Na-ion batteries (NIBs), taking advantage of Na being the fourth most earth-abundant element, have emerged as a promising candidate for such applications. Together with cost-effective electrodes, the use of NIBs can bring a radical decrease in cost compared to the widely used Li-ion batteries, while ensuring sustainability.[1] However, NIBs are still in a developmental research phase and the exploration of proper electrode materials is necessary. [2] $Na_2Ti_3O_7$, with its large abundance of raw materials, non-toxicity, and high theoretical capacity of 177 $mAhg^{-1}$, [3,4] has emerged as one of the most attractive anodes for sustainable NIBs. However, previous tests have shown that $Na_2Ti_3O_7$ suffers from (i) low electrical conductivity and (ii) structural instability, which results in poor electrochemical performance, particularly at high charge/discharge rates. Efforts to improve the cycling stability of sodium titanates have discovered $Na_2Ti_6O_{13}$ which has properties contradictory to $Na_2Ti_3O_7$; $Na_2Ti_6O_{13}$ exhibits high ionic conductivity and structural stability but suffers from low Na storage capacity [5]. In this regard, proper hybridization of $Na_2Ti_3O_7$ and $Na_2Ti_6O_{13}$ could break the limitations of each structure and offer a composite electrode for high performance NIBs [6].
One viable approach to synthesize mixed $Na_2Ti_3O_7/Na_2Ti_6O_{13}$ anode is a hydrogenation treatment.[7] When synthesized with hydrogen gas, some of the $Na_2Ti_3O_7$ spontaneously transforms into $Na_2Ti_6O_{13}$, which provides high-performance $Na_2Ti_3O_7/Na_2Ti_6O_{13}$ hybrid anodes without additional synthesis routes. This procedure typically includes two reactions of O and Na removal, i.e., $2Na_2Ti_3O_7 + H_2 \rightarrow 2Na_2Ti_3O_{6.5} + H_2O$ and $2Na_2Ti_3O_{6.5} + H_2O \rightarrow Na_2Ti_6O_{13} + Na_2O + H_2$. Above reactions imply that O and Na vacancy defects formed during the synthesis condition are closely related to the spontaneous phase transition from $Na_2Ti_3O_7$ to $Na_2Ti_6O_{13}$. However, the interplay between defects and phase transition have been neglected to date, and the fundamental driving forces underlying the phase transition remain elusive.

To better understand the role of native defects on the above phase transition behavior, we perform computational analyses on the intrinsic defect chemistry in $Na_2Ti_3O_7$. In particular, using the combined density functional theory (DFT) calculations with hybrid and PBEsol functionals, we replicate the high-temperature synthesis condition and investigate major defects formed during synthesis. The formation energies of the so-formed major defects are used to discuss the charge compensation behaviors and underlying conductivity mechanism, which can help establishing a doping strategy for anodes with improved performance. Furthermore, the effect of intrinsic defects of $Na_2Ti_3O_7$ on its atomic structure were studied to elucidate the origin of the spontaneous phase transition to $Na_2Ti_6O_{13}$, which can potentially guide further optimization of anodes employing phase transitions.

Influence of Multiphase Intergrowth on Layered Transition Metal Oxide Positive Electrodes for Sodium-Ion Batteries Eric Gabriel[1,2], Kincaid Graff[1], Dewen Hou[1,2], Changjian Deng[3], Pengbo Wang[4], Yanyan Hu[4] and Hui Xiong[1]; [1]Boise State University, United States; [2]Argonne National Laboratory, United States; [3]China Evergrande New Energy Vehicle Group Ltd, China; [4]Florida State University, United States

Layered transition metal oxides (LTMOs) are a popular class of positive electrode materials for sodium ion batteries (SIBs). Historically, research of LTMO materials as electrodes for SIBs has been focused on single phase materials. On the other hand, multiphase structures with superior properties to single phase materials have gained increased interest in recent years. We demonstrate the preparation of multiphase electrode materials through controlled doping and processing strategies. We observe in the O3-type ternary $Na_{0.87}Ni_{0.4}Fe_{0.2}Mn_{0.4}O_2$ (NFM) system that Li doping generates a secondary intergrown Li-rich phase that is mechanically coupled to the primary O3 phase during the first charge/discharge cycle, which suppresses phase transformations seen in the undoped material as observed by operando synchrotron X-ray Diffraction (XRD) measurements. The amount of the Li dopant influences both the structure of the primary O3 phase and the phase fractions of each phase, as shown by synchrotron XRD and neutron diffraction. Li doping also significantly influences the reactivity of the material surface as determined by ^{23}Na and ^{7}Li nuclear magnetic resonance. The phase transformation and surface reaction are shown to be key factors in the cycling stability of the Li doped NFM electrodes.

The Dominant Static Disorder in Perovskites Originates from Zero-Point Phonon Energy Rather Than Structural Disorder Ardalan Armin;

Swansea University, United Kingdom

Benefiting from recent advancements in the sensitivity of photocurrent spectroscopy[1], in this work, I revisit sub-gap absorption measurements with improved accuracy on state-of-the-art perovskite solar cells based on lead-halides with different numbers of cation components.

Firstly, I demonstrate that the spectral line shape of absorption features associated with mid-gap trap states are strongly influenced by thickness dependent optical cavity effects. Hence, the corresponding spectra, if uncorrected, provide no information about energetic distribution of sub-gap trap states.[2] I show that the mid-gap trap states lower the photoluminescence quantum yield through SRH recombination and thereby, they cause additional non-radiative voltage loss. These mid-gap traps are present in the bulk of perovskite, but their density is considerably larger at the interface with C60 interlayer.[3]

Secondly, I show that the determination of the Urbach energy is limited to an uncertainty of 1 meV due to inevitable variations in sub-gap absorption features caused by said cavity effects.[4] In light of this, we determine the static and dynamic disorder using temperature dependent, ultra-sensitive external quantum efficiency (EQE) measurements. The corresponding static, temperature-independent contributions of the Urbach energy are found to be 3.3±0.9 meV, 4.7±0.3 meV, and 5.1±0.5 meV for single, double, and triple cation perovskite solar cells,[5] respectively. Defect states with small trap signatures observed in sensitive sub-gap EQE are found not to dominate the perovskite static disorder. Instead, the static disorder in perovskites is only limited by the quantum noise motion of the phonons (zero-point phonon energy), which broadens their potential applicability for realizing quantum devices operating at cryogenic temperatures.

Role of Dynamic Symmetry Fluctuations for Band Gaps of Halide Perovskites Stefan A. Seidl[1], Xiangzhou Zhu[1], Guy Reuveni[2], Christian Gehrmann[1], Sebastian Caicedo Davila[1], Omer Yaffe[2] and David Egger[1]; [1]Technical University of Munich, Germany; [2]Weizmann Institute of Science, Israel

Thermal effects that include lattice expansion and electron-phonon coupling have been discussed to influence one of the most central physical quantities of halide perovskite (HaP) materials, namely their fundamental band gap. Meanwhile, these systems are known to exhibit outstanding dynamic structural properties and vibrational anharmonicity that is detectable already around room temperature. Here, by combining molecular dynamics and Monte-Carlo calculations, based on density functional theory, with reflectance measurements, we investigate the precise thermal characteristics of the band gap in the prototypical $CsPbBr_3$ HaP. We find that dynamic fluctuations among crystal symmetries play an important role for the electronic structure of HaPs and impact the band gap in these materials in a profound way. Importantly, we demonstrate that the thermal characteristics of the band gap cannot be rationalized using the average crystal symmetry at a given temperature. Using different levels of vibrational theory, anharmonic vibrational contributions are shown to be connected to the dynamic symmetry fluctuations we describe here. Our work establishes a deep and highly relevant connection between the dynamic structural and optoeletronic properties of HaPs.

Electronic Structure of Bulk and Layered Perovskites. George Volonakis and Claudine Katan; Université de Rennes 1, France

In this talk, we discuss the employment of state-of-the-art electronic structure theory for the materials modelling of novel perovskite and perovskite-like materials in bulk and layers. We first review the current opto-electronic application of Pb-free alternatives, and highlight recent efforts on the front of 'in silico' materials design. We discuss the case of halide double perovskites, and explore the link between the type and position of the atomic orbitals in the crystal and their electronic structure. This allows us to propose a classification of the octahedra types based on their electronic structure in existing compounds. Furthermore, we take this approach a step further to analyze different types of perovskite and perovskite-like materials, like the vacancy ordered double perovskites and double salts of Ag and Bi, also known as rudorffites. Finally, we take on the layered derivatives and will discuss insights provided by first-principles calculations to reveal inter-layer interactions in real materials, and establish simplified models to show the charge carrier transport limits one can attain.

SESSION EN04.02: Confinement and Excitonic Effects I
Session Chairs: Alexander Urban and George Volonakis
Monday Afternoon, November 28, 2022
Hynes, Level 3, Ballroom A

1:30 PM *EN04.02.01
Excitons in Chemically and Structurally Heterogeneous Halide Perovskites Linn Leppert; University of Twente, Netherlands

Halide double perovskites are an emerging class of photoactive materials with considerable structural and electronic diversity [1,2, 3] and reliable stability towards heat and moisture under ambient conditions. Contrary to ABX_3 halide perovskites like $CH_3NH_3PbI_3$, the band edge electronic structure of double perovskites is usually dominated by contributions from two different B site metals. This chemical heterogeneity results in a wealth of different band structure properties many of which can be understood based on simple and intuitive symmetry considerations or calculated with comparably little effort from first principles [4]. The same is true for their quasi-2D counterparts which exhibit pronounced band structure changes in the monolayer limit reminiscent of transition metal dichalcogenides [5, 6]. In contrast, much less is known about the excitonic properties of this class of materials. The calculation of accurate optical spectra is computationally demanding and whether simple physically motivated exciton models like the Wannier-Mott model are reliable for these quaternary, heterogeneous materials, is hard to predict *a priori*.

In this talk I will discuss how first principles numerical modelling techniques such as Green's function-based many-body perturbation theory can provide an atomistic understanding of excitons in chemically and structurally heterogeneous halide perovskites. I will show that these materials can feature a wide

range of different excitons, from strongly localized, bound, or resonant excitons that fall outside the tenets of the Wannier-Mott model [7] to strongly delocalized, weakly bound Wannier-Mott excitons [8]. Our results can be traced back to the symmetry and orbital character of the band edges of these double perovskites – a consequence of their chemical heterogeneity, and can be tuned via chemical substitution, dimensional reduction, layer thickness and layer stacking. We thus provide a fundamental understanding and reliable design rules for excitons in this family of materials.

Excitonic Properties of Vacancy Ordered Double Perovskites—Electron-Hole Coupling and GW Quasi-Particles Bruno Cucco, Mikael Kepenekian and George Volonakis; Univ Rennes, ENSCR, INSA Rennes, CNRS, ISCR - UMR 6226, France

Over the past decade ABX_3 halide perovskites based on Pb have emerged as a most-promising class of materials. To-date they have been employed for record-breaking solar-cells[1], highly-efficient light-emitters[2], new photo-catalysts[3] and even as X-ray detectors[4]. A_2BX_6 vacancy ordered double perovskites (VODP) are air-stable and environmentally friendly (Pb-free) that have been proposed as alternatives[5], to halide perovskites. Yet, VODP materials have not achieve the high performance of their Pb-based counterparts. In this work, we thoroughly analyze the properties of the VODP family of materials by employing state-of-art ab initio calculations to unveil the key details of the electronic structure and the effects of electron-hole coupling on the optical properties.

We sample the VODP structures by picking prototypes accordingly to the electronic configuration of the tetravalent metal at the B-site. That is, there are three possible closed-shell metal sites, with valences composed of either *s*-, *p*- or *d*-orbitals. In particular, we select known materials[5,6,7] Cs_2TeX_6, Cs_2SnX_6, and Cs_2ZrX_6 (with X=Br, I) for the groups with a valency comprised of an s, p and d closed-shell, respectively. The structural properties are first investigated, and show how the size of the vacancy, is in fact tuned solely by the size of the halogen. We assess the mechanical stability of each crystalline lattice by means of phonons calculations. The electronic structures are investigated within the GW many-body green's function method, and we obtain band-gaps spanning a range of 1.5-5.0 eV at G_0W_0. More importantly, we discuss the effects of the substitutional engineering on the dispersion of the electronic bands, and relate our findings to the expected charge carrier mobilities of each type of VODP. The optical and excitonic properties of these compounds are investigated within the independent particle approach, and by solving the Bethe-Salpeter equation (BSE). We report the exciton binding energies and dark-bright exciton exchange splitting for each type of VODP. Finally, we address the exciton symmetries by performing a complete symmetry analysis of the compound's band structure and excitonic wavefunctions, on which a direct link between these and the metal site species is established.

Overall, we explore comparatively the role of electron-hole coupling and GW quasi-particles in VODP materials, and explain its correlation with the choice of the B-metal and X-halide sites. These results shed light on the suitability and the prospect of VODP type might exhibit, due to their opto-electronic and excitonic properties. Finally, we identify the most and least promising materials that could act as photo-active materials or for selective charge transport layers in light-emitting and solar-cell applications.

Revealing Charge-Carrier Complexes and Interactions in Single Lead-Halide Perovskites Nanocrystal Brahim Lounis; Université de Bordeaux, France

Lead halide perovskites open great prospects for optoelectronics and a wealth of potential applications in quantum optical and spin-based technologies. Precise knowledge of the fundamental optical and spin properties of charge-carrier complexes at the origin of their luminescence is crucial in view of the development of these applications. On nearly bulk Cesium-Lead-Bromide single perovskite nanocrystals, which are the test bench materials for next-generation devices as well as theoretical modeling, we perform low-temperature magneto-optical spectroscopy to reveal their entire band-edge exciton fine structure and charge-complex binding energies. We demonstrate that the ground exciton state is dark and lays several millielectronvolts below the lowest bright exciton sublevels, which settles the debate on the bright-dark exciton level ordering in these materials. More importantly, combining these results with spectroscopic measurements on various perovskite nanocrystal compounds, we show evidence for universal scaling laws relating the exciton fine-structure splitting, the trion and biexciton binding energies to the band-edge exciton energy in lead-halide perovskite nanostructures, regardless of their chemical composition. These scaling laws solely based on quantum confinement effects and dimensionless energies offer a general predictive picture for the interaction energies within charge-carrier complexes photo-generated in these emerging semiconductor nanostructures.

2:45 PM EN04.02.04
Rabi Oscillations of Exciton-Polariton in Phase-Changing Lead Halide Perovskites Hyeon-Seo Choi, Minjee Ko, Jin-Woo Jung, Young-Jun Lee, Taejin Lee, Dongha Kim, Shinbuhm Lee and Chang-Hee Cho; DGIST, Korea (the Republic of)

Organic-inorganic hybrid lead halide perovskites have invoked much interest in cavity quantum electrodynamics due to their excellent excitonic properties

including strong exciton binding energy and high oscillation strength. Interestingly, the perovskites exhibit the crystallographic phase transition, resulting in tunable properties of excitons and polaritons, but the underlying physics remains unexplored. In this work, we have demonstrated tunable Rabi oscillations of exciton-polariton in the lead halide perovskite microcavity, which experiences the phase transition from orthorhombic through tetragonal to cubic phases for varying temperatures. The Rabi splitting can be tuned by the emergence of ferroelectricity to modify the exciton oscillator strength in the noncentrosymmetric tetragonal phase, where the oscillator strength and Rabi splitting are minimized. Our results provide an insight into the emerging functionalities of polariton devices by utilizing the ferroelectric semiconductors, which enable the realization of tunable quantum devices.

Exciton-Polaron Quantum Dynamics in Ruddlesden-Popper Metal-Halides Carlos Silva; Georgia Institute of Technology, United States

While polarons --- charges bound to a lattice deformation induced by electron-phonon coupling --- are primary photoexcitations at room temperature in bulk metal-halide hybrid organic-inorganic perovskites (HOIP), excitons --- Coulomb-bound electron-hole pairs --- are the stable quasi-particles in their two-dimensional (2D) analogues. Here we address the fundamental question: are polaronic effects consequential for excitons in 2D-HIOPs? Based on our recent work, we argue that polaronic effects are manifested intrinsically in the exciton spectral structure, which is comprised of multiple non-degenerate resonances with constant inter-peak energy spacing. We highlight measurements of population and dephasing dynamics that point to the apparently deterministic role of polaronic effects in excitonic properties. We contend that an interplay of long-range and short-range exciton-lattice couplings give rise to exciton polarons, a character that fundamentally establishes their effective mass and radius, and consequently, their quantum dynamics. Given this complexity, a fundamentally far-reaching issue is how Coulomb-mediated many-body interactions---elastic scattering such as excitation-induced dephasing, inelastic exciton bimolecular scattering, and multi-exciton binding---depend upon the specific exciton-lattice coupling within the structured excitation lineshape. We measure the intrinsic and density-dependent exciton dephasing rates of the multiple excitons and their dependence on temperature by means of two-dimensional coherent excitation spectroscopy.

