorium site, and the
three bound configurations of the Schottky defects. The results of the phonon-defect scattering rate reveal that among all the considered intrinsic defects, the thorium vacancy scatters the phonon most due to the substantial changes in force constant and structural distortions. But the scattering of phonons due to the substitutional defects unveils that the zirconium atom scatters phonon less effectively, like the generally observed trend. Contrary to the general trend that the substitutional atoms scatter phonon less effectively than vacancies the xenon, krypton, and iodine in thorium sites have an effect comparable to the vacancy defects. This striking difference in the phonon scattering of the substituted atoms is due to the local chemical environment changes. Xenon and krypton are noble gases, and iodine is an electronegative element, making it difficult to form bonds with the neighboring oxygen atoms. Finally, these results can serve as the benchmark for the analytical models and help the engineering scale modeling effort for nuclear design.

4:00 PM SF06.08.04
Intragranular Thermal Conductivity of Pristine and Proton-Irradiated alpha-U and delta-UZr_2 Zilong Hua[1], Hao Ma[2], Tiankai Yao[1], Shuxiang Zhou[1], Cody A. Dennett[3], Amey Khanolkar[1], Lingfeng He[1], Michael E. Manley[2] and David Hurley[1]; [1]Idaho National Laboratory, United States; [2]Oak Ridge National Laboratory, United States; [3]Massachusetts Institute of Technology, United States

U-Zr system is a promising metallic fuel candidate for the next generation of fast reactors. Its structure-induced thermal anisotropy has been expected, but related experimental investigation is incomplete. Here we present recent measurement results of thermal conductivity in alpha-U and delta UZr_2 before and after proton irradiated. Thermoreflectance measurements were conducted inside single grains with the grain size of approximately 100 micrometer. Experimental data in a wide temperature range are compared with simulation, and with the use of advanced characterization, the transport mechanisms are investigated. These new insights are expected to aid in fuel performance modeling and fuel design.

SESSION SF06.09: Material Properties Mediated by Atomic Scale Defects
Session Chairs: Yongjie Hu and Marat Khafizov
Thursday Morning, December 1, 2022
Sheraton, 3rd Floor, Fairfax A/B

8:30 AM *SF06.09.01
Defect-Scattering Mediated Lattice and Thermal Transport Yongjie Hu; University of California, Los Angeles, United States

Defect- and disorder-scattering plays an important role in the lattice and thermal transport of crystalline materials, while sometimes leads to complex behaviors and poses challenge to fundamental understanding. In this talk, we will disscuss in situ experimental characterizations and first-principles calcuations for understanding and controlling such defect-interactions. Our measurements show disorder-driven behaviors in thermal performance under controlled chemical disorders. Our computational results predict the thermal and lattice transport of disordered crystals, in good agreement with experiments. The study provides understanding of the effects of defect scattering beyond quantum perturbation theory and enables rational engineering routes to design novel functions.

9:00 AM SF06.09.02
Enthalpy-Entropy Compensation of Point Defects Diffusion in Crystalline Materials Simon Gelin; The Pennsylvania State University, United States

Experimental data accumulated over more than 120 years show not only that diffusion coefficients of impurities ordinarily obey the Arrhenius law in crystalline solids, but also that diffusion pre-exponential factors measured in a same solid increase exponentially with activation energies. This so-called compensation effect has been argued to result from a universal positive linear relationship between entropic contributions and energy barriers to diffusion. However, no physical model of entropy has ever been successfully tested against
experimental compensation data. In this presentation, I will demonstrate that atomistically computed harmonic vibrational entropic contributions account for most of compensation effects in silicon and aluminum. I will then show that, on average, variations of atomic interactions along diffusion reaction paths simultaneously soften low frequency phonons and stiffen high frequency ones. This behavior explains the origin of compensation: because relative frequency variations are larger in the lower region of the spectrum, softening generally prevails over stiffening and entropy ubiquitously increases with energy.

9:15 AM SF06.09.03
Imaging and Manipulating Surface Electronic Landscapes under Ambient Conditions Saima A. Sumaiya[1], Jun Liu[2] and Mehmet Z. Baykara[1]; [1]University of California, Merced, United States; [2]University at Buffalo, The State University of New York, United States

Electronic properties of material surfaces play a central role in their functionality for a large number of emerging applications, ranging from chemical sensors to ultrafast electronics. However, methods typically employed to measure such properties require pristine vacuum conditions, limiting the relevance of obtained results to realistic applications operating in ambient conditions. We show here that the method of conductive atomic force microscopy (C-AFM) can measure the electronic landscape of a variety of material surfaces with atomic resolution under ambient conditions, including features such as single atomic defects. In particular, we describe (i) the first observation of room-temperature charge ordering on a transition metal carbide (i.e. an MXene) thin crystal, α-Mo_2C, with signatures of rotational symmetry breaking with respect to the underlying lattice, and (ii) the capability to "switch" the charge state of defects on molybdenum disulfide (MoS_2) *in situ* by way of current vs. voltage spectroscopy. Finally, we find that the mechanism behind the atomic-resolution characterization capabilities of C-AFM involves the presence of a confined, electrically conductive pathway at the tip-sample contact, under high-speed scanning.

9:30 AM SF06.09.04
Influence of Local Charge and Magnetic Ordering on Point Defect Properties in Magnetite (Fe_3O_4) Shivani Srivastava[1], Blas Uberuaga[2] and Mark Asta[1,3]; [1]University of California, Berkeley, United States; [2]Los Alamos National Laboratory, United States; [3]Lawrence Berkeley National Laboratory, United States

Magnetite (Fe_3O_4) is found as a constituent phase in oxide scales formed on iron under a variety of corrosion conditions. When exposed to an oxidizing corrosion environment, the point defects and their transport play an important role in determining the rates of corrosion.
The work presented here employs first-principles calculations using PBE+U functional to investigate the role of local ordering of Fe^{2+}/Fe^{3+} cations in magnetite on the point defect properties occurring under equilibrium conditions. The bulk structure of magnetite, featuring coupled charge, spin and orbital order, undergoes a bulk order-disorder phase transition at around 120 K. Even above this transition, there is evidence of strong local order, consistent with results from calculations presented here. We study the effect of this local order on the energetics underlying defect formation and migration. Owing to the strong coupled charge, spin and orbital order, magnetite(Fe_3O_4) exhibits a strong dependence of defect properties on local charge order and underlying magnetic order.
We focus on sampling multiple local environments and their associated effects on
the underlying defect properties. Our results show that different local environments, generated due to ordering of Fe^{2+}/Fe^{3+} cations, stabilize different charge states of point defects such as oxygen and iron vacancies, depending on charge redistribution around the defect. We also find that iron-oxygen di-vacancies are stable in this system and have high binding energy under reducing conditions. The relatively high stabilization of defects in certain local chemical environments can lead to formation of percolation networks modifying the ionic transport in these systems. As shown in previous studies[1], the interplay of defect formation and energetics of disordering plays an important role in determining radiation tolerance of complex oxides.The implications of our results for the effects of irradiation on magnetite formation during oxidation/corrosion of iron will be discussed.

9:45 AM SF06.09.05
Symmetry-Breaking and Reconstruction at Point Defects in Solids Seán R. Kavanagh[1], Irea Mosquera-Lois[2], Aron Walsh[2] and David O. Scanlon[3]; [1]University College London & Imperial College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]University College London, United Kingdom

Point defects are a universal feature of crystalline materials. Their identification is often addressed by combining experimental measurements with theoretical models. The standard approach of simulating defects is, however, prone to miss the ground state atomic configurations associated with energy-lowering reconstructions from the idealised crystallographic environment.[1–5] Missed ground states compromise the accuracy of calculated properties.

To address this issue, we report an approach to efficiently navigate the defect configurational landscape using targeted bond distortions and rattling.[6] Application of our workflow to a range of materials (CdTe, GaAs, Sb_2S_3, Sb_2Se_3, CeO_2) reveals symmetry breaking in each host crystal that is not found via conventional local minimization techniques. The point defect distortions are classified by the associated physico-chemical factors. We demonstrate the impact of these defect distortions on derived properties, including formation energies, concentrations and charge transition levels. Our work presents a step forward for quantitative modelling of imperfect solids.

High-Valence Doping in Lithium-Excess Disordered Rock Salt Cathode Materials Bonan Zhu[1,2] and David O. Scanlon[1,2]; [1]University College London, United Kingdom; [2]The Faraday Institution, United Kingdom

Lithium-excess manganese-based disordered rock salts offer great opportunities for further increasing the capacities of lithium-ion batteries (> 300 $mAhg^{-1}$). However, the existing materials are known to exhibit undesirable capacity fading and hysteresis[1,2]. Doping with high-valance transition metals offers the opportunity for tuning the short-range order of the disordered lattice as well as lowering the valance state of Mn, thereby mitigate the capacity fading though cationic redox. In this study, we construct cluster expansion models to investigate the effect of incorporating W dopants. The short-range orderings are extracted from Monte-Carlo simulations. While the inclusion of W raises the cationic redox capacity of Mn, the preferential configuration of W-Li cation nearest neighbour reduces the concentration of zero-transition-metal channels that allow Li conduction. Quantitative analysis shows a moderate reduction of active Li content, but the existence of Li-percolating networks remains affected. On the other hand, analysis of the charge densities shows that the oxidation state of W dopants can be different from the assumed 6+ state as in WO_3, highlighting the delicate coupling between ionic and electronic structures in defective disordered materials. Effects of doping with other high-valance dopants, such as Sb, as well as co-anion doping will also be discussed.

11:15 AM SF06.09.09
The Influence of Atomic-Scale Defects on Thermal Transport in MoS_2 Pingping Chen[1], Aroop K. Behera[1], Ethan A. Scott[2], Christopher M. Smyth[2], Tzu-Ming Lu[2], Suprem R. Das[1] and C. Thomas Harris[2]; [1]Kansas State University, United States; [2]Sandia National Laboratories, United States

Transition-metal dichalcogenides, such as molybdenum disulfide (MoS_2), have attracted considerable attention as tunable band-gap semiconductors that may be fabricated in a monolayer format and that give rise to unique electrical and thermal properties. These physical properties are directly linked to the layer structure, which is sensitive to defects and impurities. While several computational studies have investigated the thermal conductivity of supported and encapsulated MoS_2, the impact of lattice defects on the thermal conductivity of MoS_2 and the thermal boundary conductance between MoS_2 and its support substrate has not been studied experimentally as a function of both defect density and layer number. In this work, we use frequency domain thermal reflectance to study the thermal transport properties of mechanically exfoliated MoS_2 flakes with controlled defect densities and a known number of layers, which are supported on sapphire substrates. The sulfur defect density is controlled via hydrogen-based plasma, and x-ray photoelectron spectroscopy is used to characterize the density of these sulfur vacancy defects. In combination with our materials characterization, we provide an effective thermal conductance analysis to explain the reduction in thermal transport due to carrier scattering by vacancies. The results from this study serve to further enhance our understanding of the fundamental physics of phonon transport in the presence of defects and provide a pathway for studying thermal transport in nanoscale electronic devices based upon 2D materials.

Ce Defect Diffusion in Ceria Using Defects Chemical Calculation and Density Functional Theory Hyun-Kyu Kim[1], Seol Hee Oh[2], Jong-Ho Lee[2] and Yeong-Cheol Kim[1]; [1]KoreaTech, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

CeO_2 shows high oxygen storage/release capacity (OSC) due to its aliovalancy between +3 and +4 as functions of temperature and oxygen partial pressure. Addition of Zr in CeO_2 enhances the OSC further, and recently $Ce_{0.75}Zr_{0.25}O_2$ (CZO) has been studied for anode support of solid oxide fuel cell. However, Zr and Ce in CZO have been reported to be separated under reduction.
Since the phase separation occurs through the constituents' diffusion, we studied Ce defects diffusion to understand the main defect for the phase separation. Ce defects are the main focus, as a rate-limiting element, because oxygen is a well-known fast diffusion element. Several defect concentrations in CeO_2 are calculated for diffusion coefficient by using defects chemical calculation. Migration enthalpy of Ce vacancy and interstitial is calculated by

using NEB method with consideration of oxygen vacancy clustering effect. Ce interstitial with an oxygen vacancy is found to be the main diffusion element under oxidation and reduction, contradicting a recent article [1].

10:35 AM SF06.10.03
Origin of Giant Magnetocapacitance Effect in $K_{0.5}Na_{0.5}NbO_3/La_{0.67}Sr_{0.33}MnO_3$ Superlattices Soumen Pradhan[1], Oleg I. Lebedev[2], Martando Rath[2], Fabien Veillon[2], Wilfrid Prellier[2] and M. S. Ramachandra Rao[1]; [1]Indian Institute of Technology (IIT) Madras, India; [2]Laboratorie CRISMAT, Normandie Universite, France

In recent years, multiferroic systems have been the subject of enormous interest due to their wide range of applications in spintronics, sensors, actuators, multistate memory devices etc. Artificial superlattices (SLs) have gained much attention in current research because of their potential to realize new functionalities like ferroelectricity, multiferroicity and superconductivity. Here, we have explored magneto-capacitance (MC) performance in SLs of pure ferroelectric and ferromagnetic sublayers for multiferroic applications. $K_{0.5}Na_{0.5}NbO_3$ (KNN)/$La_{0.67}Sr_{0.33}MnO_3$ (LSMO) SLs with LSMO sublayer thicknesses of 5, 7, 9 and 11 unit cell (u.c.) keeping KNN thickness fixed at 6 u.c. were deposited on (001)-oriented $SrTiO_3$ substrates alternately for 15 times using pulsed laser deposition (PLD) technique. The crystallinity and layer-by-layer growth of both the constituents were confirmed from X-ray diffraction as well as transmission electron microscopy. SLs with LSMO layer of 9 and 11 u.c. show coherent growth on the substrates. The Curie temperature (T_C) of ~206 K even in the SL with thicker LSMO sublayer indicates the presence of defects in the SLs. Also, spin-glass behavior in the SLs was observed below 50 K as confirmed from magnetic measurements. The insulating nature in the SLs with 7 and 9 u.c. and insulator to metal transition for 11 u.c. were observed in the transport study. However, defects induced large negative magneto-resistance (MR) of ~98% was realized at 100 K in the SLs with 9 and 11 u.c. The capacitance as well as magneto-capacitance show high value at low frequency and reduce monotonically upon increase in the frequency. This can be well explained by MR coupled Maxwell-Wagner relaxation model. Finally, the giant MC of ~766% at standard frequency of 1 kHz with 9 T magnetic field at 100 K for SL with optimum LSMO sublayer thickness of 9 u.c. can be used for multistate memory applications.

10:50 AM SF06.10.04
Viscoelastic Damping in Defect-Engineered CoNiCrFeMn High Entropy Alloy by Molecular Dynamics Simulations Akash A. Deshmukh and Raghavan Ranganathan; Indian Institute of Technology Gandhinagar, India

High-frequency mechanical vibrations and sound propagation in materials are governed by their viscoelastic behavior. Efficient viscoelastic damping is necessary to enhance the stability, safety, and service life of dynamic systems such as brake discs, shielding devices, high-frequency resonators, etc. Therefore, there is an increasing demand for the design and development of materials with high damping capability. Recently, viscoelastic studies in alloys have attracted a lot of attention as these materials possess simultaneously high stiffness and high loss tangent, thereby resulting in a high loss modulus. The inadequacy of the traditional alloys such as the low working temperature of Cu- based damping alloys, and anti-corrosion treatment of the Fe-based damping alloys have limited their applications. High Entropy Alloys (HEAs) exhibit simple solid solutions and excellent mechanical properties such as high hardness, high strength, good corrosion, and wear resistance and are good candidates for high-frequency damping applications. Moreover, defects such as stacking faults, twin boundaries, interstitials, and vacancies are intrinsic to crystals and have the ability to further enhance damping.
In the present work, three defects namely stacking fault, edge dislocation, and vacancies were introduced in the FCC single-phase solid solution CoNiCrFeMn HEA to investigate its viscoelastic response. A Modified Embedded Atom Method (MEAM) potential was used to describe the interatomic interactions. Non-equilibrium molecular dynamics simulations via oscillatory shear deformation were performed to understand the viscoelastic behavior under a frequency range spanning 3 decades, from GHz to THz. It was noted that each defect exhibited a significant enhancement in damping over the defect-free alloy, while considered individually. However, the coexistence of all three defects dramatically improved the damping performance of the alloy up to 172% more compared to the defect-free structure. Below the peak damping frequency, the loss modulus was fitted successfully by power-law scaling. The enhancement in loss moduli for various defected structures was observed to result from the anharmonic coupling of phonon modes as verified by the mode-dependent Gruneisen parameters. The inclusion of defects also shifted the peak damping frequency to larger values. This work thus demonstrates that HEAs with carefully engineered defects have promising applications in damping high-frequency vibrations.

11:05 AM SF06.10.05
Improving the Quality of Rigid PU Foam Sandwitch Insulation Panels Gulab Malunjkar[1], Hieu McElroy[2], Adebola Ogunniyi[2] and Mirella Coroneo[3]; [1]Dow Chemical International Pvt. Ltd, India; [2]The Dow Chemical Company, United States; [3]Dow Italia S.R.L., Italy

Metal-faced sandwich panels with a rigid polyurethane (PUR) or polyisocyanurate (PIR) core are used in construction as insulating panels. The discontinuous process for their production consists of injecting a reacting polyurethane (PU) mixture in a mold, usually in a single point, where the liquid flows up to 12 m in length and reacts, growing in volume and filling the cavity. The injection is well known to be a source of defects and of non-uniform foam properties, which are potentially critical factors for the final performance of the panel. The ability of a foam formulation to flow and fill the cavity of a sandwich panel can have a significant impact on the orientation of the foam cells, affecting insulation and structural properties of the foam, and affecting the tendency of a foam panel to blister when installed in the field. Developing a better way to distribute foam in a panel could, therefore, enable the reduction of defects in panels during production.

A Finite Element Method (FEM) was used to predict the filling of a mold cavity with PU foam, using different distribution devices. An advanced numerical model was used to simulate the foam injection and expansion processes in a single step. Foam flow simulation solvers were coupled with an advanced global stabilization algorithm and a multi-criteria adaptive meshing technology. These new technologies enabled a realistic prediction of foam flow and foam expansion. The finite element model was validated for an accurate foam molding solution. PU foams were then characterized independently to generate the modeling parameters for the simulation. The foam filling simulation shows realistic flow pattern inside the mold and used to predict optimal filling conditions (i.e. temperatures, gating and venting). The simulation accounts for the pressure effect inside and outside of the mold. It also predicts the density distribution in foam. With this approach, we can now perform *in silico* optimization of the foam manufacturing process to achieve defect-free foam panels.

11:20 AM SF06.10.06
Thermal Resistance Across Si-Ge Interface from Non-Equilibrium Phonons Jinchen Han, Xun Li and Sangyeop Lee; University of Pittsburgh, United States

As nanostructured devices become prevalent, interfaces often introduce large thermal resistance imposing challenges for thermal management and opening opportunities for developing ultralow-thermal conductivity materials. However, the interfacial thermal transport remains poorly understood due to complex physics and limited methodologies. Although past studies have focused on the atomistic scale phenomena at the interface, the phenomena on a larger scale, for example, the complex interplay between the interfacial scattering and intrinsic phonon-phonon scattering, have not been comprehensively studied.

Widely used methods in the past include the Landauer's formalism which ignores the intrinsic scattering of phonons and molecular dynamics simulation which has a much smaller length scale than the typical mean free paths of phonons.
To explore the role of intrinsic scattering of phonons on the interfacial thermal resistance at micro- and meso-scales, we solve the Peierls-Boltzmann transport equation in both reciprocal and real spaces using a Monte Carlo method with *ab initio* inputs. Our hypothesis is that the interfacial scattering largely distorts the phonon distribution near the interface, and intrinsic phonon scattering attempts to relax the distorted (non-equilibrium) distribution to a local equilibrium distribution. During this process, a large amount of entropy is generated according to the Boltzmann's *H*-theorem. Indeed, our solution for a Si-Ge interface shows a large degree of non-equilibrium in phonon distribution, particularly at Ge side, which makes a significant contribution to thermal resistance. Our study provides a new tool to bridge the gap for *ab initio* simulation between atomistic scale and less studied microscale. Also, it brings a new insight into the significant role of phonon-phonon scattering on interfacial thermal resistance.

11:35 AM SF06.10.07
Thermal Transport in Solid Materials with Defects and Dislocations Based on a Machine Learning Method Ze Yang and Fan Yang; Stevens Institute of Technology, United States

Thermal transport properties are essential for sustainable energy and thermal management. It is also important to incorporate the effect of defects, which widely exist in materials in real world, when calculating thermal transport properties. The prevailing methods for the calculation of thermal transport properties would be either not accurate, using the molecular dynamic (MD) simulation, or time consuming, when applying first-principles calculations. Recently, people applied a reliable method to calculate the transport properties with the combination of the advantages of MD and first-principles through machine learning. In this work, we used a machine learning method based on gaussian regression, called Gaussian Approximation Potential[1] (GAP) method, to achieve a fast and accurate prediction of thermal conductivity of unknown solid materials. We built interatomic potentials using data from density functional theory (DFT) calculation through the training of GAP and applied the potential to calculate the thermal conductivity of cubic boron nitride (cBN), which is a material with ultra-high thermal conductivity[2]. Our simulation results were compared with first-principles calculation and experimental results and showed great agreement. This method was then extended to explore the change of thermal conductivity with the effect of defects and dislocations. Instead of compensating relaxation time with dislocation models[3], our method incorporates the effect of dislocations to interatomic potentials. And our results showed good agreement with the reference.

1:00 PM *SF06.11.01
Impact of Defects on Phonon Transport in ThO_2 Miaomiao Jin[1], Marat Khafizov[2], Beihan Chen[1], Cody A. Dennett[3] and David Hurley[4]; [1]Penn State University, United States; [2]The Ohio State University, United States; [3]Massachusetts Institute of Technology, United States; [4]Idaho National Laboratory, United States

Defects in ThO2 can significantly degrade the thermal conductivity of ThO2 due to enhanced phonon-defect scattering. In this talk, the impact of point defects, dislocation loops, and grain boundaries are evaluated based on results from non-equilibrium and equilibrium molecular dynamics simulations. Specifically, for point defects, the defect concentration-dependent thermal conductivities are calculated, and these results enable the extraction of phonon-defect scattering cross-section for each type of point defect. Regarding dislocation loops, the impact of two types of experimentally observed dislocation loops (perfect and faulted) is examined considering various loop sizes and orientations. The scattering parameters are deduced based on Klemens' formalism after the simulation cell size effect is considered. In the case of grain boundaries (GBs), symmetrically tilt GBs are created over a wide range of title angles. The interfacial (Kapitza) resistance is found to correlate well with GB energy. In addition, the spectral/modal analysis of phonon contribution to the total resistance/conductance reveals the dominating phonon modes for thermal transport across GBs.

1:30 PM *SF06.11.02
The role of Extrinsic Disorder in the Phononic and Thermal Response of Multilayered Materials Giorgia Fugallo[1,2]; [1]CNRS, France; [2]Ecole Polytechnique, France

In multilayered materials, while strong covalent bonding provides the stability of the sub-nanometric elementary units, the whole assembly is held together by weak van der Waals interactions. The individual building blocks hence maintain most of their intrinsic characteristics also when arranged together to form a crystalline solid. In principle, novel material properties can be thus tailored by controlling those of the elementary units. If it is true that this bottom-up strategy in the synthesis of new materials has been intensively followed since the '80s, it is also true that more recently a growing interest has been put on the comprehension of the role that extrinsic disorder can play in the performance of these materials, with applications that goes from quantum technologies to thermoelectricity. In this talk I will present different examples of how it is possible to tune the phononic and thermal properties of multilayered materials by including structural/chemical disorder.

2:00 PM SF06.11.03
Synthesis and Characterization of a High-Entropy Spinel Oxide Single Crystal Evan Krysko[1], Lujin Min[1], Yu Wang[1], Na Zhang[1], Fankang Li[2], Kaleb Burrage[2], Masaaki Matsuda[2], Mauricio Terrones[1] and Zhiqiang Mao[1]; [1]The Pennsylvania State University, United States; [2]Oak Ridge National Laboratory, United States

High-entropy materials generally refer to compounds which involve mixing five or more elements in nearly equimolar concentrations at an equivalent atomic site. These compounds are stabilized into a single phase by the high configurational entropy caused by the varying sizes and masses of their constituent elements. Prior work has shown competing magnetic interactions enabled by high entropy generate novel magnetic phases. Given that oxides

with the spinel structure contain a variety of magnetic ordering, high-entropy spinel oxides, if successfully made, would provide a platform for the further study of high-entropy tuning of magnetism. This research aimed to synthesize a novel high-entropy oxide with the spinel structure and to determine the effects of its lattice distortions on its magnetization. In this work, an (Mg, Mn, Fe, Ni, Co)Al_2O_4 single crystal was synthesized for the first time using the optical floating zone growth technique. The sample was confirmed to be a phase pure high-entropy oxide (HEO) using X-ray diffraction (XRD) and energy-dispersive spectroscopy (EDS). Through magnetization measurements, we found (Mg, Mn, Fe, Ni, Co)Al_2O_4 exhibits a spin-glass state though the parent phases show either antiferromagnetic or ferrimagnetic ordering or spin glass. Furthermore, we also found that (Mg, Mn, Fe, Ni, Co)Al_2O_4 has much greater thermal expansion than its parent compounds from neutron scattering measurements.

We would like to acknowledge the funding from the Materials Research Science and Engineering Centers (MRSEC). The neutron scattering measurements were collected at the High Flux Isotope Reactor (HFIR) at the Department of Energy's Oak Ridge National Laboratory.

10:30 AM *SF07.01.01
Recent Progress in the Development of Intermetallic γ-TiAl Based Alloys Enabled by *In Situ* Synchrotron X-Ray Diffraction and Scattering Petra Spoerk-Erdely[1], Gloria Graf[1], Michael Musi[1], Peter Staron[2], Andreas Stark[2], Emad Maawad[2] and Helmut Clemens[1]; [1]Montanuniversität Leoben, Austria; [2]Helmholtz-Zentrum Hereon, Germany

Intermetallic titanium aluminide alloys based on the ordered γ-TiAl phase are innovative materials for lightweight high-temperature applications. In addition to their low density of roughly 4 g/cm^3, their high specific Young's modulus and strength even at elevated temperatures, and their good oxidation and burn resistance, especially their excellent creep properties make these alloys a material of choice for challenging structural applications. Following intensive research and development activities, γ-TiAl based alloys have recently entered service in the automotive and aircraft engine industries, *e.g.* as low-pressure turbine blades in environment-friendly jet engines, as engine valves in sports and racing cars, or as turbocharger turbine wheels. In the course of the past decades, the development of these complex multi-phase alloys has benefited greatly from the application of (*in situ*) synchrotron X-ray techniques. Diffraction and scattering techniques, in particular, have offered access to the atomic structure of the material and provided insights into a variety of microstructural parameters. Advanced experimental setups, which are steadily refined, have even allowed the exploration of elaborate manufacturing processes and yielded insights that have so far been inaccessible by means of conventional methods. Here, a practical introduction and overview of recent progress in this field of research are provided. Current prospects at modern synchrotron radiation sources will be illustrated by means of selected recent case studies pertaining to different stages in the development of modern γ-TiAl based alloys (*i.e.*, fundamental research, manufacturing, and fine-tuning of properties for application). In this context, available setups for *in situ* high-energy X-ray diffraction and small-angle X-ray scattering experiments will be discussed in terms of their advantages as well as their limitations. This talk reaches out not only to the TiAl scientific community, though. By addressing the key question as to how to actually simulate real-life conditions such as applied loads and high temperatures in a laboratory environment, researchers with a general background in materials science may also find in it a collection of ideas that are indeed applicable to many different materials systems.

11:00 AM SF07.01.02
Plasticity and Brittleness of the Ordered β_o Phase in a TNM-TiAl Alloy Guy Molénat[1], Jean-Philippe Monchoux[1], Michael Musi[2], Petra Spoerk-Erdely[2], Helmut Clemens[2] and Alain Couret[1]; [1]CEMES/CNRS, France; [2]Montanuniversität Leoben, Austria

The aim of this work is to study the deformation mechanisms in the ordered β_o phase containing some ω_o precipitates of a TNM-TiAl alloy ($Ti_{51.05}Al_{43.9}Nb_4Mo_{0.95}B_{0.1}$ in at.%) and to look for the origin of the low ductility at room temperature of this alloy.
The alloy produced by Spark Plasma Sintering exhibits a near lamellar microstructure made of lamellar γ/α_2 colonies surrounded by γ and β_o grains. Tensile tests were performed at room temperature to determine the mechanical properties and the ductility of the alloy. The rupture surface of the deformed material were investigated by scanning electron microscopy.
Two types of TEM (Transmission Electron Microscopy) experiments were used to explore the behaviour of these dislocations and to study the deformation mechanisms. The first one lies in investigating the deformation microstructure in thin foils extracted from bulk samples previously deformed in tension at room temperature, while the second type consists in performing *in situ* tensile tests inside a TEM that allows the direct observation of the dislocation dynamics under stress and in real time.
At room temperature, the material exhibits a limited ductility with cleavage surfaces along the lamellae interfaces of the colonies. The β_o grains contain nano-precipitates of the ω_o phase and deform plastically by both <111> superdislocations and <001> dislocations. The <111> superdislocations are dissociated into two superpartial dislocations separated by an antiphase boundary. They glide in {011} planes and have the tendency to be localized into pile-ups, an effect demonstrated as the result of the ω_o precipitation that harden the β_o grains and favour deformation concentration. The <001> dislocations are found to be split into two identical superpartial dislocations separated by a stacking fault. They are elongated along their screw orientation and also anchored at these small nano-precipitates of ω_o phase. *In situ* straining experiments performed at room temperature show that they move by jumps between these elongated configurations.
These results are discussed to explain the low ductility of this alloy. The stress concentration due to the pile-up formation on grain boundaries is assumed to induce fracture along lamellae interfaces in neighbouring lamellar colonies.

11:15 AM SF07.01.03
***In Situ* Fracture Behaviour of Tailored TNM Alloys** Michael Burtscher[1], Markus Alfreider[1], Helmut Clemens[1], Christoph Gammer[2] and Daniel Kiener[1]; [1]Montanuniversität Leoben, Austria; [2]Austrian Academy of Sciences, Austria

Titanium aluminium alloys are constantly evolving as tremendous efforts have been set to improve their mechanical properties at elevated temperatures. Thus, new alloys were developed and tailored via heat treatments to fulfil the demanding requirements of aviation and automotive applications. However, these optimizations notoriously have led to decreased room temperature ductility and reduced fracture toughness. Within this study, two advanced TNM alloys have been investigated by in-situ micromechanical notched cantilever tests and sophisticated transmission electron microscopy techniques. Using these methods, the mechanical properties of distinct interfaces regarding the fracture toughness, *J*-integral and fracture stress could be evaluated at any point during the experiment. Furthermore, the crack propagation could be tracked in-situ and sudden fracture events were linked to the failure of distinct microstructural components. The presented method allowed to identify strengthening mechanisms such as e.g. particles along common α_2/γ interfaces or bridging. To further deepen the understanding of the fracture mechanisms along this interface type, strain maps of the fully lamellar microstructure were conducted edge-on for both alloys. To do so, 4D scanning transmission electron microscopy including scanning nanobeam electron diffraction was performed. From these experiments, strain accumulations caused by misfit dislocations or silicide particles were identified and linked to fracture events. Furthermore, these results were discussed in the light of existing literature.
Based on these results, further alloy design and tailored microstructures will be adapted to enable a higher room temperature ductility and fracture toughness of these alloys.