Tuning the Structure and Dynamics of 2D Hybrid Halide Perovskites Ferdinand C. Grozema; Delft University of Technology, Netherlands

Two-dimensional hybrid perovskites are promising materials for a wide range of opto-electronic applications. Their properties markedly differ from those of their three-dimensional analogues, but they also offer additional routes to engineer their properties by introducing specific functionality in the organic component. One of the key features of 2D hybrid perovskites is their relatively soft structure that allows substantial structural fluctuations, both during synthesis and after deposition. The softness of the material leaves considerable room to manipulate the structure of the inorganic layer through external stimuli such as pressure and adsorption of molecules on the surface, or internal effects such as strain cause by the organic separating layers. The nature of the organic component directly affects the structural and dynamic properties of the inorganic lattice. [1] Such changes in the structure and dynamics translate to changes in the electronic properties of the materials. Therefore, by controlling the structure and interactions in the organic part it is possible to tune important physical parameters of the materials, including the charge carrier mobility, exciton binding energy, carrier lifetime and the decay pathways of charges and excited states.

In this work we computationally explore approaches to engineer the structural and dynamics properties of the 2D perovskite materials by introducing specific organic moieties that have additional functionality. The layer of organic molecules influences the structure and dynamics of the inorganic layer, which also has an immediate effect on the electronic structure. We have performed classical molecular dynamics simulations for a variety of 2D halide perovskites, including Ruddlesden-Popper and Dion-Jacobson structures. We show that the nature of the organic cation determines the average structure and the structural dynamics to a large extent. This indicates that these properties can be tuned significantly by exploiting specific intermolecular interactions in the organic layer. The structure and dynamics of the organic layer directly affect the structure and dynamics of the inorganic layer, for instance the disorder in the octahedral tilt angles. This should lead to marked effect on the steady state electronic properties but also offers a handle to influence the strength and nature of the electron-phonon coupling in these materials.

The soft nature of of 2D hybrid perovskites suggest a marked dependence of the electronic properties on external stimuli, for instance the strain in the material. Strain can be introduced by applying external pressure, either uniformly of by bending of the material. Using pressure dependent molecular dynamics simulations we also show that the response to external pressure depends strongly on the nature of the organic layer and also here substantial tuning is possible through structural engineering

Dimensionality-Controlled Organic Semiconductor-Incorporated Perovskite Quantum Wells Jee Yung Park and Letian Dou; Purdue University, United States

Two-dimensional organic semiconductor-incorporated perovskites (OSiP) are an emerging family of hybrid materials featuring a built-in quantum well architecture. However, to date, complete tunability in terms of structures and properties has not been established owing to synthetic challenges. Controlling the dimensionality by simultaneously manipulating slab thickness of the inorganic layers while modulating conjugation length of the organic layers is yet to be achieved. Here we demonstrate a general method to synthesize phase pure dimensionality-controlled OSiP single crystals by introducing a novel solvent system. The energy band offsets and exciton dynamics at the organic-inorganic interfaces can therefore be precisely controlled. Furthermore, we reveal that longer and more planar π-conjugated organic cations induce a more rigid inorganic crystal lattice, which leads to suppressed exciton-phonon interactions and superior optoelectronic properties as compared to conventional two-dimensional perovskites. As a demonstration, optically driven lasing behavior with dramatically decreased lasing thresholds was realized.

4:30 PM EN04.02.08
Understanding Sub-Bandgap Luminescence in Ruddlesden-Popper 2D Hybrid Perovskites Igal Levine, Rowan MacQueen, Artem Musiienko, Dorothee Menzel, Hannes Hempel, Lars Korte and Thomas Dittrich; Helmholtz-Zentrum Berlin, Germany

Broad band luminescence, and/or sub-bandgap emission in Ruddlesden-Popper 2D hybrid perovskites (hereinafter termed 2D HaPs) has been widely reported in the literature, and its origin is still under debate, with two possible suggested mechanisms – Self-Trapped Excitons (STEs), vs. defect emission, i.e. radiative recombination via defect states within the bandgap.[1–3] The latter is especially important for optoelectronic applications of 2D HaPs, since non-radiative recombination of electronic charge carriers via defect states can strongly limit the performance of devices, especially the open circuit voltage (V_{oc}) of solar cells or the quantum efficiency of light emitting diodes. Distinguishing between the two recombination mechanisms (STE and defect

emission) is challenging, yet of immense importance to identify intrinsic vs. extrinsic limiting factors, and constitutes a necessary step for further device development.
In my talk, I will focus on butylammonium lead iodide (BA_2PbI_4) single crystals, as well as exfoliated layers and thin films, and show how a combination of complementary methods involving both sub-bandgap and supra-bandgap excitation such as photoluminescence, modulated and time-resolved surface photovoltage in the fixed capacitor setup, constant final state yield spectroscopy [4], and photo-Hall measurements, suggest that *defect states* rather than STE, are the main cause for the sub-band gap emission in BA_2PbI_4 . I will discuss the nature of these defect states, their relative position (surface vs. bulk), their energetic position in the bandgap, and their impact on the optoelectronic properties of BA_2PbI_4, compared to its well-studied 3D-analog methylammonium lead iodide ($MAPbI_3$).

4:45 PM EN04.02.09
Revealing Excitonic Behaviour in Vacancy-Ordered Titanium Perovskites (Cs_2TiX_6) Seán R. Kavanagh[1], Shanti Maria Liga[2], Gerasimos Konstantatos[2], David O. Scanlon[3] and Aron Walsh[4]; [1]University College London & Imperial College London, United Kingdom; [2]ICFO–The Institute of Photonic Sciences, Spain; [3]University College London, United Kingdom; [4]Imperial College London, United Kingdom

High-performance, lightweight solar cells with low-cost and non-toxic substituents are a major target in the field of solar photovoltaics.[1–4] Perovskite-inspired materials have emerged as promising candidates for this goal, with researchers employing materials design strategies including structural, dimensional and compositional transformations to avoid the use of rare and toxic elemental constituents, while attempting to maintain high optoelectronic performance. These strategies have recently been invoked to propose titanium-based vacancy-ordered halide perovskites (A_2TiX_6) for photovoltaic operation, exhibiting suitable electronic bandgaps, strong optical absorption, benign defect properties, long carrier diffusion lengths and high stability.[5–9]

Theoretical investigations of the electronic structure of this material, however, consistently overestimate the energy band gap of this material[5,8,10–15] — the most important property for photovoltaic application. In this work,[16] we reveal strong excitonic effects as the origin of this discrepancy between theory and experiment; a consequence of both low structural dimensionality and orbital localisation.

These findings have important implications for the potential optoelectronic application of these compounds, while also highlighting the crucial importance of frontier-orbital character for chemical substitution materials design strategies.

SESSION EN04.03/EN02.04: Joint Session I: Charge Transport and Defects—Characterization and Modelling
Session Chairs: Wolfgang Tress, Alexander Urban and Kai Zhu
Tuesday Morning, November 29, 2022
Hynes, Level 3, Ballroom A

8:30 AM EN04.03/EN02.04.01
Counting Defects is the Pathway to Understand Degradation in Lead Halide Perovskites Michel De Keersmaecker, Neal R. Armstrong and Erin L. Ratcliff; The University of Arizona, United States

Stability in perovskites is often connected to the presence of electronic defects, but rarely their chemical nature, reactivity and mobility are considered. Only the development of a powerful, quality and durability evaluation tool that allows direct probing of these reactive defect densities under *operando* conditions (i.e. away from equilibrium condictions) is able to correlate their chemical, electronic and physical makeup to irreversible degration processes in lead halide perovskite films.
In this work, an electrochemical methodology based on a simple half-cell device stack using a "peel and stick" electrolyte top contact that is easily

combined with various existing spectroscopic and surface characterization techniques introduces a new measurement approach to study stability across atomic-to-molecular-to device length scales. Systematic modulation of the potential and the introduction of specific redox probes to support electron and hole injection enables us to draw the most complete electronic band structure of a perovskite and by extension any semiconductor. By reducing charging currents and improving energy resolution, unprecedented detection limits are reached when probing surface defects close to both valence and conduction band with the additional benefit of identifying their (electro)chemical reactivity. Combined with X-ray scattering and photoelectron techniques, we have recently discovered that controlled polarization allows the collection of bias-dependent structural data to gain insight into interfacial and bulk degradation mechanisms during real-time operation.
Overall, this probe has demonstrated to overcome challenges for defect quantification in printable electronic materials and to promote *operando* characterization of perovskites, organic semiconductors, quantum dots, material blends and device stacks, where the removable solid electrolyte functions as the "top contact". This type of advanced electrochemical characterization platform will prove to be crucial for the quality control of low cost (opto)electronic materials and device stacks as well as the improvement of their stability and durability in order to realize industry-scalable technologies in the field of photovoltaics, charge storage systems, photoelectrochemical cells, etc.

8:45 AM EN04.03/EN02.04.02
Effects of Hole-Transport Layer and Interface Passivation on Photoinduced Halide Segregation in Mixed-Halide Perovskite Solar Cells Vincent J. Lim[1], Alexander J. Knight[1], Robert Oliver[1], Henry Snaith[1], Michael Johnston[1] and Laura Herz[1,2]; [1]University of Oxford, United Kingdom; [2]Technical University of Munich, Germany

Mixed-halide perovskites offer ideal bandgaps for tandem solar cells, but photoinduced halide segregation compromises photovoltaic device performance. We present our recent work [1] wherein we explored the influence of a hole-transport layer, necessary for a full device, by monitoring halide segregation through in situ, concurrent X-ray diffraction and photoluminescence measurements to disentangle compositional and optoelectronic changes. Our work demonstrates that top coating $FA_{0.83}Cs_{0.17}Pb(Br_{0.4}I_{0.6})_3$ perovskite films with a PTAA hole-extraction layer surprisingly leads to suppression of halide segregation because photogenerated charge carriers are rapidly trapped at interfacial defects that do not drive halide segregation. However, the generation of iodide-enriched regions near the perovskite/PTAA interface enhances hole back-transfer from the PTAA layer through improved energy level offsets, increasing radiative recombination losses. It is further found that while passivation with a piperidinium salt slows halide segregation in perovskite films, the addition of a PTAA top-coating accelerates such effects, elucidating the specific nature of trap types that are able to drive the halide segregation process. This report highlights the importance of selective passivation techniques for achieving efficient and stable wide-bandgap perovskite photovoltaic devices.

9:00 AM DISCUSSION TIME

9:15 AM EN04.03/EN02.04.04
Visualizing Macroscopic Inhomogeneities in Perovskite Solar Cells Akash Dasgupta[1], Suhas Mahesh[2,1] and Henry Snaith[1]; [1]University of Oxford, United Kingdom; [2]University of Toronto, United Kingdom

Despite the incredible progress made, the highest efficiency perovskite solar cells are still restricted to small areas (<1 cm2). In large part, this stems from a poor understanding of the widespread spatial heterogeneity in devices. Conventional techniques to assess heterogeneities can be time consuming, operate only at microscopic length scales, and demand specialized equipment. We overcome these limitations by using luminescence imaging to reveal large, millimeter-scale heterogeneities in the inferred electronic properties. We determine spatially resolved maps of "charge collection quality", measured using the ratio of photoluminescence intensity at open and short circuits. We apply these methods to quantify the inhomogeneities introduced by a wide range of transport layers, thereby ranking them by suitability for upscaling. We reveal that top-contacting transport layers are the dominant source of heterogeneity in the multilayer material stack. We suggest that this methodology can be used to accelerate the development of highly efficient, large-area modules, especially through high-throughput experimentation.

9:30 AM *EN04.03/EN02.04.05
Models of Heterogeneity in Metal Halide Perovskites Aron Walsh; Imperial College London, United Kingdom

The deeper you stare at metal halide perovskites, the more imperfections you become aware of. Dilute point defects, such as charged vacancies and interstitials, exist in a diverse landscape of extended defects including dislocations, stacking faults, and grain boundaries. To make matters worse, there are often chemical gradients in the A, B or X crystallographic positions, e.g. in mixed formamidinium/methylammonium, tin/lead, or iodide/bromide systems. I will discuss our growing understanding of these phenomena at the atomic scale drawing from our work from materials modelling [1,2] and linked to multi-modal characterisation [3,4]. The use of defect tolerance as a metric to develop and screen (post) perovskite materials will be critically addressed. This research is part of a Leverhulme Trust funded collaboration with the group of Sam Stranks and used the UK National Supercomputer ARCHER2 which is supported by UKRI.

10:00 AM BREAK

10:30 AM *EN04.03/EN02.04.06
Charge Carrier Recombination on Different Length Scales in Halide Perovskites Samuel D. Stranks; University of Cambridge, United Kingdom

Halide perovskites are promising materials for next-generation light harvesting and light emission applications. However, an absolute understanding of charge carrier recombination on all relevant length scales is essential to maximise their potential in such applications.

Here, I will outline recent work elucidating charge carrier properties in a range of halide perovskite semiconductors from the macroscale down to the nanoscale. I will report on both 3D systems dominated by free carriers and quasi-2D and 2D systems dominated by exciton recombination, highlighting the interplay between radiative recombination, carrier trapping and carrier diffusion. I will show how these photophysical properties relate to material properties, and how this information can help to further drive material and device performance optimisation.

11:00 AM EN04.03/EN02.04.07
Investigating Lead Halide Perovskites by Synchrotron X-Ray Scanning Tunneling Microscopy Sarah Wieghold[1], Nozomi Shirato[1], Lea Nienhaus[2] and Volker Rose[1]; [1]Argonne National Laboratory, United States; [2]Florida State University, United States

Despite the remarkable success of lead halide perovskites, it was recognized early on that external factors, e.g. light exposure, elevated temperatures, or electric fields can disrupt the perovskite lattice, resulting in non-photoactive phases or even in film decomposition. This phenomenon can be mainly attributed to the ionic bonding character of the lead-halide sub-lattice: both anions and cations can migrate through the perovskite film enabled by bulk and surface defects such as vacancies, interstitials or antisite substitution. Thus, to improve the stability and performance of lead halide perovskites a fundamental understanding of the impact of external factors on the local ionic chemical environment is required, which enables the development of mitigation strategies for applications in photovoltaics and light-emitting diodes.
In this contribution, we present a novel approach to measure the change in the local halide environment in perovskite thin films under applied external electric fields by synchrotron x-ray scanning tunneling microscopy (SX-STM). We investigate the influence of various applied bias polarities on the structural change of the halide ions at the perovskite interface by probing the iodide $M_{4,5}$ absorption edge by x-ray absorption spectroscopy (XAS) in the far field by SX-STM. By performing time-dependent XAS studies, we further track the change in the halide environment under continuous cycling of the applied bias. Additionally, to investigate the impact of the electric field on the spatial variation on the surface, we perform SX-STM experiments in the near field. In this geometry, the STM tip is brought into tunneling range which results in a strong field enhancement, thus local information can be obtained with nanometer resolution. Complemented by theoretical calculations, our results provide an in-depth understanding of crystal structure changes under electric fields investigated by STM.

11:15 AM EN04.03/EN02.04.08
Strain-Induced Domains Introduce Anisotropic Charge Diffusion in Perovskite Absorber Ilka Hermes[1,2], Andreas Best[2], Kaloian Koynov[2], David S. Ginger[3], Liam Collins[4], Hans-Jürgen Butt[2] and Stefan A. Weber[2]; [1]Leibniz Institute for Polymer Research Dresden e.V., Germany; [2]Max Planck Institute for Polymer Research, Germany; [3]University of Washington, United States; [4]Oak Ridge National Laboratory, United States

A heterogeneous lattice strain distribution in the polycrystalline absorber layer of perovskite solar cells (PSCs) has been connected to a range of detrimental phenomena including an increase in nonradiative recombination,[1] an acceleration of the material degradation[2] as well as an overall loss in efficiency.[3] On the other hand, during a controlled crystallization via solvent annealing,[4] the prototype perovskite absorber methylammonium lead iodide releases lattice strain by forming well-ordered subcrystalline periodic domains that alternate in their orientation of the long crystal axis.[5] Due to their ferroelastic nature, the arrangement of such domains can be influenced by heat treatments above the critical phase transition temperature and external mechanical stress.[6, 7] While the ferroelastic domains appear to exhibit a benign effect on the nonradiative recombination,[8] we observed in our correlated electromechanical atomic force and spatial and time-resolved photoluminescence microscopy study that the domains introduce an anisotropy in the charge carrier transport: charges diffusing parallel to the domains were faster than charges diffusing perpendicular to the domains.[9] Moreover, we found that the domains appear to be oriented in a 90° angle with respect to the (110) crystal plane, thus, offering an explanation for the observed improved performance for PSCs, in which the perovskite absorber features a preferential (110) orientation.[10] Here, a faster charge transport parallel to the domains may increase the charge extraction and thereby enhance the efficiency.