11:30 AM SF07.01.04
Development of TiAl Alloys for High Temperature Applications Seong-Woong Kim, Min-Sik Kim, Ji-Sung Park and Seung Eon Kim; Korea Institute of Materials Science, Korea (the Republic of)

Research on developing new TiAl alloys for high temperature applications is introduced. At KIMS, we have developed new TiAl alloys which have excellent room temperature and high temperature properties. Especially, the new alloy showed excellent oxidation resistance in the temperature range from 900 to 1000ºC by forming stable Al_2O_3 oxidation layer. Process developement of casting, forging as well as 3d printing on the newly developed KIMS alloys was introduced. Especially, small size turbine wheel and blade were manufactured be centrifugal casting process. The results from the testing and validation of TiAl blade were shown that KIMS alloy can be used as a turbine blade above 900ºC. In addition, we proposed some underlying mechanism of high temperature strength of KIMS alloy from TEM and SEM observations. Finally, the operation test of micro gas turbine is now under examination to confirm the possibility of the application of the new alloy in the gas turbune engine.

11:45 AM SF07.01.05
Additively Manufactured β-Ti5553 with Laser Powder Bed Fusion—Microstructures and Mechanical Properties of Bulk and Lattice Parts Margaret Wu[1], Marissa Linne[1], Jean-Baptiste Forien[1], Nathan Barton[1], Jianchao Ye[1], Kavan Hazeli[2], Morris Wang[3] and Thomas Voisin[1]; [1]LLNL, United States; [2]The University of Arizona, United States; [3]UCLA, United States

Ti5553 (Ti-5Al-5Mo-5V-3Cr wt.%) is a titanium alloy with promising applications in safety-critical structures due to its high strength-to-weight ratio and near-β microstructure which opens pathways for tailoring mechanical performance based on annealing conditions. In order to utilize its advantageous properties, efficient manufacturing must be possible. Laser powder bed fusion (L-PBF) involves the layer-by-layer fabrication of complex geometries such as lattices which help reduce component weight. Moreover, L-PBF expedites part deployment since components can be built on-demand without multi-step assembly. Thus, the successful realization of L-PBF Ti5553 relies on a fundamental understanding of the alloy's additively manufactured microstructure and mechanical behavior. In support of production efforts at Lawrence Livermore National Lab and Kansas City National Security Campus, the present work investigates the hierarchical microstructures and mechanical properties of L-PBF Ti5553 bulk and lattice parts. The characterization techniques include room-temperature tensile tests, nanoindentation, scanning electron microscopy (SEM), electron backscatter diffraction (EBSD), and transmission electron microscopy (TEM). The presence of second-phase (ω) nanoprecipitates in the lattice material distinguishes its microstructure from that of the bulk and moreover, indicates the challenges in predicting bulk mechanical response based on lattice properties. The present results provide a starting framework for the successful printing of Ti5553 bulk and lattice parts by comprehensively examining the processing-structure-property-paradigm of the deposited material system.

1:30 PM *SF07.02.01
Control of Crystallographic Texture in Powder Bed Fusion Additive Manufacturing of Intermetallics and the Related Superalloys Takayoshi Nakano; Osaka Univ, Japan

Additive manufacturing (AM) enables the production of complex, net-shape geometries. Additionally, in AM of intermetallic compounds and the related superalloys, which has received less attention, the microstructure and crystallographic texture of the product can be arbitrarily controlled by selecting appropriate process parameters, thereby enabling unprecedented superior properties. This paper discusses recent progress pertaining to texture evolution mechanisms and control methods, with an emphasis on laser-beam and/or electron beam powder bed fusion (PBF). One of the unique characteristics of PBF is that the crystallographic texture can be varied as a function of position within the product by controlling the scan strategy. The transient behavior of the texture and the factor used to control it via the scan strategy are discussed. In addition, the texture evolution behavior of highly symmetrical Ni-base superalloys as well as relatively low symmetrical TiAl intermetallic compound and disilicide is discussed. The importance of the crystallographic, multiplicity, of the preferential crystal growth direction is described to understand the evolution behavior of the texture in such heat-resistance materials.

This study was supported by Grants-in-Aid for Scientific Research (JP18H05254) from the Japan Society for the Promotion of Science (JSPS). This study was also partly supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), Materials integration, for revolutionary design system of structural materials, from the Japan Science and Technology Agency (JST).

2:00 PM SF07.02.02
Direct Insight into Additive Manufacturing of TiAl with Diffraction Methods Adriana De Andrade, Florian Pyczak, Marcus W. Rackel, Jan Rosigkeit, Andreas Stark and Peter Staron; Helmholtz-Zentrum Hereon, Germany

Additive manufacturing (AM) provides inherent advantages for the processing of intermetallics. Most often intermetallics are high performance materials more expensive than competing conventional alloys. Thus, the near net shape processing capability of AM causing no material loss is advantageous. In addition, the properties of most intermetallics are very sensitive to variations of the chemical composition making the good chemical homogeneity of the powder based AM methods beneficial. Accordingly, TiAl low-pressure turbine blades for the current GE9X engine are produced by Electron Beam Melting. However, AM processes pose also many problems for intermetallics. Many intermetallic materials including TiAl are brittle compared to conventional alloys and the high heating and cooling rates experienced during AM can cause cracking and damage. The complex phase diagram of many intermetallics exacerbates this problem. TiAl for example shows a number of phase transformations and two-phase regions or in advanced alloys also three-phase and even more-phase regions between melting point and room temperature. If those phase transformations are associated with volume change or if too large volume misfits between phases exist internal stresses will occur. At lower temperatures, TiAl parts are too brittle to withstand those stresses and will fail during AM. This is one reason to use Electron Beam Melting instead of Laser Beam Melting for AM of TiAl despite the latter being less costly. Heating of the powder bed and the already processed section of the part is easier in Electron Beam Melting. With TiAl being less brittle at higher temperatures, this enables crack free processing.
In this contribution, the results of the characterization by high-energy X-ray diffraction of TiAl alloys during AM are presented. Directly after solidification, the phase constitution of TiAl is far away from the situation in the finished part. It resembles very closely the phase constitution directly at the melting point. The assumption of the final microstructure and phase constitution takes place in the layers below the surface. These experience a cyclic heat treatment due to the melting and solidification of the on top powder layer. The maximum temperature of this thermal cycle decreases with increasing distance from the melting and solidifying top layer. From the development of lattice constants and phase fractions, it is possible to reconstruct the internal processes in the material during this complex heat treatment scheme. The phase diagram is no good guide to understand the situation because the phase constitution and microstructures are away from equilibrium. Only by direct measurement one can acquire information about the microstructure formation in the TiAl part necessary to optimize the process or adapt the material to the process.

Revolutionary Approach to Develop Novel TiAl Alloys for Powder Processed LPT Blades in Jet Engines Masao Takeyama, Hirotoyo Nakashima, Ryosuke Yamagata and Yotaro Okada; Tokyo Institute of Technology, Japan

An integrated inverse design approach to accelerate the development of novel titanium aluminides for LPT blades in jet engines, specifically focusing on powder processing, such as MIM (Metal Injection Molding) and AM (Additive Manufacturing), has been undertaken, in collaboration with industries and universities, under the project of "*Materials Integration for Revolutionary Design System of Structural Materials*" in *Cross-ministerial Strategic Innovation Promotion Program* (SIP) in Japan. We have successfully developed a novel TiAl alloy with mechanical properties superior to the currently existing alloys and fabricated into 200 mm LPT blade by both MIM and AM processes. Our integrated computational materials design system is composed of three modules: "Mechanical-property Prediction Modules (MPM)", "Microstructure Design Module (MDM)"and "Process Design Module (PDM)". For example, the system works as follows: specific values of the properties required by industries, say, tensile strength and fracture toughness, are at first input into the MPM, and the MPM calculates and outputs the volume fraction of the most important microstructure constituent to meet the required properties, based on our mechanical property database (DB). Then, the volume fraction value is input into the MDM, and the MDM optimizes alloy composition and heat treatment condition to have the microstructure, based on our multi-component phase diagram DB. The proposed alloy with the composition is then cast into bar ingots and powdered by EIGA by industries. All of the powders are used for MIM (<45μm) and for AM-EBM (>45 μm) without any waste and fabricated into LPT through each PDM. Tokyo Tech is in charge of the integrated system of MPM and MDM, so that this talk focuses on some points to integrate the modules to the system. For MPM, the key is the digitalization of β/γ cellular microstructure because the bcc β-Ti phase introduced by the cellular transformation ($\alpha_2+\gamma$ -> $\beta+\gamma$) significantly affects the mechanical properties. For MDM, the most critical point is the reliable knowledge on the phase diagram with oxygen. We found that oxygen tremendously affects the phase equilibria among β-Ti, α-Ti (α_2-Ti_3Al) and γ-TiAl phases and eventually changes the transformation pathways to control the microstructures. Without this information, thus it is impossible to build up the system since a large amount of oxygen is picked up in MIM process in comparison with AM process. The details of MPM and MDM including the calculation methods will be independently presented by our co-authors in this symposium.
A part of this study has been carried under the research of SIP II in JST (Japan Science and Technology Agency).

2:30 PM SF07.02.04
Microstructure Design Module for the Development of Powder Processed LPT Blade in TiAl Alloys Hirotoyo Nakashima, Yoshihiro Gohda and Masao Takeyama; Tokyo Institute of Technology, Japan

In order to reduce the cost and time required to develop the TiAl low-pressure turbine blade for jet engines, we have built an inverse problem approach using two modules: one is the mechanical properties prediction module (MPM) to predict the microstructures that satisfy the required properties, and the other is the microstructure design module (MDM) to specify the composition range and heat treatment conditions for tailoring the microstructures. In this

presentation, the MDM is highlighted. In this module, the two-step heat treatment of the lamellar formation and subsequent aging is assumed. The temperature and composition dependence of the volume fraction of each phase, as well as the supersaturation for the discontinuous precipitation of α_2-Ti_3Al + γ-TiAl → β-Ti + γ, are calculated in the framework of CALPHAD method. Furthermore, the effects of oxygen on the phase equilibria and kinetics are considered aiming at its application to powder processes such as metal injection molding. Therefore, the key is to understand the effects of oxygen experimentally and to construct a thermodynamic database that accurately reproduces them. Two series of quaternary Ti-Al-M-O alloys (M: transient metal elements) with various oxygen levels were studied at the temperature range between 1573 K and 1273 K using the combination of wavelength dispersive spectroscopy and soft X-ray emission spectroscopy. Then, thermodynamic parameters for two quaternary systems as well as the constituent sub-systems were assessed. Selected important interaction parameters and their composition dependence were optimized based on the *ab-initio* calculation using KKR-CPA method. The newly assessed database reproduces phase boundaries in multi-component systems with an accuracy of 1% for metal elements and 0.2% for oxygen concentrations. In the presentation, we will demonstrate an alloy design based on this module.

Mechanical-Properties Prediction Module for the Development of Powder Processed LPT Blade in TiAl Alloys Ryosuke Yamagata, Yotaro Okada, Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

In order to accelerate the development of TiAl LPT blade in jet engines and reduce the extensive experimental efforts, some computational approaches to predict the required mechanical properties, in addition to the module to specialize the alloy composition to be able to control microstructure, are needed. We built up the sophisticated materials integration system for the inverse problem consisting of two modules of mechanical-properties prediction (MPM) and microstructure design (MDM). In the presentation, then, focus is places on the MPM how the ultimate tensile strength (UTS) can be predicted. Note that the output of this module is a concrete value of the microstructural constituent governing the property. Therefore, the quantitative analysis by digitalizing the microstructural constituents in needed as one of the databases (DB) of the module. Another important DB to predict the UTS is the work hardening rate of the microstructural constituents. There are two important microstructural constituents in the alloys: one is the lamellar microstructure consisting of α_2-Ti_3Aland γ-TiAl phases and the other the cellular microstructure consisting of β-Ti and γ phases, since we revealed the introduction of the cellular microstructure is effective in increasing the mechanical properties. Then, volume fraction of this β/γ cellular microstructure (V_c) was quantitatively analyzed from back-scattered electron images took from a scanning electron microscope by an image analysis software. The work hardening rate of each microstructural constituents were evaluated by two ways, one is calculating by an analysis of forward problem that dividing the differential between experimentally measured UTS and 0.2% proof strength (σ_0) by elongation (ε), the other is directly measurement by digital image correlation technique with in-situ tensile test. The UTS of alloys were able to be predicted by simple linear compound law using the UTS of α_2/γ lamellar microstructure and β/γ cellular microstructure, and V_c. And these UTS of each microstructural constituent could also be predicted using their σ_0, ε and work hardening rate. The calculated UTS could reproduce the experimentally measured UTS well, it has a margin of error of only ±5%. By using this method, the volume fraction of the microstructure constituent to meet the required properties that contribute to an input value into the MDM can be output. This work was supported by Council for Science, Technology and Innovation (CSTI), Cross-ministerial Strategic Innovation Promotion Program (SIP), “Material Integration” for revolutionary design system of structural materials.

Oxygen Diffusion and Hardening in γ-TiAl Camille Thenot[1,2], Damien Connétable[3], Daniel Monceau[3], Pierre Sallot[4], François Jomard[5] and Jean-Philippe Monchoux[1,2]; [1]CEMES-CRNS UPR 8011, France; [2]Université de Toulouse, France; [3]CIRIMAT-ENSIACET, France; [4]Safran Tech, France; [5]Université de Versailles Saint-Quentin-en-Yvelines, France

TiAl alloys are sensitive to loss of ductility by exposure in air at temperatures around 700°C and for durations as low as one hour. Though this effect is detrimental for the development of the TiAl alloys as materials for hot parts in automotive and aeronautical engines, it remains poorly understood. Thus, we address here the questions of the penetration kinetics of oxygen in a Ti-48Al-2Cr-2Nb alloy of near γ microstructure, and of the impact of this penetration on the tensile properties of this material at room temperature. For this purpose, tensile specimens have been exposed in a 20 % O_2 + 80 % Ar atmosphere, for temperatures ranging from 400°C to 700°C, and for exposure durations of one hour. The tensile tests show that, in addition to the known effect of loss in ductility, the yield stress increases significantly. Therefore, the origin of this effect has been looked for through investigations of the microscopic deformation mechanisms by transmission electron microscopy. In particular, the dislocation morphologies have been determined in samples of different oxygen concentrations. To quantitatively determine the oxygen penetration kinetics, the diffusion coefficient of oxygen in the γ phase has been determined theoretically by DFT calculations. In parallel, experimental values have been obtained for the first time, using ^{18}O isotope and SIMS concentration profile analyzes, in the following conditions: temperature from 500°C to 700°C, exposure durations from 1 h to 48 h. Surprisingly, the experimental diffusion kinetics were significantly lower than those theoretically predicted. This discrepancy is discussed in terms of potential effects of the Nb and Cr substitutional solutes on the interstitial diffusion mechanisms of oxygen. The main result of these studies is that oxygen dissolution and diffusion in the γ phase is probably not at the origin of the increase in yield stress.

3:45 PM SF07.02.07
Detailed Study of the Effect of Zirconium in Intermetallic γ-TiAl Based Alloys Michael Musi[1], Stefan Kardos[1], Lukas Hatzenbichler[1], David Holec[1], Andreas Stark[2], Melissa Allen[3], Volker Güther[3], Helmut Clemens[1] and Petra Spoerk-Erdely[1]; [1]Montanuniversität Leoben, Austria; [2]Helmholtz-Zentrum Hereon, Germany; [3]GfE Metalle und Materialien GmbH, Germany

The outstanding material-specific properties of intermetallic γ-TiAl based alloys make them excellent candidates for high-temperature structural applications in the aerospace and automotive industry. In order to seize new application areas, an increased service temperature and improved mechanical properties are necessary. Considering that modern engineering γ-TiAl based alloys consist mainly of γ-TiAl phase with some amounts of α_2-Ti_3Al phase and β_o-TiAl phase, depending on the amount of Al and additional alloying elements, strengthening of the γ phase is a key point to further advance this class of materials. A promising alloying element meeting the requirements to be an effective solid solution strengthener for the γ phase is Zr. While its beneficial effect on the mechanical properties is already known in the scientific community, a detailed study of its influence on the phase transformations in the Al range of engineering γ-TiAl based alloys is still missing. Consequently, the present work investigates six model alloys based on the Ti-(42-46)Al-(2-4)Zr (at.%) system regarding the influence of Zr on the microstructure and phase transitions. Microstructural characterization reveals a stabilization of the γ phase due to Zr, leading to an increase of the γ fraction at expense of α_2 in the microstructure, which consists predominately of lamellar α_2/γ colonies and a minor amount of globular γ phase after hot-isostatic pressing. The material’s hardness is increased due to both solid solution strengthening and lamellar refinement of the α_2/γ colonies by Zr. The phase transformation behaviour and the related impact of Zr were investigated by differential scanning calorimetry (DSC) as well as high-energy X-ray diffraction (HEXRD) utilizing synchrotron radiation. Especially, two different types of in-situ HEXRD heating experiments were conducted in order to investigate, on the one hand, the solid-state transformations below the material’s solidus temperature, and, on the other hand, by employing a newly developed experimental setup, the liquid-solid transformations at higher temperatures. Both DSC and HEXRD experiments clearly show that the Zr additions increase the temperature stability range of the γ phase, which ultimately transforms into α-Ti(Al) phase upon

heating. However, phase transformations above the γ phase dissolution temperature, especially, involving the liquid phase, are drastically shifted towards lower temperatures when alloying with Zr, thus effectively narrowing the α single-phase field region. Complementarily, heat treatments above the solidus temperature reveal microstructural features associated with these phase transformations, e.g. formation of liquid phase between the α and β grains in the three-phase α+β+L phase field region. Subsequent water-quenching results in the transformation of the liquid phase into γ phase and of the β phase into α_2 laths, respectively, while in the alloy variants rich in Al, a portion of the high-temperature α phase transforms into massive γ phase. Furthermore, the combination of X-ray diffraction and ab-initio calculations based on density functional theory (DFT) grants valuable insights into the effect of Zr and Al on the lattice parameters of the γ phase. More precisely, Zr causes a strong reduction of the tetragonality of this phase due to an asymmetric influence on the lattice parameters, i.e. a significant elongation of the shorter crystal axis, while the longer axis remains mostly unaffected.

Local Phase Transformations—A New Creep Strengthening Mechanism in Ni-Base Superalloys Michael J. Mills[1], Ashton Egan[1], Semanti Mukhopadhyay[1], Longsheng Feng[2], Fei Xue[3], Emmanuelle Marquis[3], Maryam Ghazisaeidi[1], Steven Niezgoda[1] and Yunzhi Wang[1]; [1]The Ohio State University, United States; [2]Lawrence Livermore National Laboratory, United States; [3]University of Michigan, United States

Polycrystalline Ni-based superalloys are vital materials for disks in the hot section of aerospace and land-based turbine engines due to their exceptional microstructural stability and strength at high temperatures. In the drive to increase operating temperatures and hold times in these engines, hence increasing engine efficiency and reduction of carbon emissions, creep properties of these alloys becomes increasingly important. At these higher temperatures, new deformation modes become active. Several alloy compositions and microstructure variants of commercial disk alloys are being explored, including γ' strengthened alloys as well as compositions promoting γ' and γ'' co-precipitation. Microtwinning and stacking fault shearing are important operative mechanisms in the critical 600-800°C temperature range. Advanced electron-microscopy-based techniques have been used to gain new insights into these mechanisms and the rate-limiting processes during high temperature deformation. Atomic-scale chemical and structural changes associated with stacking fault and microtwin interfaces within γ' precipitates have been identified and indicate that local phase transformations (LPT) occur commonly during creep of superalloys. Furthermore, the important deformation modes can be modulated by LPT formation, enabling a new path for improving high temperature properties. In another phenomenon related to LPT, some superalloys exhibit preferential precipitation along annealing twin boundaries (ATBs). It is surprising that ATBs act as heterogeneous nucleation sites since they are low energy boundaries. However, in superalloys that exhibit this behavior, LTP appears to occur at these ATBs and aide in nucleation of γ' (and γ'') precipitates. The implications of this effect with respect to localization of slip is being characterized using in situ deformation experiments in the SEM. This work is part of a GOALI-DMREF program funded by the National Science Foundation in which collaborators are exploring the thermodynamic driving force for LPT formation using DFT modeling, and phase field dislocation dynamics modeling is being used to explore the interaction of dislocations with γ' microstructures under the cooperative shearing and local compositional changes associated with the LPT mechanism.

SESSION SF07.03: Functional Intermetallics I

8:30 AM *SF07.03.01
Recent Progress of NiMnGa Ferromagnetic Shape Memory Alloy/Polymer Composites Hideki Hosoda[1], Wan-Ting Chiu[1], Pimpet Sratong-on[2], Masaki Tahara[1] and Volodymyr Chernenko[3,4,1]; [1]Tokyo Institute of Technology, Japan; [2]Thai-Nichi Institute of Technology, Thailand; [3]BCMaterials and University of Basque Country, Spain; [4]Ikerbasque, Basque Foundation for Science, Spain

Heusler type NiMnGa is a prototype ferromagnetic shape memory alloy (FSMA) which can be driven not only by temperature change but also by magnetic field. In conventional shape memory alloys (SMAs), shape change occurs by martensite variants reorientation (MVR), and the shape recovery occurs during heating through reverse martensitic transformation (MT) into parent (austenite) phase. Thus, the motion frequency is very limited by the heating/cooling speed. On the other hand, FSMA can be driven isothermally by magnetic field, since the actuation is caused by the reversible twin boundary motion (twinning and detwinning) of martensite variants under equivalent magnetostress. Then, FSMA is considered as a new actuator material with fast response and large stroke. The maximum actuation strain of NiMnGa is around 5.8% in 5M martensitic state and 9.6% in 7M martensitic state. A drawback of NiMnGa is that the large magnetoactuation can appear in the single crystal state only. This is because in polycrystalline state the constraint force from the neighbor grains is larger than the magnetostress and thus suppresses MVR by magnetic field. In order to overcome this problem, we have innovated polymer-matrix-based composite materials containing single-crystalline NiMnGa grain particles. By using Bi microalloying we have developed a technique which allows easy disintegration of polycrystalline NiMnGa into single grains which are magnetostrain active. At present, the value of magnetostrain of the silicone composites containing 20vol% 5M- and 7M- martensitic NiMnGa particles (Chiu et al., Scripta Mater., 2022) or 30vol.% 5M-martensitic NiMnGa particles (Sratong-on et al., Sci. Rep., 2019) is 4.0% under 0.7 T. In this presentation, we summarize recent progress of the NiMnGa FSMA / silicone polymer composites. This research is partially supported JSPS by Kakenhi 20K20544, 22H00256 and 22K14491, the Research Center for Biomedical Engineering, and World Research Hub Program of International Research Frontiers Initiative, Tokyo Institute of Technology.

Novel Co-Al-Si Shape Memory Alloys with B2-Structured Parent Phase Shunya Mochimaru, Tatsuya Ito, Sheng Xu, Xiao Xu, Toshihiro Omori and Ryosuke Kainuma; Tohoku University, Japan

Shape memory alloys, such as Ti-Ni-based (Ti-Ni, Ti-Ni-Cu), Cu-based (Cu-Al-Ni, Cu-Zn-Al), and Fe-based (Fe-Ni-Co-Al-Ta-B, Fe-Mn-Al-Ni) alloys, display shape memory effect and pseudoelasticity due to thermoelastic martensitic transformation. They have offered many technology advantages for various applications such as eyeglass frames, coupling devices, medical devices, and seismic dampers. In recent years, some Co-based shape memory alloys such as Co-Ni-Ga have been reported and they have attracted much attention because of their ability to be used at high temperatures above 373 K. In this study, we present the results of novel Co-Al-Si shape memory alloys showing the thermoelastic martensitic transformation from a B2-structured parent phase. The crystal structures of parent and martensite phases were determined by transmission electron microscopy (TEM), and the transformation temperatures were investigated by measuring the temperature dependence of electric resistivity. Furthermore, it was found that some alloys show excellent pseudoelasticity at temperatures from 298 K to 453 K. Thus, the new Co-based shape memory alloys show great promise for applications requiring high-temperature pseudoelastic properties.

9:15 AM SF07.03.03

Multi-Stage Superelasticity in $SrNi_2P_2$ Intermetallic Compound via Lattice Collapse and Expansion and the Influence of Cryogenic Temperature
Shuyang Xiao[1], Vladislav Borisov[2], Adrian Valadani[2], Guilherme Gorgen-Lesseux[3], Roser Valenti[2], Paul Canfield[3] and Seok-Woo Lee[1]; [1]University of Connecticut, United States; [2]Goethe University, Germany; [3]Iowa State University, United States

Superelastic crystalline solids are able to recover their original shape even after the large amount of deformation is applied. The shape recovery of most superelastic crystalline solids usually occurs through a reversible phase transition between martensitic and austenitic phase. Although this shear process provides up to ~10% of elastic strain, there are several issues that limit their elastic performance. Usually, this shear process requires high activation temperature to reverse the phase transition. So, it is difficult to exhibit superelasticity at cryogenic temperature. Also, the shear process often drives dislocations to move and causes large accumulation of dislocations, which eventually prevent the reversal of phase transition. Therefore, it is desirable to seek out a new class of superelastic material that can overcome these issues through a completely different superelasticity mechanism. In this presentation, we report our first discovery of the giant superlelasticity in a novel intermetallic compound $SrNi_2P_2$ via a unique phase transition process, lattice collapse-expansion and the influence of cryogenic temperature.
$SrNi_2P_2$ single crystals were grown using solution-growth technique, and *in-situ* uniaxial compression and tension tests on [001]-oriented $SrNi_2P_2$ micropillars, which were fabricated using focused-ion-beam milling, were conducted at room temperature, 200K, and 100K. Room temperature mechanical testing revealed the giant superelasiticity with a remarkably huge elastic strain limit near 20% if both compression and tension are considered. Up to our knowledge, this giant elastic strain corresponds to one of the highest elastic strain limits ever reported for crystalline solids. This excellent superelastic performance is achieved through multiple-stage lattice collapse and expansion under compression and tension by forming and breaking P-P bonds in two co-existing different crystal structures in $SrNi_2P_2$. Based on Density Function Theory (DFT) calculation and High-Resolution Transmission Electron Microscope (HRTEM), P-P bonds are formed or broken partially depending on the stress state, leading to the multi-stage lattice collapse and expansion. Fraction of P-P bonds seems to be controlled primarily by entropy under a given stress, so the total number of P-P bonds is determined by thermodynamics under a give stress and temperature. Unlike shear process of martensite-austenite transition, no dislocation is involved in the superelasticity process of $SrNi_2P_2$. Simple making and breaking bond process seems to guarantee ultrahigh fatigue life with presumably nearly infinite number of cycles. Our state-of-the-art *in-situ* cryogenic nanomechanical testing revealed that forming and breaking P-P bonds is strongly sensitive to cryogenic temperature. At lower temperature, phase transition becomes easier under compression but more difficult under tension. This difference can be explained by thermal contraction. Due to the thermal contraction at lower temperature, which reduces P-P distance, making P-P bonds becomes easier, but breaking P-P bonds becomes more difficult. One noticeable result is that even under cryogenic environment (~100K), $SrNi_2P_2$ still exhibit superelasticity, implying that $SrNi_2P_2$ is capable of shape recovery at very low temperature unlike conventional superelastic crystalline solids such as Ni-Ti intermetallic compounds. Our experimental and computational results provide a fundamental insight into understanding the superelasticity mechanisms of $SrNi_2P_2$. Furthermore, our work suggests its strong potential as a cryogenic superelastic material that could be useful to develop an impact resistance material for aerospace engineering under cryogenic environment.

9:30 AM SF07.03.04
High-Quality Intermetallic Nanoparticles from Amalgams Maksym Yarema and Jasper Clarysse; ETH Zurich, Switzerland

Amalgamation is the alloying of two metals, one of which is in liquid form. While broadly applied in metallurgy or dentistry, amalgamation process is yet majorly disregarded for nanotechnology. Recently, we developed the nanoscale amalgamation reaction for the synthesis of intermetallic and alloyed nanoparticles. [1] Starting from monometallic seeds, we carry out a thermal decomposition of metal-amides to dispatch low-melting metals to the surface of nanoparticles and thus trigger a time-efficient and homogeneous alloying to bimetallic compositions. Our new synthesis is convenient and reproducible universal method for high-quality intermetallic nanoparticles, providing uniform compositions and phase purity already after a few minutes of reaction (whereas short reaction time is the key for excellent size distributions). Finally, nanoscale amalgamation gives access to unique bimetallic nanoparticles of very dissimilar metals (for example easily reducible Au, Pd or Pt with much more active Ga or Zn), which is impossible via traditional co-precipitation methods. Combining metals at the nanoscale is a powerful strategy for many applications: large surface area for efficient catalysis, size-dependent properties for ultralow-power phase-change memory and high-Q factor plasmonic applications, small diameter for effective nanomedicine or ultrafine-grain thermoelectrics and additive manufacturing are just to name a few. Our synthesis supplies high-quality intermetallic nanoparticles for this wide range of emerging applications.

Observation of Non-Hookean Huge Elastic Deformation in a Bulk Heusler-Type Cu–Al–Mn Alloy Sheng Xu, Xiao Xu, Toshihiro Omori and Ryosuke Kainuma; Tohoku University, Japan

The familiar metals and alloys in our daily lives are mostly crystalline materials, and they elastically deform because of temporary stretching or contracting of bonds between atoms. The ideal elastic strain for a crystalline metal is the strain at which the lattice itself disintegrates and hence set a firm upper bound of the elastic strain of the material. Theoretically, this strain value can be in the order of 10% for most crystalline metals with absolutely no defects. However, a macroscopic block of conventional crystalline metals practically suffers a very limited elastic deformation of <0.5% with a linear stress–strain relationship obeying Hooke's law. In this presentation, we present our recent results on the experimental observation of a large tensile elastic deformation with an elastic strain of >4.3% in a Cu–Al–Mn single-crystalline alloy with an $L2_1$-ordered structure at its bulk scale at room temperature. The large macroscopic elastic strain that originates from the reversible lattice strain of a single phase is demonstrated by in-situ microstructure and neutron diffraction observations. Furthermore, the tensile elastic reversible deformation, which is nonhysteretic and quasilinear, is associated with a pronounced elastic softening phenomenon. The increase in the stress gives rise to a reduced Young's modulus, unlike the traditional Hooke's law behavior. This non-Hookean huge tensile elastic deformation behavior is discussed in terms of the strong lattice anharmonicity in the present bulk Heusler-type Cu–Al–Mn crystalline alloy. The experimental discovery of a non-Hookean huge elastic deformation offers the potential for the development of bulk crystalline metals as high-performance mechanical spring materials for use as metallic seals and connectors, or for new applications via "elastic strain engineering."

10:30 AM *SF07.03.06
Potential of Multi-Element Alloys as High-Temperature Shape Memory Alloys Yoko Yamabe-Mitarai; The University of Tokyo, Japan

Shape recovery in shape memory alloys (SMAs) occurs by reverse martensitic transformation from martensite to austenite phases. SMAs are used in wide applications such as medical devices, actuators, and household electric applications etc. If SMAs can be used at high temperatures, their application will expand, for example, in aerospace field. TiNi intermetallic compounds is the most used SMAs. The crystal structures of the martensite and austenite phases in TiNi are B2 and B19' in Strukturbericht expression, respectively. However, the martensitic transformation temperature (MTT) of TiNi is lower than 100 °C. To use SMAs at high temperatures, MTT should be increased. Various attempts have been made to increase the MTT of SMAs, such as addition of

alloying elements to TiNi or selection of other intermetallic compounds with high MTT. We have focused on TiPt and TiPd as high-temperature SMAs (HT-SMAs) due to their high MTT above 500 °C. Martensitic transformation, microstructure, and shape recovery of TiPt or TiPd alloys have been investigated. The addition of alloying elements was a certain effect on strength improvement of austenite, but not sufficient. It also had the disadvantage of lowering the MTT in many cases. Recently, multi-component alloys, in particularly medium- or high-entropy alloys, have been attracted as new structural materials because their severe lattice distortion and sluggish diffusion are expected to improve the high-temperature strength of SMAs. In this presentation, phase transformation, microstructure and shape recovery of multi-component SMAs together with TiPt or TiPd base SMAs will be introduced.