Heterointerface and Intragrain Microstructures of Perovskite Semiconductors Yuanyuan Zhou; Hong Kong Baptist University, China

Heterointerface and intragrain microstructures can be key factors influencing performance of perovskite semiconductors, which have been less studied. In my talk, I will discuss our recent advances on the high-resolution characterization and novel tailoring of these microstructures, advancing our fundamental understanding of microscopic structure-property-performance relationship in perovskites. Specifically, I will demonstrate the design and synthesis of an interpenetrating interface of charge-transport layer/perovskite which mitigates the (opto-)mechanical issue of perovskite solar cells, followed by a discussion on the use of a novel scanning transmission electron microscopy methodology to unravel performance-limiting intragrain interfaces in perovskite solar cells.

SESSION EN04.04: Structure-Property Relations and Stability
Session Chairs: Linn Leppert and Sarah Wieghold
Tuesday Afternoon, November 29, 2022
Hynes, Level 3, Ballroom A

1:30 PM *EN04.04.01
Inelastic Light Scattering from Disordered Crystals Omer Yaffe; Weizmann Institute, United States

In the past several years, my group investigated the structural dynamics of halide, oxide, and sulfide perovskite crystals by means of Raman scattering.
The structural dynamics of the perovskite crystals are fascinating because they exhibit a plethora of anharmonic effects such as soft modes, order-disorder phase transitions, and local fluctuations.
Such effects have significant implications on the electronic properties (e.g. dielectric response, carrier lifetimes, and carrier mobilities) of the crystals, especially at finite temperatures where these properties are invariably truly relevant.
Importantly they may lead to the relaxation of the symmetry-based selection rules for Raman scattering.
On one hand, the resulting Raman spectra are difficult to interpret, on the other, they are rich in information regarding the crystal properties.

In this talk, I will review our journey to unlock the mysteries of perovskite structural dynamics, using Raman spectra.
First, I will demonstrate and discuss a common discrepancy between x-ray diffraction data showing perfect single crystals and Raman data showing disorder.
Next, I will explain how we use generalized models of scattering to settle this discrepancy.
Finally, I will show that the intensity of the scattered light, which is an underused experimental observable, can be utilized to learn much regarding crystal properties such as dielectric response.

2:00 PM EN04.04.02
Structural Dynamics and Sharp Band-to-Band Transitions in Halide Perovskites Sebastian Caicedo Davila, Christian Gehrmann, Xiangzhou Zhu and David Egger; Technical University of Munich, Germany

Solar cells based on halide perovskites (HaPs) have achieved remarkable performance, comparable with conventional, high-quality inorganic semiconductors. However, a variety fundamental aspects in these materials remain enigmatic. For example, an important difference to conventional semiconductors is that HaPs exhibit strong vibrational anharmonicities already at around room temperature, which impact key optoelectronic properties, such as carrier transport, Urbach energy, among others. In this contribution, we investigate the impact that anharmonic lattice dynamics have on the optical absorption of the prototypical HaP, $CsPbBr_3$. Using molecular dynamics simulations based on density functional theory, we disentangle and better understand the effect of Cs dynamics on the pair-distribution function, as well as its coupling to the Pb-Br framework. Furthermore, we show that large Br displacements occur on planes transversal to the Pb-Br-Pb bonding axis. This *transversality* results in ultrashort dynamic correlations and sharp joint-density of states at finite temperature, as revealed when we contrast the results for HaPs to the case of PbTe, which shares several important properties with $CsPbBr_3$, but cannot exhibit any *transversality*. Finally, we discuss the interrelations of lattice anharmonicity, structural flexibility and bonding mechanisms in HaPs, and how they can enable their outstanding optoelectronic properties, which could provide guidelines for future materials design.

2:15 PM EN04.04.03
The Origin of Phase Impurities in FA-Rich Halide Perovskites and Their Impact on Both Performance and Stability Tiarnan A. Doherty[1], Stuart Macpherson[1], Satyawan D. Nagane[1], Dominik Kubicki[2], Affan Iqbal[1], Elizabeth Tennyson[1], Francesco Simone Ruggeri[3], Sofiia Kosar[4], Andrew Winchester[4], Young-Kwang Jung[5], Yu-Hsien Chiang[1], Kyle Frohna[1], Miguel Anaya[1], Keshav M. Dani[4], Aron Walsh[6], Paul Midgley[1] and Samuel D. Stranks[1]; [1]University of Cambridge, United Kingdom; [2]University of Warwick, United Kingdom; [3]Wageningen University & Research, Netherlands; [4]Okinawa Institute of Science and Technology, Japan; [5]Yonsei University, Korea (the Republic of); [6]Imperial College London, United Kingdom

Halide perovskite materials exhibit promising performance characteristics for low-cost optoelectronic applications. Photovoltaic devices fabricated from perovskite absorbers have reached power conversion efficiencies above 25.5 % in single-junction devices and 29.5% in tandem devices. Formamadinium (FA) lead iodide ($FAPbI_3$) and FA-rich perovskites are preferred for photovoltaic applications, but their widespread adoption is hindered by the rapid degradation of the desirable corner-sharing cubic (3C) phase to an undesirable wide bandgap, face-sharing, hexagonal (2H) phase under ambient conditions. Alloying FA with small amounts of Cs^+ and methylammonium (MA) on the A site cation of the ABX_3 perovskite structure has proven a promising strategy for stabilizing photoactive perovskite phases. For example, photovoltaic devices fabricated with compositions such as $Cs_{0.05}FA_{0.78}MA_{0.17}Pb(I_{0.83}Br_{0.17})_3$ (triple cation) perovskites have achieved high device efficiencies with greatly enhanced reproducibility and ambient stability [1]. Recently, there has also been renewed interest in methods to stabilize pure $FAPbI_3$ through strategies such as the incorporation of MA via treatment with methylammonium thiocyanate vapour [2], addition of formamidinium formate [3] or methylammonium formate [4].
The mechanism of improved stability obtained from these approaches is generally explained as either originating from a tuning of the Goldschmidt tolerance factor towards the perfect cubic perovskite structure via cation mixing in the case of Triple Cation perovskites [1,5], by templating growth of the corner-sharing cubic structure in stabilized-$FAPbI_3$perovskites[2,4], or by reducing intrinsic defect density [3]. The key tenet in all these explanations is that the final photoactive perovskite material, regardless of stabilization approach, is a cubic perovskite structure and that this is the structure that should be pursued for optimal stability and performance. Here, we reveal that rather than being cubic, FA-rich perovskites exhibit a slight degree of octahedral tilting that frustrates the transition from the corner sharing photoactive phase to hexagonal photoinactive phases[6]. Local regions of stabilised FA-rich perovskite films that do not exhibit octahedral tilting, transition to nanoscale hexagonal phase impurities that are rich in performance limiting defect clusters[7]. Finally, we show that by modulating the magnitude of octahedral tilting through compositional modification in FA-rich perovskites, the density of these sinister hexagonal phase impurities, and thus overall film photostability, can be tuned. Combined, our talk provides insight into the common origin of performance losses and photostability issues in FA-rich perovskite materials as well as a pathway to mitigate them[8].

Looking Inside Halide Perovskites Using On-The-Fly Machine Learning Force Fields Menno Bokdam; University of Twente, Netherlands

Recent developments in the field of high efficiency perovskite solar cells are based on stabilization of the perovskite crystal structure of $FAPbI_3$ while preserving its excellent optoelectronic properties. Compositional engineering of, for example, MA or Br mixed into $FAPbI_3$ results in the desired effects, but detailed knowledge of local structural features, such as local (dis)order or cation interactions of formamidinium (FA) and methylammonium (MA), is still limited. This knowledge is, however, crucial for their further development. In this talk, I will present how recent developments in Machine Learning accelerated ab-initio Molecular Dynamics (MD) enable the required length and time scale simulations that can assist in solving some of the open questions. For example, the generated large isothermal-isobaric ensembles can be used to calculate the ^1H-^1H dipolar coupling coefficients that can be compared with those obtained by nuclear magnetic resonance spectroscopy measurements[1]. Furthermore, we can calculate the momentum resolved phonon spectrum by 'measuring' their frequencies and lifetimes directly from velocity auto-correlation functions[2]. We observe that the lifetime of many phonon modes is of the order of the inverse of its frequency. This shows the strong anharmonicity of the potential energy surface of halide perovskites, and the necessity of MD approaches. Overall, there is qualitative and quantitative agreement between experiment and theory on several experimental observables, which leads us to think that the simulated crystals structure trajectories provide a realistic insight into the ionic dynamics of the studied samples.

Stressing Halide Perovskites—Nanoscale Investigation of the Properties of Perovskite Thin Films Sarah Wieghold[1] and Lea Nienhaus[2]; [1]Argonne National Laboratory, United States; [2]Florida State University, United States

Solution-processed perovskite thin films consist of small grains with a size of 20 - 2000 nm connected by grain boundaries. As a result, there is a vast inhomogeneity in the optical and electronic properties of the different grains/GBs within one film, which can reduce the achievable energy output. In addition, facile ion movement under external stimuli (light or electric fields) adds additional complexity to the system.
To gain insight into the optoelectronic and structural response of the perovskite thin film to these external stressors present under operating conditions, we utilize scanning tunneling microscopy (STM). Single molecule absorption STM (SMA-STM) can probe the local inhomogeneity of the surface properties of the perovskite thin film under illumination by locally mapping the additional photogenerated tunneling current. To understand whether the local changes are caused by optoelectronic changes under illumination or structural changes, we utilize synchrotron X-ray STM (SX-STM). Pump-probe wide-angle X-ray scattering indicates the presence of lattice deformations under optical illumination, highlighting that the photocarriers distort the lattice, and thus, can change the underlying density of states as observed by SMA-STM.

4:00 PM EN04.04.06
Multiscale Modelling of Defects in Halide Perovskites—Implications for the Phase Stability and Degradation Reactions Induced by Thermochemical Stress Mike Pols[1], Adri C.T. van Duin[2], Sofia Calero[1] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]The Pennsylvania State University, United States

The outstanding optoelectronic properties of metal halide perovskites (MHPs) have attracted a lot of attention from the optoelectronic community recently. Despite the significant increase in efficiency, the commercialization of perovskite optoelectronic devices is hampered by long-term stability problems. This is because the common fabrication method, i.e. solution processing, is known to produce polycrystalline films with a wide variety of defects, such as point defects, surfaces and grain boundaries. Although the optoelectronic effects of these defects have been widely studied, a detailed understanding of their impact on the long-term stability, particularly an understanding of the degradation dynamics at the atomic scale, is still lacking.

In this presentation, I will outline our recent advances in studying the dynamical processes and their implications on the stability of halide perovskites using computational multiscale modelling. Our approach combines several levels of theory, including reactive force fields (ReaxFF) [1, 2], density functional tight-binding (DFTB) [3] and machine learned force fields (MLFF) [4]. The multiscale approach allows us to obtain important insights into the dynamical properties at the atomistic scale at various time scales, including phase transitions, phase stability, defect migration and defect-induced degradation reactions in the bulk, at surfaces and near grain boundaries for perovskites with various compositions. The atomistic insights gained in these simulations allow us to propose strategies to passivate and mitigate these defects and thereby stabilize the materials.

Mutual Influence of (Anti)Solvents and Precursors on Halide Perovskite Formation Mriganka Singh, Maged Abdelsamie, Tim Kodalle and Carolin M. Sutter-Fella; Lawrence Berkeley National Laboratory, United States

Halide perovskites with mixed A- and X-site cations and anions, respectively, are important to overcome challenges such as thermal and structural instabilities, as well as moisture sensitivity. Triple cation, mixed halide perovskite compositions have been reported to be more thermally stable, exhibit less phase impurities, and are less affected by the processing conditions than single cation perovskites. In this work, we present a multimodal in situ study on the formation of $Cs_{0.05}FA_{0.81}MA_{0.14}Pb(I_{0.85}Br_{0.15})_3$ by combining structural information from grazing-incidence wide-angle synchrotron X-ray scattering (GIWAXS) and optical properties from photoluminescence (PL) spectroscopy. This study covers the predominantly used solvents and solvent systems DMF, DMSO and mixtures thereof. We are looking at the solvent-antisolvent interaction and evaluate if the antisolvent induces oversaturation

accompanied by solvate phase formation or if it removes the solvent and thereby suppresses solvate phases. We find that the non-perovskite delta-$FAPbI_3$ appears in all crystallization pathways. It is strongly correlated with the antisolvent dripping and temporally close to the perovskite phase formation. It was also found that the delta phase is more stable in DMF than in DMSO systems. These findings provide novel insights into solvate and perovskite phase evolution and its mutual correlation with the solvent and antisolvent to allow for better synthetic control.

Intrinsic Light Instabilities in Metal Halide Perovskites Jeremy G. Hieulle[1], Muhammad U. Farooq[1], Joana A. Ferreira Machado[1], Ajay Singh[1], Anurag Krishna[2], Anders Hagfeldt[2] and Alex Redinger[1]; [1]University of Luxembourg, Luxembourg; [2]École Polytechnique Fédérale de Lausanne, Switzerland

Solution-processed metal halide perovskite solar cells are currently under the spotlight due to their high-power conversion efficiencies and easy fabrication. However, the commercialization might be hampered by certain drawbacks such as device degradation and hysteresis [1]. Several hypotheses have been formulated concerning the physical origins of the rapid deterioration of the perovskite absorbers, such as vacancies, ion migration, and phase segregation [2-3]. Recent reports in the literature, investigating the perovskite degradation by X-ray photoelectron spectroscopy suggest that X-ray exposure triggers the release of the organic cations as well as the dissociation of PbI_2 into metallic lead Pb(0) and I_2 [4-8]. However, ***a fundamental understanding of the role of low energy light (white light) on the intrinsic degradation mechanism taking place in metal halide perovskite is still lacking***.

In this work, we combined scanning probe microscopies (STM, AFM, KPFM), and X-ray photoelectron spectroscopy (XPS) to systematically investigate the effect of light, X-ray, and temperature on the intrinsic stability of the metal-halide $(FAPbI_3)_{0.97}(MAPbBr_3)_{0.03}$ perovskite interface. In contrast to what is usually admitted [6-8], white light has a stronger effect on perovskite degradation as compared to X-rays. Importantly, we show that cooling down the sample helps reduce the formation of Pb(0) and prevents the release of the organic cation during sample analysis. Kelvin Probe microscopy measurements allowed us how to link the losses of the organic cations and iodine to changes in the work function of several hundred meV. The STM measurements reveal drastic changes in the local density of states. We do observe a bandgap shrinkage and strong lateral variations after light exposure. A model, explaining the compositional and electronic changes at the surface will be presented. In addition to providing useful insights into the intrinsic light-induced degradation of perovskite, our findings also offer useful guidelines for more accurate and non-invasive XPS analyses of this highly sensitive material system.