11:00 AM SF07.03.07
Actinide Nitride Thin Films—Outlook and Future Directions Kevin D. Vallejo[1], Brelon J. May[1], Cody A. Dennett[2], Paul Simmonds[3] and David Hurley[1]; [1]Idaho National Laboratory, United States; [2]Massachusetts Institute of Technology, United States; [3]Boise State University, United States

Actinide-based materials possess unique physics due to the presence of 5*f* electrons. Owing to their importance as critical nuclear energy materials, their study has mainly focused on these applications, leaving plenty of fundamental physics aspects open for investigation. Examples include the three magnetic phases of Th, which are directly correlated to its impurity density, and the charge density wave anomaly present in α-U at low temperatures. The effective examination of unique quantum phenomena in these materials requires high purity monocrystalline samples. However, the formation of large area single-crystalline actinide compounds is particularly underexplored relative to other material systems because of limited source availability and safety regulations. High quality actinide containing samples will help provide more accurate experimental values for physical properties used by atomistic computer modelling approaches. In turn, this will enable more accurate models of compounds with strongly correlated electron systems. However, current thin-film synthesis techniques for actinide-based materials make use of alloys or functionalized compounds which leave behind impurities and affect crystal quality. Molecular beam epitaxy (MBE) presents an attractive avenue for the study of actinide heterostructures because of the high degree of control over purity, dimensionality, strain, and interfaces between monolithically grown materials. MBE also uses high purity elemental sources and is known for producing highly crystalline material. Thus, by using this technique for synthesis of these complex materials, we can reduce the presence of elemental impurities and defects and simplify the characterization and interpretation of the physical properties. Idaho National Laboratory has recently installed an MBE chamber equipped with electron beam sources, several high temperature cells, and a nitrogen plasma source to facilitate the deposition of low vapor-pressure elements. This work looks to establish the foundational knowledge for the synthesis and characterization of actinide-nitrides with complex oxidation states; wherein, initial studies will employ transition metals as early-stage surrogates for actinide-based nitride materials. We aim to synthesize single crystal, epitaxial (UN) and thorium nitride (Th_3N_4), both of which are promising nuclear fuel candidates for upcoming reactor architectures. The properties of these crystal phases has been an active research field and the synthesis and characterization efforts will be greatly benefited from MBE grown samples. Experimental validation of computational models will result in faster nuclear fuel validation and implementation of nuclear reactors for clean energy solutions.

11:15 AM SF07.03.08
Molecular Beam Epitaxy of Novel Nitrides Brelon J. May, Kevin D. Vallejo, David Hurley and Krzysztof Gofryk; Idaho National Laboratory, United States

Nitride materials have a diverse set of applications, but the system is significantly underexplored compared to oxides. Several recent papers have revealed that there are numerous stable nitride compounds which have yet to be created. Vacuum deposition is an ideal method for the discovery and study of novel materials as it allows for stabilization of materials outside of thermodynamic limits through engineering of the growth kinetics. It also allows for delicate stoichiometry control, enabling careful tuning of composition-dependent physical properties, and materials with high crystallinity and purity. The preparation of monocrystalline samples from ultra-pure atomic sources will allow for examination of the physical properties of these materials without the added complications of grain boundaries or impurities, and to elucidate any directional dependence of these properties which may be present in low-symmetry crystals. This work aims to synthesize single crystalline thin films in this relatively uncharted material space using molecular beam epitaxy (MBE). Growth windows, the vacuum deposition equivalent to commonly employed thermodynamically limited phase diagrams, will be established for a variety of materials. These outline the parameters required to achieve specific phases and include substrate temperature, flux ratios, growth rate, and strain. The focus for the work here is initially given to the exploration of transition metal nitrides containing Cr, Zr, Mn, Nb, Ti, and Ni. The factors which control the formation of different crystalline phases and stoichiometries will be investigated for binary and ternary compounds. While various new ternary phases involving these elements have been predicted to be stable, the physical properties have not been predicted. However, the properties of the binary constituents and the select few known ternary compounds are of interest to various facets of research including: magnetics, semiconductors, superconductors, plasmonics, thermoelectrics, high hardness, stability in extreme environments, and anti-corrosive coatings, these novel ternary compounds will likely have similar properties. Additionally, developing the growth windows for compounds containing elements with complex oxidation states will provide a platform for additional studies involving heavier elements with 5*d*, 4*f*, and eventually 5*f*-electrons. Utilizing these elements in carefully engineered crystal structures is particularly interesting because of their high sensitivity to temperature, strain, increased spin-orbit interactions, as well as magnetic and electric fields. MBE is known for the precise deposition of thin films with sharp interfaces. This will allow for the synthesis of multilayer heterostructures of different materials with compatible crystal symmetry, enabling the combination of multiple properties, study of interface effects, and comparison to random alloys with the same overall composition. Select elements can also be combined with the well-studied Group-III Nitride material system, laying the foundation for future integration of these novel materials with existing semiconductor optoelectronics.

11:30 AM SF07.03.09
Effect of Elastic Strains on the Catalytic Activity of Intermetallic Compounds for the Hydrogen Economy Carmen Martínez[1,2], José Manuel Guevara[1] and Javier Llorca[1,3]; [1]IMDEA Materials Institute, Spain; [2]Universidad Complutense de Madrid, Spain; [3]Universida politécnica de Madrid, Spain

The hydrogen economy strongly depends on two critical reactions for the production of hydrogen and the generation of green energy, namely the hydrogen evolution reaction (HER) and the oxygen reduction reaction (ORR). Pt is the best catalyst in both cases (HER and ORR) and allows high reaction rates to be reached in an acidic environment with very small overpotentials. Nevertheless, Pt cost and scarcity limit the widespread application of this strategy to use hydrogen as a clean energy source. Thus, there is a significant interest in discovering cheaper and more abundant catalysts to replace Pt.

In this investigation, a high-throughput simulation strategy based on first principles simulations has been implemented to discover intermetallic compounds with high catalytic activity for the HER and ORR through the application of elastic strains. The methodology was initially validated for 13 late transition metals. To this end, the adsorption energy of the intermediate species (H*, O*, and OH*) in the catalytic process was determined by density functional theory calculations on surface slabs with different orientations (fcc(111), hcp(0001), and bcc(101)) subjected to different strain states (uniaxial, biaxial, shear, and a combination of them) up to the mechanical stability limits, as indicated by phonon calculations. This information was used to calculate the catalytic activity of each transition metal for both HER and ORR, and the theoretical results were in agreement with the experimental data in the literature [1,2].

Afterward, this methodology was used to explore the catalytic activity for the HER and the ORR of intermetallic compounds with stoichiometries AB and

A3B and fcc, hcp, and bcc lattices. To this end, the potential intermetallic candidates were screened from the Materials Project database, and those that were toxic, radioactive, or unstable were discarded, leading to a sample of approximately 300 compounds. Those with oxygen adsorption energies lower than -2.5 eV were also discarded due to the formation of oxides under working conditions and the adsorption energies of the intermediate species (H*, O*, and OH*) were calculated for the most stable surfaces of each material using density functional theory calculations. This information was used to determine the catalytic activity and further calculations for the intermetallic compounds with the best performance introducing the effect of elastic strains. The results show that the scaling relations (that limit the catalytic performance of transition metals) are not maintained in the case of intermetallic compounds due to the variation in the most favorable adsorption site for the different adsorbates. Moreover, elastic strains can be used to improve the catalytic performance of intermetallic compounds by changing the free energy barrier associated with the rate-limiting reaction or even the rate-limiting reaction. The present investigation provides a general framework to assess the effect of elastic strains on the catalytic activity of intermetallic compounds and the design of new catalysts with improved performance and/or selectivity of the intermediate species.

Microwave Heating of Nanocrystals for Rapid, Low-Aggregation Intermetallic Phase Transformations Daniel J. Rosen[1], Alexandre Foucher[1,2], Emanuele Marino[1], Shengsong Yang[1], Eric A. Stach[1] and Christopher B. Murray[1]; [1]University of Pennsylvania, United States; [2]Massachusetts Institute of Technology, United States

The use of intermetallic Pt–Co nanocrystals (NCs) for the electrocatalytic oxygen reduction reaction is quickly gaining interest thanks to the higher electrochemical stability of the intermetallic $L1_0$ phase compared to a random alloy A1 phase. However, the thermal treatment that enables the intermetallic phase transformation also causes considerable NC aggregation, resulting in a significant loss of electrochemically active surface area. Herein, we report the use of microwave radiation to induce the intermetallic phase transformation in Cu-doped Pt–Co NCs. We demonstrate that microwave radiation reduces NC aggregation while allowing for a complete phase transformation in only 30 s. These microwave-treated NCs demonstrate higher mass activity for the oxygen reduction reaction while maintaining electrochemical stability similar to the thermally annealed samples.

Eliminating Heavy Rare-Earth Elements in Permanent Magnets Through Grain Boundary Engineering Wei Tang[1], Gaoyuan Ouyang[1], Iver E. Anderson[1,2], Jun Cui[1,2] and Matthew J. Kramer[1,2]; [1]Ames Laboratory, United States; [2]Iowa State University, United States

High performance electric motors for electric vehicles, efficient wind generators and a variety of commercial and industrial motors all require high-performance permanent magnets (PM) which can maintain their energy product at temperatures up to 200°C. For the Nd2Fe14B based PMs, this has been achieved primarily by replacing the Nd with heavy rare-earth elements (Tb, Dy and Ho). Of the rare-earth elements (REE), these are truly rare, with the cost of Dy typically about 10x that of Pr and Nd. The heavy REEs increase the temperature range by enhancing anisotropy field and lowering its temperature dependence. They also lower the remanence of the alloy relative to the light REE. While applying the Dy only to the surfaces of the magnetic reduces the overall amount needed, it does increase the processing steps needed for the final product. An alternative approach to enhancing the temperature range is to reduce the grain size (dia.< 2 μm), so that grain sizes are closer to those of the magnetic domain size, hence improving the resistance to demagnetization. However, reducing the grain size in sintered magnets is fraught with several challenges. Not only does the grain size need to be reduced, but the distribution of grain sizes also needs to be top-size limited since a small number of large grains can have a disproportionately large effect on decreasing coercivity. Finer grained samples are more susceptible to oxidation, harder to fully magnetically align and, most importantly, need to be sintered to full density without excessive grain growth. We will present results from various methods for reducing grain size, passivating the grains, and using sintering aids to minimize grain growth.

2:00 PM SF07.04.02

FeCoMnAl Soft Magnetic Alloys Ian Baker[1], Youxiong Ye[1], Scott Lish[1], Liubin Xu[2], Si Chen[3], Yang Ren[3], Aparna Saksena[4], Baptiste Gault[5], Markus Wittman[1] and Haixuan Xu[2]; [1]Dartmouth College, United States; [2]The University of Tennessee, Knoxville, United States; [3]Argonne National Laboratory, United States; [4]Max Planck Strabe 1, Germany; [5]Imperial College London, United Kingdom

Soft magnets play a vital role in the efficient energy conversion in a variety of important industries including wide-bandgap semiconductors, electric vehicles, aeronautics and aerospace, particularly at high temperatures. Improving the efficiency of modern power electronics and electrical machines via advanced soft magnets has the potential to significantly contribute to global energy savings, thereby leading to a reduction of the associated carbon footprint. Here, we present microstructural characterization and property measurements on two novel FeCoMnAl alloys, one single-phase B2 and one nanostructured B2 + b.c.c., which have good soft magnetic properties up to ~873 K. Both alloys exhibits a high saturation magnetizations, high Curie temperatures, low coercivities, and high electrical resistivities. TEM-based ALCHEMI analysis showed that in the B2 phase the Al atoms preferentially occupy one sublattice site whereas the other elements tend to partition between both sublattice sites. DFT calculations predict magnetic properties consistent with the experimental results and indicate that Fe, Co, and Mn elements predominately contribute to the ferromagnetism.

2:15 PM SF07.04.03

Rapid Multi-Property Assessment of Additively Manufactured Co-Fe-Ni Alloys Varun Chaudhary[1], Wei H. Teh[2], Shilin Chen[2], Shakti P. Padhy[1], Cheng C. Tan[2] and Raju V. Ramanujan[1]; [1]Nanyang Technological University, Singapore; [2]Institute of Materials Research and Engineering, Singapore

New materials exhibiting an attractive combination of magnetic, mechanical and electrical properties can play a vital role in improving the performance of next generation rotating electrical machines. However, developing such a material using conventional approaches is expensive, time consuming and misses googols of possible compositions and processing parameters. On the other hand, the accelerated discovery approach relies on high throughput synthesis, characterization, property evaluation, predictive machine learning (ML) and modelling to rapidly screen a huge number of compositions. The assessment of the structure as well as the magnetic, mechanical, and electrical properties of compositionally graded Co-Fe-Ni alloy samples processed by laser additive

manufacturing (AM) was rapidly carried out. The AM process facilitated the rapid synthesis of a compositionally graded material library and the subsequent assessment of several properties. A large change in these properties was observed as a function of composition. Saturation magnetization varied from 60 to 230 emu/g, coercivity from 0.5 to 66.4 Oe, resistivity from 9.4 to 72.6 μΩ cm, microhardness from 90 to 400 Hv, ultimate tensile strength from 465 to 1167 MPa etc. Novel compositions, e.g., $Co_{30}Fe_{60}Ni_{10}$, $Co_{10}Fe_{80}Ni_{10}$, etc., with an optimum magnetic-mechanical-electrical property set have been identified by our approach. This work is supported by the AME Programmatic Fund by the Agency for Science, Technology and Research, Singapore under Grant No. A1898b0043.

Development of Magnetic Refrigeration Materials for Cryogenic Applications Hossein Sepehri Amin, Xin Tang, Jiawei Lai, Anton Bolyachkin, Tadakatsu Ohkubo and Kazuhiro Hono; NIMS, Japan

Hydrogen will play a major role in the establishment of a renewable-energy-based society and realization of carbon neutrality. However, one of the major challenges is the storage and transportation of hydrogen: the H_2 gas has large volume and its liquefaction is necessary. The current available technology for hydrogen liquefaction is conventional gas compression systems based on the Joule-Thompson effect, which is costly and inefficient at low temperatures. Cryogenic magnetic refrigeration (CMR) is a prospective environmentally friendly technology for temperature below 120 K, and it can theoretically exhibit a higher efficiency as compared to those of conventional gas compression systems. In the CMR, the gaseous hydrogen is pre-cooled down to ~77 K by using liquid nitrogen, and, at the second stage, the magnetic liquefier provides a further decrease in temperature down to 20 K (H_2 liquefaction temperature). However, the lack of magnetic refrigerant materials with high magnetic entropy change in a wide temperature range of 77-20 K required for the hydrogen liquefaction is a bottle-neck for practical applications of MR cooling systems
In this talk, we will first demonstrate how data science can be used to develop magnetocaloric materials with giant and reversible magnetocaloric effect at the cryogenic temperatures. We conducted machine learning on a dataset extracted from literature on Fe_2P based alloys to predict optimum alloy composition which results in a decrease of transition temperature below 100 K. Combination of machine learning and experimental validations resulted in realization of rare-earth free $(Mn,Fe,Co)_2(P,Si)$ based compounds which exhibit a large magnetocaloric performance in isothermal magnetic entropy change (ΔS_m) of 7.5–11.5 J/kgK at the temperatures below 100 K [1]. This study demonstrates that data-driven development of magnetocaloric materials can efficiently boost the optimization of their properties, thus aiding the practical applicability of magnetic refrigeration technology. In the second part of the talk, we will show a series of materials with a giant magnetocaloric effect (MCE) in magnetic entropy change ($-\Delta S_m > 0.2$ $Jcm^{-3}K^{-1}$) in the $Er(Ho)Co_2$-based compounds, suitable for operation in the full temperature range required for hydrogen liquefaction (20-77 K) [2]. We found that the giant MCE becomes reversible, enabling sustainable use of the MR materials, by eliminating the magneto-structural phase transition revealed by detailed cryogenic and in-situ microstructure characterizations. We will discuss how this discovery can lead to the application of $Er(Ho)Co_2$-based alloys for hydrogen liquefaction using MR cooling technology for the future green fuel society.

3:30 PM SF07.04.05
High-Resolution Magnetic Domain Wall Imaging by DPC STEM Yoshiki O. Murakami[1], Takehito Seki[1,2], Yuichi Ikuhara[1,3] and Naoya Shibata[1,3]; [1]University of Tokyo, Japan; [2]JST Presto, Japan; [3]Japan Fine Ceramics Center, Japan

Permanent magnets are utilized in many applications such as the main power motor in electric vehicles. It is known that the coercivity, the resistance to changes in magnetization, of magnets can be significantly improved by suppressing the formation of magnetization reversal nuclei and preventing the growth of the reversal nuclei[1]. Micromagnetic simulations predicted that the local change in magnetic properties such as magnetocrystalline anisotropy is crucial to prevent the growth of the reversal nuclei[2]. Thus, the coercivity may be improved by optimizing microstructures consisting of the phases with different magnetic properties. The existence of various phases in microstructures has been reported in high coercive Nd-Fe-B permanent magnets[3], but the key microstructural features to improve the coercivity are still not well understood. It is thus essential to identify one-by-one relationship between microstructural features and their magnetic properties. One of the methods to directly measure the local magnetic properties is to measure the magnetic domain wall (DW) width. DW width varies with the change in the ratio of exchange stiffness and magnetocrystalline anisotropy where the DW is located. The larger DW width indicates larger exchange stiffness or smaller magnetocrystalline anisotropy. However, direct and precise measurement of DW width requires high spatial resolution, since DW is a nanometer-sized magnetic structure.
Differential phase contrast scanning transmission electron microscopy (DPC STEM)[4] is an imaging technique of local electromagnetic fields inside specimens. Combined with recently developed magnetic-field-free atomic resolution STEM [5], DPC STEM now enables visualization of nanoscale magnetic structures in magnetic free environment. Furthermore, one can obtain structural information in the same field of view through other STEM techniques such as high-angle annular dark field images and electron energy loss spectroscopy (EELS).
In this study, we directly measured DW width in La-substituted Nd-Fe-B magnets by DPC STEM. In this magnet, Nd is non-uniformly substituted by La, and the magnetocrystalline anisotropy is expected to locally fluctuate with Nd concentration. To confirm the correlation of DW width and Nd concentration, we measured DW width by DPC and analyzed Nd composition by EELS at the same area. The results show the DW width increases with the decrease in Nd concentration. Details will be reported in the presentation.

Thermomechanical Nanomolding in 2D Mehrdad Kiani[1], Quynh Sam[1], Hyeuk Jin Han[1], Yeon Sik Jung[2] and Judy Cha[1]; [1]Cornell University, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Fabrication of intermetallic nanostructures over wafer-scale distances is critical for applications such as catalysis, energy storage, and microelectronics. Current top-down and bottom-up fabrication approaches, such as CVD or colloidal synthesis, are limited to simple material compositions, have poor morphology and size variance, and lack control of crystallinity. Recently, thermomechanical nanomolding, whereby a polycrystalline feedstock is pressed through a mold with 1D pores at an elevated temperature (~$0.5T_m$), has been shown by Jan Schroers’ group at Yale University to form periodic arrays of single crystal, defect free nanowires. Since composition is determined by the feedstock material, this technique can be easily used to form nanowires of a wide range of intermetallic compounds.
Building upon this work, we investigated thermomechanical nanomolding for fabrication of 2D nanostructures. Using 2D Si trenches with a SiO_2 liner as a

mold, we successfully nanomold both single element and intermetallic compounds over ~1 cm distances. SEM, EBSD, and S/TEM imaging confirm that 2D linear trenches can be formed with no apparent gaps; however, the final structures are not always single crystal, in contrast to 1D nanomolding. While 1D nanowire growth is driven by interfacial diffusion, the lower surface to volume ratio and post-mold structures indicate that other growth mechanisms, such as deformation twinning and grain reorientation, play an important role during nanomolding.

4:00 PM SF07.04.08
Controlling Devitrification in FeSiB Amorphous System for Advanced Soft Ferromagnets Xiaoyu Zhang[1], Wentao Liang[1], Rafael Perez del Real[2], Manuel Vazquez[2] and Laura Lewis[1,1]; [1]Northeastern University, United States; [2]Instituto de Ciencia de Materiales de Madrid, Spain

The performance of advanced soft ferromagnets relies on the formation of an optimized nanocrystalline structure through controlled devitrification from amorphous precursors. This structure is conventionally achieved via small additions of early/late transition metal elements (Nb, Cu, *etc*.) that allow for tuning of devitrification kinetics but also degrade saturation magnetization. Here, building from an in-depth study of as-quenched amorphous nanostructures produced by different rapid solidification conditions, we identify that specifics of small quenched-in crystallites strongly determine devitrification kinetics in FeSiB system free of transition metal additions.
Samples of composition $Fe_{79}Si_{11}B_{10}$ were fabricated into two forms: 1) melt-spun ribbons of ~25 μm in thickness and 2) water-quenched microwires of ~150 μm in diameter. While identical chemical composition and overall X-ray amorphous structure of both as-quenched forms are confirmed, nanoscale differences are revealed by high-resolution transmission electron microscopy. In specific, the water-quenched microwires feature small (~30 nm in diameter) Fe(Si) crystallites dispersed throughout their volume, in contrast to the melt-spun ribbons that exhibit amorphous structure with Fe(Si) nanocrystalline islands (~2 nm in thickness, ~50 nm in diameter) confined to the surfaces. Analysis of calorimetric data reveals that the microwires devitrify via nucleation from pre-existing nuclei, resulting in reduced activation energy, followed by diffusion-controlled grain growth. On the other hand, the ribbons exhibit continuous nucleation followed by interface-controlled growth. It is contemplated that the different devitrification behavior exhibited by the two sample types is attributed to their unique nanostructural state, which is subtly affected by the rapid solidification conditions. These results provide insights into the control of devitrification to achieve high-moment, high-performance nanocrystalline soft ferromagnets without alloying additions.

Thermomechanical Nanomolding of Topological Materials Quynh Sam[1], Mehrdad Kiani[1], Hyeuk Jin Han[2] and Judy Cha[1]; [1]Cornell University, United States; [2]Yale University, United States

Topological intermetallic nanomaterials have novel symmetry-protected electronic states that are advantageous for applications such as catalysis[1], electronics[2], and quantum computing[3]. Fabrication of intermetallic nanomaterials is hindered by the lack of high throughput synthesis methods that allow for tight control of phase, morphology, and stoichiometry. Here, we present the use of thermomechanical nanomolding (TMNM) to fabricate nanowires of topological intermetallic materials. Developed by Jan Schroers' group at Yale University, TMNM is a scalable fabrication process where a bulk feedstock is pressed through a mold with nanosized pores at elevated temperatures and pressures. Starting with a polycrystalline feedstock, TMNM forms defect-free, single crystalline nanowires with consistent growth orientation and composition.[4] TMNM is materials agnostic and has been successfully used to create nanowires of several different topological materials.[5] Furthermore, high pressures and temperatures used in the molding process can be exploited to study phase stability with the possibility of producing metastable phases through nanoscale confinement effects.

We used TMNM to fabricate nanowires of several different topological intermetallic materials. Due to the presence of symmetry-protected surface states, these topological materials have enhanced electronic properties that make them attractive candidates for next-generation interconnect materials. High-resolution S/TEM analysis reveals formation of high-quality, single-crystalline nanowires with consistent composition. Surprisingly, we observe that high levels of vacancies can be tolerated in these single-crystalline molded nanowires without forming any extended defects, such as nanoscale voids or phase separation. The molded nanowires show promising electrical properties where their resistivity values do not increase with decreasing dimensions of the nanowires, in contrast to the increasing resistivity of Cu interconnects at the nanoscale. Thus, we present TMNM as a high throughput fabrication method to form nanowires of topological intermetallic materials with controlled structure and electrical properties with promising applications in energy-efficient computing technologies.

Topological Metal Nanowires for Interconnect Gangtae Jin[1,2], Hyeuk Jin Han[2], James L. Hart[1], Quynh Sam[1], Mehrdad Kiani[2] and Judy Cha[1,2]; [1]Cornell University, United States; [2]Yale University, United States

Topological semimetals (TSMs) possess topologically protected surface states near the Fermi level with high carrier densities and high mobilities, holding distinct potential for low-dissipation on-chip interconnects that may outperform current copper interconnects for continued dimensional scaling of CMOS technologies. To explore the feasibility of nanoscale interconnects using TSMs, synthesis of TSMs with controlled dimensions, structural characterization, and transport properties at the nanoscale are essential. Here, we report synthesis of various TSM nanowires (MoP_2, CoSi, FeGe) with controlled dimensions and crystallinity by chemical vapor deposition and nanomolding. The demonstration of nanostructured TSM nanowires provides opportunities for careful investigations of design rules for TSMs-based nanoscale interconnects.

SF07.05.02
Microstructure Characterization of Spark-Plasma Sintered Compacts of MoSiBTiC Powder Produced by Gas Atomization Shuntaro Ida, Hayato Arai, Kohei Umeda, Xi Nan, Nobuaki Sekido and Kyosuke Yoshimi; Tohoku University, Japan

The creep strength of the first-generation MoSiBTiC alloy (Mo-5Si-10B-10Ti-10C, at%) is superior to that of SiC_f/SiC composites, and the specific strength of this alloy is comparable to that of ceramics matrix composite at 1250°C. On the other hand, its high strength properties make hot forging and processing into complex shapes difficult. Therefore, the processing of the MoSiBTiC alloy by powder metallurgy has been investigated. In this study, the powder and sintered compact of the first-generation MoSiBTiC alloy were prepared by electrode induction gas atomization (EIGA) and spark-plasma-sintering (SPSed compact).
The spherical powder of the first-generation MoSiBTiC alloy was produced by the EIGA method. The microstructure of the powder was much more refined than that of the alloy produced by the arc-melting method (Cast sample). Interestingly, some solidification steps in the Cast sample disappeared in the powder. These differences are attributed to the rapid cooling effect of the EIGA method. Dense and sound powder compacts were successfully obtained by the SPS process. The composition of the SPS compacts was close to the nominal composition of the first-generation MoSiBTiC alloy. Therefore, it was found that there were no significant compositional changes during the powder process. The microstructure of the SPSed compact was considerably (almost one order) finer than that of the Cast sample, with random crystallographic orientation distribution and less anisotropic morphology along the solidification direction observed in the Cast sample.

SF07.05.03
Oxide Scale Analysis of Cr and Nb-added MoSiBZrC Alloy Xinyu Yan, Xi Nan, Shuntaro Ida, Nobuaki Sekido and Kyosuke Yoshimi; Tohoku University, Japan

Mo-Si-B alloys with the addition of ZrC, so-called MoSiBZrC alloys, combine moderate room-temperature fracture toughness and superior high-temperature strength. This is because of the synergistic effect of toughening and high-temperature strengthening by the ZrC phase. However, MoSiBZrC alloys, as well as MoSiBTiC, suffer from catastrophic oxidation at and above 700 °C, caused by the rapid volatilization of MoO_3. For this reason, many efforts have been made to improve oxidation performance. For instance, our previous studies revealed that Cr addition can remarkably improve the oxidation resistance of the MoSiBTiC alloy. Also, it was reported that Nb addition to Ti alloys decelerates the diffusion of oxygen ions in the oxide scale and contributes to the formation of compact oxide layers. Therefore, in the present study, the effect of Cr and Nb additions on the oxide scale formation of MoSiBZrC alloy was analyzed.
Alloy ingots with selected compositions were prepared by conventional arc-melting in an Ar atmosphere. The oxidation tests were carried out at 800 °C. Compared with the base MoSiBZrC alloy, the alloys with Cr and/or Nb additions exhibited considerably reduced weight losses during oxidation. The Cr addition increased the oxidation resistance of the MoSiBZrC alloy because the high amount of Cr dissolved in the Mo solid solution phase and formed as protective $Cr_2(MoO_4)_3$. The Nb addition decreased the thickness of the oxide layer. In the alloys with Cr and Nb addition, the $CrNbO_4$ layer formed beneath the $Cr_2(MoO_4)_3$, which further decelerated the diffusion of O^{2-} ions. Moreover, in the Cr-added alloys, a substantial amount of cracks were observed in the substrate near the oxide-substrate interface, but the crack density decreased by the Nb addition. It is considered that the Nb addition might effectively work to suppress the spallation of the oxide scale.

SF07.05.04
On the Possibility of the Yield Stress Anomalous Increase in $L1_2$- Fe_3Ge Zhenghao Chen and Haruyuki Inui; Kyoto University, Japan

The $L1_2$-ordered structure is one of the most wide-known structures in the field of high-temperature structural materials owing to its superior high-temperature strength. This is believed to be attributed to the anomalous increase of yield stress with increasing temperature (referred to as yield stress anomaly, YSA), which is caused by a thermally activated (111)-(010) cross slip of Anti-phase boundary (APB) coupled $\boldsymbol{b}$=1/2[101] superpartial dislocations. However, not all $L1_2$-compounds are necessary to exhibit the YSA phenomenon. The $L1_2$-Fe_3Ge was considered one of those for a long time. This was related to the fact that slip on the (010) plane is exclusively activated in $L1_2$-Fe_3Ge with their polycrystal specimens that either the (111) slip or the YSA was believed not to occur. Besides, unfortunately, the preparation of single-crystal specimens in bulk size is extremely difficult. For that reason, almost nothing is known at present about the deformation behavior of the $L1_2$-Fe_3Ge in detail.
In the present study, we investigate the compressive deformation behavior of $L1_2$-Fe_3Ge in their micropillar single-crystal specimens at room temperature. Emphasis is placed on the deformation microstructures of the $L1_2$-Fe_3Ge through detailed transmission electron microscopy (TEM) investigation, paying special attention to whether or not the YSA occurs in this $L1_2$-compound.
For the compression orientation near [001], the (111) slip in $L1_2$-Fe_3Ge is successfully observed. This is the first time to experimentally observe the (111) slip in $L1_2$-Fe_3Ge. The critical resolved shear stress (CRSS) for (111) slip is estimated as ~240MPa, which is resulted to be approximately 8 times higher than that for (010) slip (~35MPa). The extremely huge gap in the CRSS between the (111) slip and the (010) slip is considered responsible for the absence of the (111) slip in polycrystal deformations. Typical dislocation structures corresponding to the Kear-Wilsdorf lock are observed after deformation on (111) slip, suggesting a possibility of the occurrence of YSA in $L1_2$-Fe_3Ge, even at room temperature. This exciting discovery brings $L1_2$-Fe_3Ge an opportunity to serve as the γ' strengthening phase in γ/γ' two-phase superalloys and hence opens a new category in the field of high-temperature structural materials, the Fe-based superalloy strengthened by $L1_2$-Fe_3Ge variants.

SF07.05.05
Controlling Mg_2Si Intermetallic Phase in Al-Si-Mg Alloy by Laser Additive Manufacturing Process and Post Heat Treatments Keito Saki[1], Yuki Otani[1], Naoki Takata[1], Asuka Suzuki[1], Makoto Kobashi[1] and Masaki Kato[2]; [1]Nagoya university, Japan; [2]Aichi Center for Industry and Science Technology, Japan

Laser powder bed fusion (L-PBF) process is one of the metal additive manufacturing techniques capable of producing complex geometrical forms. The AlSi10Mg alloy with a nominal composition of Al-10Si-0.3Mg (mass%) is one of the representative Al alloys used for the L-PBF process. The L-PBF manufactured AlSi10Mg alloy exhibits a fine cellular microstructure consisting of the α-Al matrix with supersaturated Si solid solution and surrounding Al/Si eutectic network. The characteristic microstructure is considered to contribute to a superior strength of the L-PBF processed Al-Si alloys compared to the conventional cast alloys. In general, Al-Si-Mg alloys are artificially aged to achieve high strength by promoting the fine precipitation of Si and the β-Mg_2Si phase (including the metastable phase) in the α-Al matrix. It has been reported that nanoscale precipitates of the Mg_2Si phase introduced by aging treatments contributed to the further hardening of the L-PBF manufactured AlSi10Mg alloy. The insight can open an opportunity for further strengthening of L-PBF manufactured Al-Si-Mg alloys by controlling a combination of the Mg_2Si phase with the Si phase. In this study, we designed an alloy composition of Al-10Si-4.5Mg (mass%) based on the calculated phase diagram of the Al-Si-Mg ternary system. Thermodynamic calculations assessed relatively high fractions (approximately 8% in equilibrium) of the Mg_2Si phase in the designed alloy composition. We made an attempt at the L-PBF processing using an Al-10Si-4.5Mg alloy powder. The microstructural characteristics were clarified for the L-PBF processed samples and then the age-

hardening behavior associated with the precipitation of the Mg_2Si phase will be investigated.
The gas atomized Al-10Si-4.5Mg alloy powder with a mean particle size of approximately 20 mm was applied for the L-PBF manufacturing using a ProX DMP 200 machine (3D Systems). The applied process parameters were as follows: scan speed (v) = 0.6~1.8 m/s, laser power (P) = 51~140 W, laser spot size ~100 μm, powder layer thickness = 30 μm, and hatch distance = 100 μm. The relative density was measured by the Archimedes method. The Al-10Si-4.5Mg alloy samples with an approximate dimension of 15 mm × 15 mm × 10 mm were manufactured under the conditions of v = 1.0 ~ 1.8 m/s and P = 77 ~ 128 W. The samples manufactured under v = 1.0 m/s and P = 128 W exhibited a highest relative density of 92 %. Microscopic cracks perpendicular to the building direction were often observed in all of the manufactured samples. Such crack propagation would be a dominant contributor to the reduced relative densities of the Al-10Si-4.5Mg alloy samples. The manufactured samples exhibited melt-pool structures composed of many elongated α-Al phases (primary solidified) surrounded by numerous granular Mg_2Si phases and fine Si phases (formed in eutectic reactions). The microstructural morphology was in good agreement with the calculated Scheil solidification sequence of liquid (L)+α → L+α+Mg_2Si → L+α+Mg_2Si+Si in the alloy composition. On the other hand, a relatively coarse equiaxed cellular microstructure decollated with granular Mg_2Si phase was observed at the melt-pool boundaries. The relatively coarse and brittle Mg_2Si phase localized at melt-pool boundaries may contribute to the crack propagation perpendicular to the building direction. The hardness of the as-manufactured sample was over 180 HV, which was much higher than that of the AlSi10Mg alloy (~130HV). This superior hardness would be attributed to the granular Mg_2Si phase. Si and Mg solute contents inside the α-Al matrix were approximately 2.2 and 1.0 mass%, respectively. The high solute contents indicate the possibility of further precipitation strengthening by the post heat treatments. The age-hardening behavior and its associated precipitation of the Mg_2Si phase (together with Si phase) will be presented.

SF07.05.06
Controlling α/Al_6Fe Two-Phase Eutectic Structure in Cast Al-Fe Alloys by Addition of Mn and Cu Elements Naoki Okano, Naoki Takata, Asuka Suzuki and Makoto Kobashi; Nagoya University, Japan

Aluminum (Al) alloys are widely used in transportation equipment and aerospace because of their lightweight and high specific strength. Al-Fe alloys have been investigated as candidate materials for high-temperature applications, but the coarsened θ-$Al_{13}Fe_4$ phase *(mC*102) has a detrimental effect on the mechanical performance of the cast Al-Fe alloys. In rapidly solidified alloys, the refined Al_6Fe metastable phase (*oC*28) would increase strength without compromising ductility. The refined Al_6Fe metastable phase would transform into the coarsened θ stable phase at elevated temperatures, resulting in the reduction of high-temperature strength in thermal exposure. The stabilization of the Al_6Fe phase by the addition of a third element (Mn or Cu) would be effective to improve the microstructural stability at elevated temperatures. In the present study, Mn and Cu were selected as the added third elements in terms of the crystal structure of Al_6Fe phase. The added Mn is expected to replace the Fe sublattice of the Al_6Fe phase (*oC*28) and form a stable Al_6(Fe, Mn) phase in the Al-Fe-Mn ternary system. In the Al-Fe-Cu ternary system, α phase is in equilibrium with the $Al_{23}CuFe_4$ phase with the same orthorhombic crystal structure (*oC*28), suggesting that the Al_6Fe phase would be stabilized by Cu addition. Herein, for understanding the effects of Mn and/or Cu additions on the formation of Al_6M (M: Fe, Mn, Cu) phase in the solidification microstructures of Al-Fe alloys, we fabricated Al-Fe-Mn, Al-Fe-Cu ternary alloys, and Al-Fe-Cu-Mn quaternary alloys solidified at different cooling rates. The solidification microstructures and high-temperature strength were systematically investigated.
Various Al-Fe alloys with compositions of Al-1%Fe, Al-1%Fe-1%Mn, Al-1%Fe-1%Cu, and Al-1%Fe-1%Cu-1%Mn (mol%) were prepared by solidification at different cooling rates. The raw materials were melted in an induction furnace in the temperature range of 800-900°C for 1800 s in an Ar atmosphere. The molten materials were prepared at two different cooling rates. Some were cooled by switching off the power source to the furnace (cooling rate: 0.3 °C×s^{-1}). The others were cast into an iron mold to form rod-shaped ingots at a higher cooling rate (145 °C×s^{-1}).
In the furnace-cooled Al-1%Fe alloy, the coarsened θ-$Al_{13}Fe_4$ stable phase was formed in the α (fcc) matrix. The cast Al-1%Fe alloy exhibited several elongated α phases surrounded by refined α/Al_6Fe eutectic structure. In the Al-1%Fe-1%Mn alloy, the Al_6(Fe, Mn) phase appeared regardless of the cooling rate. The refined α/Al_6(Fe, Mn) two-phase eutectic microstructure occupied almost the entire area in the cast sample. In the furnace-cooled Al-1%Fe-1%Cu alloy, the $Al_{23}CuFe_4$ phase was formed in the final solidification zone. The cast Al-1%Fe-1%Cu alloy showed the same microstructural morphology as the cast Al-1%Fe binary alloy, and the Cu tended to distribute into the Al_6Fe phase. The fine eutectic microstructure was observed in the cast Al-1%Fe-1%Cu-1%Mn alloy as well as in the cast Al-1%Fe-1%Mn alloy. The added Cu and Mn elements were enriched in the intermetallic phase, which may contribute to the stabilization of the Al_6M phase.
The 0.2% proof stress of the cast Al-1%Fe alloy was about 90 MPa at room temperature and decreased with increasing temperature. The 0.2% proof stress at 300°C was about 50 MPa. With the addition of 1 mol% Mn and Cu, the 0.2% proof stress at room temperature increased to 120~130 MPa. The combined addition of Mn and Cu increased the 0.2% proof stress to about 150 MPa, and the reduction in strength level by increasing test temperature appeared less pronounced for the Al-1%Fe-1%Mn-1%Cu quaternary alloys. The moderate reduction in strength could be due to the fine eutectic structure containing the Al_6M phase stabilized by Mn and Cu elements.

SF07.05.07
Expansion of Pettifor Structural Map to Search for High-Concentrated Solid Solution-Based Multi-Phase Alloys Syuki Yamanaka, Ken-ichi Ikeda and Seiji Miura; Hokkaido University, Japan

Recently, novel alloy design methods using high-concentrated solid solutions, such as high-entropy alloys, are attracting attention. By introducing the strengthening phase to a high-concentrated solid solution with excellent mechanical properties, it is expected to produce high-performance materials. Because the number of combinations of multiple elements is too large, a guideline for selecting constituent elements for searching for new high-concentrated solid solution-based multi-phase alloys is needed. Our goal is to develop a rapid screening scheme for multi-component material development.
The Pettifor maps are useful maps for binary compounds A_xB_y with various x/y ratios in an easy-to-understand notion in terms of the Mendeleev number [1]. Given that it can describe a wide range of binary compounds, the order of the Mendeleev number is related to factors governing the binary interaction energy, such as electron concentration. Therefore, this idea is expected to be effective in describing the stability of not only binary compounds but also binary solid solutions. By creating the map for solid solutions and combining it with the conventional Pettifor map for binary compounds, both combinations that form a stable solid solution and the compound that may equilibrate each other can be found in a short time survey without checking a huge number of phase diagrams one by one. For a typical example, in the case of a ternary alloy with Co and Al additions to pure Ni, these maps will tell us Co forms an fcc continuous solid solution with Ni, together with the candidates of Al-containing compounds such as Ni_3Al-$L1_2$, NiAl-B2 and CoAl-B2. For the relationship between the binary system and multi-component system, our previous works revealed that many multi-component compounds are derived by substituting a specific site of a binary compound for other elements, e.g., $(Ni, Co)_3(Al, Ta, W)$ derived from $L1_2$-Ni_3Al [2,3]. This knowledge leads us to expect that, information such as the crystal structure of binary solid solutions is helpful to evaluate the stability of multi-component solid solutions. The main aims of the present work are to investigate the stability of multi-component solid solutions thermodynamically, create the map for binary primary solid solutions and confirm our idea is effective in selecting the constituent elements in multi-component systems.
Under such considerations, the map proposed in this study includes detailed information about each binary solid solution such as its crystal structure, its maximum solubility and the presence of its competing phases within the 1,411 binary phase diagrams in a single map. This map clearly shows which solutes dissolve largely in which solvents, allowing an immediate evaluation of the potential for multi-component high-concentrated solid solution formation. Then, by comparing this map with the Pettifor maps, the compound to be selected as a stable phase in a multi-component system can be

estimated. For example, considering the Ti addition to CoCrFeMnNi alloy, the stabilization of the solid solution by combining Co, Cr, Fe, Mn and Ni can be confirmed in the map of this study. Also, in the conventional Pettifor maps, as the candidate compounds composed of the constituent element with Ti, there are only the Laves phases ($TiCo_2$, $TiCr_2$, $TiFe_2$ and $TiMn_2$) in the AB_2 map and the B2 compounds (CoTi, FeTi and MnTi) in the AB map. In previous experiments [3], it was confirmed that the high-concentrated fcc phase equilibrates with AB_2 Laves compound in Ti-added CoCrFeMnNi alloy. Thus, our scheme can easily estimate the combination of a stable high-concentrated solid solution and the candidate compounds. This study will enable the rapid development of high-performance multi-component materials.

Plastic Deformation Behavior of Single Crystalline Pearlitic Steel Investigated by Micropillar Compression Method Mutsumi Morisaki, Nobuyuki Kadota, Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan

Pearlitic steel has been used in a wide variety of practical applications, such as rails, bridge cables and high-strength wires because of their ultra-high strength, which is closely related to their lamellar structure composed of alternating ferrite (α) and cementite (θ-Fe3C) layers. The strength of pearlitic steel wires has known to be improved further by cold drawing, which results in the refinement and alignment of the lamellar structure. However, the detailed mechanism of the microstructure evolution during cold drawing process has not been fully clarified yet. This is mainly because of the lack of information on plastic deformation behavior of cementite. Recently, we have systematically investigated room temperature deformation behavior of cementite single crystals as a function of the loading axis orientation by utilizing micropillar compression method and have successfully identified five different slip systems operative at room temperature and their critical resolved shear stress (CRSS). In the present study, we have applied the micropillar compression method to investigate plastic deformation behavior of individual pearlite lamellar grains, whose loading axis orientations are (nearly) parallel to the lamellar boundary planes with the Bagaryatsky orientation relationship ($(112)_\alpha//(010)_\theta$, $[-110]_\alpha//[001]_\theta$). Operative slip systems in each lamella and their transfer behavior through lamellar interfaces were investigated experimentally through the trace analysis of slip traces appeared on side surfaces of micropillar specimens. When the loading axis was nearly parallel to $[-110]_\alpha$ and $[001]_\theta$, both α-Fe and θ-Fe3C lamellar were confirmed to plastically deform by the activation of their primary slip systems with their slip traces propagating continuously through many alpha-theta interfaces. In contrast, when the loading axis was about 15 degrees away from $[-110]_\alpha$ and $[001]_\theta$, non-primary slip systems were activated in both phases, while the continuation of slip traces was maintained. Possible factors that control the operative slip systems in both phases were discussed based on the information on the operative deformation modes in θ-Fe3C obtained by our previous micropillar experiments, geometrical relationship between slip systems in alpha and theta phases, and strain compatibility at alpha-theta interfaces.

SF07.05.10
Bi-Doping Strategy for Achieving Single Crystal Particles of Ni-Mn-Ga and Investigations of Ni-Mn-Ga/Polymer Composites Towards Smart Materials Wan-Ting Chiu[1], Pimpet Sratong-on[2], Masaki Tahara[1], Volodymyr Chernenko[3,4,1] and Hideki Hosoda[1]; [1]Tokyo Institute of Technology, Japan; [2]Thai-Nichi Institute of Technology, Thailand; [3]UPV/EHU Science Park, Spain; [4]Basque Foundation for Science, Spain

The shape change of the ferromagnetic shape memory alloy (FSMA) is manipulatable via applying an external magnetic field [1]. The NiMnGa-based alloys are considered promising FSMAs for applications as magnetic field-driven devices; however, their high brittleness inhibits their practicability. Therefore, in this work, a grain separator, Bi element, was intentionally introduced into the polycrystalline NiMnGa alloys to separate the grains and make NiMnGa alloys even brittle. The introduced concentration of the Bi element was variating from 0.00 at.% to 0.05 at.% to optimize the doping amount and the properties of the bulk NiMnGa specimens. The Bi-doped polycrystalline NiMnGa alloys were then mechanically disintegrated into single-crystalline particles by a well-controlled crushing system. The NiMnGa single crystal particles were utilized for the fabrications of the composites with the volume fraction (vol.%) of the single-crystal particles at 20% by an integration of the single-crystal particles with a silicone polymer matrix. The single crystal NiMnGa particles/silicone polymer composite materials were successfully fabricated for realizing the applications of the high-speed actuator.
The Bi doping studies were performed using concentrations of 0.00, 0.01, 0.03, and 0.05 at.%. Elemental mapping (i.e., Ni, Mn, Ga, and Bi) of each alloy was conducted to reveal the distribution details of each element. It is found that with the addition of the Bi separator to the NiMnGa polycrystalline bulk materials, the grains were successfully separated. In addition, it was shown that the higher concentration of the Bi doping, the more grain boundaries could be observed. This effect was already saturated at 0.03 at.%. The average grain size, analyzed by using ImageJ software, was around 210 μm for NiMnGa polycrystalline bulk alloys doped by 0.03 and 0.05 at.% Bi. A co-existence of the 5M- and the 7M-martensite phases was found in the single crystal NiMnGa particles at 27 ºC, whereas at 39 ºC only a single 5M-martensite phase, and at 51 ºC only the parent austenite phase (A), were observed. Hence, the following sequence of phase transformations was observed 7M/5M→5M→A [2].
The micro-strains of particles in composites with volume fraction of particles of 20 vol.% (co-existence of 5M- and 7M-martensite phases), Composite A (CA), and 30 at. % (5M-martensite phase), Composite B (CB), were measured by a micro-CT and analyzed by a polar decomposition method [3]. The composites were compressed from 0% to 50% of the total deformation strain. It was found that the particle composed of 7M-martensite performed the largest micro-strain among all the tested particles. On the other hand, the 5M-martensite particles in CA and CB composites exhibit similar micro-strain. It is worth noting that the loading-unloading hysteresis of CA was reduced greatly owing to the released spatially interference among the particles.

SF07.05.11
A Study on the Relationship Between the Size and Magnetic Properties of $Nd_2Fe_{14}B$ Through the Fabrication of Fine-Grained Magnets Using Submicron Fe Jeong Hyun Kim[1], Myeongjun Ji[1], Cheol-hui Ryu[1] and Young-In Lee[1,2]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]The Institute of Powder Technology, Korea (the Republic of)

With the demand for high efficiency in green technology fields such as energy conversion systems, wind turbines, and electric vehicles, $Nd_2Fe_{14}B$ sintered magnets have to store high energy density and be stable for devices in various operating temperatures. For high coercivity in accordance with this requirement, several attempts are being investigated to develop heavy rare-earth element (HRE)-lean or free Nd-Fe-B magnets. A promising approach to achieve coercivity enhancement while avoiding scarcity of resources and the expense of remanence due to antiferromagnetic coupling between HRE and Fe is to control the microstructure, such as grain size. The size-dependent coercivity tends to maximize when the magnetic dimension reaches a critical diameter (about 260nm for $Nd_2Fe_{14}B$) where only a single domain is supported. Furthermore, the fine grains suppress domain reversal at high temperatures, improving the thermal stability of the coercivity and its suitability to the motor operating environment.
As an attempt at grain refinement, conventional metallurgy techniques mainly controlled the milling parameters to reduce the size of feedstock particles but

had limitations in size reduction. Accordingly, bottom-up synthesis accompanied by a reduction-diffusion (R-D) process, which overcomes the limitations of top-down methods and has advantages such as low energy consumption, low raw material cost, and uniform morphology, has emerged as an attractive way to control the particle size. Motivated by the advantages of chemical-based synthesis, the size control of $Nd_2Fe_{14}B$ particles has been conducted in a few studies through concentration of the solution and R-D conditions as variables, but magnetic properties predominantly depended on crystallinity and composition rather than size. In addition, there is an inherent limitation that it is difficult to even sinter due to low productivity, imperfection, and oxidation of nanoparticles, as a result, research to confirm the size effect on magnetic properties of $Nd_2Fe_{14}B$ by a chemical-based method has not yet been reported. Therefore, it remains a major assignment to develop the magnetic properties of a sintered magnet by forming submicron grains using chemically synthesized particles of an appropriate size.
In this study, we adopted an effective approach using submicron Fe powder to synthesize $Nd_2Fe_{14}B$ by applying the size dependence of final magnetic particles on transition metal precursors. Chemical-based methods including ultrasonic spray pyrolysis (USP) and hydrogen reduction process for the synthesis of submicron seed powder were proposed and performed. And then in order to fabricate a fine-grained Nd-Fe-B sintered magnet with high magnetic properties, the R-D process and sintering conditions were optimized using the synthesized submicron iron. Finally, the interaction between oxygen content and physical and magnetic properties according to the size of $Nd_2Fe_{14}B$ was systematically investigated and the effect of size on magnetic properties was elucidated by controlling the particle size of $Nd_2Fe_{14}B$ using Fe seed particles with a size varying from nano to microscale.

SF07.05.12
Controlling Chemical Ordering in Permanent Magnet Compounds Xiaoyu Zhang, Brian Lejeune and Laura Lewis; Northeastern University, United States

Next-generation advanced permanent magnets require high magnetocrystalline anisotropy that is donated by chemical ordering. While it remains highly challenging to control chemical order in the “holy grail” FeNi permanent magnet system (*aka* tetrataenite), the analogous proxy system of MnAl provides a good platform for investigating and understanding the chemical ordering in ferromagnets. To this end, the disorder (hcp ε-phase) – order ($L1_0$ τ-phase) phase transformation in $Mn_{55}Al_{45}$ compound is investigated here. Structural, magnetic, and calorimetric data confirmed the attainment of $L1_0$ ordered τ-MnAl upon heating two different quenched forms of metastable, disordered ε-MnAl: melt-spun ribbon solidified from a molten precursor and water-quenched one from the already solidified ribbon. While both quenched $Mn_{55}Al_{45}$ samples exhibit nominally phase-pure (~ 99 wt.%) ε-MnAl phase, the ordering transformation of the melt-spun ribbon occurs ~40 degrees lower than that of the water-quenched one. Kinetic analysis reveals that the ordered τ-phase in the melt-spun ribbon develops from pre-existing nuclei, in contrast to that in the water-quenched alloy that exhibits a constant nucleation rate with fewer quenched-in nuclei. It is contemplated that specifics of as-quenched microstructure that originate from quenching conditions tailor the chemical order in the MnAl system. The results of this work provide insights into controlling phase stabilities and chemical ordering kinetics in other relevant ferromagnetic systems of applied interest as permanent magnets.

En Route to High Coercivity in Rare-Earth-Lean Permanent Magnet Materials Henri J. Baldino[1], Kevin W. Jinn[1], Chaoya Han[2], Alexander Gabay[2], Brian Lejeune[1], Chaoying Ni[2], George Hadjipanayis[1,2] and Laura Lewis[1,1]; [1]Northeastern University, United States; [2]University of Delaware, United States

Permanent magnets enable clean energy technologies such as wind turbine generators and hybrid vehicle regenerative motors. The expanding importance of these materials married with unpredictable supply restrictions underscores the importance of developing high-performance magnet substitutes of lower critical element content. To this end, the rare-earth-lean $(Sm,Zr)(Fe,Co,Ti)_{12}$ (“1-12”) compound has theoretical high-temperature performance that can surpass that of the NdFeB supermagnets, if only sufficient magnetocrystalline anisotropy energy could be converted into high coercivity to resist demagnetization. Advancing this objective, novel synthesis approaches have recently produced 1-12 powder containing single, defect-free crystallites of extremely high coercivity. In this work we correlate magnetic data with structural data to hone in on the characteristics of these high-coercivity crystallites, with the goal understand the impact of synthesis conditions on the intrinsic and technical magnetic properties of this compound.

Magnetic and particle size data were collected from 1-12 ferromagnetic powders made by a tailored synthesis process that combined mechanical activation with high-temperature calciothermic reduction. The data were analyzed to correlate processing conditions, including thermal treatment temperature and acetic acid concentration (utilized to remove unreacted calcium metal) from the powders. While all powder crystallites possess nominally the same composition, magnetic hysteresis loops indicate the presence of multiple hard magnetic phases, with a maximum of 15% of the powder exhibiting a record 2.2 T coercivity at room temperature. The underlying structural characteristics of the powder crystallites, including the evolution of particle transformations to form the desired 1-12 compound, are investigated to elucidate the origins of magnetic performance and provide guidance for its amplification.

The Hydrogenated Intermetallic Compound $Pd_{70}Ag_{30}$ Both Amorphous and Crystallin—Their Electronic Properties Oscar A. Ibañez Martínez[1], Renela M. Valladares[1], Isaías Rodríguez[2], David Hinojosa[2], Salvador Villarreal[2] and Ariel A. Valladares[2]; [1]Facultad de Ciencias, UNAM, Mexico; [2]Instituto de Investigaciones en Materiales, UNAM, Mexico

Metal-Hydrogen alloys have been studied due to their widespread applications; in particular, the palladium-hydrogen system manifests superconductivity [1]. Palladium, alloyed with noble metals (Ag, Au, Cu) also shows superconductivity when hydrogenated with a ratio of 80% hydrogen; in this case, the superconducting transition temperature is maximum, T_C=15.6 K [2] for a concentration of $Pd_{70}Ag_{30}$. In this work we computationally generated and studied an amorphous structure of the intermetallic palladium-silver alloy $Pd_{100-x}Ag_x$, x=30 at% and compared it with the crystalline counterpart. The amorphization process follows the *undermelt-quench* approach [3] on a 216-atom supercell of the PdAg alloy using *ab initio* molecular dynamics. Hydrogen was interstitially inserted for a ratio H/(Pd+Ag) = 0.8 in the supercells. The obtained structures were characterized with the Pair Distribution Function (PDF). In order to compare crystalline and amorphous hydrogenation, the topology and the electronic structures were obtained. In this work they will be contrasted, analyzed and discussed.

Structural and Electronic Properties of the α and β Phases of the Intermetallic Compound $PdBi_2$ Both Amorphous and Crystalline Gerardo Antonio Martinez, Renela M. Valladares, David Hinojosa, Isaías Rodríguez and Ariel A. Valladares; UNAM, Mexico

The study of superconducting alloys has shown that the intermetallic compounds are an attractive family of materials. Those that contain bismuth may exhibit superconductivity [1, 2, 3]. Within these alloys we find the intermetallic crystalline phases α-$PdBi_2$ and β-$PdBi_2$ with T_c =1.73 K and 4.25 K respectively [4]. In this work we report the study of the topology and electronic structure of both the amorphous and crystalline phases of the above-mentioned intermetallic compounds. The amorphization was accomplished by using the process called the *undermelt-quench* approach [5]. This process is based on *ab initio* molecular dynamics and consists in heating the supercells to temperatures just below the liquidus temperature and then cooling it down to close to absolute zero. This process was applied to the α and β phases of the material, using supercells with a total of 216 atoms for the binary system. In order to compare the crystalline and the amorphous systems, the topology and electronic structure were obtained and these results will be presented and discussed.

A Lightweight Ti-Al-Based Shape Memory Alloy with B2-Ordered Structure Yuxin Song, Sheng Xu, Xiao Xu, Toshihiro Omori and Ryosuke Kainuma; Tohoku University, Japan

The β-type Ti-based alloys have recently attracted much attention due to their exceptional properties such as low Young's modulus, shape memory effect and gum-metal-like behavior. Among them, β-type Ti-based shape memory alloys such as Ti-Nb-Ta-Zr and Ti-Mo-Al, which undergo thermoelastic martensitic transformation from a β (body-centered cubic) parent phase to an α'' (orthorhombic) martensite phase, show great promise for applications in medical devices due to their superelasticity and biocompatibility. However, the transformation strain by superelasticity is usually small to be less than 3% in these conventional β-type Ti-based shape memory alloys. In this talk, we report a novel B2-structured Ti-Al-Cr shape memory alloy with a greater superelastic strain. The crystal structure and lattice parameters of both parent phase and martensite phase were determined using the X-ray and neutron diffraction methods. The mechanical properties of the alloy were evaluated by uniaxial tensile or compressive tests on single-crystal samples at room temperature. It was found that the alloy exhibits excellent superelastic behavior with a recoverable strain over 7%. The experimentally observed transformation strain is consistent with the calculated one using the lattice parameters on the base of lattice deformation theory. This newly-developed Ti-Al-Cr shape memory alloy is a promising candidate for medical applications. This alloy is also characterized by its lower density than that of the conventional β-type Ti-based alloys containing high-density Nb or Mo, having potential as a lightweight shape memory alloy.

Crystallographic Characterization of Zirconium-Based Samples Containing Tin, Niobium and Iron elements—*In Situ* High-Temperature X-Ray Diffraction Results Jeong Min Ha, Tae Hyun Kwon, Jeong-Woo Nam, Youngsoo Kim and Young-Sang Youn; Yeungnam University, Korea (the Republic of)

In situ high-temperature X-ray diffraction (HT-XRD) is an useful technique that can provide very valuable information on *in situ* crystallographic properties such as lattice parameter and phase transformation at a certain temperature. Through *In situ* HT-XRD, we have studied the crystallographic characterization of zirconium-based samples containing minor alloying elements of tin, niobium, and iron at a temperature range of 30–870 °C with intervals of 40 °C. The *a*- and *c*-axes lattice parameters of the hexagonal Zr crystal structure were calculated from the *in situ* HT-XRD spectra using the Pawley refinement. We confirmed that the *a*-axis lattice parameters of the hexagonal Zr crystal structure for the zirconium-based samples with tin element are decreased compared to those for a pure zirconium sample, in contrast to the zirconium-based samples with other minor alloying elements (i.e., niobium and iron). This effect is the greatest when 3 wt% tin was added in zirconium. On the other hand, the *c*-axis lattice constants for all the zirconium-based samples are not declined by the minor alloying elements as compared to the pure zirconium.

Computational Approaches for Studying the Nucleation of Voids at the Nanoscale Vicente Munizaga, Peng Yi and Michael L. Falk; Johns Hopkins, United States

Solid state precipitation and growth of different phases inside solid solutions is an important part of the design and manufacturing of metallic alloys. Intermetallic precipitates are one of the most effective methods to strengthen metals because such precipitates often resist dislocation motion.

One optimal microstructure for improving the strength of metals is a high density of small precipitates. It has recently been demonstrated that in Mg alloys this microstructure can result from the defects generated by the mechanical deformation [1]. Vacancies and voids are commonly found among these defects.

The agglomeration of vacancies has been in the center of our attention because these structures may play a crucial role in the nucleation of intermetallic precipitates that remains poorly characterized. It is known that voids can change the composition in their vicinity by attracting or repelling solute [2]. This could promote or suppress the nucleation of precipitates.

Furthermore, the formation of voids from agglomeration of vacancies is itself a nucleation process that is not fully understood. Current models assume that voids nucleate from a uniform concentration of vacancies [3]. However, in direct molecular dynamics simulations we have observed that agglomerations of vacancies could remain locally stable before creating a well-defined internal surface. This could suggest that the nucleation of a void with a defined internal surface could involve a two-step process.

Nucleation is known to be a "rare event", which means extracting kinetic information from computational simulations is challenging. By means of Replica Exchange Transition Interface Sampling (RETIS) we can quantify aspects of the void nucleation process through the sampling of independent phase-space paths. The resulting data is useful for elucidating the kinetics of void nucleation. Using this data, we aim to validate or improve existing void nucleation models.

Corrosion Prediction of Advanced High-Strength Steel Using *In Situ* Electrochemical Atomic Force Microscopy with Deep Learning ChangHyo Sun[1], Panithan Sriboriboon[1], Junghun Han[2], Sang-Jin Ko[1], Jung-Gu Kim[1], Sejung Yang[2] and Yunseok Kim[1,3]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]KIST-SKKU Carbon-Neutral Research Center, Korea (the Republic of)

Observing the physical properties of each microstructure is the key to understanding the various properties of metals. For instance, corrosion, such as oxidation and reduction, can be influenced by microstructures. Recently, as corrosion begins at the nanometer or micrometer scale, local corrosion studies related to microstructures using microscopic techniques are being conducted. However, to understand the corrosion mechanism, it is not sufficient to observe morphological change by ex-situ experiments. Furthermore, understanding the overall corrosion mechanism requires observing microstructures in real time and even predicting surface changes. In this presentation, various physical properties such as height, surface potential, and capacitance gradient according to microstructure in advanced high-strength steel, which is applied automotive, were investigated by atomic force microscopy (AFM). Furthermore, we performed the prediction of morphological change through a combination of in-situ electrochemical AFM (EC-AFM) images and deep learning techniques for understanding the corrosion mechanism. We show that the combination of deep learning to in-situ EC-AFM images can show not only identification of microstructures, but also insight into the corrosion mechanism. Consequently, this approach can be easily applied to other intermetallic-based alloys.

SESSION SF07.06: Structural Intermetallics III
Session Chairs: Martin Heilmaier and Alexander Knowles

Bcc-Superalloys—bcc Refractory Metals Reinforced By Ordered-bcc Intermetallic Precipitates Alexander J. Knowles; University of Birmingham, United Kingdom

The microstructure template of a disordered matrix reinforced by ordered-intermetallic precipitates offers a potent design strategy for high temperature materials, enabling strength alongside damage tolerance, which has been central to the success of fcc Ni-superalloys. Such a strategy is equally applicable to bcc-based systems, which offer advantages of increased melting point, lower cost, and/or lower density. However, whilst bcc-superalloys based upon a refractory metal, Ti, Cr or Fe matrix, strengthened by ordered-bcc intermetallic precipitates are possible, further research and development is need for them to become a commercial reality.

In this talk, opportunities for bcc-superalloys systems will be discussed, from binaries to ternaries and more complex alloys, including Refractory High Entropy Superalloys. It will then discuss our latest developments in tungsten-based bcc-superalloys, beta-Ti superalloys and chromium superalloys. Prospectives will be given for the onward development of the bcc-superalloy concept for application in nuclear fusion, Gen-IV fission, gas turbines and concentrated solar power.