Structural Dependence of Light-Induced Halide Segregation in Mixed-Halide Lower-Dimensional Perovskites Kunal Datta, Alessandro Caiazzo, Zehua Chen, Geert Brocks, Peter Bobbert, Shuxia Tao, Martijn Wienk and René Janssen; Technische Universiteit Eindhoven, Netherlands

The advent of layered Ruddlesden-Popper phases promises the development of efficient lead-halide perovskite optoelectronic devices. Such lower-dimensional phases are more defect tolerant and resistant to environmental stressors, compared to three-dimensional (3D) analogs, leading to high operational stability.[1] Mixed-halide compositions which are relevant for multijunction photovoltaic applications are, however, poorly characterized and as a result, the occurrence of light-induced instabilities is not well-understood in lower-dimensional phases. In 3D mixed-halide perovskites, such light-induced halide segregation leads to the formation of low-energy iodide-rich phases that act as trap sites, thereby limiting charge-carrier collection and limiting photovoltaic performance.[2]

This work uses a model phenethylammonium-based series of lower-dimensional perovskites (n = 1, 2) and characterizes the occurrence of light-induced halide segregation through time- and temperature-dependent photoluminescence spectroscopy. It is found that the two-dimensional (2D) phase is largely resistant to halide segregation, even at high light intensity. Density functional theory calculations show that this is a consequence of preferential occupancy of halide (iodide and bromide) ions and halide vacancy defects between the axial and equatorial lattice sites which limits ion migration pathways in the 2D phase.[3]

A co-solvent engineering approach is then used to develop a structurally stratified mixed-halide films with lower-dimensional (n = 1,2) phases at the substrate interface and higher-dimensional (approx. 3D) at the air interface, verified by grazing-incidence wide-angle X-ray scattering.[4] An intermediate quasi-2D phase (n = 2) thus formed shows vulnerability to light-induced instability, similar to a 3D phase, with a characteristic red-shift related to the formation of iodide-rich phases. However, the entropic re-mixing of halide ions that occurs in 3D perovskites when stored in dark conditions is absent in quasi-2D phase; this is due to a higher activation barrier for ion migration in the quasi-2D phase which can occur at elevated temperatures to restore the well-mixed phase.

Collectively, these observations show that the structural nature (2D, quasi-2D or 3D) of mixed-halide perovskites plays a strong role in determining iodide-bromide phase stability in mixed-halide compositions. The contrast appears in both the occurrence of halide segregation under illumination and its reversal in the dark, guiding material design decisions for efficient and stable devices based on mixed-halide compositions.

Manipulating the Fundamental Building Blocks of All-Inorganic Metal-Halide Perovskites Toward Novel Electronic Behavior Maria C. Folgueras, Jianbo Jin, Yuxin Jiang, Mengyu Gao and Peidong Yang; University of California, Berkeley, United States

Metal-halide perovskites are viewed as next-generation semiconductor materials due to their facile solution processability and interesting photophysical and optoelectronic phenomena. The properties of the traditional all-inorganic ABX_3 perovskites ($A = Rb^+, Cs^+$; $B = Pb^{2+}, Sn^{2+}$; $X = Cl^-, Br^-, I^-$) are dominated by the three-dimensional (3D) network of metal-halide $[BX_6]$ octahedra within the crystal structure, as these octahedra serve as both the structural and functional units of the material. Manipulation of these octahedral units thus enables modulation of the perovskite crystal's electronic structure and optoelectronic properties and is traditionally achieved by (1) tuning the crystal's dimensionality, and/or (2) varying the crystal's B-site and X-site elements to form pure-halide and mixed-halide compositions. However, another mode of manipulation is to physically isolate the fundamental octahedral building block within the lattice, as is the case in the zero-dimensional (0D) vacancy-ordered double perovskites of form A_2BX_6. In particular, all-inorganic Cs_2TeX_6 ($X = Cl^-, Br^-, I^-$) single crystals are an excellent platform for exploring the effect that the isolation of $[TeX_6]^{2-}$ octahedra in the crystal structure has on structural and electronic properties. Serving as the vibrational centers, the isolated octahedra inform the presence of strong exciton-phonon coupling and anharmonic lattice dynamics, as well as the likelihood of a random distribution of 10 octahedral symmetries within the mixed-halide compositional spaces. Serving as the absorbing and emitting centers, the isolated octahedra exhibit compositionally tunable absorption (1.50-3.15 eV) and emission (1.31-2.11 eV) energies. Due to greater molecular orbital overlap between neighboring octahedra with increasing halide anion size, there is a transition from a more molecule-like electronic structure in Cs_2TeCl_6 and Cs_2TeBr_6 – as expected from the effective 0D nature of these single crystals – to a dispersive electronic structure in Cs_2TeI_6, typical of 3D bulk single crystals. Furthermore, by manipulating the ionic bonding in these crystals, 0D semiconductor perovskite inks of Cs_2TeX_6 are readily produced, in which Cs^+ cations and $[TeX_6]^{2-}$ octahedral complex anions are stabilized in polar aprotic solvents without the presence of ligands. The successful stabilization of the fundamental $[TeX_6]^{2-}$ octahedral molecules in solution creates multifunctional inks with the ability to reversibly transform between the liquid ink and the solid-state perovskite crystalline system in air within minutes, highlighting the crucial role of solvated octahedral complexes toward the rapid formation of phase-pure perovskite structures in ambient conditions. Given that these fundamental octahedral building blocks (with maximum length of 5-6 Å) can be stabilized in solution without ligands (as opposed to colloids, whose stability requires the use of ligands), these inks open the possibility to design new perovskite materials and to probe fundamental energy transfer and electronic properties intrinsic to the octahedral building block.

Ultrafast Carrier and Quasiparticle Dynamics in Strongly Confined $CsPbBr_3$ Nanoplatelets Etienne Socie[1], Brener RC Vale[2] and Jacques-E. Moser[1]; [1]EPFL, Switzerland; [2]University of Campinas, Brazil

Over the past decade, lead halide perovskites have received considerable attention thanks to their impressive optoelectronic properties. Today, perovskite-based devices are one of the most efficient single-junction solar cells, with a power-conversion efficiency reaching 25.7%. In the same way, nanostructures of the same material emerged with tremendous potential for light-emitting and lasing applications. In addition, their complex and dynamic structure makes them fascinating for fundamental photophysical studies, not only to apply in the context of the device improvements but also for a much broader class of semiconductor materials.
Typically, charge carrier dynamics on the ultrafast and fast (fs to ps) timescales are monitored by time-resolved spectroscopic techniques using ultrashort laser pulses. The aim of this work is to associate transient absorption (TA) and time-resolved photoluminescence (TRPL) spectroscopy for investigating early photophysical mechanisms in low-dimensional perovskite nanocrystals (PNCs). While most available TRPL experimental techniques are limited by a temporal resolution of a few picoseconds, we employ broadband fluorescence upconversion spectroscopy (FLUPS) to obtain 2D spectro-temporal data with a sub-ps time resolution.
After discussing the synthesis and standard characterization of colloidal blue-emitting $CsPbBr_3$ nanoplatelets (NPls) we investigate the charge carrier dynamics under weak and strong excitation regimes. Under low excitation intensities, the NPl dynamics are dominated by an ensemble of independent excitons and show complex photophysical behaviors. Besides, at high pump fluences, enhanced carrier-carrier interactions induce stable and emissive biexcitons. The properties and recombination mechanisms of the biexcitons follow typical quantum well signatures. Finally, we unveil that the NPls can easily form a complex with organic acceptors attached at the surface, quenching the material emission. Excitation energy-dependent FLUPS measurements display fast interfacial charge transfer from the perovskite band edge and ultrafast hot carrier transfer from higher energy levels.

EN04.05.03
Difference in Degradation-Induced Trap Formation Between Mixed Lead Tin and Tin Halide Perovskites Vincent J. Lim[1], Aleksander M. Ulatowski[1], Christina Kamaraki[2,3], Matthew T. Klug[2], Laura Miranda[2], Michael Johnston[1] and Laura Herz[1,4]; [1]University of Oxford, United Kingdom; [2]Oxford PV, United Kingdom; [3]University of Bath, United Kingdom; [4]Technical University of Munich, Germany

Metal halide perovskites have the potential to surpass the single-junction detailed-balance limit with a tandem device architecture, taking advantage of their bandgap tunability. Mixed lead-tin halide perovskites offer the ideal bandgap as the bottom subcell for such photovoltaic device due to their bandgap bowing effect. However, they suffer from instability in ambient air, more so than their lead counterparts. Likewise, tin halide perovskites, promising for their lead-free nature, also suffer from severe instability. The degradation mechanism in mixed lead-tin halide perovskites has been thought to be similar to that of tin halide perovskites, namely through tin vacancy formation and self p-doping. We highlight our recent work [Lim *et al.*, Adv. Energy Mater. (**2022**)] wherein we investigated and contrasted the difference in optoelectronic degradation and trap formation between mixed lead-tin and tin halide perovskites in ambient air. Both compositions suffer from optoelectronic degradation, due to trap state formation, over hours of ambient air exposure. However, we report deep trap state formation in lead-tin perovskites during ambient air exposure, which accelerate charge-carrier recombination, without significant impact on charge-carrier mobilities. In contrast, tin-only perovskites undergo shallow tin vacancy trap state formation and hole donation. This report highlights the need for specifically tailored passivation techniques for mixed lead-tin iodide perovskites. We expect such treatments will ultimately improve air stability, facilitating the commercialization of all-perovskite tandem devices.

Lim, V. J.-Y. *et al.*, Air-Degradation Mechanisms in Mixed Lead-Tin Halide Perovskites for Solar Cells, Adv. Energy Mater. (**2022**), 2200847, DOI: 10.1002/aenm.202200847

EN04.05.04

Advanced Kelvin Probe Force Microscopy Methods to Study Mixed Halide Perovskites Pascal N. Rohrbeck[1], Yenal Yalcinkaya[1,2], Konstantinos Bidinakis[1], Lukas D. Cavar[2], Peter Reichel[2] and Stefan A. Weber[1,2]; [1]Max Planck Institute for Polymer Research Mainz, Germany; [2]Johannes Gutenberg University, Germany

Although perovskite solar cells (PSCs) are a good alternative to silicon solar cells, the basic physics and mechanisms of limiting efficiency are not fully understood.
Atomic force microscopy (AFM) methods are ideal for studying nanoscale electrical devices such as batteries, solar cells, and diodes. Using electrical operation modes enables studying nanoscale surface properties such as contact potential differences [1], dielectric properties, space charge layers and local photovoltages [2]. In addition, using a pulsed or AC excitation enables probing dynamics, as well.
In our group, we develop and use the Kelvin probe force microscopy (KPFM) techniques to answer unsolved questions about efficiency losses due to non-radiative recombination processes and stability problems in atmospheric conditions at the nanoscale. These methods, such as time-resolved KPFM (tr-KPFM) and pump-probe KPFM (pp-KPFM), can be used to investigate dynamics in the perovskite like ultra-fast photovoltage behaviour due to migration of excitons or ions.
Also we use frequency-dependent capacity mapping[3] for investigations in the capacitance, capacitive charging and dielectric properties e.g., at grain boundaries.
This will help to understand the loss mechanism and therefore improve efficiencies of perovskite solar cells in the macroscale.

EN04.05.05
Limits from Charge Carrier Doping, Mobility and Lifetime on the Potential Performance of Sn and Pb-Based Halide Perovskites Hannes Hempel[1], Klaus Schwarzburg[1], Francisco Pena-Camargo[2], Martin Stolterfoht[2], Fatima Akhundova[1], Artem Musiienko[1] and Thomas Unold[1]; [1]Helmholtz Zentrum Berlin, Germany; [2]University of Potsdam, Germany

Measuring the quantum yield of photoluminescence is a powerful and widely used technique to characterize photovoltaic materials. It can reveal an upper limit for the potential solar cell performance from measurements on neat thin films and can even predict the implied current-voltage (*JV*) characteristics. However, the contributions from charge carrier doping and lifetimes to the implied voltage are usually not distinguished, and ideal charge carrier transport is assumed for the *JV* prediction. To gain more insights into the performance limiting factors, we use time-resolved photoluminescence, which allows us to determine the charge carrier lifetimes, doping, and mobilities for lead and tin halide perovskites.
Carrier lifetimes are probed under solar AM1.5-equivalent illumination employing sinusoidal modulation as well as under solar AM1.5-equivalent illumination superimposed with a weak pulsed photoexcitation. Such illumination conditions directly yield the relevant lifetime for photovoltaic application and avoid photoluminescence decays that are not connected to charge recombination. The charge carrier lifetimes of a few microseconds measured for lead-based are much larger than the few ns obtained on tin-based perovskites, which translate into larger voltage losses for the tin perovskite solar cells. The doping is accessed from the initial photoluminescence amplitude and increases from ~10^{13}cm^{-3} for lead perovskites to >10^{17}cm^{-3} for tin perovskites. This doping of the lead perovskite is much smaller than the photogenerated carrier concentration under solar illumination at open-circuit conditions and also smaller than the charge needed to affect the built-in potential under short circuit conditions. Hence, it has a negligible impact on the solar cell performance and lead-perovskite can be considered intrinsic. In contrast, the doping of the tin-based perovskites is much larger than the photogenerated carrier concentration under solar illumination and partially compensates for the low charge carrier lifetime, and significantly contributes to the implied Voc.
The charge carrier mobility is obtained from the initial decay component of photoluminescence after pulsed photogeneration. For the Pb-based perovskites, the charge carrier diffusion through the thin film takes ~100 ns and is described with a mobility of 0.4 cm^2/Vs, which is in line with complementary Hall measurements. This mobility is significantly lower than the terahertz-derived mobility of ~32 cm^2/Vs for the nm-scale intragrain transport and indicates strong transport barriers at grain boundaries which leads to fill-factor losses in the solar cells.

EN04.05.06
Synthesis, Study and Applications of Halide Perovskites at the Ionic Octahedron Level Jianbo Jin[1], Maria C. Folgueras[1], Cheng Zhu[1], Mengyu Gao[1], Lina Quan[2] and Peidong Yang[1,3]; [1]University of California, Berkeley, United States; [2]Virginia Tech, United States; [3]Lawrence Berkeley National Laboratory, United States

Metal halide ionic octahedron, $[MX_6]^{n-}$ (M = metal cation, X = halide anion), is the fundamental building block and functional unit of metal halide perovskites. The optoelectronic and chemical properties of the extended perovskite solids are dictated by the assembly, connectivity, and interaction of these octahedra. Hence, building up a fundamental understanding at the level of metal halide octahedron will lay the foundation for the synthesis, study, and applications of their solid assembly. The first part of the report will focus on new design principles for constructing new perovskite materials. In particular, when one considers the octahedron as a super ion/atom, the halide perovskites can be described as extended ionic octahedron networks (IONs) stabilized with counterions. Based on the IONs design principle, a new metal halide perovskite ($Cs_8Au_{3.5}In_{1.5}Cl_{23}$) was successfully synthesized as the first example, where three different metal halide octahedra were packed in the style of ABO_3-type lattice. In addition to IONs, a new family of (Crown-ether@A)$_2$M(IV)X$_6$ was achieved with supramolecular molecule crowned alkali metals as the counterions and assembled from a structurally and optoelectronically tunable “dumbbell” structural unit in solution. We will also report how non-ambient conditions affect the packing, connectivity, and configuration of metal halide octahedron, and how it dictate the properties of the solid assembly. Two levels of distortions, including within and among the $[BiBr_6]^{3-}$ octahedra, have been identified in low-temperature measurements, which reveal the symmetry-related electronic and excitonic behaviors.

EN04.05.08
Cationic Liganding is at the Origin of Quantum Well Orientation and Population Distribution in Reduced Dimensional Perovskites Kasra Darabi, Dovletgeldi Seyitliyev, Boyu Guo, Fazel Bateni, Tonghui Wang, Masoud Ghasemi, Laine Taussig, Milad Abolhasani, Kenan Gundogdu and Aram Amassian; North Carolina State University, United States

Layered hybrid perovskite (LHP) films exhibit highly anisotropic properties including charge and energy transport along quantum wells (QWs), as well as energy and charge transfer between QWs of different sizes. The control of QW orientation and population distribution within LHP films is therefore critically important to various applications ranging from solar cells to LEDs, lasers, and field-effect transistors. It is not surprise, then the hybrid perovskites community has deemed it a scientific and technological imperative to understand the origins of QW orientation and population distribution in LHP films. Despite tremendous recent efforts to understand the mechanism of crystallization in these materials, significant questions remain about the origins of crystalline texture, QW orientation and distribution in LHPs. Here we elucidate the precise solution-to-solid conversion of the sol into the LHP thin film by the aid of using multimodal in-situ characterization techniques such as grazing-incidence wide-angle X-ray scattering (GIWAXS), UV-vis absorption, and photoluminescence (PL). We identify, for the first time, the presence of oriented colloidal templating nanostructures (CTNs) during spin coating at the sol-air interface, that are highly emissive but do not diffract, well before the onset of crystallization of the QWs or 3D phases. According to our in-situ observations along with quantitative analysis, we propose a growth model for CTNs that can explain the underlying reason behind tremendous texture in these thin-films. Furthermore, we test our hypothesis by engineering CTNs during antisolvent drip to manipulate the texture as well as QWs distribution in LHP thin films.