9:00 AM SF07.06.02
Phase and Microstructure Stability of BCC-V/MAX Two-Phase Alloys With Quaternary Additives Seiji Miura[1], Hiroto Kudo[1], Shiho Takebe[1], Nobuaki Sekido[2] and Ken-ichi Ikeda[1]; [1]Hokkaido University, Japan; [2]Tohoku University, Japan

Max phases have attracted attentions because of its high strength, high melting point and low density [1]. The present authors conducted a broad reserach for establishing the BCC-V based materials with Max phase V_2AlC as a dispresoid for strengthening. It was found that BCC-V matrix alleviates the delamination tendency of MAX phase during plastic deformation even at relatively lower temperature, however, the microstoructure stability of V-Al-C ternary alloys is not enough. In this study effect of various quaternary elements on the microstructure stabilization is investigated.
Based on the V-Al-C ternary phase diagram [2], we prepared alloy ingots with and without quaternary additives such as Cr, Ti, Mo and W. An Ar-arc melting machine was used to melt the sample several times, and a part of ingot sealed in a evacuated silica tube was subjected to a heat-treatment at 1473 K for 1 week. Microstructure observation using FE-SEM and WDS analysis for determining the composition of each phase is conducted, and the EBSD analysis was also conducted to understand the crystallographic orientation relationship between BCC-V and MAX phase.
It was confirmed that the alloys with and without the heat-treatment have two-phase microstructure, however, plate-like V_2AlC-MAX phase in as-cast alloys with Ti spheroidized during the heat-treatment. On the other hand, the MAX phase in alloys with Cr, Mo or W keep its plate-like structure even after the heat-treatment. It was confirmed that V has large solubility of Cr, Mo and W, while Ti tends to be in MAX phase because Ti forms MAX phase (Ti_2AlC). In our previous study it was found that the BCC-V and MAC phase has a certain crystallographic orientation relationship. The lattice mismatch between BCC-V and MAX in ternary alloys are evaluated to be about 9%, and the value increases in alloys with Ti because Ti increases the lattice constant of MAX by replacng smaller V atom. On the other hand either Mo and W increase the lattice constant of BCC-V solid solution, resulting in decreasing the lattice mismatch between BCC-V phase and MAX phase. Smaller inter-phase boundary energy between BCC-V and MAX phase caused by smaller lattice mismatch might be a reason why Mo and W stabilize the microstructure of alloys. In the presentation a part of the mechanical testing will be presented.

New Proximate Structures for {110}(111)-Type Antiphase Boundaries in BCC-Derived Ordered Intermetallics Justin Mayer, K. V. Vamsi, Ram Seshadri and Tresa M. Pollock; University of California, Santa Barbara, United States

A new model, known as the diffuse multi-layer fault model (DMLF), has provided an accurate high-throughput method for evaluating the energetics of planar faults within alloys of complex composition. Specifically, the DMLF, which approximates a planar fault through a series of proximate structures that capture the local bonding environment within the vicinity of the fault, has been used recently to assess the energetics of planar faults within FCC alloys [1] as well as the {111}a/2(110) antiphase boundary observed within FCC-derived $L1_2$ ordered intermetallics. [2] Within this work, we report on the successful extension of this model to the antiphase boundaries present on {110} planes within the BCC-derived B2 and $L2_1$ ordered intermetallics. Through coupling the DMLF to a large database of symmetrically distinct atomic configurations on a host BCC lattice, proximate structures have been identified for the {110}a/2(111) antiphase boundary within the B2 and $L2_1$ intermetallic and the {110}a/4(111) antiphase boundary observed in the $L2_1$ intermetallic. Density functional theory calculations are employed to validate the accuracy of the formation energies of these newly identified proximate structures relative to those calculated *via* the more conventional, and computationally costly, supercell method. The use of the B2 and $L2_1$ proximate structures to predict the thermodynamic stability of planar faults in BCC-derived ordered intermetallics with a complex composition will also be discussed.

B2 Precipitation-Strengthened Refractory Compositionally Complex Ta-Mo-Ti-Cr-Al alloys Martin Heilmaier[1], Alexander Kauffmann[1], Stephan Laube[1], Aditya Tirunilai[1], Daniel Schliephake[1], Bronislava Gorr[1], Steven Schellert[2] and Hans-Juergen Christ[2]; [1]Karlsruhe Institute of Technology, Germany; [2]University Siegen, Germany

Refractory compositionally complex alloys (RCCA) are promising candidates for high-temperature structural applications [1]. Many of the reported alloys consist of A2 or B2 phases with additional intermetallic phases often located at grain boundaries. However, to achieve good mechanical performance at elevated temperatures as well as sufficient ductility at room temperature, the proper formation of a strengthening phase is crucial. Recently, Senkov and co-workers [2] reported a microstructure with coherent cuboidal precipitates and promising high-temperature strength in the Al-Mo-Nb-Ta-Ti-Zr system. However, the alloy lacks ductility at room temperature, which could be
attributed to an ordered B2 matrix phase with disordered A2 precipitates.
Following along above conceptual path we report here on the current status of our investigations within the Ta-Mo-Ti-Cr-Al system which exhibits a promising combination of strength and oxidation resistance at elevated temperatures [3]. The objective is to attain a suitable multi-phase microstructure of A2 matrix and B2 precipitates. Thermodynamic calculations were employed with an in-house database to predict specific transformation sequences of ordering and diffusion-controlled phase separation within this system. As already observed in the Ta-free subsystem MoTiCrAl, Al has a significant effect on the ordering transition of A2 towards B2 [4]. However, in the case of the MoTiCrAl system, no multi-phase phase field has been predicted and confirmed after the homogenization. This changes by the addition of Ta, as a multi-phase field is predicted [5]. To minimize the formation of inherently brittle Laves phase, the Cr concentration was adjusted accordingly [6]. The microstructure of two compositions (high and low in Al, respectively) were investigated experimentally by scanning and transmission electron microscopy, while the phase transitions were determined by means of differential scanning calorimetry. The microstructure of the alloy with high Al concentration exhibited a B2 matrix with A2 precipitates; in contrast, an A2 matrix with B2 precipitates was determined in the Al-lean alloy. The necessary reaction sequences are discussed in detail and provide information about the phase diagram structure necessary to reproducibly obtain the desired two-phase microstructures. Microstructural peculiarities, such as segregation at planar defects as well as their implications on the mechanical properties will be discussed.

10:45 AM SF07.06.06
Evolution of a Novel Ta-Nb-Ti Multi-Component Alloy for Potential Biomedical Applications Maximilian Regenberg[1], Janett Schmelzer[1], Georg Hasemann[1], Jessica Bertrand[2] and Manja Krueger[1]; [1]Otto-Von-Guericke Universität Magdeburg, Institute of Materials and Joining Technology, Germany; [2]Universitätsklinikum Magdeburg, Germany

The modern material class of equiatomic multi-component alloys, especially high-entropy alloys (HEAs) gained tremendous attention in the scientific community over recent years. This can be attributed to two main reasons: Firstly, the new concept of combining several elements (at least 5 principal elements with concentrations between 5 and 35 at. % [1]) in contrast to conventional alloys, mostly containing only two or three elements in addition to the main alloy constituent. This results in a broad variety of possible combinations thus leading to completely novel materials. Secondly, recently developed refractory metal based high-entropy alloys (RHEAs) have shown properties that are superior to the ones of current state-of-the-art alloys, which are based on several unique thermodynamic effects [2–5]. However, besides the outstanding mechanical properties, abrasion resistance and thermal resistance, a vast variety of chemical elements used in RHEAs also belong to the category of biocompatible elements, hence leading to potentially new biomedical materials.

In consideration of this background and due to the excellent biocompatibility of the constituents [6], an equiatomic composition of Ta, Nb and Ti as multi-component base alloy was chosen for investigations.
The alloy examined was produced using an arc melting furnace under Ar atmosphere, metallographically prepared and investigated respectively. Scanning electron microscopy (SEM) analysis revealed the presence of a dendritic microstructure, with an enrichment of high-melting elements in the dendrites, as well as Ti in the interdendritic regions (verified by means of EDS mappings). Microstructure analysis by means of X-ray diffraction (XRD) showed, that there are two types of body-centered cubic (bcc) crystal structures (Im-3m I: a = 3.287 Å; Im-3m: a = 3.291 Å) present in the as-cast state. To get a better understanding of the microstructure evolution, heat-treatment experiments regarding different temperatures and times were performed. Moreover, the biocompatibility of the novel alloy Ta-Nb-Ti was evaluated by means of cell (f.e. osteoblasts) attachment, as well as monocyte inflammatory response analysis and compared to samples of elemental Ta, Nb, alloy Co-28Cr-6Mo and alloy Ti-6Al-4V. First results indicate competitive osteoblast attachment, as well as comparable expressions of fibrosis markers in comparison to the conventionally used biomedical materials. In addition, the Ta-Nb-Ti alloy showed reduced inflammatory capacity, indicating a high potential for use as prospective biomedical material.

11:00 AM SF07.06.08
Nanostructured NiAl-(Cr,Mo) In-Situ Composites Processed by Selective Electron Beam Melting Jan Vollhüter, Andreas Förner, Abdullah Jamjoom, Zongwen Fu, Steffen Neumeier, Carolin Körner and Mathias Göken; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The intermetallic B2 phase NiAl possesses promising properties as a high-temperature material with a very high melting point, low density, good thermal conductivity, and excellent oxidation resistance. However, the high-temperature strength and the room temperature fracture toughness show poor performances which disqualify the usage of single-phase NiAl for structural applications as a high-temperature material. However, the addition of 28 at. % Cr and 6 at. % Mo to NiAl leads to an eutectic alloy, which forms a two-phase rod-like or lamellar eutectic microstructure during directional solidification. These in-situ composites show superior mechanical properties over single-phase NiAl. New additive manufacturing methods, such as selective electron beam melting (SEBM) provides very high cooling rates which produces nanostructured composites with very small lamellar spacings between the B2-NiAl and the bcc Cr solid solution. The room temperature fracture toughness of NiAl-(Cr,Mo) composites benefits from a smaller lamellar spacing and the creep strength can be superior to the creep strength of TiAl-alloys.
In this study, dense and crack-free specimens of eutectic NiAl-(Cr,Mo) in-situ composites have been processed via selective electron beam melting using an Arcam A2 machine. In dependence on the processing parameters, a lamellar network-like microstructure can be obtained. For alloys with a lower Mo content, also rod-like structures introduced by discontinuous precipitation can be found in the additively manufactured composites. These discontinuous precipitations are triggered by an in-situ heat treatment in the building chamber or an ex-situ heat treatment. The different types of microstructures are investigated by their mechanical properties, microstructure, and chemical composition. APT investigations are used to further analyze and understand the formation of the nanostructured phases. The high-temperature properties are analyzed by compression and creep experiments, whereby the post-creep defect structure is further investigated by TEM to understand the deformation mechanisms. Furthermore, the room temperature fracture toughness of the different morphologies is studied by testing FIB-milled micro bending cantilevers. The best creep results and high-temperature flow stress are shown by the network-like composites, while the lamellar composites show superior fracture toughness. Consequently, the correlation between microstructure and mechanical properties requires a trade-off between room temperature- and high-temperature properties.

Fabrication of AlCoCrFeNi High Entropy Alloy via Binder Jetting and Direct Energy Deposition: Characterization, Microstructural Modification, and Analysis Jide E. Oyerinde, Justin Almeida, Ioannis Mastorakos, Philip Yuya and Ajit Achuthan; Clarkson University, United States

Additively manufactured high entropy alloys are in the early stage. More studies are required on how their compositions, processing routes, and microstructural evolutions intertwine to influence their (mechanical) properties for various fields of applications. In this study, the equiatomic AlCoCrFeNi high entropy alloy was fabricated via two additive manufacturing routes: binder jetting (3DBJ) and direct energy deposition (DED). The response of the samples to isothermal heat treatment was investigated and compared with the as-printed samples. The microstructural evolution was studied using backscattered electrons images from scanning electron microscopy (SEM). Energy dispersive spectroscopy (EDS) was used to probe the constituent's composition/distribution. The different phases present in the microstructure were investigated using X-ray diffractometer (XRD) and electron-backscattered diffraction (EBSD) techniques. Moreover, the mechanical properties data captured via nanoindentation were evaluated and mapped to show a representation of how they vary through the bulk alloy. Interplays of these essential parameters are responsible for the various mechanical properties exhibited by the alloy. The isothermal heat treatments significantly modified the microstructures of the alloy. However, the 3DBJ and DED samples respond differently, as diffusion mechanisms like grain boundary precipitation, precipitate-free zones (PFZ), and widmanstatten structure were more observable in the 3DBJ samples. The 3DBJ samples exhibit higher values of mechanical properties than the DED samples. The higher mechanical properties in 3DBJ samples are also linked to intermetallics such as sigma phase and ordered BCC (B2). Consequently, the effects of these phenomena are summarized by the difference between the properties of the as-printed samples (2 - 13 GPa hardness, 130 - 240 GPa reduced modulus) and those of the heat-treated samples (4 – 8 GPa hardness, 160 – 200 GPa reduced modulus). The ongoing exploits provide significant insight into how to exploit the immense opportunities AlCoCrFeNi high entropy alloy has for fields of applications such as the tools, automobile, structures, and aerospace industries.

Heat-Resistant Cr-Alloys Strengthened by Intermetallics—Microstructure, Oxidation and Creep Uwe Glatzel[1], Petra Pfizenmaier[1], Mathias Galetz[2] and Anke S. Ulrich[1]; [1]University of Bayreuth, Germany; [2]DECHEMA Forschungsinstitut (DFI), Germany

A two phase alloy of Cr, bcc, solid solution matrix strengthened by a Cr_3Si, A15 ordered, intermetallic phase was investigated with the goal of achieving an alloy with properties "Beyond Nickel-Based Superalloys". In comparison to the commonly used Ni-base superalloys, these Cr-Si alloys may enable higher working temperatures and lower densities slightly above 7 g cm^{-3}. In addition, Cr is the only refractory metal which intrinsically builds an oxide scale suitable for protecting the alloy from oxidation. Si improves the oxide scale formation even further as well as a high temperature strength by precipitation of an intermetallic phase Cr_3Si. We observed that the addition of further alloying elements such as Mo, Ge, and Pt leads to an improvement in creep properties (Mo), oxidation resistance (Ge), and nitridation resistance (Pt) by maintaining the two-phase microstructure. Creep tests were conducted at temperatures at 980°C and higher and reveal promising results. The microstructures, scales, and reaction products were investigated by XRD, SEM, EPMA and Image Analysis.

2:00 PM SF07.07.02
Printability of V-Si-B Alloys: Mechanical Properties and Oxidation Performance Janett Schmelzer[1], Silja-Katharina Rittinghaus[2] and Manja Krueger[1]; [1]Otto-von-Guericke-University Magdeburg, Germany; [2]University of Wuppertal, Germany

There nearly is no other industry placing such high demands on materials as aircraft construction. Due to the mature design of the aircraft engines, further competition will take place with innovative materials and manufacturing processes. In the vicinity of the combustor, where engine parts are burden with temperatures higher than 500 °C, Ni-based superalloys have been state-of-the-art for many years. However, Ni-based superalloys come along with a high density (~ 8.5 g/cm^3). Weight reduction is an important issue to achieve the target of increased thermodynamic efficiency including less fuel consumption and a reduced amount of exhaust emissions. To this end, research activities focus on new light-weight materials with good high-temperature properties to increase the thrust-to-weight ratio in aircraft engines by replacing Ni-based superalloys. Vanadium points out as an interesting candidate, since it offers the lowest density (ρ = 6.11 g/cm^3) in comparison to other high-melting metals. Moreover, alloyed with Si and B, a multi-phase microstructure consisting of a vanadium solid solution (V_{ss}) phase next to the intermetallic phases V_3Si and V_5SiB_2 [1,2] forms, which offers a low ductile-brittle-transition as well as enhanced high temperature strength and creep resistance next to an improved oxidation resistance [1]. However, conventional ingot metallurgical processing of V-Si-B material and subsequent machining is energy- and time-consuming due to the different behavior of the ductile solid solution phase and the brittle silicides. This work presents the first study on additive manufacturing of a high melting point near-eutectic V-based alloy via additive manufacturing (AM) process. The feasibility of printing pre-alloyed V-Si-B powder material was demonstrated. V-Si-B powder was manufactured via gas atomization (GA) process out of solid raw materials meeting the requirements for AM regarding flowability and particle size. After developing suitable process parameters for the generation of crack-free samples, the microstructure of the materials was analyzed in detail using SEM/EDS and EBSD analyses. An overview about the ambient and high temperature material properties of a V-9Si-5B alloy is given. In terms of high-temperature mechanical properties, the brittle-to-ductile transformation temperature (BDTT) and the creep rate at a potential application temperature were determined as well as first investigations on the oxidation resistance.

Microstructure and Mechanical Properties of Ternary Eutectic V-Si-B Alloys Georg Hasemann[1], Weiguang Yang[2], Ruth Schwaiger[2] and Manja Krueger[1]; [1]Otto von Guericke Universität Magdeburg, Germany; [2]Forschungszentrum Jülich GmbH, Germany

The V-Si-B system has gained scientific interest as a new low-density, refractory metal-based structural intermetallic alloy system. The alloy design is strongly influenced and driven by the developments in the field of Mo-Si-B alloys and shares some interesting structural and microstructural features. Very recently, the formations of ternary eutectic V_{SS}-V_3Si-V_5SiB_2 microstructure has been reported [1] which contains the same isomorphous phases as the ternary eutectic in the well-studied Mo-Si-B system: a refractory metal-based solid-solution phase (Mo_{SS} or V_{SS}) and the two intermetallic phases with either an A15 (Mo_3Si and V_3Si) or a $D8_l$ (Mo_5SiB_2 and V_5SiB_2) structure. In contrast to the Mo-based system, where the intermetallic Mo_3Si represents the major phase within the ternary eutectic microstructure, the V_{SS}-V_3Si-V_5SiB_2 eutectic features the ductile solid-solution phase as the major component. This fact makes the V-Si-B ternary eutectic very interesting in terms of its mechanical properties.
The present work is focused on the compressive stress-strain behavior of different near-eutectic V-Si-B alloy. Compression tests were performed using an electro-mechanical universal testing machine and a constant crosshead speed corresponding to an initial (engineering) strain rate of 10^{-3} s^{-1}. The yield stresses were determined by the 0.2% offset method. The temperature dependence of its yield stress between room temperature and 1000 °C was investigated in the as-cast and annealed state (1400 °C for 100 hrs) of the fully eutectic alloy V-9Si-6.5B and were compared to literature values of different V-based alloys [2–4].

Microstructure Designs and Processing for Mo-Si-B Alloys John H. Perepezko[1], Dan J. Thoma[1], Longfei Liu[1], Phalgun Nelaturu[1], Ankur K. Agrawal[1], Fan Zhang[2] and Laurence Marks[3]; [1]University of Wisconsin--Madison, United States; [2]Computherm LLC, United States; [3]Northwestern University, United States

Recently, considerable effort has been devoted to the development of ultra-high temperature structural materials as alternatives to Ni-based superalloys to improve the energy efficiency of gas turbine systems. Among the several potential candidates, Mo-Si-B alloys have received much attention due to their high melting point and high temperature strength, but also have some remaining challenges to improve ductility, lower density and enhance environmental

resistance. In the Mo-Si-B system microstructures with a Mo solid solution (Mo_{ss}) Mo_3Si and Mo_5SiB_2 (T_2) phases have been the focus of attention. However, the Si solubility in the Mo_{ss} phase diminishes the ductility and toughness. In order to address this issue, a new series of Mo-Si-B alloys in the Mo_{ss}+T_2 +Mo_2B three phase region has been designed to examine the effect of the lower Si solubility limit in the Mo_{ss} phase on the microstructure, hardness and oxidation behavior. The results showed that the Mo-Si-B alloys in the Mo_{ss}+T_2 +Mo_2B three phase region have higher fracture toughness and the same level oxidation resistance as alloys in the Mo_{ss}+T_2 + Mo_3Si three phase region. Selected additions of Al and Ti enable a density reduction to below 9 gm/cm^3. In order to examine the Al addition effect on the Mo_{ss}+T_2 +Mo_2B three phase region the microstructures and oxidation of Mo-Si-B alloys at different Al addition level was examined at 800, 1100, 1200, and 1300°C for both isothermal oxidation and cyclic oxidation exposure along with an analysis of the oxidation kinetics and oxide layer morphologies.
While refractory metal intermetallic alloys (RMIA) offer an attractive option to extend operational capability beyond what is currently available with Ni-base superalloys the processing of the RMIAs to manufacture dimensionally controlled shapes in a commercially cost-effective way is challenging. For RMIAs the directional solidification approach used for Ni base superalloys has serious difficulties. For example, there are very limited choices for suitable mold materials that are nonreactive with the alloy melt. The solidification path for large ingots in RMIAs involving intermetallic silicide and boride phases usually yields product phases that are not part of the equilibrium phase microstructure. Due to the high-temperature stability and sluggish diffusion in refractory metals, homogenization requires very high temperatures (>1500ºC) and long annealing times (>1 day) that are not commercially cost effective. A conventional powder metallurgy processing approach for RMIAs involves several steps including the hot pressing of RMIA powders, high-temperature sintering, and then usually a hot isostatic press (HIP) treatment to achieve full density. Even with these multiple processing steps, it is difficult to produce complex shapes with accurate geometric control. To circumvent these challenges, an additive manufacturing (AM) route offers a new, rapid and effective strategy. With AM methods such as directed energy deposition (DED) and liquid powder bed fusion (LPBF), alloying is accomplished by the melting and reactive synthesis of component powder mixtures to full density so that the size scale of any nonequilibrium solidification products is limited that facilitates post-alloying homogenization. This approach has been demonstrated to yield the fabrication of homogeneous alloys with well-defined shapes. Besides the successful use of AM, the guidance from computational thermodynamics to identify compositions that meet density, strength and ductility goals and the use of dimensionless numbers to guide the AM process has been essential to achieve fully dense component with the desired microstructures.

Environmental Protection Coating System for Refractory Metal Alloys in Extreme Environments Ranran Su and John H. Perepezko; University of Wisconsin-Madison, United States

The refractory multi-principal elements alloys (RMPEAs) are promising structural materials to help increase power efficiency in high-temperature oxidation environments, while the intrinsic poor oxidation resistance of the refractory elements limits their application. The oxidation behavior of a refractory high entropy alloy WMoTaNbV is investigated at 1300°C. By using an innovative two-step coating strategy with Mo-precoat followed by Si-B pack cementation, a multilayer Mo-Si-B coating with strong oxidation resistance and compatibility as well as a diffusion barrier is developed. The coating can protect the substrate at 1300°C for more than 750 h of thermal cycles. An RMPEA boride phase develops at the alloy/coating interface after longtime service and acts as an additional diffusion barrier to maintain the coating integrity. The oxidation test results demonstrated that this two-step coating system provides robust oxidation protection at high temperatures and can be widely applied in RMPEAs.

Pesting Resistance in High Mo Containing Alloys Alexander Kauffmann, Daniel Schliephake, Susanne Obert, Aditya Tirunilai, Frauke Hinrichs, Bronislava Gorr and Martin Heilmaier; KIT, Germany

Refractory metal based alloys exhibit intrinsically high creep resistance at anticipated application temperatures beyond 1100 °C due to high solidus temperatures. However, apart from ductility issues at low temperatures, oxidation resistance at elevated temperatures is often observed a fundamental problem for the further development of this group of alloys.

Among others, Mo-based alloys have attracted particular research interest [1]. However, the disordered, body centered cubic solid solution, rich in Mo and required to obtain reasonable toughness and low brittle-to-ductile transition temperatures, usually forms volatile MoO_3 already at temperatures below 1000 °C. The progress of oxidation occurs rather fast and typically leads to a complete disintegration of the part within short periods of time. Thus, this so-called pesting behavior is a catastrophic type of oxidation.

In the present study, we provide recent results on the development of pesting-resistant high Mo containing alloys specifically addressing this fundamental problem when oxidation resistance is considered [2-6]. The alloys with this surprising and not expected property are Ti-rich, two-phase or three-phase alloys from the Mo-Si-Ti system. All of the identified alloys feature: (i) Fine-scale microstructures of the solid solution and one or two silicides originating from eutectic reactions, solid state transformations or combination thereof. (ii) Surprisingly adherent and passivating TiO_2/SiO_2 duplex and/or TiO_2 top layers after oxidation in laboratory air that limit the oxidation progress and the contribution of evaporation at temperatures of 800 up to 1200 °C. (iii) Low densities in conjunction with reasonable creep resistance. A holistic overview is provided about the nature of the TiO_2 which is typically not considered a passivating oxide and the microstructural and chemical requirements of pesting resistance.

Apart from Mo-Si-Ti, further alloys were developed also featuring fine-scaled microstructures of Mo-rich solid solution and silicide phases. Indeed, another alloy from the Mo-Si-Cr system exhibiting pesting resistance was identified but significantly differentiating in the mechanism to suppress MoO_3 formation at 800 °C [7]. The common and differentiating features of the two developments are highlighted to provide further insights into research opportunities.

Oxidation Behavior of Spark Plasma Sintered Compacts of MoSiBTiC Powder Produced by Gas Atomization Xi Nan, Hayato Arai, Kohei Umeda, Shuntaro Ida, Nobuaki Sekido and Kyosuke Yoshimi; Tohoku University, Japan

The first generation MoSiBTiC alloy with the nominal composition of 65Mo–5Si–10B–10Ti–10C in at% exhibits excellent high temperature creep resistance and specific strength for application at the temperature up to at least 1300°C. But the oxidation behavior should also be paid attention to since it is a big issue for such Mo-based alloys and could be well affected by the microstructure at the material surface. In this study, gas atomized MoSiBTiC powder was used to produce the compact by spark plasma sintering (SPS) method, and a relative density of almost 100% was achieved. Compared to the conventional arc-melted MoSiBTiC alloy, also prepared in this work, SPS compact showed greatly refined microstructure and a small compositional change during the process. By the microstructure refinement, the oxidation performance of the SPS compact slightly deteriorated at 800°C but improved at 1100 °C. Moreover, the effect of microstructure refinement on the oxidation behavior at a higher temperature such as 1500 °C is not remarkable. This distinction at the three temperatures is considered to be attributed to different reasons. Surface modification using the pack cementation method was also applied to the SPS compact to further improve the high-temperature oxidation resistance. With the development of an approximately 100 µm thick silicide layer on the top surface, the sample exhibited remarkably enhanced oxidation resistance at the temperature up to at least 1300 °C.

Data-Driven Researches Under the Concept of Materials Integration Masahiko Demura; National Institute for Materials Science, Japan

The concept of Materials Integration is to computationally link among processing, structure, property, and performance for accelerating materials research and development [1,2] and is comparable to that of Integrated Computational Materials Engineering. To embody the Materials Integration, we have developed a system named MInt (Materials Integration by Network Technology) [3]. In MInt, one can implement any types of prediction models based on computational simulations, theoretical or empirical formulas, and machine learning algorithms as a module. Furthermore, one can connect several modules to design a workflow that comprehensively predicts from processing through microstructure to property and/or performance. MInt executes a workflow by delivering the output data from a module to the input port of the next module and stores all the computational results in order. MInt is a platform to accumulate the materials scientists' knowledge digitalized as modules and workflows, which are stored not in isolation but in the form of graph network. At this moment, the modules and workflows implemented in MInt are mainly for conventional structural alloys such as steels, aluminum, and Ni-based superalloys, but one can expand its application fields by adding new modules and workflows.

Data-driven approach plays an important role in Materials Integration. Firstly, it is useful to make the prediction modules more accurate; for example, data assimilation technique can adjust model parameters included in the computational simulation or the theoretical or empirical formula to improve predictability. Secondary, it helps to build a comprehensive workflow even if all the mechanisms are not fully understood. For a missing link, machine learning provides a non-linear regression model based on experimental data without physical background. On top of that, certain data-driven methods, such as sparse modeling and feature importance analysis, contribute to finding the physical picture. Lastly, it provides a realistic means of solving the inverse problem, i.e., finding the optimal material and processing that meets the desired performance. Since MInt provides an application programing interface to execute the workflow and extract the computed results, one can apply any types of optimization algorithms including Bayesian optimization, Monte-Carlo tress search and so on. In this talk, I would like to share some examples of where the data-driven approach has worked.

Multi-Variate Process Models for Predicting Site-Specific Microstructure and Properties of Inconel 706 Forgings Jennifer L. Carter[1], Nishan Senanayake[1] and Tiffany Dux[2]; [1]Case Western Reserve University, United States; [2]Howmet Forging, United States

The performance of superalloy forgings hinges on the careful design of the thermomechanical history to promote distributions of oft-dependent microstructural features. Establishing predictive process-structure-property (PSP) models to tailor manufacturing routes requires immense cost due to the time-consuming tasks of quantifying statistically significant observations of different predictors and performance metrics across multiple lengthscales [1]. Power analysis indicates that for a simple multivariate linear model of one performance metric, P, dependent on six input process predictors (k = 6) (i.e., P = f(k_1, k_2, …k_6)) with 80% predictive power would require over 120 observations; to predict n performance metrics (P_1, P_2, ...P_n), a statistical study protocol would require 120n observations (ANOVA would require 175n). Measuring a statistical number of observations of predictors and metrics is challenging at both ends of the lengthscale spectra. Nanoscale precipitates, like the distribution of the ��′ and ��″ precipitates in Inconel 706 have required transmission electron microscopy which does not readily lend itself to transition from qualitative analysis to statistical measures [3]. While conventional mechanical testing, on the other hand, requires relatively large volumes of material for a single observation. In both cases, these predictors and metrics are observed destructively resulting in development efforts that take many years to establish the database necessary for PSP models. Since PSP models benefit from an iterative design paradigm, this motivates the development of high-throughput measurements, both experimental approaches [4, 5] and physics-based predictions [6] if the dramatic design paradigm shift predicted by the Materials Genome Initiative.
In this paper, high-throughput measures of the precipitation distributions in Inconel 706 from experimental observations and physics-based simulations are used to reduce the necessary "physical" observation space necessary to predict PSP models. Heritage data from five years of development work conducted by Howmet Aerospace Forgings were used to demonstrate the method. DEFORM simulations of thermal history were used to supply time-temperature boundary conditions to CALPHAD simulations in ThermoCalc/PRISMA of the resulting ��′ and ��″ precipitate distributions at discrete locations within thermomechanically processed Inconel 706. Computer vision algorithms were developed to observe features in scanning electron micrographs. These features were used to tailor the CALPHAD interfacial energy and predict features from other processing conditions. In this manner, the number of physical observations of ��′ the ��″ distributions is reduced by 25x (100's to 4); and it relies on more readily available experimental and computational approaches allowing for industrial use with limited available technical resources. When combined within the heritage data frame, gradient

boost machine learning PSP models were trained following a 4:1 train-split procedure. The predictive power of many models was 80% or higher, estimated by ��^{2} value on the test data.

Modeling Antiphase Boundary Energies of Ni_3Al-Based Alloys Using Automated Density Functional Theory and Machine Learning Enze Chen[1,2], Artur Tamm[3], Tao Wang[4], Mario E. Epler[4], Mark Asta[1,2] and Timofey Frolov[5]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of Tartu, Estonia; [4]Carpenter Technology Corporation, United States; [5]Lawrence Livermore National Laboratory, United States

Ni-based superalloys are a superior class of structural materials used in aircraft turbines and power plants due to their excellent high-temperature strength, creep resistance, and corrosion resistance. Antiphase boundaries (APBs) are planar defects within the Ni_3Al precipitates that contribute to the strengthening of these superalloys, which motivates a better understanding for how chemical heterogeneity affects the APB energy. The APB energy varies with not only solute chemistry and concentration, but also sublattice site preference in the ordered ($L1_2$ structure) Ni_3Al precipitates. In order to systematically study these effects and optimize the APB energy in Ni_3Al intermetallics, we leverage high-throughput calculations to generate a large dataset of APB energies and we analyze what these data reveal about influential properties in superalloy design [1].

First, we use a thermodynamic model implemented in PyDII [2] combined with density functional theory (DFT) calculations to predict the site preference of alloying additions to Ni_3Al. We employ more high-throughput DFT calculations to calculate the APB energy for over 100 ternary Ni_3Al-based alloys and we generate a set of physically-motivated descriptors to build machine learning (ML) models for the APB energy from these data. The ML models not only give accurate predictions of the APB energy, but they also provide insight into the correlations between different descriptors and the APB energy, thus demonstrating how our automated, data-driven approach recovers known physics [1]. We discuss how this methodology allows us to intelligently screen for promising superalloy chemistries through validation with commercial superalloys that are far more compositionally complex than our training set.