EN04.05.11
Halide Effect on White Light Emission from Low Dimensionality Perovskites Ido Hadar and Bar Bader; The Hebrew University of Jerusalem, Israel

Hybrid halide perovskites are a novel class of semiconductor materials with promising and versatile optoelectronic properties, enabled by their chemically flexible structures and dimensionality. The diversity in the metal ions, halide anions, and organic spacers enables a wide range of materials with highly tunable properties and variable dimensionalities. These materials are studied for various applications such as solar cells, detectors, and light-emitting diodes. The ability to control and adjust the optical properties for a required application is significant. Thus, an improved understanding of the structure and optical mechanisms is crucial.
Specific low-dimensionality hybrid halide perovskites exhibit white-light emission at room temperature, associated with self-trapped excitons (STE), making them ideal candidates for illumination applications. We study the correlation between chemical and structural motifs of low dimensionality (2D, 1D) halide perovskites and their STE emission. Our current research is focused on studying how the composition and specifically exchanging of the halide anions (Br to I or Cl) while maintaining the structural motifs affect the STE properties. We found a reversed correlation between the bandgap energy of these structures and the STE central peak.

EN04.05.12
Spatiotemporal Engineering of Carrier Dynamics by Nanopatterning Halide Perovskite Surfaces Taehee Kim, Do Hyung Chun, Jong Hyeok Park and Dongho Kim; Yonsei University, Korea (the Republic of)

Halide perovskites are popular choice for photoactive layer material in high-performance optoelectronic applications. These devices work by extracting or injecting charge carriers from/into the perovskite layer, through the interface in contact with transporting layers. Thus, in order to exploit the device efficiency to its fullest, it is of critical importance to engineer the charge carrier transport and recombination kinetics at the surface of perovskite layer[1,2]. In-situ nanoscale patterning is an explicit strategy to manipulate the perovskite surface, which benefits both the performance and the ambient stability of perovskite-based devices[3,4]. However, such virtues of nanopatterning crystallization of perovskites remain underrated due to the lack of understanding of the fundamental photophysics beneath.
With the aid of interplay between nanoscale spatial scanning and temporally resolved photon-recording, fluorescence lifetime imaging microscopy (FLIM) provided a powerful means to explore the surface energetics of nanopatterned perovskites. Grain growth process of $MAPbI_3$ perovskite was assisted by nanopattern template and resulted in a more compact surface morphology with lower grain boundary angle. Nanoscale patterns with various geometry delicately modified the carrier kinetics at grain surfaces. Carrier density dependence of FLIM statistics revealed a large deceleration of bimolecular recombination rate, indicating a broader energetic distribution of carriers accompanied by band structure alteration upon pattern imprinting. Time-resolved imaging of carrier density profile uncovered the enhancement of carrier transport in hole-patterned perovskite, both at top and buried surfaces. Increase in initial diffusivity implies a higher chances of charge extraction, which was attributed to the combined effect of decreased carrier effective mass and reduced defect density at surface by grain boundary healing effect. Solar cell and photodetector devices were fabricated, and performance results suggested an optimal device structure to properly utilize the nanopatterned perovskite surfaces. Robust tuning of surface carrier kinetics proves in-situ nanopatterning a versatile tool for engineering the photoactive layer and should inspire creative design protocols for future optoelectronic devices.

Bright Exciton Fine Structure Splitting and Direction Selective Exciton-Phonon Coupling in $(PEA)_2Pb_nI_{3n-1}$ 2D Perovskites Michal Baranowski[1], Katarzyna Posmyk[1], Natalia Zawadzka[2], Mateusz Dyksik[1], Alessandro Surrente[1], Duncan Maude[3], Watcharaphol Paritmongkol[4], Adam Babinski[2], Maciej R. Molas[2], Miroslaw Maczka[5], William Tisdale[4] and Paulina Plochocka[3,1]; [1]Wroclaw University of Science and Technology, Poland; [2]University of Warsaw, Poland; [3]Laboratoire National des Champs Magnetiques Intenses, France; [4]Massachusetts Institute of Technology, United States; [5]Institute of Low Temperature and Structure Research, Poland

Two-dimensional (2D) metal-halide perovskites have emerged in the recent decade as revolutionary semiconductor materials for light emission and energy harvesting applications. At the same time, 2D perovskites constitute a fascinating playground for fundamental exciton physics studies. Strongly enhanced excitonic effects [1] together with characteristics for ionic crystal coupling of excitonic species to lattice vibration [2], [3] and low symmetry of the crystals challenge our understanding of this elementary excitation. The low symmetry of 2D perovskites lattice affects simultaneously the exciton structure [4] and phonon modes degeneracy [5] leading to nontrivial mutual dependencies between lattice dynamics and electronic excitation resulting in a complex absorption and emission spectrum whose detailed origin is the subject of ongoing controversy.
Here we employ low-temperature magnetooptical spectroscopy to reveal the bright exciton fine structure of $(PEA)2Pb_nI_{3n-1}$ single crystals. We observe two nondegenerate orthogonally-polarized bright in-plane free exciton states for n=1,2,3 both in reflectance and photoluminescence spectra. We show that the redshifted multiple-peak PL response often ascribed to free exciton transition is a manifold of phonon-dressed states that preserve the polarization of the corresponding FX state[4]. Therefore our results corroborate the most simple picture of exciton FSS derived from symmetry considerations. Moreover, we observe fine structure splitting also for the transition corresponding to exciton phonon replica. Interestingly in this case the energy separation of the two orthogonal states is different than for the zero phonon lines. This strongly indicates the selective coupling of two in-plane excitons states to different non-degenerate high-energy phonon modes, highlighting the importance of the internal lattice symmetry of 2D perovskites for the optical response.

Photocatalytic Degradation of Alkyl Halide Molecules and Anion Exchange in Dispersions of $CsPbBr_3$ Perovskite Nanocrystals Selin Donmez, Sisi Wang and Hedi M. Mattoussi; Florida State University, United States

Since the first successful implementation of bottom-up growth of colloidal cesium lead halide perovskite nanocrystals (PNCs), these materials have generated intense interest and much activity. This has been motivated by the combination of unique photophysical properties with the ionic nature of the semiconducting cores. One interesting property of these materials is the ability to substitute the halide elements in the crystal lattice through anion exchange.
Here, we present a detailed investigation of the photo-assisted anion exchange reaction of $CsPbBr_3$ NCs dispersed in chlorinated solvents. We probe the kinetics of this process by varying the irradiation source, time, structure of the solvent molecules and the corresponding reduction potentials. We further carry out a thorough characterization of the PNC intermediates during the irradiation period until complete anion exchange, using optical and fluorescence spectroscopy measurements, powder X-ray diffraction (PXRD) and supplement them with x-ray fluorescence spectroscopy (XRF) to track changes in the crystal structure and stoichiometry. Our findings indicate that the PNC acts as a photocatalyst promoting the degradation of solvent molecules, via a dissociative electron transfer process. The transformation requires photons with energy that exceeds the bandgap of the materials. It also generates reactive chloride ions, triggering intensity- and time-dependent anion exchange concomitant with shifting of the optical characteristics of the samples.

Valence Band Dispersion of the Structural Ground State $CH_3NH_3PbI_3$ Studied by Angle-Resolved Photoelectron Spectroscopy Jeehong Park[1,2], Soon Sang Huh[3,4], Young Woo Choi[1], Soohyung Park[5], Hyoung Joon Choi[1], Changyoung Kim[3,4] and Yeonjin Yi[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Van der Waals Research Center, Korea (the Republic of); [3]Institute for Basic Science, Korea (the Republic of); [4]Seoul National University, Korea (the Republic of); [5]Korea Institute of Science and Technology, Korea (the Republic of)

Lead halide perovskites (LHP) are a novel class of semiconducting materials which have attracted considerable research interest in a wide range of optoelectronic applications due to their long charge carrier lifetimes and carrier diffusion lengths despite the low-cost fabrication methods. Different hypotheses, including the Rashba effects, Fröhlich large polaron formation and ferroelectricity, have been proposed to elucidate the microscopic origin of peculiar charge carrier dynamics of LHPs. Although these effects are generally accompanied by the modifications of their underlying electronic structure, the key experimental evidence has been lacking so far.

Here, we investigate the electronic structure of structural ground state of CH3NH3PbI3, the archetypical hybrid-type LHP material, studied via spin- and angle-resolved photoelectron spectroscopy (ARPES) combined with ab initio density functional theory (DFT) calculations. By establishing careful optimizations of sample preparations and experimental protocols, we present the pristine quality of ARPES with the key spectral features revealed for the first time. With our in-depth analysis of measured electronic dispersions, we comprehensively discuss the Rashba effect and Fröhlich large polaron formation in the uppermost valence band of CH3NH3PbI3.

Microstructural Evolution of Perovskite Solar Cells During Thermal Annealing Holger Roehm, Alexander D. Schulz, Tobias Leonhard, Alexander Colsmann and Michael J. Hoffmann; Karlsruhe Institute of Technology, Germany

$MAPbI_3$ amongst other OMH perovskites is undergoing tetragonal-to-cubic phase transitions within the operational temperature range of solar cells. Many properties of these hybrid perovskite materials, such as piezoelectricity, pyroelectricity, ferroelectricity and ionic conductivity are directly linked to the crystal phase and temperature of the sample. Notably, polar domains that form in $MAPbI_3$ thin-films during the solar cell fabrication have been observed,[1,2,3] We have previously shown that poling of these domains can be achieved in an external E-field that is similar to built-in fields in solar cells during operation.[4]

In this work, we use Piezoresponse Force Microscopy to monitor an evolution of these domains that is triggered by common thermal treatment of perovskite solar cell at 100°C.[5] Our findings suggest that control over the domain structure in these light absorbing, semiconducting compounds may be essential in order to maximize performance and stability of hybrid perovskite solar cells. In particular, microstructural changes due to stress and strain when the thin-films undergo a tetragonal/cubic phase transition are an often overlooked factor responsible for degradation of perovskite solar cells. We show that local crystal defects can form and vanish both at ferroic domain walls and crystal grains and in turn modulate ionic conductivity and diffusion.

EN04.05.19
Kinetic Origins of High Preferential Crystal Orientation in Quasi-2D Perovskite Solar Cells Lukas Lehner[1], Stepan Demchyshyn[1], Kilian Frank[2], Alexey Minenkov[1], Dominik Kubicki[3], Bekele H. Teklemariam[1], Christoph Putz[1], Niyazi Serdar Sariciftci[1], Bert Nickel[2], Markus Scharber[1] and Martin Kaltenbrunner[1]; [1]Johannes Kepler University, Austria; [2]Ludwig-Maximilian University, Germany; [3]University of Warwick, United Kingdom

Pure 2D and mixed 2D/3D perovskites have emerged as a more stable and versatile class of materials for solar cell absorbers compared to their pristine 3D counterparts. However, the large organic cations employed to generate these lower-dimensional structures tend to inhibit charge transport across the device, decreasing performance. Therefore, aligning the organic sheets vertically to the substrate to facilitate unimpeded flow of electrons is critical to realize high power conversion efficiencies. While different methods of achieving such a preferential orientation have been reported, a complete general mechanistic understanding of the process has not yet been put forward. Here, using an organic chloride as an additive and a fluorinated cation as an organic spacer, we

achieve a high degree of preferential crystal orientation of up to 93% and perovskites withstanding 98% relative humidity for more than 10 h without significant degradation. By interrupting the film formation and investigating partially crystallized perovskite films, we can directly observe the initial stages of the crystallization after nucleation. From these observations, together with advanced microscopic and spectroscopic analysis, we are able to formulate a physical and chemical description of the crystallization dynamics that can be expanded to many preferred-orientation-inducing methods. Understanding these general principles behind controlling the nucleation process not only allows the rational design of novel additives for future photovoltaic research, but also more defect tolerant systems as the technology transitions from the lab to roll-to-roll processed mass production.

EN04.05.20
Chemical Engineering of Strain in $MAPbI_3$ Thin Films Yenal Yalcinkaya[1], Ilka Hermes[2], Tobias Seewald[3], Katrin Amann-Winkel[1], Lothar Veith[1], Lukas Schmidt-Mende[3] and Stefan A. Weber[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]Leibniz Institute for Polymer Research, Germany; [3]Universität Konstanz, Germany

In this study, we introduce a alternative chemical method for adjusting the strain in methylammonium lead iodide ($MAPbI_3$) perovskite crystals by varying the ratio of $Pb(Ac)_2$ and $PbCl_2$ in the precursor solution. To observe the effect of chemical engineering on crystal strain, we used piezoresponse force microscopy (PFM) and X-ray diffraction (XRD) methods. We observed larger ferroelastic twin domains with higher $PbCl_2$ amount which indicates increased strain. We support our increased strain interpretation with XRD patterns with intensive twinning features. We speculate that this strain behaviour is a result of different evaporation rates of methylammonium acetate and methylammonium chloride which caused a strain gradient as we revealed by time-of-flight secondary ion mass spectroscopy (ToF-SIMS) and grazing incidence x-ray diffraction (GIXRD) measurements. We also observed longer charge carrier lifetimes in $MAPbI_3$ films with larger twin domains, as time-resolved photoluminescence (TRPL) results revealed. With these results, we demonstrate an easy way to adjust the strain within lead halide perovskite films chemically.

EN04.05.21
Transport and Crystallization Modeling of Perovskite Thin Film Formation Jesse Starger, Aaron Fafarman, Jason Baxter, Nicolas Alvarez and Richard Cairncross; Drexel University, United States

Over the last decade, solution-processing of organometallic halide perovskites has provided a promising path forward for scalable, low-cost photovoltaic devices. A fundamental understanding of crystallization and mass transfer processes in drying thin-films is needed to enable scalable “low energy” processing methods, like slot-die coating, where both solvent mass transfer and crystal growth can drive the microstructure. Absorber layer microstructure, grain size, grain boundaries, and compositional heterogeneity are known to affect device performance, and can be similarly controlled by process parameters such as drying rate and temperature during coating. However, the precise origins of important microstructural features like pinholes, and ultimately the process-structure-performance relationships are difficult to predict.
Here, a 1D transient model for perovskite crystallization at a boundary is developed. The model accounts for lateral solute and solvent gradients parallel to the substrate surface but neglects vertical gradients through the thickness of the wet film. Lateral gradients in a drying film are driven by solute depletion due to crystallization but are counteracted throughout the wet film by evaporation of solvent which depends on the local solvent concentration. Using a first-order rate law for crystallization, crystallization rates over the drying lifetime of the film are shown to vary by an order of magnitude due to rapid depletion of solute in the wet film at the solid-liquid interface when diffusion-limited. The velocity and height of the crystallization boundary is used to predict a solidified crystal film profile which can be adjusted through two convenient dimensionless parameters; a modified Peclet number and a modified Biot number that capture the crystallization (kinetic) and drying (mass transfer) timescales, respectively. The curvature and inflections in the thickness profile are shown to depend on solute concentration at the growing boundary determined by competing crystallization and evaporative driving forces, which also depend on temperature and solvent vapor pressure. By accounting for both crystal growth and thin film drying, this early model sets the foundation for addressing more complex process-structure relationships – such as the development of microstructure in 2D and 3D, predicting local composition and impurity partitioning, engineering solvent mixtures, and enabling novel operating strategies using temperature or solvent gradients.

EN04.05.22
Simulating Self-Trapped Excitonic Emission in Halide ‘Defect Perovskites’ Christopher Savory; University College London, United Kingdom

Inorganic lead halide perovskites have demonstrated comprehensive promise in LEDs, however lower dimensional perovskites and perovskite-like materials, have shown similar self-trapped excitonic behaviour and resultant broadband white light emission.[1] The Pb-free ‘defect perovskite’ $Cs_2M^{(IV)}X_6$ (M = Zr, Hf, Sn, X = Cl, Br) compounds,[2,3] in which half the perovskite ‘B’ site cations are absent, are among those in demonstrating broadband emission – although quantum efficiencies vary between compounds, and the precise mechanism of emission is unclear. Here, we demonstrate how ab initio calculations can shine some light on these issues.
In this study, we simulate an ansatz of the emitting excitonic state using a supercell method with hybrid Density Functional Theory, avoiding the need for the explicit solution of the Bethe-Salpeter equation, while still obtaining accurate estimates of the photoluminescence of the halide defect perovskites – previously used in the simulation of other halide emitters.[4] Beginning with the successful double perovskite emitter $Cs_2AgInCl_6$[5] and its experimental photoluminescence as a benchmark, we move on to the defect perovskite families, and demonstrate the influence of both cation and anion to the excitonic properties – whether the luminescence energy or the barrier to the exciton self-trapping. We also relate these results to the degree of electronic, as well as structural, localization in these systems, and use additional QSGW+BSE calculations available through the code Questaal[5] to support our results. Through these simulations, we hope to guide the understanding and future synthesis of Pb-free efficient light emitters.

EN04.05.24
Enhanced Exciton Diffusion in a $CsPbBr_3$ Binary Nanocrystal Superlattice Thomas Sheehan[1], Taras V. Sekh[2,3], Maksym V. Kovalenko[2,3] and William Tisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]ETH Zürich, Switzerland; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Control of exciton transport is critical for the operation of quantum dot (QD) solids in optoelectronic devices. Exciton diffusion in perovskite QDs typically occurs through Förster resonant energy transfer, which depends on both the optical properties and spatial arrangement of the quantum dots. Recent synthetic advancements have allowed for more control over both these factors in binary nanocrystal superlattices (BNSLs), but the resulting effect on exciton diffusion is not well understood. Here, we use time-resolved photoluminescence microscopy to compare the exciton diffusivity as a function of

temperature in a BNSL containing both 5.3 nm and 17.7 nm $CsPbBr_3$ QDs, an ordered film of 17.7 nm $CsPbBr_3$ QDs, and a disordered film of 5.3 nm $CsPbBr_3$ QDs. We find that although photoluminescence from the BNSL is dominated by emission from the 17.7 nm QDs, the exciton diffusivity is higher in the BNSL than in the ordered 17.7 nm QDs at every temperature. Additionally, at cryogenic temperatures, the exciton diffusivity in the BNSL is about twice as large as the exciton diffusivity in either of the monodisperse samples. Our results demonstrate that the lack of structural disorder in superlattices can lead to more efficient exciton transport.

EN04.05.27
Photo-Induced Charge Carrier Dynamics of Metal Halide Perovskite Yasuhiro Tachibana[1,2]; [1]RMIT University, Australia; [2]Osaka University, Japan

Perovskite solar cells have been recognized as a newly emerging solar cell with the potential of achieving high efficiency with a low cost fabrication process. In particular, facile solution processed cell fabrication facilitated rapid development of optimum cell structure and composition. Over the last few years, the cell efficiency has exceeded 25%.

Highly efficient charge transfer reactions including high charge separation efficiency and swift charge transport are required with minimum charge recombination to achieve the high solar cell performance. Based on previous intensive studies, high efficiency has been achieved by two different film structures: planar heterojunction and mesoporous structures. The latter typically consists of a nanocrystalline TiO_2 film as an electron transport material, lead halide perovskite and *spiro*-OMeTAD as a hole transport material. Several studies were conducted to understand dynamics of electron and hole injections from the perovskite, their charge carrier transport, and interfacial charge recombination.[1-5] Several parameters have been identified to influence these charge carrier dynamics, and therefore the solar cell performance.[1-5] Clarifying these parameters is extremely important to understand the charge transfer mechanisms to further improve solar cell performance.

In this presentation, we will present parameters controlling charge separation and recombination dynamics at the perovskite interfaces employing a series of transient absorption and emission spectroscopies. Nanosecond transient emission spectroscopy (Vis-ns-TES) clarifies charge separation processes, while Vis-NIR submicrosecond-millisecond transient absorption spectroscopies (NIR-smm-TAS) identify charge separation efficiency and charge recombination rates. Correlation of the dynamics results with the solar cell performance will be discussed [1-5].

Symmetry Breaking and Switching in 2D Halide Perovskites David B. Mitzi; Duke University, United States

Detailed crystal structure and symmetry underlie most structure-property correlations in halide perovskites and related semiconductors. For example, symmetry reduction generally may lead to nonlinear optical effects, ferroelectricity, and Rashba/Dresselhaus spin splitting (when accompanied by strong spin orbit coupling). On the other hand, glass-crystal transitions have been used to modulate electrical/optical properties by orders of magnitude and have been used in optical storage disks and phase-change memory. In this talk we will discuss approaches to control ordering and symmetry through organic cation choice and application of external stimuli (e.g., temperature) in 2D metal halide perovskites. Appropriate choice of the organic cation enables reduction of the melting temperature of the hybrids, as well as control over ordering within the melt during cooling, thereby allowing for demonstration of a reversible glass-crystalline transition with distinct kinetics. Further, cation choice can also be used to modulate crystal-to-crystal transition kinetics and can enable stabilizing two different structural types (and crystal symmetries) at the same temperature, depending on thermal cycling. The above approaches to control phase transitions will be discussed and are fundamentally important as well as potentially being of interest for applications connected with degree of crystallinity, symmetry and phase switching.

9:00 AM EN04.06/EN02.06.02
Unveiling Type I Nested Bandgap Heterostructure Arrangement in Two-Dimensional Ruddlesden – Popper Perovskites Xinjue Zhong[1], Xiaojuan Ni[2], Siraj Sidhik[3], Hong Li[2], Aditya D. Mohite[3], Jean-Luc Brédas[2] and Antoine Kahn[1]; [1]Princeton University, United States; [2]The University of Arizona, United States; [3]Rice University, United States

Two-dimensional (2D) Ruddlesden-Popper perovskites (RPPs) are composed of *n* layers of inorganic metal-halides sandwiched between bulky organic bilayers, with a general chemical formula $A_2A'_{n-1}M_nY_{3n+1}$ where A and A' are cations, M is a divalent metal, and Y is a halide. RPPs with desirable optoelectronic properties, high structural and chemical tunability and improved environmental stability have been demonstrated as promising alternatives, or additions, to their three-dimensional (3D) counterparts for the fabrication of light-emitting and light-harvesting devices.
To achieve successful design for such applications, it is necessary to better understand the electronic properties of these materials, such as their energy level positions and band alignment in 2D/2D and 2D/3D structures. However, these fundamental properties are still under debate because of difficulties in producing phase-pure 2D perovskites with high *n* values and an absence of reliable characterization of all frontier energy levels. Moreover, a clear determination of exciton binding energies (E_b) in RPPs, which range from a few hundred to tens of meV depending on *n*, is crucial for understanding charge carrier separation and extraction in solar cells.

Here, we use optical absorption, ultraviolet and inverse photoelectron spectroscopies (UPS / IPES), combined with density functional theory (DFT), to determine the electronic structure of high purity films of $BA_2MA_{n-1}Pb_nI_{3n+1}$ (n = 1-5). We show that the valence band maximum (VBM) and conduction band minimum (CBM) of the films, and their associated ionization energy (IE) and electron affinity (EA), sequentially converge toward those of $MAPbI_3$[1] as n increases, with corresponding decreasing bandgap. Based on this trend, we demonstrate that the $BA_2MA_{n-1}Pb_nI_{3n+1}$ series exhibit a type I, nested band gap heterostructure arrangement, consistent with the initial report on the comparison between the n = 1 system and bulk $MAPbI_3$.[2] Using DFT calculations for valence and conduction band states, we identify the contribution of organic and inorganic components to the density of states, with the calculated bandgaps consistently following the trend of the experimental results. By combining the electronic and the optical bandgaps, we further determine the exciton binding energy vs. n, the thickness of the inorganic layer. E_b ranges from 320 meV for n = 1 down to 100 meV for n = 5, which is well fitted by the empirical scaling law developed by Blancon et al.[3]
These findings on the electronic structures and excitonic effects of $BA_2MA_{n-1}Pb_nI_{3n+1}$ provide a better understanding of the structure-property relationships in 2D RPPs and give directions for incorporating these materials into optoelectronic devices.

Controlling and Mapping the Dynamic Transformation of Layer-Thickness for Synthesis of Phase-Pure 2D Perovskites Jin Hou[1], WenBin Li[1], Hao Zhang[1], Siraj Sidhik[1], Austin Fehr[1], Jacky Even[2], Jean-Christophe Blancon[1] and Aditya D. Mohite[1]; [1]Rice Univeristy, United States; [2]INSA Rennes, France

Two-dimensional halide perovskites (2D-HaP) are a sub-class of 3D perovskites (3D-HaP), which imbibe their properties from four exciting classes of novel materials - quantum wells, atomically thin 2D materials, organic semiconductors, and 3D-HaP perovskites. However, there is still a lack of systematic control of the crystallization and purity of 2D-HaP despite the huge amount of efforts on the synthesis of new 2D-HaP families with new organic spacers and tunable quantum thicknesses which will bring additional functionalities and further flexibility. For a 2D-HaP family, each member is identified by the number of perovskite layers(n). A main challenge is: purity is decreasing when targeting higher quantum well thicknesses (generally n≥4). But high inorganic layer thicknesses are more desirable for their smaller band gaps, closer to 3D-HaP's while maintaining a good stability. The previous attempts to synthesis n≥4 2D-HaP all lead to mixed phases in crystals. A lack of control of the purity of the 2D phase can bring several issues, (i) a crystal containing a distribution of n values leads to a heterogeneous film once it is made into light harvesting layer in solar cell. This heterogeneity causes losses in the open circuit voltage, which inevitably lower the efficiency of the device;(ii) Preventing Investigating single-n crystal for fundamental exploration since it relies on the isolation of a crystallite in an heterogeneous bulk crystal, leading to other issues (damages, limitation of size). Indeed reproducibility of phase pure 2D-HaP is a long-existing issue, as the current approach to get a well-defined n member especially for higher n number relies either on a large number of crystallization attempts or isolation from a n-mixing phase. Therefore, a direct, reproducible approach to control the crystallization of a broad range of members from the same family is needed. Despite several attempts in the literature, the classical synthesis (CS) which relies only on the tuning of the precursor stoichiometry has not yield so far a satisfactory control of the purity indicating there are other parameters need to be proposed. Here, we show that both the solution crystallization time and temperature, besides the stoichiometry of precursors, hugely impacts the quantum well layer thickness in the 2D-HaP crystal. By increasing the time of crystallization and/or the temperature of the solution in the classical method of synthesis, the resulting 2D-HaP crystal transforms from lower n-values to higher n-values, shown by X-ray diffraction measurements. To understand the underlying mechanism, we modified the previously reported space confinement method by tuning the annealing time and temperature - termed as thermodynamically controlled space confinement (TCSC) which slows down the crystallization rate of the 2D-HaP crystal in solution allowing us to finely control each of the parameters. In-situ X-ray diffraction and absorption spectroscopy results on the TCSC crystals reveal that increasing the time and/or temperature systematically changes the n-value of the 2D-HaP. In-situ photoluminescence spectroscopy and imaging results demonstrate that the 2D-HaP crystal undergoes layer thickness (n) transformation to higher values through the crystal edge as a function of time. A new machine learning (ML) approach is introduced to accelerate the assisted mapping of the resulting multi-parameter phase diagrams. The ML model is further assessed by in-situ optical spectroscopy results in which intercalation occurs as we increase time of crystallization. Lastly a proof-of-concept synthesis of high n-values (n=6) 2D-HaP phase pure single crystals is shown, indicating the ability to fabricate 2D-HaP that are thermodynamically metastable. We also analyzed the transformation behavior in a family of Dion-Jacobson 2D-HaP, indicating that the new growth methodology is universal among 2D-HaP.

Heterointerfaces, Defects and Durability Science in Perovskites Edward H. Sargent[1,2]; [1]University of Toronto, Canada; [2]Northwestern University, United States

Much of the impressive progress in perovskite optoelectronics derives from improved management of interfaces. This includes perovskite:perovskite heterointerfaces, such as betweeen 3D and 2D perovskites, including recent works that allow variously electron-selective vs. hole-selective 2D layers. It also includes management via self-assembled monolyaers at the perovskite:contact interface. I will review progress and its links to defect physics and durability science.

Stability Challenges in Mixed-Metal and Mixed-Halide Perovskites for Multijunction Solar Cell Applications Laura Herz; University of Oxford, United Kingdom

Organic-inorganic metal halide perovskites have emerged as attractive materials for solar cells with power-conversion efficiencies of single-junction devices now exceeding 25%. Such success has renewed interest in multi-junction cells that may exceed the single-cell Shockley-Queisser efficiency limit. However, a range of remaining challenges and opportunities remain relating to the stability of lead iodide-bromide[1] and tin-lead iodide[2] perovskites that currently present the most promising candidates for the required low- and high-energy-bandgap materials, respectively.

In the context of silicon-perovskite tandem cells, we discuss the peculiar mechanisms underlying detrimental halide segregation in mixed iodide-bromide lead perovskites with desirable electronic band gaps near 1.75eV.[1,3,4] We reveal that, surprisingly, halide segregation results in negligible impact to the THz charge-carrier mobilities.[4] However, remarkably fast, picosecond charge funnelling into the narrow-bandgap I-rich domains leads to enhanced radiative recombination.[3] Performance losses in photovoltaic devices may therefore potentially be mitigated by deployment of careful light management strategies. We further demonstrate[4] how a combination of simultaneous in-situ photoluminescence and X-ray diffraction measurements is able to demonstrate clear differences in compositional and optoelectronic changes associated with halide segregation in $MAPb(Br_{0.5}I_{0.5})_3$ and

$FA_{0.83}Cs_{0.17}Pb(Br_{0.4}I_{0.6})_3$ films. While $MAPb(Br_{0.5}I_{0.5})_3$ exhibits rearrangement of halide ions only in localized volumes of perovskite, $FA_{0.83}Cs_{0.17}Pb(Br_{0.4}I_{0.6})_3$ lacks such low-barrier ionic pathways and is, consequently, more stable against halide segregation. However, under prolonged illumination, it exhibits a considerable ionic rearrangement throughout the bulk material, which may be triggered by an initial demixing of A-site cations, altering the composition of the bulk perovskite and reducing its stability against halide segregation.[4]

We further discuss the air stability of mixed lead-tin halide perovskites, which provide ideal bandgaps for the bottom subcell of all-perovskite tandem photovoltaic devices. Such degradation pathways are not yet fully understood, especially for the perovskites in the middle of the $APb_xSn_{1-x}I_3$ solid solution line, which offer the narrowest bandgaps across the range. We contrast the degradation mechanisms of $APb_xSn_{1-x}I_3$ perovskites, reporting clear differences between mixed lead-tin (x = 0.5) and tin-only (x = 0) perovskites. The dynamic optoelectronic properties, electronic structure, crystal structure, and decomposition products of the perovskite thin films are examined in situ during air exposure. We show that both perovskite compositions suffer from the formation of defects over the timescale of hours, as indicated by a significant reduction in their charge-carrier diffusion lengths. For tin-only perovskite, degradation predominantly causes the formation of energetically shallow tin vacancies and hole doping. However, for mixed lead-tin perovskite, deep trap states are formed that significantly accelerate charge-carrier recombination, yet leave mobilities relatively unaffected. These findings highlight the need for passivation strategies tailored specifically to mixed lead-tin iodide perovskites.

11:00 AM EN04.06/EN02.06.06
Elucidating the Relationship Between A-Site Mixing and Non-Radiative Carrier Capture Lucy Whalley; Northumbria University, United Kingdom

The unusual defect chemistry and physics of lead halide perovskites has attracted significant attention as point defects in these materials are associated with a range of processes including ion diffusion, hysterisis and degradation.[1,2] While the high voltages and light-to-electricity conversion efficiencies indicate a low rate of non-radiative electron-hole recombination relative to other photovoltaic materials, understanding non-radiative capture processes remains crucial for the development of high-efficiency devices with increased stability.

The most stable materials employ mixed cations on the perovskite A-site, however the reason for this improved performance is not fully understood. While there has been a number of computational defect studies for the single cation compounds, most commonly methylammonium (MA) lead iodide, less is known about the impact of cation mixing on the defect physics of these materials.
We will present results from the quantum chemical simulations of single cation (MA) and mixed cation (Ma/Cs) materials. We will consider both the pristine materials and the materials with an iodine interstitial defect, which has been established as an active site for non-radiative charge trapping.[3]

First we will demonstrate that cation mixing on the A-site leads to increased octahedral tilting in the minimum energy (relaxed) structures of the pristine materials. This supports previous results which show that octahedral tilts are "locked-in" for the mixed-cation compounds.[4] We will then analyse the quantum mechanics of carrier trapping at the iodine interstitial. We will show that the lattice relaxation after charge capture is also mediated through octahedral tilting of the inorganic cage, and so can be tuned through A-site composition. Using a computational framework for calculating non-raditaive capture rates from first-principles[3,5] we will quantify the impact that cation mixing has on the rates of electron and hole capture at the iodine interstitial.

Finally, we will demonstrate that due to the rotational motions of the A-site molecular cation after charge capture, the commonly used approximation of linear interpolation for constructing the potential energy surface cannot be applied to this system. Instead, we will discuss the use of Kabsch interpolation and anharmonic potential energy surfaces for systems where rotational motion is significant. Our results highlight the interplay between halide perovskite composition, structural dynamics and defect physics, and we expect these findings to be more widely applicable to systems where dynamic octahedral tilting is evident.