The Effect of Antiphase Boundary Tubes on the Strengthening of FeAl and Ni_3Al Rachel D. Osmundsen and Ian Baker; Thayer School of Engineering at Dartmouth College, United States

Intermetallic alloys show a dramatic increase in their work hardening rate (WHR) when ordered. For example, $L1_2$-ordered Ni_3Fe has a ~50% greater WHR than f.c.c. disordered Ni_3Fe. Starting in 1962, antiphase boundary (APB) tubes, which are a defect unique to deformed ordered alloys, were theorized to explain this phenomenon. APB tubes have since been identified via transmission electron microscopy (TEM). Theories abound as to how ABP tubes increase the strengthening of intermetallics, but there is little experimental evidence in favor or against these theories. Understanding the structure-property relationship between APB tubes and strengthening is important as ordered alloys are common strengthening components in structural superalloys, e.g. Ni_3Al-type precipitates in Ni-based superalloys.

In this work, experiments performed on B2-ordered FeAl and $L1_2$-ordered Ni_3Al show that APB tubes do no impact the WHR of ordered intermetallics. Single crystals of B2-ordered FeAl were deformed and the microhardness was measured with APB tubes present and then after the APB tubes were annihilated (with no additional changes in the deformation microstructure). The hardness did not change, showing that APB tubes do not affect the strengthening of FeAl. In $L1_2$-ordered Ni_3Al, the exact annihilation temperature of APB tubes was not already known. So, single crystals of $L1_2$-ordered Ni_3Al were lightly deformed and observed in the TEM. *In-situ* TEM heating was performed to determine the APB tube annihilation temperature. The annihilation temperature was then compared to the existing literature on the mechanical properties of Ni_3Al and it was determined that APB tubes do not affect the strengthening of Ni_3Al. APB tubes may be more accurately viewed as evidence of the motion of the complex superdislocation interactions that are the source of the high WHR in intermetallics, rather than the source of the strengthening themselves.

Improving the High-Temperature Strength of $L1_2$-$Co_3(Al,W)$ by Ni and Ta Additions Zhenghao Chen, Kyosuke Kishida and Haruyuki Inui; Kyoto University, Japan

Microstructures of the ternary Co-Al-W system consist of two phases, an ordered $Co_3(Al,W)$ phase ($L1_2$ crystal structure, usually designated as the γ’ phase) and a face centered (fcc) Co-rich solid solution. There has been a significant research activity in the development of Co-based superalloys where $Co_3(Al,W)$ is the strengthening phase with an initial expectation that high-temperature mechanical properties of Co-based superalloys would outperform those of Ni-based alloy. This was related to the fact that precipitation of the γ’ phase in the γ matrix occurs coherently and forms cuboidal precipitates like in Ni-based superalloys with the advantage that both the melting temperature and the elastic stiffness are higher for Co than for Ni. However, in spite of the expectation, the high-temperature creep strength of Co-based superalloys which were so far developed are modest, only comparable to those of Ni-based superalloys of the first generation. A lower phase stability of γ’ phase, which causes a low high-temperature strength was suggested to be responsible for this disappointing find. In fact, the addition of elements that increase the γ’ phase stability ($L1_2$-stabilizer) is reported to improve the creep properties of the Co-based alloys. The γ’ high-temperature strength is also expected to be improved in these alloys but nothing is known at present about how a higher high-temperature strength of the γ’ phase is achieved by $L1_2$-stabilizer additions.
In the present study, we investigate the compression behavior of $L1_2$-compounds $Co_3(Al,W)$ with Ni and Ni+Ta additions, which are known as $L1_2$-stabilizers, in a temperature range from room temperature to 1000ºC, in order to elucidate the effects of stability of the $L1_2$ phase on the mechanical properties. Emphasis is placed on the deformation microstructures of these $L1_2$ compounds through detailed transmission electron microscopy (TEM) investigations, paying special attention to how the anomalous increase in yield stress (often referred to as ‘yield stress anomaly’ in $L1_2$ compound research)

occurs in these $L1_2$ compounds.
The result shows that the addition of Ni and Ta increases the high-temperature strength of the γ' phase. The strength increase is shown to be more significant as the amount of additions of these elements and thereby the stability of the $L1_2$ phase increases. The reduction of the onset temperature of yield stress anomaly (YSA-onset) due to the increased complex stacking fault (CSF) energy and the increased anti-phase boundary (APB) energy is considered to account for the strength increase at high temperatures. The increased strength of the $L1_2$ phase due to a higher phase stability thus partly accounts for the improved creep strength of Co-based superalloys upon alloying with Ni and Ta.

10:45 AM SF07.08.07
On the Origin of the Superior Mechanical Properties of the Equiatomic Cr-Co-Ni Medium-Entropy Alloy Le Li[1], Zhenghao Chen[1], Hisanori Tanimoto[2], Haruyuki Inui[1] and Kyosuke Kishida[1]; [1]Kyoto University, Japan; [2]University of Tsukuba, Japan

High- and medium-entropy alloys (HEAs/MEAs) have attracted extensive interest for their extraordinary and promising mechanical performance, such as excellent combination of strength and ductility that increase at cryogenic temperatures and exceptional fracture toughness. Systematic work has revealed that the equiatomic Cr-Co-Ni MEA exhibits remarkably higher strength and ductility than the Cr-Mn-Fe-Co-Ni and other subsets. The improved strengths have motivated intensive detailed research to explore their micro-scale origins via experimental approaches and theoretical calculations. These results have implied that the type and bonding of atoms, instead of number of elements, are more important for solid solution hardening in HEAs. The high strength is believed to be related to the severe and ubiquitous crystal lattice distortion, such as the mean-square atomic distortion (MSAD) model. The excellent tensile ductility of the Cr-Co-Ni MEA is generally attributed to the high propensity of deformation twinning resulting from its low stacking fault energy. Thin layers of the hexagonal close packed (HCP) structure are formed in association with deformation twins in the Cr-Co-Ni MEA. This indicates that not only TWIP (twinning induced plasticity) but also TRIP (transformation induced plasticity) are responsible for the excellent tensile ductility of the Cr-Co-Ni MEA as in the case of high-Mn steels. On the other hand, the local chemical inhomogeneity derived from preferred bonding between specific atoms, usually termed short-range ordering (SRO), is widely believed to be another reason for its peculiar properties. The effect of SRO on the atomic-scale structures have been investigated extensively in theoretical calculations. In experimental work, a few studies have indicated that the formation of SRO can act as additional obstacle to dislocation motion, while no measurable effect of SRO on strength are claimed in other studies. However, it is well known that in polycrystals grain size and boundaries induce scattered results of mechanical response. Therefore, single crystals are of prime important to investigate the critical resolved shear stress (CRSS), stacking fault energy (SFE) and twinning shear stress as well as the possible effects of SRO on these parameters. In the present study, we investigate the plastic deformation behavior of bulk single crystals of the equiatomic Cr-Co-Ni after various heat treatment, in order to experimentally deduce materials parameters (such as CRSS for slip, twinning shear stress as well as SFE) and the contribution of SRO in Cr-Co-Ni MEA. Single crystals of Cr-Co-Ni were grown from a polycrystalline rod with an optical floating-zone furnace. The single crystals were annealed at 1473 K for 168 hours as the beginning materials. Then, the specimens were further annealed at 573-1373 K for various duration to introduce SRO. Tensile and Compressive tests were conducted at room and liquid nitrogen temperatures. A careful tilting observation along various zones were conducted to get the diffraction information by transmission electron microscopy, and the results were compared with those obtained by theoretical simulation for atomic structures with various degrees of SRO. Synchrotron X-ray diffraction was also applied to characterize the atomic-scale structures.

11:00 AM SF07.08.08
Strain Rate Dependence of Flow Stress in Single-Crystal Micropillars of bcc FeCrNi Solid Solutions Tianqi Zhu[1], Naoki Takata[1], Makoto Kobashi[1] and Masataka Yoshino[2]; [1]Nagoya University, Japan; [2]JFE Steel Corporation, Japan

Multi-component alloys with a single-phase microstructure (generally known as medium/high entropy alloys) have recently emerged as a new class of alloys. In particular, body-centered cubic (bcc) solid solution alloys exhibit superior strength retention up to high temperatures but low toughness at ambient temperature. This issue is closely related to the ductility control of conventional ferritic stainless steels with FeCrNi solid solutions at various temperatures. To fundamentally understand the roles of solute elements in plastic deformation of multi-component bcc FeCrNi alloys, we investigated the strain rate dependence of flow stress in single-crystals of bcc Fe-Cr-Ni alloys with different solute Cr and Ni contents by micropillar compression tests in terms of thermal activation of dislocation motion.
Fe-Cr binary alloys (with 18% and 40% Cr) and Fe-18%Cr-Ni ternary alloys (with 1% or 2% Ni) were used in the present study. These alloy ingots were hot-rolled to approximately 4 mm thickness and solution-treated at 1300 °C for 1800 s, followed by water quenching. The solution-treated alloy samples exhibited fully recrystallized microstructures with the bcc single-phase. High-index orientations for the favorable activation of a single slip system were selected for the compression directions (corresponding to the crystallographic directions normal to the sample surface). We used a Focused Ion Beam (FIB) to fabricate cylindrical micropillar specimens with different diameters (d) of approximately 2 and 5 μm on the sample surface of the solution-treated alloys. We performed the micropillar compression tests at a wide range of initial strain rates ($\sim 10^{-5} s^{-1}$ to $\sim 10^{-2} s^{-1}$) using a load-controlled mode at ambient temperature. The measured values of flow curves were used to calculate the strain rate sensitivity (m). Afterward, the slip traces of the compressed micropillars were observed to identify the activated slip system. Transmission electron microscope (TEM) to evaluate the dislocation morphologies before and after the micropillar compression test.
In the Fe-18%Cr binary alloy, single-crystal micropillars with d = 2 μm exhibited a relatively high strain-rate sensitivity (m = 0.12) of stress required for the slip initiation. The m value became lower (0.04) in the large-sized micropillars with d = 5 μm. The m value was equivalent to one of pure iron. The added solute Ni element in bcc solid solutions reduced the m value in both specimen sizes. The Fe-18%Cr-2%Ni ternary alloy exhibited low m values below 0.01. All compressed micropillars showed the predominant activation of the [111] (12-3) single slip system. These results suggested the sluggish kinetics of kink-pair nucleation and motion of screw dislocations interacted with solute Ni atoms. The Fe-40%Cr binary alloy showed higher yield strength and much lower m values than the Fe-18%Cr alloy, regardless of the specimen size. The compressed micropillars of the Fe-40%Cr alloy micropillars exhibited the slip activation on multi-planes (from (110) to (11-2)). These results suggest the interaction of dislocations on multi-planes might be enhanced by high-concentrated Cr solute element in bcc solid solutions. The roles of solute Ni and Cr elements in the thermal activation process of dislocation motion will be discussed in terms of the activation volume of plastic deformation.

11:15 AM SF07.08.09
Microstructure, Mechanical Properties and Long-Term Stability of FeMnNiAlCr High Entropy Alloys for Concentrated Solar Power Systems Edwin S. Jiang and Ian Baker; Dartmouth College, United States

As one of the major approaches in harvesting and converting solar energy, concentrated solar power (CSP) offers advantages in cost-effective energy storage and the capability to provide electricity when the sun is absent. Following Carnot's theorem, the CSP systems prefer higher operation temperature for higher conversion efficiency. However, currently-employed tubing materials cannot work at temperatures exceeding 873 K due to mechanical, corrosion, and oxidation limitations. To solve this challenge, high entropy alloys (HEAs) are being considered due to their novel mechanical properties especially at high temperatures. In this study, we present microstructural characterization, tensile strength, and creep resistance of FeMnNiAlCr high entropy alloys, with different Mn content (x = 32.9 – 42 at. %) at temperatures of 873-1023 K. The effect of recrystallization, which is achieved by cold-rolling and annealing, on the microstructures and mechanical properties were also studied. Both as-cast and recrystallized alloys exhibit high strength, good creep resistance, and long-term stability at high temperature. *In-situ* deformation experiments were conducted in the transmission electron microscope to

examine the deformation mechanisms. The results suggest the potential of FeMnNiAlCr HEAs as a cost-effective candidate for CSP systems.

SESSION SF07.09: Structural Intermetallics VI

Design and Behavior or High Intermetallic Content Al-Ce Alloys Scott McCall[1], Hunter Henderson[1], Seungjin Nam[2], Ryan Ott[2] and Orlando Rios[3]; [1]Lawrence Livermore National Lab, United States; [2]Ames Laboratory, United States; [3]The University of Tennessee, Knoxville, United States

The thermodynamic and kinetic features of the Al-Ce alloy system enable the intermetallic volume fraction of intermetallic particles to be increased significantly, while remaining processable by conventional and advanced manufacturing processes. Here, we present recent work to establish Al-Ce alloys for casting, wrought, and additively manufactured alloys that leverage high intermetallic fraction for enhanced properties. Thermodynamic features are combined with thermophysical and structural properties to fashion alloys with property sets tailored to intended applications. Furthermore additional alloying elements can induce complex changes in phase distribution and strength, both of which are also a function of solidification rate. Promising Al-Ce-X-Y and sometimes -Z candidates for particular applications will also be discussed.

Phase Stability of A_2B-Type GCP Compound in Ni-Cr-Mo System Alloys at Elevated Temperatures Ryota Nagashima, Hirotoyo Nakashima and Masao Takeyama; Tokyo Institute of Technology, Japan

Most of the geometrically close-packed (GCP) compounds are A_3B type, whereas a very few A_2B type GCP compound exists. The Ni_2Cr (*oP*6) is one of them. According to the Ni-Cr phase diagram, this phase is a Kurnakov-type compound and is stable up to 867 K. Recently, our systematic phase diagram study on Ni-Cr-Mo ternary system experimentally reveals that a single-phase region of $Ni_2(Cr, Mo)$ with *oP*6 crystal structure exists as an island with compositions around Ni-15Cr-15Mo (at.%), up to about 1073 K, approximately 200 K higher than the binary Ni_2Cr compound. The reason why Mo in solution in Ni_2Cr phase stabilizes the phase is bonding energy between Cr and Mo in Cr site should be negative, because thermodynamical calculation shows that modifying ternary-interaction parameter $L_{Cr,Mo:Ni}$ to negative is the most strongly contributes to reproduce the experimental phase diagram in other thermodynamical parameters, *e.g.* end-members and interaction parameters among binary and ternary elements. This result is very attractive from both fundamental and engineering viewpoints. The Ni_2Cr phase could be an alternative strengthener to Ni_3Al-γ' phase in Ni-based alloys, if we can further increase the phase stability. In this study, then, in order to verify the mechanism of the increase in phase stability of Ni_2Cr compound by Mo addition, effect of 5th and 6th group elements on the phase equilibria at elevated temperatures were systematically examined. Thermodynamic calculations to evaluate the phase stability of this phase is also conducted, by taking the interaction parameters among the three elements into account. Two series of alloys were prepared: series I with nominal compositions of Ni-15Cr-15(Mo, M) (at.%) by replacing Mo with M by every 5 at.% and series II with those of Ni-15Cr-15Mo-5M by addition of 5at.%M to Ni-15Cr-15Mo. These alloys were prepared by arc melting in argon atmosphere with non-consumable tungsten electrode as 35 g button ingots. These ingots were firstly cold rolled by 40% in height, and solution treated at 1473 K for 24 h, followed by a water quench, in order to eliminate the micro segregation. Then, they were equilibrated at 1173-973 K for up to 1000 h. It was found that, in any alloys containing M, the observed $Ni_2(Cr, Mo)$ single phase region in the ternary system was reduced, even in the case of V where Ni_2V is also the A_2B type GCP compound with the *oP*6 structures. Instead, the stable A_3B-type GCP phases of Ni_3V-γ'' ($D0_{22}$), Ni_3Nb-δ ($D0_a$) and Ni_3Ta-δ ($D0_a$) appears in the quaternary systems, indicating that the M elements apparently destabilize the *oP*6 phase with respect to the A_3B-type GCP phases. The A_2B type GCP phase has B-B bonding unlike A_3B type, so the total bonding energy should always be smaller for A_2B than A_3B ($\Omega_{A\text{-}B} < 0$). The thermodynamically stable existence of the $Ni_2(Cr, Mo)$ phase, despite the thermodynamic existence of the Ni_3Mo-δ phase in the binary system, must be caused by not only the interaction among ternary elements but also size effects. Based on these results, together with the thermodynamic calculations on the observed A_2B and A_3B type GCP phases, elements which do not form A_3B type GCP phase would possibly be effective in increasing the stability of Ni_2Cr. The size effect as well as atomic scale considerations on the difference in phase stability between A_3B and A_2B type GCP phases will also be touched in detail. A part of this research was supported by JST-Mirai Program Grant Number JPMJMI21E7, Japan.

2:15 PM SF07.09.03
Direct Observation of Zonal Dislocations in σ-FeCr by Atomic-Resolution Scanning Transmission Electron Microscopy Kyosuke Kishida, Masaomi Okutani, Hirotaka Suzuki and Haruyuki Inui; Kyoto University, Japan

Dislocations are the lattice defects that are mainly responsible for plastic deformation of crystalline materials through their glide motion. The glide motion of dislocations on a slip system generally takes place on a crystallographic plane between two adjacent atomic layers in the case of most metallic materials with relatively simple crystal structures such as face-centered cubic (FCC) and body-centered cubic (BCC) metals. However, the dislocation glide process in materials with complex crystal structures has not been fully clarified yet, because it can be very complicated often involving multiple atomic planes during dislocation glide. One of the dislocation glide models predicted to operate in complex materials is the zonal dislocation model, in which non-uniform atom shuffling is predicted to occur in multiple atomic planes called shear zone. The zonal dislocation model was introduced by M.L. Kronberg to describe possible glide motion of dislocations of the {110}<001> slip in β-U with the tetragonal Ab structure (identical to $D8_b$ structure of σ-FeCr). However, it has never been experimentally verified to occur. This is because β-U is one of the typical radioisotopes, which prevents from further detailed experimental study of its dislocations. Another reason is that the brittleness of the sigma-phase arising from the complex crystal structure has made impossible for plastic flow to occur by dislocation glide. Recently, we have systematically investigated fundamental deformation behavior of hard and brittle materials by utilizing micropillar compression method and have successfully identified the activation of {110}<001> slip in σ-FeCr at room temperature. In the present study, we investigated dislocation core structures of {110}<001> slip in σ-FeCr by atomic-resolution scanning transmission electron microscopy and confirmed that <001> dislocations glide on {110} are of the zonal-type but the thickness of the shear zone was different from that predicted by Kronberg. New atomic shuffling model in the shear zone was proposed based on the experimentally observed dislocation core structure.

2:30 PM SF07.09.04
Strengthening by Controlled Al_6Fe Intermetallic Phase in Al-Fe Based Alloys Additive-Manufactured by Laser Powder Bed Fusion Naoki Takata[1], Wenyuan Wang[1], Takanobu Miyawaki[1], Yue Cheng[1], Asuka Suzuki[1], Makoto Kobashi[1] and Masaki Kato[2]; [1]Nagoya University, Japan; [2]Aichi Center for

Industry and Science Technology, Japan

In recent, laser powder bed fusion (L-PBF) has emerged as one of the most representative metal additive manufacturing techniques capable of producing metallic components by using a scanning laser beam to selectively melt consecutive bedded-powder layers. The L-PBF process enables not only the manufacturing of complex geometrical forms but also the fabrication of Al alloys with superior mechanical properties. The L-PBF manufactured Al–2.5Fe (mass%) binary alloy exhibits a high tensile strength of approximately 300 MPa due to the fine morphology of Al_6Fe metastable phase (orthorhombic, *oC*24). The strength level slightly decreases after long-term exposure at elevated temperatures, indicating the feasibility of employing lightweight heat-resistant materials. However, increasing Fe alloy content significantly reduces L-PBF processability due to the formation of coarsened $Al_{13}Fe_4$ stable phase. It is therefore required to stabilize the fine Al_6Fe phase by third alloy elements for further strengthening without a loss of L-PBF processability for Al–Fe alloys. The present study was undertaken to investigate the effect of selected third elements (Mn or Cu) on the microstructure and mechanical properties of the Al–Fe binary alloy additive manufactured by the L-PBF process.
In this study, attempts of L-PBF processing using the gas-atomized Al–2.5Fe–2Mn or Al–2.5Fe–2Cu (mass%) ternary alloy powder with an average particle size of about 20 mm were made. Rectangular alloy samples were fabricated using a metal AM ProX DMP 200 machine (3D Systems, USA) under a wide range of laser scan speed (0.6 ~ 1.4 m/s) and laser power (102 ~ 204 W). The applied laser-scanning hatch distance, powder-bed thickness, and beam focus size were 0.1 mm, 0.03 mm, and ~0.1 mm, respectively. The results of measuring the sample density provided the optimum laser parameter sets for the manufacturing of both alloy samples with high relative densities above 99 %, indicating high L-PBF processability for the Mn or Cu added Al–Fe alloy powders. The L-PBF manufactured samples exhibited microstructure consisting of a number of melt pools in which regions locally melted and rapidly solidified due to scanning laser irradiation. The added Mn element was partitioned into the refined Al_6Fe phase, resulting in the formation of $Al_6(Fe, Mn)$ phase with an orthorhombic structure (*oC*24). A certain amount of solute Mn (approximately 0.8 mass%) was detected in the a-Al matrix. Numerous nanoscale particles of $Al_6(Fe, Mn)$ phase were homogeneously dispersed in the α-Al matrix, whereas relatively coarsened $Al_6(Fe, Mn)$ phases with a cellular morphology appeared localized along melt-pool boundaries. Similar microstructures containing the $Al_{23}CuFe_4$ phase (orthorhombic, *oC*24) were observed in the L-PBF processed Al–2.5Fe–2Cu alloy samples. These results indicate the added third element could stabilize the refined Al_6Fe phase formed in rapid solidification by the L-PBF process. The L-PBF processed Al–2.5Fe–2Mn and Al–2.5Fe–2Cu alloys exhibited higher strength of approximately 360 MPa than the Al–2.5Fe binary alloy and an adequate tensile ductility of approximately 10 % in total elongation at ambient temperature. The high-temperature strength of the L-PBF manufactured ternary alloys will be presented.

Effect of Product Shape on Microstructure and Mechanical Properties of Ti-48Al-2Cr-2Nb Alloys Fabricated by Additive Manufacturing
Hiroyuki Y. Yasuda[1], Ken Cho[1], Hajime Kawabata[1], Masao Takeyama[2] and Takayoshi Nakano[1]; [1]Osaka University, Japan; [2]Tokyo Institute of Technology, Japan

Additive manufacturing is one of highly efficient processes to fabricate TiAl low pressure turbine blade. In the present study, large triangular prisms and small cylindrical rods of Ti-48Al-2Cr-2Nb alloys were prepared by electron beam powder bed fusion (EB-PBF) to examine the effect of product shape on the microstructure and mechanical properties. The microstructure after EB-PBF depends on the process parameter such as beam current and scanning speed. Under an optimum condition, peculiar banded structure composed of duplex-like structure and equiaxed γ grains (γ band). Such microstructure is homogeneously formed in cylindrical rods 10 mm in diameter. On the other hand, in the case of the triangular prisms, the microstructure vary from area to area. In the thick area, the banded structure is formed, while typical lamellar structure composed of the α_2 and γ phases can be seen in the thin area. It is also noted that hardness distribution was also inhomogenous depending on the microstructure. In EB-PBF process, an electron beam moves showing a snake pattern. In the thin area, the beam moves forth and back quickly, resulting in an increase in temperature. This leads to the formation of the lamellar structure. In order to get homogeneous microstructure throughout the triangular prisms, the process parameter is changed from area to area. As a result, homogeneous microstructure consisting of the banded structure was formed and the hardness distribution of the triangular prisms also became homogeneous.

8:15 AM SF07.10.02
Relationship Between Microstructure and Mechanical Properties of β-Containing TiAl Alloys Fabricated By Additive Manufacturing
Ken Cho[1], Hirotaka Odo[1], Hiroyuki Y. Yasuda[1], Hirotoyo Nakashima[2], Masao Takeyama[2] and Takayoshi Nakano[1]; [1]Osaka University, Japan; [2]Tokyo Institute of Technology, Japan

In recent years, TiAl alloys containing the β phase are expected to expand the application scope of the alloys due to their superior mechanical properties at high temperatures. Electron beam powder bed fusion (EB-PBF) that is one of the additive manufacturing processes for metallic materials has attracted much attention as a fabrication process of TiAl alloy parts for aerospace applications with complex geometries. Furthermore, it is possible to obtain unique microstructures by repeated and rapid fusion and solidification during the EB-PBF process, resulting in excellent mechanical properties. In the present study, relationships between microstructure and mechanical properties of β-containing TiAl alloys prepared by the EB-PBF process were investigated focusing on the influence of the input energy density. Specimens fabricated at low energy densities contain ultrafine lamellar structure composed of the α_2 and γ phases, together with the β/γ cells discontinuously precipitated at the lamellar grain boundary. The ultrafine lamellar grains and the β/γ cells are effective in increasing strength and ductility of the alloys, respectively. In addition, we developed new heat treatment processes to control the morphology of the microstructure. The alloys subjected to optimum heat treatments exhibit higher strength and larger ductility at 1023 K, compared with the cast alloys.

Modeling Titanium Aluminide Based Alloys from Atomic to Lamellar Scales
Sridhar Narayanaswamy, Mark Jhon, Jerry Quek, Balaji Selvarajou, Guo Tianfu and Wang Zhao; IHPC, Singapore

Titanium aluminide-based alloys have found use in the aerospace industry in applications such as low pressure turbine blades due to their light weight and

high temperature properties. It is necessary to develop a deep understanding of the structure-property correlations of these materials in order to understand how to engineer their mechanical properties. To this end, we have used models at multiple length scales to explore the relationship between temperature, microstructure, and mechanical properties. At the atomic scale, we performed a critical evaluation of existing empirical potentials and found that potentials based on the Embedded Atom Method and the Modified Embedded Atom method were capable of replicating most (but not all) mechanical properties as compared to DFT and experiment. For example, all existing models tend to overestimate the thermal expansion coefficients in the α2-Ti3Al structure. At the lamellar structure, we developed a crystal plasticity model that explicitly accounts for the alternating lamellae of γ-TiAl and α2-Ti3Al. By phenomenologically including experimentally observed trends such as the temperature-dependent yield stress anomaly and deviations from Hall-Petch behavior, we were able to establish relationships between orientation dependent deformation, structural length scales such as lamellae thickness, and stress state.

8:45 AM SF07.10.05
Kink-Band formation in Various Mille-Feuille Structured Mg- and Al-Based Materials Koji Hagihara, Toko Tokunaga and Shuhei Ohsawa; Nagoya Institute of Technology, Japan

Mg-based LPSO phase is known to contribute to increase in both of strength and ductility of Mg alloys. As a deformation mode in it, kink-band formation is recently focused. A kink band is a deformation band formed by the explosive generation of dislocations in a localized region and their subsequent alignment along a direction normal to the slip plane. However, details of its formation criteria have not yet been clarified. According to the study on the LPSO phase, its unique crystal structure which is constructed by the alternative stacking of soft and hard layers, called mille-feuille structure, are supposed as plausible factors to govern the formation of deformation kink bands.
To confirm these assumptions, we have examined the deformation behavior of several directionally solidified Mg-based and Al-based two-phase eutectic alloys with lamellar microstructure as a model material, such as $Mg/Mg_{17}Al_{12}$, Mg/Mg_2Yb and Al/Al_2Cu. Consequently, the formation of kink-bands was confirmed in all the alloys, as expected. The details of the deformation microstructure and accompanying deformation behavior will be discussed in the presentation.

9:00 AM SF07.10.06
Precipitation from Microscopic Segregation in Ni-Based Superalloy Additively Manufactured by Powder Bed Fusion—A Phase-Field Study Yuichiro Koizumi, Masayuki Okugawa, Makoto Wakabayashi, Kazufumi Nose and Sei Hirooka; Osaka University, Japan

Powder bed fusion (PBF) is a category of additive manufacturing (AM) applied to the fabrication of metal parts with various materials, including superalloys. Solidification by PBF is characterized by a high cooling rate of around 1 million K/s. Recent studies have revealed the very fine submicron-sized celluller structures associated with solute segregations between the cells in Ni-based superalloys fabricated by the PBF process. Such segregation is expected to affect the precipitation of the γ'- phase. In this study, we utilized phase-field simulation to investigate the precipitation of γ'-phase from the solute segregation formed by rapid solidification in PBF. The multiphase-field method was applied to the simulation of microstructural evolution in directional solidification under various solidification conditions focusing on solute segregation. A composition consisting of five major elements of Inconel738LC alloy was selected as the model. Initially, cellular structure with intercellular micro-segregation was generated by simulating directional solidification under a condition with a cooling rate of 10^6 K/s, solidification rate of 10^{-1} m/s, and temperature gradient of 10^7 K/m, which is a typical solidification condition in PBF process. γ' forming elements, (i.e. Al and Ti) segregated at the intercellular region. The growth of γ' precipitates and the relaxation of the segregation occurred simultaneously, and there was no significant influence of the segregation on the precipitates in the subsequent aging at relatively high temperature. In contrast, the precipitation occurred preferentially at the intercellular segregation in the case of aging at relatively low temperature. This work was supported by Council for Science, Technology and Innovation, Cross-ministerial Strategic Innovation Promotion Program, "Materials Integration for revolutionary design system of structural materials" (Funding agency: JST) .

Transitions Among Stress-Induced Martensitic Phases in Ti-10V-2Fe-3Al During Continuous Deformation Abhishek Rastogi and Suresh Neelakantan; Indian Institute of Technology Delhi, India

Revealing the possibility of transition among stress-induced martensitic phase during continuous cold deformation in metastable β titanium alloy, Ti-10V-2Fe-3Al (Ti-1023) is the main objective of this study. In general, martensitic transformations induced either by quenching or load application have a significant influence on the mechanical properties of metastable β-Ti alloys. It is known that martensitic transformation in metastable β-Ti is highly dependent on the alloy content and deformation. With the increase in β stabilizing elements, HCP-α' martensite transforms to orthorhombic-α'' martensite upon quenching from a single β phase. However, deformation-dependent martensitic transformation involves the role of lattice strain and atomic shuffle. β to α'' and β to α' transformation differ in terms of atomic shuffle displacement, wherein the former requires less displacement than the latter [4]. Therefore, β to α'' transformation can be considered crystallographically incomplete as compared to β to α' transformation. At sufficiently high strain, it can be assumed that the formation of the α'' is exhausted, and other stress-induced deformation mechanism may also activate, resulting in the possibility of α'' to α' transformation. In the present investigation, Ti-1023 alloy was solution treated in the single β phase-field followed by water quenched. Solution-treated samples were unidirectionally cold rolled to 5%, 15%, 25%, 35% and 43% thickness reduction levels. The resulting microstructures are extensively analyzed by XRD and TEM analysis. XRD and TEM confirm the transformation of β to α'' to α'. Lattice parameters ratios, as well as volumetric strain (%) calculations, provide indications about the transitions of α'' to α'. Furthermore, the TEM results confirm the dominant presence of α'' martensites at low cold rolling percentage compared to α' martensites observed at high cold rolling percentage. It has been observed that the driving force for martensitic transformation is the combined effect of lattice strain induced by cold rolling and the different alloying elements influencing the atomic shuffle displacements. A correlation of the lattice strain and alloying elements with atomic shuffle displacements on the transformation of β to α'' to α' in Ti-1023 has been established.

Phase-Field Simulation of Antiphase Domain Growth for $D0_3$ Ordered Fe_3Al Alloy Yuheng Liu, Madoka Watanabe, Masayuki Okugawa, Tsubasa Sato and Yuichiro Koizumi; Osaka University, Japan

[Introduction] The mechanical or magnetic properties of the ordered phases are closely related to the antiphase domain (APD) structures, such as the APD size and the characteristics of antiphase domain boundaries (APBs). For example, it has been reported that pseudoelasticity is caused in Fe_3Al by the interaction between APBs and dislocations [1]. Phase-field (PF) simulation has been proved to be an effective way of studying the formation and time-evolution of APD for ordered phases. Koizumi et al. [2] studied the ordering mobility in nearly stoichiometric Fe_3Al at constant temperatures by the PF method. The objective of this study is to develop PF simulations applicable to temperature variations for the APD growth in $D0_3$ ordered Fe_3Al alloy, aiming at the optimization of aging conditions for ordering in the future.
[Methods] PF simulations of ordering in Fe-28at.%Al alloy were performed for the cases of constant cooling rate and isothermal aging. The dimension of the simulation domain area was a cube with a size of 30 nm. Thermodynamic equilibrium at 873 K was assumed as the initial state for all simulations. The evolution of $D0_3$ APD during cooling to 673 K at rates of 0.1~1000 K/s and that during aging at constant temperatures of 673 K, 723 K, and 773 K for 1 h after cooling at 100 K/s were examined and compared with experimental results.
[Results] The simulation results for the case of constant cooling rate showed that the growth of the $D0_3$ APD takes place before the detectable long-range order (LRO) appears. Moreover, slower cooling rates resulted in larger APD sizes. On the other hand, although the ultimate LRO obtained by isothermal aging at a lower temperature is higher than that at a higher temperature, $D0_3$-LRO exhibited a significant increase earlier in aging at higher temperatures. Besides, the growth of $D0_3$ APD also begins earlier when aging at higher temperatures, which is due to the larger ordering mobility at the higher temperature. In conclusion, isothermal aging at higher temperatures after cooling at a higher rate is considered suitable for the fast growth of $D0_3$ APD in the Fe_3Al.

Observation of Multiple Weyl Points in SmAlGe Compound Parul Jain[1,2]; [1]Indian Institute of Technology Delhi, India; [2]G C Faridabad, India

Topological semimetals with multiple topological phases have gained renewed interest from the materials research community as new materials started to appear with tunable or concurrent quasiparticle excitations of different types.
Here, in this work, using Density Functional Theory (DFT) we studied a new topological semimetal SmAlGe, which has similar lattice structure to LaPtSi, a newly identified candidate [1] with multiple topological phases. The magnetic properties emerging from the *4f* elections of Samarium in SmAlGe grant further scope to tune the topological states magnetically. First, we find that the material SmAlGe is thermodynamically more stable in the antiferromagnetic phase. All the further calculations are done on this ground state antiferromagnetic phase. Second, we analyse and report the splitting of *4f*-orbital in the 12-fold coordination of Sm in presence of spin-orbit coupling. Finally, we study the topological properties of the material. Band-structure shown in the figure 1(b) reveals multiple Lorentz symmetry violating (Type-II) Weyl nodes very close to the fermi energy. Further, we studied the exotic surface states using a Wannier-based tight-binding Hamiltonian.

Resilience in Lightweight Ceramic Architected Materials Enabled by Curvature and Geometry Carlos M. Portela and Somayajulu Dhulipala; Massachusetts Institute of Technology, United States

The field of architected materials has enabled engineered materials with mechanical properties that were previously thought unattainable. For instance, hollow truss-based lattices demonstrate high stiffness- and strength-to-weight ratios but these structures suffer from a bending-dominated response and stress concentrations at the sharp joints, the latter of which result in failure. Such stress concentrations become particularly challenging when working with nominally brittle materials, such as ceramics. As an alternative, aperiodic and asymmetric morphologies attained through spinodal decomposition (spinodal metamaterials) may provide a route to combat these stress concentrations due to their finite (low) curvature and bicontinuous morphologies. Such morphologies could provide a pathway to engineer ceramic materials with unique combinations of properties such as low density, high stiffness, and extreme mechanical resilience.

In this study, we explore the effect of curvature and geometric anisotropy on the stiffness, strength and toughness of spinodal metamaterials. The spinodal morphologies are generated using a computational spinodal decomposition framework where tunable anisotropy is introduced by energetically penalizing preferential directions for interface formation, resulting in a mean-curvature and Gaussian-curvature distribution that is dependent on the direction of the surface normal. Using a two-photon lithography process, we fabricate prototypes of these anisotropic spinodal morphologies possessing nanoscale ceramic coatings and spatially varying curvature distributions and perform in-situ nanomechanical uniaxial compression experiments to determine their curvature-dependent stiffness, strength, and toughness. Complemented by analytical and finite element models of the as-fabricated morphologies, we demonstrate a relation between curvature distributions, the stress distribution, and the mechanical properties of these metamaterials. Our findings present the potential of architected spinodal metamaterials as a route to create new ceramic-based materials with widely tunable properties.

Exploring Process-Microstructure-Property Relationships in Inorganic Materials—From Advanced Manufacturing to Mechanical Characterizations Jun Lou; Rice University, United States

Fabricating inorganic materials with designed three-dimensional nanostructures is an exciting yet challenging area of research and industrial application. We recently developed an approach to 3D print high quality nanostructures of silica with sub-200 nm resolution and with flexible capability of rare earth element doping [1]. The printed SiO_2 can be either amorphous glass or polycrystalline cristobalite controlled by the sintering process. The 3D printed nanostructures demonstrate attractive optical properties. For instance, the fabricated microtoroid optical resonators can reach quality factors (Q) over 10^4. Moreover, importantly for optical applications, doping and co-doping of rare earth salts such as Er^{3+}, Tm^{3+}, Yb^{3+}, Eu^{3+} and Nd^{3+} can be directly implemented in the printed SiO_2 structures, showing strong photoluminescence at the desired wavelengths. Additionally, mechanical properties of the 3D printed silica and its composite nanostructures have been carefully studied.
On the other hand, nanomaterials such as carbon nanotubes, hexagonal boron nitride (h-BN) and graphene platelets, are promising candidates for reinforcing ceramic matrix composites. To quantitatively study the toughening behavior in two-dimensional (2D) material reinforced ceramics, pull-out experiments were conducted to investigate the properties of the interface between multi-layer h-BN nanosheet and polymer-derived ceramic (PDC) using nanoindentation-assisted micro-mechanical devices integrated with scanning electron microscopy (SEM) [2]. The failure process was monitored *in situ* with precise quantitative measurements of the relative displacements across the interface that were obtained with digital image correlation (DIC). A micromechanical analysis shows that the interfacial failure in these materials is governed by the interfacial strength at small length scales, rather than the interfacial fracture energy.

11:30 AM *SF08.01.03
Multiscale Mechanics of Bioinspired Material Intelligence Markus J. Buehler; Massachusetts Institute of Technology, United States

Digital biomaterials are designed through an integrated approach of large-scale computational modeling, material informatics, and artificial intelligence/machine learning to optimize and leverage novel smart material manufacturing for advanced mechanical properties. In this talk we show how we use mechanics to fabricate innovative materials from the molecular scale upwards, with tailored mechanical properties, while sourced from sustainable resources, and breaking the barriers between living and non-living systems. Applied specifically to protein-based materials, this integrated materiomic approach is revolutionizing the way we design and use materials, and has the potential to impact many industries, as we harness data-driven modeling and manufacturing across domains and applications. The talk will cover several case studies focused on the discovery of unifying mechanical principles covering distinct scales and modalities, from spider webs and silk, to collagen, to biomineralized materials, as well as applications to food and agriculture, showing we mechanics can be applied to uncover universal scaling laws that govern mechanical behavior. We further discuss manufacturing methods that enable us to synthesize computationally designed architectures with high precision, spanning multiple scales from the nano to the macro level.

SESSION SF08.02: Advanced Ceramics and Glasses II

Embedded Printing in Ceramics Eduardo Saiz[1], Shitong Zhou[1], Iuliia Elizarova[1], Florian Bouville[1], Philip Withers[2] and Xun Zhang[2]; [1]Imperial College London, United Kingdom; [2]The University of Manchester, United Kingdom

Ceramics exhibit a range of unique properties that make them the ideal candidates for many applications, particularly those involving demanding environments. However, these same properties, such as the high hardness, that make ceramics so interesting also make their shaping challenging. In addition, many high-end applications demand the integration of ceramics in multicomponent composites and devices with a sophisticated degree of structural control. Additive manufacturing is opening new opportunities to address these needs but presents its own set of challenges. In this presentation we introduce embedded printing as an alternative to introduce structures in dense ceramic bodies. This is achieved by printing in a self-healing ceramic gel

that enables the printing in its interior followed by subsequent healing to form a dense, defect-free ceramic that encapsulates the printed structure. We will discuss the necessary matching of the properties of the viscoelastic response of gel and ink in order to print structures inside the ceramic that retain their shape and illustrate the technique with a couple of case studies. One is the printing of sacrificial structures to introduce complex microchannel arrangements in a ceramic body. The other is to embed metallic structures designed to enhance fracture resistance by orders of magnitude.

2:00 PM SF08.02.02
Addressing Nanoscale Heterogeneity in Compositionally Complex Ceramic Oxides Katharine Page[1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States

The recent emergence of multicomponent, high-entropy oxides (HEOs) has sparked research into novel ceramics with significant compositional and structural diversity. The wide range of achievable materials presents promising research opportunities, as they may be custom-designed to enhance performance in any of a number of important applications, such as thermal barrier coatings and solid oxide fuel cells. In these arenas and in many others, the extent to which high entropic lattice disorder versus specific chemical short-range order, nanoscale phase segregation, and intrinsic defect/disorder states are achievable remains an open research question. We present detailed investigation of the defects, local atomic order, microstructure, and thermomechanical properties achieved in a family of rare-earth and transition metal-based pyrochlore and fluorite HEOs prepared through compositional tuning and variation in synthesis/processing conditions. A combination of local to long-range electron, X-ray and neutron scattering probes are employed to investigate the complex configurational diversity and associated structure-property trends in the series. Experimentally derived models are supported by Density Functional Theory calculations and Metropolis Monte Carlo simulations. We demonstrate that nanostructured oxides produced through polymeric steric entrapment and other low temperature reaction routes are promising precursors for the synthesis of compositionally complex pyrochlore/fluorite ceramics with specific nanoscale ordering motifs. We also discuss the exquisite level of experimental characterization and theoretical modeling that may be required to understand the phase stability, atomic structure, and respective properties of emerging HEO materials classes, highlighting some remaining challenges.

2:15 PM SF08.02.03
3D Printed Silica with Nanoscale Resolution Boyu Zhang[1], Xiewen Wen[1], Weipeng Wang[1], Hua Guo[1], Guanhui Gao[1], Qiyi Fang[1], Christine Nguyen[1], Xiang Zhang[1], Jiming Bao[2], Jacob T. Robinson[1], Pulickel Ajayan[1] and Jun Lou[1]; [1]Rice University, United States; [2]University of Houston, United States

SiO_2 (silica) is one of the most widely used inorganic materials that demands fabrication methods with nanoscale resolution. Fabricating silica with designed three-dimensional nanostructures is an exciting yet challenging area of research and industrial application. The emerging technology of additive manufacturing (AM) can create fine structures through layer-by-layer deposition to generate complex architectures and simplify fabrication processes. AM of fused silica glass was realized via stereolithography with the resolution of tens of microns. However, the relatively low spatial resolution limits their applications in micro-electronics, MEMS, and micro-photonics. To address the limitation, we propose an approach to 3D print silica nanostructures with sub-200 nm resolution via two-photon polymerization. The technique involves 2PP enabled AM of functionalized colloidal silica nanocomposite ink, followed by pyrolysis and sintering, where the post-processing procedure determines the crystallinity of the structures produced, which can be either amorphous glass or polycrystalline cristobalite. In this technique, making a suitable “ink” containing silica nanoparticles (NPs) and two-photon polymerizable precursor is the dominating factor. The nanocomposite ink has low viscosity, high transparency, and high heat conductivity. The 3D printed nanostructures demonstrate attractive optical properties. The fabricated microtoroid optical resonators can reach quality factors (Q) over 10^4. Moreover, doping and co-doping of rare earth salts such as Er^{3+}, Tm^{3+}, Yb^{3+}, Eu^{3+} and Nd^{3+} can be directly implemented in the printed SiO_2 structures, showing strong photoluminescence at the desired wavelengths. Especially for Er^{3+}, the final printed structures exhibit photoluminescence around 1.55 μm, making the proposed technology a powerful tool for optical telecommunication applications. It is also envisioned that arbitrary 3D structure of crystalline silicon can be fabricated by magnesium reduction of printed crystalline silica, making the dream of 3D printing silicon chips a reality.

Using a Convolutional Neural Network to Identify the Microstructural Features that Lead to Anisomorphic Grain Growth Amanda Krause; Carnegie Mellon University, United States

Grain growth, a common mechanism in ceramic processing, is difficult to predict because it is influenced by many factors, including porosity, raw powder size and shape, impurities and sintering conditions. To parse out these effects, grain growth studies commonly rely on qualitative comparisons of micrographs because of inadequate physical descriptors of grain size and shape. However, new data techniques can extract high order parameters that better describe microstructural features. In this study, we establish whether a convolutional neural network (CNN) can distinguish two initial microstructures of calcia-doped alumina, which appear similar by traditional grain growth metrics but then evolve differently during grain growth. If a unique signature can be extracted, it can provide mechanistic-insight into grain boundary motion for improved grain growth predictions.
The goal here is to collect a signature that distinguishes two alumina microstructures prepared with the same raw materials, slip casting process, and sintering conditions. However, one sample is slip cast in a magnetic field, which causes the equiaxed particles to rotate and preferentially align the c-axis of their unit cell, resulting in a bulk crystallographic texture. Recent studies show that the textured microstructure evolves differently from the untextured sample, resulting in a larger grain size and unique grain morphology. Here, we will evaluate the developed CNN used to identify these microstructures. Briefly, the CNN is trained from at least five micrographs with ~200 grains each from each timestep. The CNN consists of two convolutional layers with an increasing number of filters to learn increasingly abstract features.
The convolutional layers are followed by three fully connected layers with a decreasing number of nodes. The signature is extracted as a scalar quantity from the penultimate layer in the network. We will discuss the accuracy of the CNN to predict the microstructure’s processing path and its implications regarding how crystallographic orientation influences grain growth. Furthermore, we will demonstrate the need for a new higher order physical descriptor of microstructures.

3:30 PM SF08.02.06
Machine-Learned Quantification of Local Structure and Its Effects in Fracture of Silica Glass and Deformation of Metallic Glass Thomas J. Hardin and Mark Wilson; Sandia National Laboratories, United States

The variety of local atomic environments found in a glass far exceeds that found in a crystalline material. This makes the task of linking physically important phenomena (e.g. crack nucleation or shear transformation) to local structural risk factors particularly challenging in glassy materials. We present case studies in two simulated materials (silica glass and a binary metallic glass) using unsupervised machine learning techniques (the Gaussian Integral Inner Product Distance with agglomerative clustering and diffusion maps) to extract local structural features, and supervised machine learning to link those features to mechanical behavior. We pinpoint preexisting defects in the as-quenched state as risk factors leading to fracture nucleation in silica, and show how detailed quantification of structural evolution in a metallic glass shear band points the way to improved stateful plastic models. We also consider the

comparative merits of human-designed versus machine-learned structural descriptors for glass and look forward to ways to use them synergistically. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525 (SAND2022-8095 A).

3:45 PM SF08.02.07
Machine Learning Approaches for the Automatic Design of Micro-Architected Triply Periodic Minimal Surface Scaffolds for Bone Tissue Engineering Pasquale Vena[1], Luca D'Andrea[1], Silvia Ibrahimi[1] and Massimo W. Rivolta[2]; [1]Politecnico di Milano, Italy; [2]Università degli Studi di Milano, Italy

Due to their peculiar architecture, Triply Periodic Minimal Surfaces (TPMS) find applications in many engineering domains. The increasing capability of additive manufacturing (AM) technologies allows the printing of microstructured materials with unparalleled spatial resolution and repeatability. This makes the design of TPMS-based material systems and device a feasible approach. Application of TPMS structure in Bone Tissue Engineering scaffolds design is particularly attractive. Indeed, scaffolds made with bioactive materials like glass ceramics and Hydroxyapatite and with specific morphological (such as porosity, pore interconnectivity, micro-feature characteristic size) and mechanical properties can be designed by taking advantage of the TPMS features.
The design of biomechanically reliable BTE scaffolds, possibly following a patient-specific approach, is still a complex task that is based on multidisciplinary input such as biomechanics, transport properties and mechanobiology. Classical optimization approaches may be unsuitable for such a complex approach in which multiple objectives need to be met simultaneously. For this purpose, the use of Machine Learning methodologies can be a suitable approach to support the selection of a design with prescribed multi-disciplinary properties.
In this study, we assessed whether a ML model may support the identification of TMPS architectures by leveraging biomechanical and morphological parameters as design inputs. The ML model was composed by three components. The first and second ones predict the geometrical parameters whereas the third one identifies the architecture type (i.e. diamond, gyroid and IWP). To do so, two regression and one classification problems were designed. Here, we considered three different TPMS architectures fully parametrized by two geometrical parameters. A dataset of TPMS architectures was created by solving the direct problem, i.e. imposing the geometrical parameters and the architecture type. Elastic and strength properties have been obtained through finite element modeling; while post-processing of the simulated micro-CT images of the TPMS structure was used to assess morphological parameters (the main ones are: wall thickness, wall spacing, volume fractions and geometrical anisotropy). Fluid transport properties were estimated by assessing the effective pore connectivity index. A total amount of 38 features were extracted from each of the 1258 designs (352, 476, 430 designs for diamond, gyroid and IWP, respectively).
The pseudo-experimental dataset was partitioned into a training set (60%), a validation set (20%) and a test set (20%). A ML greedy feed-forward feature selection algorithm was used with the aim of selecting the most informative descriptors. Once the selection of the most relevant features was identified the optimal design was obtained by defining the optimal values of the features.
The effectiveness of the predictive capability of the proposed approach was quantified by comparing the optimal structure obtained through the regressions and the actual values of the features for geometry extracted from the validation sets.
The results obtained through this approach have proven the suitability of the proposed ML algorithm to design suitable TPMS scaffold architectures, allowing for patient specificity which prescribes specific biomechanical (stiffness and strength) and transport properties (mainly related to the morphological parameters).

SESSION SF08.03: Poster Session: Advanced Ceramics and Glasses

SF08.03.01
Vitrification Range and Plasma Resistance of Bismuth Aluminosilicate Glass Young Min Byun[1,2], JaeHo Choi[1,2], YoonSung Jung[1,2], Kyung Won Min[1,2], Won Bin Im[1] and Hyeong-Jun Kim[2]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institue of Ceramic Engineering and Technology (KICET), Korea (the Republic of)

Reducing contaminant particles in the semiconductor etching process has been an important issue for improving the yields of semiconductor production. Recently, the plasma resistance glass (PRG) proposed as a new material to replace the plasma resistant material made of crystalline ceramics. Etching rate of PRG was lower than that of quartz glass, alumina, and sapphire. There is almost no change in the microstructure even after etching, so it is expected to be a suitable material for reducing particulate contaminants. Components to be aware of in the semiconductor process include alkali metals, heavy metals, etc. It can cause a defect of internal voltage on the oxide film, reduced lifetime, and crystal defects. Research has shown that the etching rate was an index of plasma resistance. It depends on the boiling temperature of the fluoride compound formed by a chemical reaction of plasma fluorine radicals. Bismuth was the component remaining after excluding the components to be avoided in the semiconductor process, and at the same time, the boiling temperature of BiF_3 is 900°C. It was expected to contribute to the reduction of the etch rate. However, since bismuth aluminosilicate glass was not well known, information about the clear vitrification range and properties of glasses were lacking. In this study was to investigate the vitrification range of Bi-Al-Si-O, which has not been studied, and to evaluate the plasma resistance. So we intend to investigate the vitrification range, thermal, physical properties, and plasma resistance of the ternary phase diagram.

SF08.03.02
Reliability of Chemical Strengthened Soda-Lime Glass Containers Kyung Won Min[1,2], Jae Ho Choi[1,2], YoonSung Jung[1,2], Young Min Byun[1,2], Won Bin Im[2] and Hyeong-Jun Kim[2]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

Soda-lime glass has been used for a long time as a glass container because of its ease of melting, the abundance of raw materials, and cheapness. However, the glass container is damaged due to contact and collision between the containers, in the process of washing, filling, and capping, so the strength of the container is reduced to one-thousandths. HEC (Hot End Coating) and CEC (Cold End Coating) are applied to compensate for the decrease in the strength of glass containers. It is known that the mechanical properties of soda-lime glass can be improved using chemical strengthening. Therefore, in this study, the chemical strengthening was applied under annealing conditions to increase the strength of the container. For chemical strengthening, melted KNO_3 was spray-coated on a glass container. The strengthening temperature was performed at $T_g \pm 50$°C. for 1 hour and then the cooling rate was 5°C/min until 100°C. After washing the strengthened glass container, mechanical properties and surface changes were confirmed. After that, reliability evaluation was conducted

through surface roughness change according to the presence or absence of HEC and chemical strengthening. Reliability was confirmed by measuring the impact strength value.

SF08.03.03
Processing Brittle Ultrahard Material and Glass with Polycrystalline Tools Using Electro-Discharge and Mechanical Machining System Eun-Ji Gwak, Jongkeun Sim, Chungmo Kang, Jae Hyeon Ahn, Jun Sae Han, Tae-Jin Je and Doo-Sun Choi; Korea Institute of Machinery & Materials(KIMM), Korea (the Republic of)

Ultra-hard and brittle materials have drawn enormous attention as a master mold or itself in manufacturing flexible displays, IT-electronics-semiconductor devices and bio-diagnostic kits when they have holes, channels or other free forms whose dimensions are in micro- and nano-scale. Especially, in machining those hard and brittle ceramic into ultra-fine feature size under 100 μm, errors in size or shape can be occurred by run-out during tool-setting. In this research, we introduce a newly developed ultra-precision machining system with both electro-discharge and mechanical machining modules for brittle ceramic materials using PCD(polycrystalline diamond) and PCBN(polycrystalline boron nitride) tools and suggest optimized machining conditions using a machining signal analyzing system. Force and acoustic emission data were obtained and correlated with resulting morphologies on material surfaces.

Acknowledgement : This work was supported by the Technology Innovation Program (20010984, Development of multiple machining system technology integrated electro discharge and mechanical working for ultrahigh hard material and application machining technology using micro tool having size of 20 μm) funded By the Ministry of Trade, Industry & Energy(MOTIE, Korea) and by the Korea Institute of Machinery and Materials (NK238E).

SF08.03.04
Study of Transparent Layer by Type of SiO_2 Raw Material of Quartz Glass Crucible YoonSung Jung[1,2], Jae Ho Choi[1,2], Kyung Won Min[1,2], Young Min Byun[1,2], Won Bin Im[1], Seung-Min Kang[3] and Hyeong-Jun Kim[2]; [1]Hanyang University, Korea (the Republic of); [2]Korea institute of Ceramic Engineering and Technology, Korea (the Republic of); [3]Hanseo University, Korea (the Republic of)

Quartz crucible for manufacturing silicon ingots has a two-layer structure with inner and outer layer. The inner layer, which is in direct contact with the molten silicon, should minimize silicon contamination due to incorporation of impurities and crucible fragments. Therefore, a high-pure SiO_2 synthetic raw powder had been used. In this study, crucibles were prepared using the three types of high-pure SiO_2 synthetic powder; (1) powder produced by crushing and heat-treating the gel manufactured by the sol-gel method (2) powder manufactured by sol-gel method, crushed and heat-treated (3) powder produced by water glass ion exchange method, crushed and heat-treated. Both the synthetic powder had a purity of 6 N and a particle size of D_{50} 70 to 160μm, and the microstructure of the powder showed a difference depending on the production method. Therefore, there was a difference in the distribution of bubbles generated in the transparent layer of the crucible. We also confirmed the possible effect on ingot quality as the number of bubbles in the transparent layer increases.

SF08.03.05
Visualization of Crystalline Phase in Glass by Atom-Decomposed XRD Simulation Yuji Inoue[1], Tomoyuki Tamura[1], Ryo Kobayashi[1], Ayaka Kidani[1] and Reo Katayama[2]; [1]Nagoya Institute of Technology, Japan; [2]Nagoya University, Japan

Recently, the development of functional glasses with the phase separation has been extensively researched, and the phase separation process is required to be clarified. However, for glasses without periodic structures, the diffraction patterns generally show broad peaks, and it is difficult to analyze the local structures only by XRD experiments.
In this study, we have developed a tool to analyze local structures by atom-by-atom decomposition of the XRD patterns for atomic configurations obtained by molecular dynamics simulations. We can visualize local structures that contribute significantly to a XRD peak of interest using atom-decomposed XRD patterns. Furthermore, we can analyze the effects of local structures such as coordination number on XRD patterns.

SF08.03.06
Graph Theory-Based Structural Analysis on Density Anomaly of Silica Glass Aik Rui Tan[1], Shingo Urata[2], Masatsugu Yamada[2] and Rafael Gomez-Bombarelli[1]; [1]Massachusetts Institute of Technology, United States; [2]AGC Inc., Japan

Understanding the structure of glassy materials is a tremendous challenge both experimentally and computationally. Despite decades of scientific research, for instance, the structural origin of the density anomaly in silica glasses is still not well understood. Atomistic simulations based on molecular dynamics (MD) produce atomically resolved structures, but extracting insights about the role of disorder in the density anomaly is challenging. Here, we quantify the topological differences between structural arrangements from MD trajectories using a graph-theoretical approach. Structural differences in silica glasses exhibiting density anomalies are captured using a graph similarity metric. To balance the accuracy and speed of the MD simulations, we utilized force matching potentials to generate the silica glass structures. This approach involves casting all-atom glass configurations as networks, and subsequently applying a graph-similarity metric (D-measure). Calculated D-measure values are then taken as the topological distances between two configurations. By measuring the topological distances of silica glass configurations across a range of temperatures, distinct structural features could be observed at temperatures higher than the fictive temperature. In addition, we compared topological distances between local atomic environments in the glass and crystalline silica phases. This approach suggests that more coesite-like and quartz-like local structures, emerge in silica glasses when the density is at a minimum during the heating process.

SF08.03.07
Understanding the Mixing and Properties of High Entropy Perovskites Ali Nasrallah, Ge Wang, Derek Sinclair and Colin Freeman; The University of Sheffield, United Kingdom

High-Entropy Oxides (HEOs) have gathered a lot of attention over the past few years particularly around their formation and properties[1–4]. The perovskite lattice (ABO_3) is a particularly exciting opportunity as mixing can be carried out on both the A or B site presenting a wealth of enthalpic and entropic possibilities to achieve a single-phase solid solution with a favourable Gibbs free energy[4].
Using a combination of computational modelling and experimental studies, we have examined several 3-, 4-, and 5-B element oxides with combinations of (Ga, Y, In), Nb, (Ti, Zr, Sn). We have studied the influence of a range of factors including the ionic size of the sites, the tolerance factor and the ionic size variation which we can then link to the formation of single-phase materials.
Our experiments on Ba-based perovskites demonstrate that single phases can be formed in a range of 4 and 5-B element perovskites with mixed valence charges (e.g. 3+, 4+ and 5+) but mixing was far more challenging with only 3-B element systems. By adjusting the A-site using Sr and Ca we were able to reduce the ionic size penalties and form further 3-B site single phase systems indicating that the size of the A cation also has an effect on the mixing process.
We have coupled the experimental work with a mixture of classical and ab initio simulation work examining the enthalpy of mixing and comparing to the

phase formation from experiment. Our DFT simulations have identified the different mixing and hybridisation characteristics of the ions which affects their ability to mix and can run counter to expected ion size behaviour. Our classical simulations have optimised and examined hundreds of different structures which allows us to comment on the ideality of the solid solutions formed and the competition between entropy and enthalpy in the stability of a phase. We are also able to examine different secondary structures and how their enthalpic stability compares.
From our results, we offer thoughts on the differing rules governing the mixing processes in these perovskite phases.

Effect of TiO_2 Nanoparticle Coating on the Mechanical Properties of Glass Fibers Md Kawsar Ahmed[1], Ali Bagheri Behboud[1], Arda Kurucu[1], Göksenin Kurt Çömlekçi[2] and Mustafa Ordu[1]; [1]Bilkent University, Turkey; [2]Sisecam Science Technology and Design Center, Turkey

Glass fibers are extensively employed as the reinforcing material in composites in a variety of fields such as renewable energy and aerospace. Bare E-glass fibers were coated with different concentrations of rutile TiO_2 nanoparticles to improve mechanical strength of fibers. Microscopic and spectroscopic analyses were performed on the fibers to investigate the presence of nanoparticles over the surface of individual filaments. Tensile tests were performed on the coated and uncoated fibers by following standardized preparation and characterization techniques. Results show that nanoparticle-coated fibers are less likely to fail at a given strength compared to uncoated fibers. Moreover, the tensile strength of the fibers has increased between 7.31% and 11.71%, depending on the concentration of TiO_2 nanoparticles in the solutions.

SF08.03.10
First-Principles Local-Stress Calculations for Oxide Glass Materials Takumu Ito[1], Tomoyuki Tamura[1] and Shingo Tanaka[2]; [1]Nagoya Institute of Technology, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

In glass materials, local physical properties vary due to distributions of coordination numbers, interatomic distances and bond angles. Therefore, it is essential to understand local atomic configurations in glass materials. Classical molecular-dynamics simulations have been widely performed. Recently, first-principles simulations based on density functional theory (DFT) have also been applied to glass models. However, by plane-wave based DFT methods, a total energy and a stress tensor can be obtained as quantities integrated or averaged in an entire supercell. To understand on the nature of local structures in glass materials, the analysis of local distribution of energy and stress is important. In this study, we analyzed atomic stresses in oxide glass materials using first-principles local-stress calculations [1] developed by one of our groups.
Generally, in oxide materials, cations show tensile stresses and anions show compressive stresses. For a SiO2 glass model [2], atomic stresses of four-coordinated Si and two-coordinated O have a wide distribution due to the deviation in local atomic environments, but average values are close to those of the quartz-type SiO2 crystal. We found that formation energies of oxygen vacancies depend on sites and have strong correlations with atomic stresses. In a P-Si-Na-O glass model [3], the coordination number of Si is distributed from 4 to 6, and oxygen atoms can be classified into bridging oxygens (BO) and non-bridging oxygens (NBO). Tensile stresses of six-coordinated Si are higher than those of 4-coordinated Si and are close to those of the stishovite SiO2 crystal. We found that compressive stresses of NBO are smaller than those of BO and has a strong correlation with adsorption energies of protons. From these results, the analysis of atomic stresses is effective in predicting defect formation processes.

SF08.03.11
Advanced Manufacturing of Chalcogenide Glass Through Femtosecond Laser Processing—From Waveguides to 3D Dimensional Micro-Structures Fabrication Gözden Torun[1], Kathleen Richardson[2] and Yves Bellouard[1]; [1]Galatea Lab., Ecole Polytechnique Federale de Lausanne, Switzerland; [2]CREOL and College of Optics and Photonics, United States

The advanced 3D micro- and nano- structuring of mid-IR material, such as chalcogenide glass, is of high-interest for the fabrication of photonic devices in general, and for spectroscopy applications in particular. Yet, the processing of these materials at microscales remains challenging and limited.
Here, we investigate the use of femtosecond laser for producing arbitrary three-dimensional patterns with varying physical properties in four ternary chalcogenide glass compositions: $Ge_{23}Sb_7S_{70}$, $Ge_{23}As_7S_{70}$, $Ge_{23}Sb_7Se_{70}$, and $Ge_{23}As_7Se_{70}$.
Interestingly, under specific laser exposure conditions, we observe the occurrence of both, densification and self-organization patterns formation, for which we explore the response to chemical etching. Furthermore, in an attempt to unravel generic laser-induced transformation mechanisms common to the four glass compositions investigated here, we systematically correlate pulse-to-pulse structural changes with material's inner structures evolution, using both, elemental and micro-Raman observations.
These observations emphasize the potential of ultrafast lasers not only for introducing waveguiding properties in chalcogenide glass, but also, for patterning them at the micro-scale.