Data Driven Composition and Octahedral Engineering of Halide Perovskites Jiaqi Yang, Panayotis T. Manganaris and Arun Kumar Mannodi Kanakkithodi; Purdue University MSE, United States

Halide perovskites are highly desired for optoelectronic applications, because of the excellent tunability of their properties from composition engineering and octahedral distortion and rotation. However, the infinite possibilities of compositions via cation and/or anion-site mixing and octahedral manipulation raise considerable challenges when exploring the stability and properties of halide perovskites, both experimentally and computationally. In this work, we address this issue using high-throughput density functional theory (DFT) computations and discover trends and design rules to aid prediction and screening across large chemical spaces.

We generate a large DFT dataset of ABX3 halide perovskite alloys with several elemental and molecular choices at A, B and X sites, and arbitrary mixing allowed on each site.[1] This dataset covers ~ 500 compounds across a 14-dimensional ionic space and is currently restricted to alloying with pseudo-cubic 2x2x2 supercells. To further explore property tuning, we create hundreds of random distorted and rotated structures for Cs/MAPbX3 perovskites (MA = methylammonium, X = I/Br/Cl). Many critical properties are calculated using standard GGA-PBE and hybrid HSE06 functionals, including decomposition and mixing energies, electronic band gap, and Spectroscopic Limited Maximum Efficiency (SLME) based on computed optical absorption spectra.[2]

A screening process is applied across the dataset of ~ 500 pure and mixed composition perovskites, in terms of the stability, bandgap, deviation from cubicity (to account of any excessive distortion in lattice parameters), degree of octahedral distortion, and finally, some established perovskite stability metrics such as the tolerance and octahedral factors .[3-5] This leads us to 49 stable compositions with attractive properties which are ranked according to SLME and compared with the literature as well as recommended for synthesis and characterization. Using Pearson correlation coefficients and unsupervised learning techniques such as PCA and T-SNE, we unravel qualitative relationships between elemental/molecular combinations, octahedral

distortion, and computed electronic and optical properties. We further develop a unique perovskite descriptor with compositional, physical, and octahedral information, which are used to train regression-based machine learning (ML) models and predict properties of thousands of novel compounds.

In order to make the dataset openly available to researchers, we developed NanoHub[6-7] tools that help visualize our entire DFT database, create new structures with arbitrary octahedral distortion and rotation, and make ML predictions for any compositions of interest. The high-throughput DFT framework and tools from this work are promising for accelerating the design of halide perovskites for various applications such as solar cells, photodiodes, electronics, and infrared sensors, and are currently being coupled with active experiments for validation and discovery.

Exploration of the Compositional Space in Methylammonium Free Lead Halide Perovskites for High-Performance Solar Cells Juan Pablo Correa Baena; Georgia Institute of Technology, United States

The certified power conversion efficiency (PCE) of state-of-the-art organic-inorganic metal halide perovskite solar cells (PSCs) has surpassed 25%. The most widely studied methylammonium (MA) lead iodide undergoes a structural phase transition and degradation due to the volatile MA cation, detrimental to the long-term stability of the devices. Formamidinium (FA), used as the majority cation in most PSCs with a PCE of >20%, is thermally more stable and has a more optimal red-shifted bandgap. However, FA with the relatively large ionic radius induces titled PbI_6 octahedra in $FAPbI_3$, leading to the photoinactive yellow δ-phase at room temperature. Herein, iodide and FA in $FAPbI_3$ were gradually replaced by bromide and cesium (Cs) with smaller radius to understand their role on yellow δ-phase suppression and to systematically explore the compositional space via regulating the tolerance factor, revealing the crucial link between the crystal structure and optoelectronic properties of the mixed-cation (FA/Cs) lead mixed-halide (I/Br) perovskite. The FA/Cs-Pb-I/Br films were probed by advanced synchrotron X-ray characterization to understand halide phase segregation, which has been found to be detrimental for solar cell performance.

Nanoscale Effects in Perovskite Solar Cells Observed by Scanning Force Microscopy Stefan A. Weber[1,2], Ilka Hermes[1,3], Yenal Yalcinkaya[1,2], Pascal N. Rohrbeck[1], Konstantinos Bidinakis[1] and Rüdiger Berger[1]; [1]Max Planck Institute for Polymer Research, Germany; [2]Johannes Gutenberg University, Germany; [3]Leibniz Institute for Polymer Research, Germany

Perovskite solar cells have electrified the solar cell research community with astonishing performance and surprising material properties. However, the widespread commercialization of perovskites in solar cells and other optoelectronic applications still requires a more detailed knowledge about fundamental material properties. My group is specialized in the investigation of these properties on nanometer length scales using scanning force microscopy [1-4].
In 2016, we discovered a distinct nanoscale stripe domain structure in $MaPbI_3$ perovskite crystals that is characteristic for ferro-elastic twin domains [1]. Using a combination of piezoresponse force microscopy (PFM) and photoluminescence microscopy, we found that this domain structure leads to an anisotropic charge transport across the crystal [2]. To utilize this effect in devices, a precise control of the domain configuration would be desirable. To this end, we explored the possibilities of both physical and chemical strain engineering [3]. Next to these intrinsic properties of perovskites, the specific interactions at the various interfaces in devices are of critical importance. To visualize the functionality of different layers, we developed a method to prepare smooth cuts through a solar cell device. We subsequently map the potential distribution across the device using time-resolved Kelvin probe force microscopy (tr-KPFM) [4,5]. We could show that the formation and release of ionic interface charges determine the time scales for current-voltage hysteresis in perovskite solar cells. Our results highlight that precise control over interfaces in perovskite solar cells is the key, not only for controlling and suppressing hysteresis but also for their long-term stability in perovskite solar cells.

Nanoscale Charge Carrier Lifetimes Revealed by Intensity Modulated Scanning Kelvin Probe Microscopy Kevin Ho, Rajiv Giridharagopal, Yangwei Shi, Yujing Lin and David Ginger; University of Washington, United States

Halide perovskites are known to be tolerant to defects while exhibiting long carrier lifetimes. At the same time, it is known that lifetimes are spatially-dependent, with grains and grain boundaries exhibiting different levels of nonradiative recombination and therefore different carrier dynamics. In order to approach the radiative efficiency limits in these devices, it is essential to understand the variation of carrier trapping and de-trapping dynamics between grains and grain boundaries and to improve the carrier dynamics at these locations. Here, we use intensity modulated scanning Kelvin probe microscopy (IM-SKPM) to directly image carrier dynamics at the tens of nanosecond timescale, with high spatial resolution on the order of ~80-100 nanometers. We apply IM-SKPM to study the perovskite $FA_{0.83}Cs_{0.17}Pb(Br_xI_{1-x})_3$ with varying halide composition. We observe lower carrier lifetimes from IM-SKPM at the

grain boundaries, suggesting that the boundaries are not benign and result in higher carrier trapping. Furthermore, we use IM-SKPM to study how surface passivating agents affect the distribution of carrier lifetimes. The perovskites were passivated with (3-aminopropyl)triethoxysilane (APTMS) which allowed us to investigate the effect of passivation on the local variation of charge carrier dynamics. After passivation, we found that the IM-SKPM lifetimes increased due to a reduction of trap densities. However, a variation in the carrier lifetimes was still observed corresponding to the non-uniformity of the passivator. Importantly, these results show that IM-SKPM can be correlated with the photoluminescence lifetime trends, but at nanoscale spatial resolution far below the optical diffraction limit.

2:15 PM EN04.07.03
Explaining the Negative Capacitance by the Chemical Inductor Effect in Halide Perovskite Cell Devices Juan Bisquert and Antonio Guerrero; University of Jaume I, Spain

A negative capacitance effect is observed in perovskite solar cells and other types of hybrid organic-inorganic solar cells. This effect reduces the resistance and affects the performance of the solar cell as well as the degradation characteristics. We apply the concept of the chemical inductor for a better understanding and control of the negative capacitance. The chemical inductor is a combination of a fast and a slow conduction modes that couple to form an inductor arc in the impedance spectrum. We discuss the interpretation of the slow recombination mechanisms in terms of ion-controlled dynamics and we obtain the information for a better characterization of the hybrid photovoltaic devices.

Interface Defects in Halide Perovskite Semiconductor Devices Philip Schulz[1,2]; [1]Centre National de la Recherche Scientifique, France; [2]Institut photovoltaique d'Ile de France (IPVF), France

Hybrid organic inorganic metal halide perovskites (MHPs) denote a family of compound semiconductors, which established a novel class of optoelectronics, most prominently known for the perovskite solar cell. While the power conversion efficiency of these photovoltaic devices saw a steep rise in the past decade, tailoring the interfaces between the MHP film and charge transport layer became the major control lever to enhance performance. The use of photoemission spectroscopy to analyze the chemical and electronic properties of these interfaces has been challenging due to many possible chemical reactions at the buried interfaces [1].
Here, we present synchrotron- and lab-based hard X-ray photoelectron spectroscopy (HAXPES) experiments to address the particular chemistry of MHP, beginning with the interface between and SnO_2, grown by atomic layer deposition on top, using photon energies of 2 and 6 keV. We find evidence for the formation of new chemical species (PbO, N and halide-containing compounds) and changes in the energy level alignment at the MHP/SnO_2 interface. The spectra exhibit binding energy shifts that may indicate upward band bending of the MHP energy levels. Assuming flat band conditions at the MHP surface prior interface formation, this upward band bending may form an electron transport barrier detrimental to cell performance.
We also employed the methodology to evaluate lead-free halide perovskite films based on formamidinium tin iodide ($FASnI_3$), for which tin fluoride (SnF_2) is a commonly used additive enabling a retardation of tin oxidation and a reduction of tin vacancies. We targeted films deposited on the organic hole transport layer PEDOT:PSS. For solar cells with optimized performance, the local SnF_2 distribution in the perovskite bulk and possible chemical reactions at the (buried) interface between PEDOT:PSS and the perovskite film are analyzed by photoelectron spectroscopy using soft (Al Ka) as well as hard (Ga Ka) X-ray photons. Our measurements revealed that SnF_2 significantly improves the layer morphology, but preferably precipitates at the PEDOT:PSS/MHP interface where it forms a SnS interlayer of approximately 1.2 nm thickness induced by a chemical reaction with sulfur-containing groups at the PEDOT:PSS surface. Our work adds a new aspect to the discussion of high-efficiency Sn-based perovskite solar cells which still commonly make use of PEDOT:PSS as HTL material in contrast to Pb-based solar cells, where alternatives to PEDOT:PSS are gaining growing interest [2].

4:00 PM EN04.07.05
Understanding the 2D/3D Heterostructure Interface in Highly Efficient Green PeLEDs Alexandra Ramadan[1,2], Robert Oliver[1], Woo Hyeon Jeong[3], Boubacar Traore[4], Junke Jiang[4], Bo Ram Lee[3], Jacky Even[4], Claudine Katan[5] and Henry Snaith[1]; [1]University of Oxford, United Kingdom; [2]The University of Sheffield, United Kingdom; [3]PKNU, Korea (the Republic of); [4]INSA Rennes, France; [5]ISCR CNRS, France

Light emitting diodes (LEDs) based on metal halide perovskite semiconductors have attracted considerable research interest due to their potential for low cost, high efficiency LEDs with excellent colour purity and bandwidth. In particular, two dimensional (2D) - three dimensional (3D) hybrid perovskite heterostructures (often described as quasi-2D structures) have been subject to considerable investigation within the perovskite LED community as one route through which to produce highly efficient devices.[1,2] It has been shown that in these heterostructures the emission wavelength and device performance can be informed by the organic cation used to form the 2D perovskite structure.[3] To ensure the optimal continued development of optoelectronic devices based on these structures it is essential that we have a comprehensive understanding of the 2D/3D interface structure and the charge transport across this interface.

To probe this interface we develop a range of quasi-2D perovskite emitting layers, based on a $(BABr)_x(CsPbBr_3)_{1-x}$ (where BA = butylammonium) structure with varying amounts of the 2D perovskite. We implement these emitters in PeLED devices and demonstrate excellent electroluminescence external quantum efficiencies > 16 %. We observe a strong relationship between the 2D content of these heterostructures and the efficiency of the corresponding PeLEDs. We investigate the structure of the 2D-3D heterostructures using X-ray diffraction and observe a mixture of n=1 and n=2 2D-perovskite structures in addition to the 3D perovskite. We comprehensively study the charge carrier dynamics of a range of $(BABr)_x(CsPbBr_3)_{1-x}$ structures using absolute and time-resolved photoluminescence studies. We find that the 2D perovskite only influences the emission profile of our LEDs in specific cases and that
the predominant role of the 2D perovskite structure is to confine the size of the 3D perovskite domains and therefore boost the absolute electro- and photo-luminescence of the 3D perovskite domains.

To understand the charge transport across the interface between the 2D and 3D perovskite structures we investigate the energetic band alignment using a combination of ultraviolet photoelectron spectroscopy studies (UPS) and density functional theory (DFT) modelling. We demonstrate that charge transfer between the 2D and 3D perovskite structures is determined by the type of 2D structure (whether the structure is n=1 or n=2) and we suggest a route to predicting whether a 2D structure will contribute to the emission of an LED. We show that there is a critical 2D/3D compositional limit for achieving high efficiency devices. Whilst we do not find a mixture of 2D perovskite structures impacts LED efficiency, we show that there is a tight tolerance window for

the n=1 perovskite structure and once this window is exceeded it has a large detrimental effect on device performance.

Our work highlights the importance of understanding the 2D/3D heterostructure interface in engineering highly efficient devices and we show our initial results exploring the impact of phase pure 2D/3D perovskite heterostructures on PeLED performance.

4:15 PM EN04.07.06
Understanding via Thermal Evaporation How Capping Layers Transform the Lead Halide Perovskite Surface Carlo Andrea Riccardo Perini[1], Andres Felipe Castro Mendez[1], Tim Kodalle[2], Carolin M. Sutter-Fella[2] and Juan Pablo Correa Baena[1]; [1]Georgia Institute of Technology, United States; [2]Lawrence Berkeley National Laboratory, United States

In this contribution we compare interfaces treated with PEAI, a bulky cation, via solution and via thermal evaporation. We highlight differences in crystallinity, uniformity, and stability of the layers deposited via the two different routes using measurements as SEM, XPS, GIWAXS, and PL mapping. Finally, we test the bulky cation evaporated layers in complete devices stacks, reaching power conversion efficiencies > 20 %. Our observations suggest that bulky-cations deposited via vapor enable superior control of the exposed perovskite surface with respect to solution cast films. Both solution and vapor routes lead to the formation of 2D Ruddlesden-Popper phases at the treated interface, but result in different n, where n is in $A'_2A_{n-1}B_nX_{3n+1}$, where A' is PEA, A is Cs,MA,FA, B is Pb, and X is the halide. We also demonstrate the role of interface termination of the underlying 3D perovskite film in the transformation of the 3D perorvskite surface to 2D Ruddlesden-Popper structures. The impact of the interface termination is studied by using solution and vapor deposition routes to tailor the non-passivated surface to the stoichiometry desired. Furthermore, the solvent used for deposition via solution of the bulky cations is shown to introduce extra defects at the interface, which can be avoided via vapor depositing the organohalide salts. As a result, solar cells incorporating the vapor deposited layers show an increase in the median power conversion efficiency and better thermal stability than solution deposited films. Our observations indicate that vapor deposition routes are a valid tool to explore the transformation dynamics of the interface and enable a higher degree of control on the formation of the interface, which in turn leads to enhanced efficiency of perovskite solar cells passivated via vapor.

4:30 PM EN04.07.07
Do's and Don'ts of SCLC Analysis for Perovskite Materials Vincent Le Corre; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

The space-charge-limited current (SCLC) measurement is one of the most common methods used to study the mobility and defect density in semiconductors. This method has the advantage of separating the measurement of the material properties with respect to electron and hole by the use of single-carrier devices. The apparent simplicity of the method made it very popular in both organic and perovskite photovoltaic research communities. Here, we discuss the often overlooked pitfalls of SCLC analysis for perovskite materials.
First, we introduce a revisited analysis of SCLC measurements on perovskite single-crystals to obtain its trap densities. In fact, simulations clearly show that the presence of mobile ions severely complicates the SCLC analysis. Therefore, we also propose pulsed-SCLC as a new measurement procedure that helps to reduce the impact of mobile ions. We also show that the use of full drift-diffusion fitting of the pulsed-SCLC data allows for more accurate measurements of the mobility but also of both trap and mobile ion densities.
Secondly, we explore the many limitations of SCLC for thin-film perovskite devices. We discuss the importance of reporting the hysteresis, using the appropriate scan speed to do the measurement, and choosing the right charge transport layers. These seemingly experimental 'details' can have a strong influence on both the values of the defect density and the mobility extracted from the SCLC analysis.