SESSION SF08.04: Advanced Ceramics and Glasses III

8:45 AM SF08.04.02
Phase-Dependent Mechanical Stability of 3D Zirconia Microstructures Jedrzej P. Winczewski[1], Stefan Gabel[2], Stefan Zeiler[2], Manuel Herrera[3], Arturo

Susarrey Arce[1], Han Gardeniers[1] and Benoit Merle[2]; [1]University of Twente, Netherlands; [2]Friedrich-Alexander-Universität Erlangen-Nürnberg (FAU), Germany; [3]Centro de Nanociencias y Nanotecnología, Universidad Nacional Autónoma de México, Mexico

In the past decade, significant progress has been made in the three-dimensional (3D) structuring of different classes of materials on the microscale. Direct laser writing (DLW) permits unprecedented shape control and resolution among the additive manufacturing approaches. One of the viable routes focuses on the surface functionalization of the 3D structures, e.g., via electroplating[1] or atomic layer deposition[2], which can be combined with other processes for the removal of the polymeric core to obtain hollow architectures. Alternatively, solid-beam structures can be formed via tailor-made solutions enabling the fabrication of solid-beam structures composed of materials other than solely organic polymers have been extensively studied. The recent endeavors resulted in several tailor-made solutions extending the range of materials that can be 3D-printed to metals (e.g., Ni[3]), ceramics (e.g., ZnO,[4] TiO_2[5]), and composites (Au nanoparticle-laden polymer[6]). From the perspective of mechanical stability, such materials often exhibit excellent chemical, mechanical and physicochemical stability when compared with polymeric materials.

In this study, we investigate the additive manufacturing of microscale 3D zirconia structures and the dependence of their mechanical stability on the crystallographic phase. We are using our previously-established method,[7] we first pattern pre-ceramic structures, which transform into the self-miniaturized ceramic replicas upon the annealing in the air. We then modify the photoresin composition to improve the material performance under extreme stresses. The *in situ* nanomechanical material performance is assessed in a nanoindentation study for different 3D architectures and crystallographic phases of zirconia. Focused ion beam tomography is conducted better to understand the inner structure of the 3D materials. Besides, the additional focus is dedicated to precisely determining the crystallographic phase (X-ray powder diffraction, Raman Spectroscopy), chemical composition (X-Ray photoelectron spectroscopy), and defects of the materials (Cathodoluminescence) to better understand the opportunities and current limitations of the presented methodology.

The capability of our additive manufacturing methodology is presented with various 3D lattice structures of micro-to-nano feature sizes. Besides the sole focus on improving the material and structure performance under high strains, our methodology can be utilized to fabricate phosphors,[7] which can in the future find applications in, e.g., 3D light-emitting devices.

Keywords: additive manufacturing, zirconia, direct laser writing, nanoindentation.

High Hydrogen Impurity—A hidden Role Aggravating PECVD Amorphous SiN_x Coating Cracking Yutao Dong, Xin Yin and Xudong Wang; University of Wisconsin-Madison, United States

Silicon nitride (SiN_x) film has been widely utilized in passivation coating and dielectric devices due to its chemical stability and excellent insulating properties. Films developed by the plasma-enhance chemical vapor deposition (PECVD) approach exhibit superiority with good uniformity and high deposition rate. However, under a normal PECVD process, residual stress usually builds up along with increasing SiN_x thickness [1]. High film stress will lead to SiN_x film cracking to restrict the practical applications. Though there are studies about SiN_x film stress aiming to improve film toughness, limited information has been dug out to build up the relationships between chemical composition, atomic arrangement, and film stress.
In this work, we uncovered the hidden role of high H impurity in PECVD amorphous SiN_x films at the initial growth due to low deposition temperature in normal deposition conditions. Thin and thick SiN_x films grown on silicon (Si) wafers were selected to compare H impurity and bond configuration at different deposition stages. Both X-ray photoelectron spectroscopy (XPS) and Fourier-transfer infrared spectrum (FT-IR) spectrums indicated higher H impurity at the incipient growth as N-H bonds which were much shorter than the Si-N bonds as backbone of SiN_x matrix. Those shorter N-H bonds resulted in a shrinking tendency to induce extra tensile strain at the SiN_x/Si interface. Therefore, at critical thickness, the original SiN_x film exhibited severe cracking initiated from the SiN_x/Si interface and propagated vertically through whole SiN_x film. To avoid high H impurity concentration near SiN_x/Si interface, Si wafer was soaked in reaction chamber with sufficient time to make sure it was under stable deposition temperature. Correspondingly, SiN_x films were more homogenous with consistent atomic spacing. As a result, these long-soaking grown SiN_x films could tolerate stress with 42% fewer cracks film compared to original SiN_x films. In addition, crack length statistical analysis indicated that only ~14% of crack length was longer than 4 cm in long-soaking SiN_x compared to ~52% of crack length above 4 cm in original SiN_x film. This work provides a long-soaking strategy to regulate interfacial tensile strain attributed to unreacted N-H bonds and alleviate cracks in thick SiN_x PECVD coating.

Study of the Effect of Chromium Doping on the Grain Boundary Character of WC-Co Max Emmanuel[1], Oriol Gavalda-Diaz[1,2], Ben Britton[1,3], Katharina Marquardt[1] and Finn Giuliani[1]; [1]Imperial College London, United Kingdom; [2]The University of Nottingham, United Kingdom; [3]The University of British Columbia, Canada

Cemented carbides (WC-Co) are a class of composites that combine the hardness of a metallic carbide (WC) with the toughness of a metallic binder (Co). Applications of WC-Co include metal cutting, mining, construction, and wood and plastic working. The main reason for their consumption in a wide array of applications is their unique combination of high hardness and toughness relative to other hard materials such as ceramics (e.g. aluminium oxide and silicon carbide) and diamond. Cemented carbide remains a growing market with an increase in annual world consumption from 10 t in 1930 to 50000 t in 2008. With the growth in demand for WC-Co, it is beneficial to understand WC-Co more thoroughly.

Fracture and wear affect the performance and lifetimes of tools composed of WC-Co. Cracks in WC-Co has been found to predominantly propagate along WC/WC and WC/Co interfaces at low cobalt contents as is the case in typical commercial grades [1]. Hence, it is useful to gain an understanding of WC boundaries given that the material toughness is related to energy dissipation, which in turn corresponds to crack path. This knowledge can be employed for

grain boundary engineering (GBE) of WC-Co tools with superior performance and lifetimes.

In this work an evaluation of the WC grain boundary character distributions (GBCD) for the most abundant boundary type (Σ2) has been analysed for a standard (WC-10wt%Co) and a chromium doped (WC-10wt%Co-1wt%Cr%) WC-Co sample. This evaluation is based on Rohrer et al.'s five parameter GBCD analysis [2]. Statistically, relative boundary populations are determined from GBCD analysis. Since boundary populations are inversely correlated with boundary energies, GBCD analysis will give an indication of relative grain boundary energies. Fracture energies of these boundaries were measured via double cantilever beam (DCB) tests. Relative populations of Σ2 boundaries on each sample was then compared with their respective measured fracture energies.

It was found that the area fraction of Σ2 boundaries increased threefold with chromium doping. Furthermore, it was found that the length fraction of Σ2 boundaries were greater within WC/WC boundaries compared to all possible WC interfaces in the WC-Co microstructure regardless of doping. Fracture energies of 3.57 ± 0.28 Jm^{-2} were measured for Σ2 boundaries on the standard sample. In contrast a successful (stable crack growth) DCB test could not be performed on the chromium doped variant. It was hypothesised that the chromium doping altered the boundary chemistry of the Σ2 boundaries as observed from the increased fraction of Σ2 boundaries in the doped sample. This in turn likely increased the Σ2 boundary fracture toughness and hence the reason for the failed DCB tests on the doped sample.

Hybrid Multiscale Ceramics—Enhanced Mechanical Behavior and Energy Applications Diletta Giuntini[1,2]; [1]Eindhoven University of Technology, Netherlands; [2]Technische Universität Hamburg-Harburg, Germany

Nano/micro-structured ceramics combine the unique features of ultrasmall building blocks and their organization into tailored architectures to foster emergent properties up to the macroscale. Many functional applications open up, such as in catalysis, energy and optoelectronics. One of the current main challenges in materials science and engineering is the fabrication of such multiscale materials, and more specifically bridging scales in materials manufacturing. To obtain finely tuned macroscale properties, building blocks assembly and optimization of both material constituents and interfaces are key. This talk will tackle these aspects for some promising examples or nano- and micro architected ceramic-based materials. Insights will be shown on how to tailor macro-mechanical behavior and functional properties via fundamental investigations and a strategic combination of different material processing technologies.

Bioinspired Glass Composites with Damage-Sensing Functionalities Tommaso Magrini[1], Florian Bouville[2], Alessandro Lauria[3], André R. Studart[3] and Chiara Daraio[1]; [1]California Institute of Technology, United States; [2]Imperial College London, United Kingdom; [3]ETH Zürich, Switzerland

Lightweight composites have become key structural materials for aircrafts and future energy-efficient transportation systems. Nevertheless, the design of composites featuring high strength and high fracture toughness remains an open challenge due to the usual trade-off between these sets of properties in most manmade materials. Taking inspiration from the strong and tough hierarchical architecture of mollusk shells, I designed and fabricated fracture-resistant glass-reinforced composites by combining soft polymer layers with alternating, nacre-like layers that are infiltrated with the same polymer.[1] In my talk, I will highlight the fracture behavior and the toughening mechanisms that govern the high crack growth resistance of these hierarchical glass composites. In particular, I will focus on the effects of plastic deformation and bridging by the polymer phase on the early- and late stages of the fracture process. These effects have been elucidated by using a mechanochromic organic phase, capable of pre-emptively detecting and reporting the evolution of damage through a simple optical readout. The composites signal the presence of damage via a fluorescence color change that arises from the force-activation of mechanophore molecules embedded in the organic matrix.[2] By optical imaging mechanically loaded composites it is possible to localize damage prior to fracture and to elucidate the key role of plasticity during rupture of the hierarchical composites. Although several examples have shown that polymers can be made damage-reporting using mechanophores, just a handful of examples have targeted the reinforcing phase for the same purpose. To fill this gap, I will also highlight progresses on how high-aspect-ratio glass-reinforcing particles, directly gathered from the upcycling of glass industry residuals, can be engineered to provide optical warnings before and during extended fracture events. With this research, I aim at displaying how multifunctional bioinspired glass composites, capable of combining high strength, high toughness and damage-sensing properties can be fabricated and characterized. I will provide new insights into the interplay of multiscale toughening mechanisms in hierarchical bioinspired architectures and I will offer guidelines for the design of novel multifunctional bioinspired composites.

Ultrafast High-Temperature Sintering of Dense Alumina with Bioinspired Microstructures Rohit P. Behera, Matthew J. Reavley, Zehui Du, Gan Chee Lip and Hortense Le Ferrand; Nanyang Technological University, Singapore

Bioinspired microstructures in ceramics have the potential to fulfil combined unusual properties such as local anisotropy with high hardness, stiffness and toughness, but their current fabrication methods remain challenging due to the time-consuming, energy-extensive sintering method. Here, we report a strategy to sinter dense ceramics with bioinspired heterogeneous microstructures that have tunable stiffness and toughness within seconds. This strategy combines a colloidal directed assembly i.e., magnetic assisted slip casting (MASC) with templated grain growth (TGG) using ultrafast high-temperature sintering (UHS). The hierarchical microstructural designs result from the local orientation of alumina microplatelets coated with Fe_3O_4 nanoparticles dispersed in a matrix of alumina nanoparticles. After UHS, the presence of Fe_3O_4 led to ceramics with about 98% density and a toughness (K_{I0}) of 5.89 $MPa.m^{0.5}$ in nacre-like orientations. We further explored periodically oriented and multi-layered microstructured ceramics using different compositions to attain an overall toughness (K_{I0}) of about 5.73 $MPa.m^{0.5}$ combined with enhanced energy dissipation rates of ~200 J. m^{-2} that can exhibit high local stiffness and toughness across multiple directions. Our proof-of-concept specimens demonstrate that MASC and UHS can fabricate dense, tough and

preferentially textured ceramic in time-saving, cost-effective and energy-efficient ways, opening the design space for achieving ceramic parts with local structural properties.

11:00 AM SF08.04.09
Understanding Fracture Mechanisms in Tough Ceramic Composites Inspired from Nacre Victoria Vilchez and Florian Bouville; Imperial College London, United Kingdom

Compared to metals and polymers, ceramics are great candidates for applications involving extreme environments like high temperatures, radiations, humidity or corrosion. The iono-covalent nature of their bonds make them very strong and stiff materials, although intrinsically brittle. This poor resistance to damage propagation greatly limits the use of ceramics in high-performance domains that cannot tolerate catastrophic failure, such as aeronautics or biomedical applications. For this reason, improving toughness has been a major axis of research in ceramic engineering over the past decades. To this day, the key mechanisms highlighted to improve ceramics' resistance to crack growth mostly reside in a fine control of the microstructure. This includes reinforcing the bulk matrix with fibers and fillers to bridge the crack behind its tip or adding features that resist progression ahead of the crack tip such as residual compressive stresses and transformation toughening. More recently, other microstructures inspired from biological materials have been investigated, specifically ceramic-based materials such a bone, dentin, or nacre. Indeed, millions of years of evolution have gifted these materials with sophisticated hierarchical structures that enable them to resist fracture propagation despite being primarily composed of brittle ceramics. Among these materials, nacre stands out as having one of the simplest microstructures yet exhibiting many toughening mechanisms. Nacre is one of the main components of many seashells and is composed of 95 vol% calcium carbonate platelets stacked in a brick-and-mortar fashion. This microstructure provides nacre with intricate toughening mechanisms such as deflection, branching, interlocking, shearing, viscoelastic dissipation, all acting at different length scales. Taking inspiration from nacre, many processes and compositions have been developed to produce tough ceramic-based composites. Using the current standards of fracture mechanics, it has been proven that nacre-like composites exhibit higher values of fracture toughness and improved crack-resistance curves compared to bulk ceramics. However, characterizing fracture in such materials that exhibit high degrees of deflection and branching remains a challenge, and all the mechanisms that account for improved damage resistance in nacre-like composites have not been characterized or explained. We have worked on characterizing fracture propagation in ceramic-based nacre-like composites, with the aim of determining the role of microstructure and composition on the mechanical response. To this end, we have developed analytical tools validated by finite element analysis to measure crack resistance curves of highly deflected and branched cracks. We have used it to study and reveal the influence of specific parameters related either to the composition, such as the interphase and addition of residual stresses, or to the microstructure, with the presence of short- and long-range order, on the crack propagation behavior in brick-and-mortar structures.

Direct 3D Printing of Biomimetic Bioceramic Scaffolds by Cement Routes Caner Durucan and Hüseyin Engin Sever; METU, Turkey

Bioceramic-based 3-dimensionaly constructed structures and scaffolds are widely used for hard tissue engineering applications and as hard tissue analogs. Robocasting, where a bioceramic powder-binder combination in paste form is used as feed material can be used to develop 3D preforms. The hardening and shape preservation of the printed structures is usually achieved by subsequent polymerization of the organic component. In this study, a novel hybrid printing paste mainly composed of calcium phosphate cement (CaPC) has been developed to achieve *in situ* hardening during printing process. The cement component is a-tricalcium phosphate($Ca_3(PO4)_2$), which readily converts to hardened hydroxyapatite ($Ca_{10}(PO_4)_6(OH)_2$ or HAp) upon hydration. The hydration product in a calcium-deficient HAp, in that sense it offers higher bioactivity and osteoconductive property as it is resembling chemistry of natural bone mineral better than any other CaP. Parametric printing studies has been performed to to determine optimal formulation of the printing paste. Meanwhile, validation of the processing approach, i.e. cement-conversion kinetics, HAp formation efficiency/extent, shape preservation for 3D-printed structures, mechanical properties has been examined. In addition, a microstructural modification approach to control and alter microporosity adaptable to 3D-printing process by incorporation of an inorganic pore generator has been demonstrated. .

Pyrolyzed Ultra-Sharp Glassy Carbon Microneedles Chaoqun Zhou, Aykut Aksit, Betsy Szeto, Richard L. Li, Anil K. Lalwani and Jeffrey W. Kysar; Columbia University, United States

We report glassy carbon ultra-sharp microneedles pyrolyzed from a polymeric precursor structure fabricated via Two-Photon Polymerization lithography (2PP). The glassy carbon microneedles have tip radius of curvature of 1 µm, diameters ranging from 22 µm to 26 µm, and lengths ranging from 106 µm to 126 µm. They are capable of safely penetrating the 1.5 mm wide and 35 µm thick round window membrane in a guinea pig model that serves as a barrier between the middle and inner ear spaces. The precursor needle has a tip diameter of 7.5 µm, a base diameter of 100 µm and a length of 600 µm. To maintain structural integrity during pyrolysis, we show that the exposed surface area to volume ratio of the polymeric precursor needs to be within a certain range. Upon designing the polymeric precursor structure under these constraints, the structures can shrink by up to 81% during pyrolysis while maintaining structural integrity. The pyrolyzed glassy carbon is elastic with a brittle failure mechanism with a Young's modulus of 9.0 GPa and characteristic strength of 710 MPa. Furthermore, glassy carbon is known to be biocompatible. We show that the pyrolyzed ultra-sharp glassy carbon microneedles perforate the round window membrane safely and can serve to enable safe direct delivery of therapeutics into the inner ear delivery. In addition to glassy carbon microneedles, this pyrolysis process can be adapted to fabricate many other biomedical devices.

2:00 PM SF08.05.03
Thermoplastic Extrusion of Piezoelectric Lead-Free Ceramics for Biological Membrane Applications. Simone Santucci, Astri Bjørnetun Haugen and Bhaskar Reddy Sudireddy; Technical University of Denmark, Denmark

The inclusion of piezoelectric ceramics has been in recent years a fast increasing hot topic. Piezoelectric lead-free materials such as BaTiO3 or K0.5Na0.5NbO3 (KNN) have been studied in a wide range of applications such as neural and bone tissue repair, or bacterial/planktonic membranes [1,2]. For many of these applications, porous systems are necessary in order to increase the active surfaces and maximize the interaction with the biological matter. A promising manufacturing method for porous ceramics is thermoplastic extrusion. This method produces robust cylindrical membranes, also in presence

of pores former, and it is also scalable up to industrial levels [3].
In the case of planktonic/bacteria membranes, the device requires high piezoelectricity (depending on the application can be > 100 pC/N), suitable pores size and distribution (1-10 μm), and strong support. However, pores decrease the magnitude of piezoelectric effect both locally and in the overall device. Here we manufactured tubular porous piezoelectric membranes by thermoplastic extrusion, using graphite and/or polymethyl methacrylate (PMMA) as pore formers and lead-free ceramics as support material. The influence of pore formers on the microstructure, mechanical properties and piezoelectric effect is studied, as well as the sintering temperature and extrusion parameters. The overall device is suitable for biological applications, in particular planktonic/bacteria membrane. Finally, the manufacturing process is scalable and easily integrable in an industrial environment.

Characterizing the Local Yield Surface in Simulated Glasses Spencer Fajardo[1], Bin Xu[1], Dihui Ruan[1], Rahul Meena[1], Michael Shields[1], Thomas Hardin[2], Michael Chandross[2] and Michael L. Falk[1]; [1]Johns Hopkins University, United States; [2]Los Alamos National Laboratory, United States

Amorphous materials, unlike their crystalline counterparts, have no obvious defects that help facilitate plastic instability, and so methods that predict the locations of plastic events are highly sought after. Two-dimensional model glasses have been used extensively to study amorphous materials and to develop a theoretical basis for determining the location of plastic events. One method that has resulted from such investigations is the Local Yield Stress (LYS) method in which nanoscale regions of the material are probed to quantify the incremental stress necessary to induce plastic rearrangement. The resultant local yield stress depends on the sense of the mechanical load applied on a local region. Higher accuracy predictions can be obtained by sampling many disparate mechanical loads. Doing so allows one to develop a more accurate picture of the "local yield surface," the limiting stresses that the material can withstand before yielding along all possible mechanical loadings. In three dimensions, the number of distinct mechanical tests needed to accurately sample the local yield surface increases. The resulting dataset is computationally expensive to produce. We seek to use this data to compactly characterize this high-dimensional "surface" and to enable extrapolation along deformations that were not explicitly tested in the original dataset. This can, in principle, be accomplished by describing the local yield surface in terms of a discrete number of Shear Transformation Zones (STZs). By characterizing the number of STZs in a local region we will be able to predict areas of high plasticity more accurately in amorphous materials, eventually leading to the accurate modeling of plastic response and the design of materials with mechanical properties catered to specific needs.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Validating a Facile Approach to Measuring Fracture Toughness by Instrumented Indentation Without Imaging Crack-Lengths Jacob L. Hempel, Andrew Meyer, Ryan C. Hill and Yang-Tse Cheng; University of Kentucky, United States

Probing the fracture toughness of brittle materials by measuring the crack-length generated from indentation experiments is often practiced in many areas of materials research. However, when the cracks are too small to be measured accurately, an energy-based approach has recently been proposed by several researchers. In the work presented here, this approach is compared with the well-known crack-length method on six different materials. We found that the energy-based method and crack-length method yield significantly different results for all materials but converge if the energy method is modified with a correction factor using a calibration sample.

3:15 PM SF08.05.07
Visualization of the Final Stage of Sintering in Nanoceramics with Atomic Resolution Tanna E. Fiuza, Marlon Muniz da Silva, Jefferson Bettini and Edson R. Leite; Brazilian Center for Research in Energy and Materials, Brazil

Sintering is a thermally active process, in which densification (or pore elimination) and grain growth can occur. In general, the driving force for densification is lowering the surface free energy by replacing solid–gas interfaces, leading to a new solid-solid interface with a lower system's free energy [1-6]. The optimization of the ceramic's densification process lies in a better comprehension of the sintering steps and related mechanisms. Many models satisfactorily describe the sintering at a micrometric scale, however, nanometric effects make the direct extrapolation of these models to the nanoscale more complicated [7-9]. By high-resolution transmission electron microscopy, particularly real-time measurements, we followed the pore elimination process in a self-standing ZrO_2 thin film produced by monoclinic ZrO_2 nanoparticles. The absence of carbon membrane and the surface cleaning by removing the capping ligands produced an ideal scenario to perform the experiments. We found a high anisotropic pore elimination, with a gradual and linear decrease in pore area as a function of time. The pore shrinkage occurs with atoms from a rough surface being redistributed on the solid-gas interface, while atoms are attached to a faceted surface. In the final stage, the pore becomes rounded and shrinks until complete elimination. Also, the pore acts as a pin, reducing GB mobility. In summary, these results can contribute to a better understanding of the sintering process in nanoceramics, and to the improvement of kinetic models that better describe the densification process at the nanoscale.

Experimental Mechanical Characterization of 3D-Printed Hydroxyapatyte and Finite Element Model Implementation of High Porous Scaffold for Bone Tissue Engineering Luca D'Andrea[1], Francesco Baino[2], Enrica Verné[2], Martin Schwentenwein[3], Dario Gastaldi[1] and Pasquale Vena[1]; [1]Politecnico di

Milano, Italy; [2]Politecnico di Torino, Italy; [3]Lithoz GmbH, Austria

Bone is a self-healing tissue, but some pathologies, aging, non-physiologic conditions and trauma may cause a critical size bone defect that cannot heal spontaneously. The implant of bioceramic scaffolds is a promising approach for the treatment of these pathologic conditions. Among bioceramics, hydroxyapatite (HAP) is a good candidate for its chemical affinity with the native bone's mineral component, thus ensuring biocompatibility and promoting osteo-integration. As HAP mechanical property is heavily influenced by its brittle nature, a robust experimental characterization of the bulk material is required for the design of mechanically reliable scaffolds.
Furthermore, recent developments in 3D printing technologies allow for a wide variety of micro-structured devices meeting patient-specific needs. In this work, we deal with HAP material obtained through DLP-stereolithography which is a printing technology allowing for very fine spatial resolution and high printing fidelity. However, as the technological process includes a sintering phase at high temperature, the properties of the obtained material are strongly affected by the intrinsic defects which characterize the final product. For this reason, in this study, the mechanical characterization of the material samples having a simple geometrical shape and obtained through the same process as that used for the scaffold production and having the same characteristic size of the microstructural features of the scaffolds is proposed.
For this purpose, we 3D-printed three different kinds of beams (i.e. simple beams, notched beams and cantilevers) in small scale (approximate size of beams 1mmx0.4mmx10mm). The samples have been subjected to confocal laser imaging, micro-Computed Tomography scanning and mechanical tests. The confocal laser scanning provided the size of the samples having the purpose to complement mechanical tests and to assess printing fidelity; the micro-CT analyses had the purpose to quantify the intrinsic porosity of the material resulting from the sintering process. The mechanical tests were micro-bending test and Berkovich nanoindentation.
The micro-bending tests were used to assess the flexural stiffness and strength, while the nano-indentation tests have been used to verify whether elastic property exhibits a scale effect, expected in case micro-defects occur in the material.
Using the same material and 3D-printing technology, high porous scaffolds were manufactured through DLP stereolithography. Micro-Computed Tomography scans were performed on the scaffolds to obtain the real geometry of the scaffolds. After a proper binarization process, a finite element model was implemented using the real geometry and the mechanical parameters found in the above-described experiments. Micro-CT based finite element analyses on the 3D-printed scaffolds were performed with the aim to determine the macroscopic elastic and strength properties of the scaffolds. The obtained macroscopic properties are validated through comparison with macroscopic experimental data already available.
The experimental and numerical framework presented in this work has shown the capability of in-silico models of 3D-printed scaffolds to predict biomechanically relevant properties, provided that intrinsic properties of the materials are available with specific reference to the manufacturing process parameters and geometrical size of the micro-architecture.

Processing and Mechanical Behavior of 3D Printed Ceramic Lattices and Their Derived Interpenetrating Phase Composites Zehui Du[1], Yida Zhao[1] and Pengcheng Ye[2]; [1]Nanyang Technological University, Singapore; [2]Creatz3D Pte Ltd., Singapore

Ceramics and their derived composites which are lightweight and with high strength and high toughness have been long sought after for various engineering applications. In this work, various alumina ceramic based microlattices, including Simple Cubic, Octet Truss and Kelvin Cell have been fabricated using computer-aided design tool and stereolithography 3D printing process, Subsequently, interpenetrating phase composites (IPCs), with the ceramic lattices as backbone and infiltrated with a second phase (e.g., epoxy or aluminum alloy), have been further developed. The mechanical behavior of the ceramic lattices and the IPCs under quasi-static compression tests has been systematically studied by experiments and simulation. Results show that Simple Cubic lattices generally initiate the fractures at the struts in the outermost lattice planes, while the Octet Truss and Kelvin Cell lattices fracture at the (110) diagonal plane. With a second phase infiltrated into the lattices, the resultant composites inherit similar fracture behavior as their corresponding lattices, but in a more gradual manner. The stiffness and compressive strength of the lattices follow the order of Simple Cubic > Octet Truss > Kelvin Cells. The compressive strength of IPCs is generally higher than that of the ceramic lattices. Composites with 50 vol% alumina simple cubic lattices and filled with epoxy exhibit a high compressive strength of 440 MPa and energy absorption of 12 J/g (at 16% strain). The energy absorption is almost 100% higher than that of epoxy and much better than that of the ceramic lattices. The factors controlling the mechanical properties of the lattices and IPCs, including relative density, topology, matrix materials and lattice defects arising from 3D printing, will be discussed and the perspectives on the application of the lattices and IPCs will be given in the presentation.

Ceramic Fibres with Controlled Micro- and Macrostructures by Sol-Gel Electrospinning Shiling Dong[1], Barbara Maciejewska[1], Maria Lissner[1], Daniel Thomson[1], David Townsend[1], Robert Millar[2], Nik Petrinic[1] and Nicole Grobert[1,2]; [1]University of Oxford, United Kingdom; [2]Williams Advanced Engineering Limited, United Kingdom

Electrospinning is a well-developed technique for fabricating one-dimensional (1D) fibres in the form of two-dimensional (2D) nonwoven mats. In junction with sol-gel synthesis, single and multiphase ceramic fibres made of oxides and nitrides have been produced. Such ceramic fibre mats, with a unique combination of large surface area, high porosity, flexibility, show great premises for advanced applications such as flexible electronics and sensors. However, the ability to tune the morphology, porosity and the macroscopic shape of fibre product is still limited. For example, it is challenging to produce highly porous three-dimensional (3D) fibre architectures which are desired in tissue engineering, air filtration, absorbent, etc. Thus, developing strategies to control the micro- and macrostructures of ceramic fibres is the key to facilitate their practical implementation and broaden potential usages.

Here, we report several solution modification strategies to effectively tune the structure of electrospun fibres, allowing customised fibre porosity and surface area. At the microscopic level, inducing liquid-liquid phase separation in spinning solution leads to core-shell fibre structures without the need of employing a complex spinneret. The pores size and shape can be controlled by varying the ratio of alkoxides, solvent, and polymer component. Also, electrospin the solutions with homogeneously dispersed submicron-sized polymer powders gives hybrid fibres. Such powders act as pore-forming templates to render mesopores and macropores inside fibre after calcination. At the macroscopic level, modifying the electrical conductivity of the spinning solution triggers different electrodynamic behaviour of electrified solution jet. The as-spun fibres spontaneously assemble into sponge-like macrostructure with centimetre-scale height, which is in sharp contrast to the conventional electrospun thin nonwovens. After calcination, the resultant ceramic fibre

sponges show extremely high porosity (about 99.9%), high specific surface area (up to128 m2/g), excellent flexibility and elasticity. Overall, we introduce novel solution modification strategies towards a new class of electrospun ceramic fibres with unprecedentedly controlled micro- and macrostructures.

Abstract: The scope of this paper is to produce efficient and low-cost silicon carbide multilayers. The method is formed on self-propagating high-temperature synthesis of binary silicon-carbon based reactive multilayers. In order to do so the silicon carbide is fabricated by means of the magnetron sputtering method. The silicon and carbon bilayers were fabricated with two different bilayer thicknesses. The silicon and carbon are deposited in an alternative layer with a total thickness of 1 μm. The entire system is annealed by rapid thermal analysis at different temperatures starting from 500 C to 1100 C and heating uprate. In order to find the phase formation, morphology, and reaction enthalpy the samples were investigated with XRD, SEM and FTIR. From XRD analysis we could find that the formation of the silicon-carbide phase was initiated from 700 C with increasing bilayer thickness the silicon carbide phase formation was partially suppressed by the silicon recrystallization due to resulting lower carbon diffusion into silicon. The transformation process proceeds in a four-step process. From this, it was noted that when compared to low bilayer thickness samples, the formation of the SiC phase is delayed with increasing bilayer thickness and needs a high temperature. The grain size and morphology of the samples were well studied with SEM analysis and the measured average thickness of the Si and the C layers are 53 and 48 nm, respectively.

Keywords: phase transition, reactive materials, reaction enthalpy, X-ray diffraction, differential scanning calorimetry

Crystallization Kinetics of Ordered Mesoporous Alumina Under Transient Joule Heating Leyan Wang and Kwan Wee Tan; Nanyang Technological University, Singapore

Well-ordered mesoporous alumina materials derived from block copolymer self-assembly are desirable for many applications such as environmental separation and carbon sequestration. We have developed an improved synthesis protocol mixing block copolymers with stable alumina sol precursors to access various ordered morphologies, including 2D hexagonal cylinders and 3D cubic lattices, as well as 2D lamellar and multiscale hierarchically ordered mesoporous architectures, to our knowledge for the first time. Coupling block copolymer self-assembly with Joule heating provide further enhancements yielding highly crystalline ordered alumina and alumina/carbon structure within second timeframes. Here we will describe the Joule heating-induced crystallization kinetics studies of block copolymer-directed mesoporous alumina and other oxide systems. The X-ray scattering data fits well with established models providing a clearer understanding of crystal growth under such nonequilibrium transient high-temperature conditions.