Fundamental Insights into Halide Ion Migration and Exchange in Persovkites Nanocrystals Sakiru L. Abiodun and Andrew B. Greytak; University of South Carolina, United States

Halide perovskite nanocrystals have been identified as a prospective candidate for future optoelectronic devices. such as solar cells, LEDs, scintillators, and photo/radiation detectors. Their excellent optoelectronic properties such as large absorption coefficient, high carrier mobility, wide color gamut, long electron-hole diffusion lengths, and tunable bandgap energy are largely responsible for their wide acceptability in various electronic devices. However, despite the recent developments, the problem of instability remains a major obstacle toward their commercialization. For example, ion migration has been reported to cause phase separation in mixed halide perovskite-based optoelectronics which ultimately leads to instability and a decrease in photovoltaic performance. Therefore, many researchers have devoted attention to understanding the process of this ion migration in various mixed halide perovskites $CsPb(I_{1-x}Br_x)_3$ of different compositions. However, to date, the processes underlying this anion migration and exchange remain under debate and largely unclear. Here, we elucidated the processes involved during halide ion exchange and migration in lead perovskite nanocrystals. In addition to this, we also quantify the thermodynamics of this ion exchange, therefore, revealing the origin of phase separation commonly encountered in mixed $CsPb(I_{1-x}Br_x)_3$ halide perovskites-based optoelectronics. Our fundamental understanding of the process of this anion exchange and migration will help provide better-informed guidelines toward engineering perovskite nanocrystals for different applications such as tandem cells and efficient devices for lighting and display technology.

EN04.08.04
$(PEA)_2PbI_4$ Perovskite Fabry-Perot Microcavity Design Martin Gomez, Victoria Quiros-Cordero, Natalie Stingelin, Carlos Silva and Juan Pablo Correa Baena; Georgia Institute of Technology, United States

Two-dimensional (2D) halide perovskites, multiple quantum-well organic-inorganic heterostructures with confined excitons, exhibit promising light-emitting applications due to their tunable narrow emission bandwidth, high photoluminescence quantum yield and low rates of non-radiative recombination. However, it is still challenging to achieve room temperature lasing from pure 2D perovskites, high crystallinity and reduced grain boundaries are desired to achieve photonic lasing. Grain boundaries are known to increase recombination and impede population inversion. A way to overcome this challenge is by using perovskites as active layers in optical microcavities and exploiting the strong light-matter coupling regime. The extremely light effective mass of exciton polaritons unlocks the possibility of achieving low threshold polariton lasing in which, unlike conventional photonic lasing, there is no need for population inversion. Hence, to further exploit the optical properties of 2D perovskites for lasing applications, more efforts should be invested in the study of 2D perovskite embedded microcavities. Here we have designed, fabricated, and characterized different architectures of $(PEA)_2PbI_4$ embedded Fabry-Perot cavities and studied the design parameters that lead to strong light-matter coupling.

EN04.08.05
Time-Resolved Kelvin Probe Force Microscopy to Investigate Grains of Mixed Halide Perovskite Solar Cell Material Pascal N. Rohrbeck[1], Yenal Yalcinkaya[1,2], Saba Gharibzadeh[3,3], Paul Fassl[3,3], Konstantinos Bidinakis[1], Ulrich W. Paetzold[3,3] and Stefan A. Weber[1,2]; [1]Max Planck Institute for Polymer Research Mainz, Germany; [2]Johannes Gutenberg University, Germany; [3]Karlsruhe Institute of Technology, Germany

Perovskite solar cells (PSCs) have become a good competitor for silicon-based solar cells. Nevertheless, local defects in the perovskite crystal structures limit the efficiency due to non-radiative charge recombination losses. [1]
The occurrence of these defects is coupled to the nanoscale structure, e.g., to grain boundaries (GB) and crystal facets. Atomic force microscopy (AFM) methods are ideal for studying nanoscale electrical devices such as batteries, solar cells, and diodes.
Moreover, Kelvin probe force microscopy (KPFM) is a valid method to investigate the local effect of defect passivation on the nanoscale of perovskite materials.[2] We investigated different perovskite materials by using a Time-resolved kelvin probe force microscopy (tr-KPFM) method. By observing the time- and position-dependent photovoltage, we were able to gain insight into the local defect densities. Further we were also able to uncover the local effect of passivation on individual perovskite grains and grain boundaries by measuring an extended photovoltage decay lifetime. [1]
The results show that high defect densities in perovskites materials can be avoided with passivation strategies. When improving the efficiencies of perovskite solar cells this method can help to understand the mechanism behind the non-radiative recombination processes and ion migration processes to make them even more competitive to others like Si-based solar cells.

Plastic Deformation and Fracture in Metal Halide Perovskite Single Crystals and Polycrystalline Bulk Materials Meaghan Doyle, Madhuja Layek, Zhenghong Dai and Nitin P. Padture; Brown University, United States

Metal halide perovskites (MHPs) have emerged as promising light absorber materials for use in perovskite solar cells (PSCs). Although significant progress has been made in enhancing the efficiency and operational stability of PSCs, their mechanical reliability needs to be improved if they are to operate efficiently for many years. However, the mechanical properties of MHPs have not been fully explored. This is especially important because MHPs possess poor mechanical properties — they are compliant, soft, and brittle. To that end, we have used nanoindentation and micro-indentation to study the plastic deformation and fracture properties of MHP single crystals of various compositions. This includes slip-system analyses, time-dependent creep, environmental effects, and estimation of the fracture toughness. Similar studies are also performed on polycrystalline bulk materials to understand the roles of grain boundaries and anisotropy. Through this we aim to provide a more comprehensive understanding of plastic deformation and fracture of MHPs, which is relevant for understanding and enhancing the mechanical reliability of PSCs.

EN04.08.07
Study of Bi-Doped $MAPbI_3$ Single Crystal for ETL-Free Perovskite Solar Cell Application Sarah S. Youn[1], Yunae Cho[2], Gee Yeong Kim[3] and William Jo[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of)

Hybrid perovskite single crystals show great potential in photovoltaic applications due to their high stability, absence of grain boundaries, lower intrinsic trap density, and higher carrier mobility compared to polycrystalline thin films. Therefore, the application of thin-film single crystal (THSC) to solar cells is expected to provide improved stability and efficient device performance. To obtain high-quality single crystal solar cells, the space-limited inverse temperature crystallization (ITC) method is widely used in the THSC synthesis process, in which a perovskite single crystal is grown between two hydrophobic hole transport layer (HTL) coated ITO glasses [ref]. After growing the THSC, an electron transport layer (ETL) and electrode are generally deposited on top. In this work, we design an ETL-free device by n-doped perovskite THSC, which reduces one process of continuous layer deposition for solar cell fabrication. Bismuth (Bi) can be used to change the doping concentration in perovskite single crystal. We present the electrical properties of the charge carrier concentration and conductivity changes of Bi-doped $MAPbI_3$ (MAPI-Bi) and compare it with pristine MAPI by space charge limited current, conductivity (parallel & perpendicular), and scanning probe microscopy measurements. The optical properties are also studied using Raman and PL measurements. Our study will provide an insight to fabricate an ETL-free solar cell device via doping the perovskite layer. By expanding our strategy to p-doped single crystals, a simpler solar cell structure with no charge transport layers can be considered.

Optically-Induced Long-Lived Chirality Memory in the Color Tunable Chiral Lead-Free Semiconductor (R)/(S)-$CHEA_4Bi_2Br_xI_{10-x}$ (x = 0 - 10) Shangpu Liu[1], Markus W. Heindl[1], Natalie Fehn[2], Sebastian Caicedo Davila[2], Lissa Eyre[1], Silva Kronawitter[2], Gregor Kieslich[2], David Egger[2] and Felix Deschler[1]; [1]Walter Schottky Institut, Germany; [2]Technical University of Munich, Germany

Hybrid organic-Inorganic networks that incorporate chiral molecules have attracted great attention due to their potential in semiconductor lighting

applications and optical communication. Here we introduce the chiral organic molecules (R)/(S)-1-cyclohexylethylamine (CHEA) into bismuth-based lead-free structures with an edge-sharing octahedral motif, to synthesize chiral lead-free (R)/(S)-$CHEA_4Bi_2Br_xI_{10-x}$ crystals and thin films. Using single-crystal X-ray diffraction measurements and density-functional theory calculations, we identify crystal and electronic band structures. We find the difference in the chirality of (R)- and (S)-$CHEA_4Bi_2Br_{10}$ compound induces opposite spin textures in the x and z directions of band structures. We then investigate the materials' optical properties and find circular dichroism, which we tune by the bromide-iodide ratio over a wide wavelength range from 300 - 500 nm. Further, we employ transient absorption spectra and time-correlated single photon counting to investigate charge carrier dynamics, which show long-lived excitations with unexpected optically-induced chirality memory up to 10s of nanosecond timescales. Our demonstration of chirality memory in a color-tunable and chiral lead-free semiconductor opens a new avenue for the discovery of high-performance, lead-free spintronic materials with optical functionalities.

EN04.08.12
Thermal Annealing-Sensitive Morphology Evolution of Tin-Perovskite Absorbers for Efficient Lead-Free Perovskite Solar Cells Donghan Kim and Jae Woong Jung; Kyunghee University, Korea (the Republic of)

Tin-based perovskite absorber is the potent candidate for replacing the lead-based perovskite solar cells (PSCs) due to the suitable tolearance factor for perovskite lattice, suitable band-gap, and low toxicity. At present, tin-based perovskite absorbers adopting ABX_3 structure generally suffer from reproducibility and stability issues mainly due to rapid crystal growth and quick oxidation of tin cation. In order to optimize the crystal growth in perovskite absorber laye, we varied the thermal annealing time (duration) of tin-perovskite absorber layer after antisolvent-assisted spin-coating deposition, and the influence of annealing time on the film morphologies and electrical properties were systematically studied. Surprisingly, the film morpology was strongly dependent on the thermal annealing time, and it is found that instantaneous thermal annealing as quick as 1 min is enough to prepare high-quality tin-perovskite absorber layer with compact grains, diminished grain boundaries, and less defect density. And then, no distinct evolution of film morphology was observed after 1 min thermal annealing. For the photovoltaic properties, thermal annelaing for 1 min optimally delivered >6% efficiency. Details experiment results and discussion will be presented in the presentation.

EN04.08.15
Quantitative Structure-Property Relationships in Mixed Ion Hybrid Perovskite by Multi-Modal Mapping of Phase Diagrams Tonghui Wang[1,1], Ruipeng Li[2], Hossein Ardekani[1,1], Mahdi Ramezani[1], Ryan Wilmington[1,1], Robert Epps[1], Kasra Darabi[1,1], Boyu Guo[1,1], Milad Abolhasani[1], Kenan Gundogdu[1,1] and Aram Amassian[1,1]; [1]North Carolina State University, United States; [2]Brookhaven National Laboratory, United States

Hybrid perovskites are part of a highly tunable material class with >1,000 unique compounds and countless mixed-ion alloys currently being investigated for optoelectronic and energy applications. The absence of phase diagrams for mixed ion perovskites limits the establishment structure-property relationships for mixed ion alloys required for optoelectronic applications. We take the view that quantitative structure-property relationships (QSPRs) constructed around phase diagrams provide the most robust framework for materials design and engineering. However, QSPRs are still rare in materials research, let alone in the field of hybrid perovskites. Here, we introduce a new approach to map QSPRs reliably, rapidly and efficiently using research automation combined with on-chip micro-experimentation. We demonstrate the RoboMapper, a compact robotic laboratory which miniaturizes the traditional workflow (formulation, coating/printing) by three to four orders of magnitude to integrate compositional arrays of arbitrary hybrid perovskite composition maps on a single substrate for efficient multi-modal data collection. Compared with traditional manual workflows and existing full-scale serial automation, the RoboMapper is shown to be 5-10 times faster and reduces the material cost, toxic waste, and greenhouse gas emissions by more than an order of magnitude. We successfully demonstrate sophisticated QSPRs for the quaternary system $FA_{1-y}Cs_yPb(I_{1-x}Br_x)_3$ system that map the structure and phase, optical properties and photostability using multi-modal characterizations, including optical microscopy, micro-diffraction, and micro-photoluminescence. Our QSPR models are demonstrated to be predictive for phase, bandgap and photostability and are tested with targeted bandgaps, such as 1.7eV for perovskite-silicon hybrid tandem solar cells, to discover new compositions exhibiting the ideal bandgap with improved photo-stability in air.

EN04.08.16
The Mechanical Properties of Polycrystalline Metal Halide Perovskite Thin Films and Polycrystalline Bulk Materials Madhuja Layek, Meaghan Doyle, Zhenghong Dai, Hector F. Garces and Nitin P. Padture; Brown University, United States

Over the past years, metal halide perovskites (MHPs) have attracted considerable attention owing to their remarkable application potential in the field of optoelectronics, especially photovoltaics. Despite this keen interest in MHPs, little information can be found on their mechanical properties. However, to manufacture efficient and reliable perovskite solar cells (PSCs) that can operate satisfactorily for decades, it is critical to study the mechanical properties of MHPs which are inherently compliant, soft, and brittle. To that end, here we have employed the curvature-measurement technique to estimate the Young's modulus and coefficient of thermal expansion of polycrystalline MHP thin films of various compositions. Also, we have synthesized MHP powders of different compositions and sintered them into dense polycrystalline bulk pellets and measured their Young's modulus directly using uniaxial compression. This is in an effort to understand the effect of grain size on Young's modulus and other relevant mechanical properties of MHPs. Our aim is to provide an in-depth understanding of the mechanical properties of MHPs, which are key to understanding and enhancing the mechanical reliability of PSCs.

EN04.08.17
Enhanced Crystal Growth of Perovskite Materials Duane L. Simonson; Research Support Instruments, Inc., United States

The design and preparation of durable active materials is a priority for more efficient solar cell and light (LED) source development. The use of perovskite hybrids (such as methylammonium lead halide series) has dominated the attention of researchers over the past few years. Their use is still limited by the longevity issues with temperature, humidity, and other factors. In this work, the use of polymer templates for enhanced perovskite crystal growth is explored. In these systems, the nucleation suppression and growth of very few crystals allows one inch sized bulk crystals to be grown directly (no seeding) from water solutions in very small volumes (100 mL saturated solution). Emphasis on lower toxicity copper, bismuth, and cesium materials will be discussed, along with advanced processing into thin films.

EN04.08.19
A Guide Through the Layered Perovskite Landscape—Mismatch, Inter-Layer Interaction and Perovskitoids Mikael Kepenekian[1,2], Bruno Cucco[1], George Volonakis[1], Claudine Katan[1,2] and Jacky Even[3]; [1]Université de Rennes 1, France; [2]CNRS, France; [3]INSA Rennes, France

If 3-dimensional (3D) halide perovskites have shown spectacular results in optoelectronic devices, they offer limited choice of metals and organic cations. This is not the case of layered (2D) halide perovskites A_2MX_4 (A: organic cation, M: metal ion, X: halide) that impose far less constraints over the chemical design of the organic spacer [2,3]. The number of suitable candidates for A then becomes so large that guidelines would be desirable for the design of future devices. Here, based on computational investigations conducted on experimental and model systems, we propose to contribute to the writing of those rules.

We start by exploring the concept of lattice mismatch [4] that offers a direct insight in the structural stability and optical properties of multi-layered perovskites by considering them as heterostructures formed by single-layer and 3D perovskites [5]. Then, we inspect the interaction between layers that has been shown to have great influence over the optoelectronic properties of the materials [6-8]. We establish the structural parameters governing the amplitude of the interaction as well as its limits. Finally, we present new directions to explore for the design of low-dimensional materials with the recently proposed perovskitoid materials based on a mixing of corner- and edge-sharing octahedra [9].

EN04.08.20

Nano-Volumetric Photoconductivity Mapping for Hybrid Perovskites with Tomographic AFM Luis Ortiz[1], Mingwei Hao[2], Jingfeng Song[1], Yuanyuan Zhou[2] and Bryan D. Huey[1]; [1]University of Connecticut, United States; [2]Hong Kong Baptist University, Hong Kong

Thin film solar cells such as the promising hybrid perovskite systems typically possess high densities of grains, grain boundaries, and buried interfaces. Their effects on ultimate device performance and reliability are difficult to ascertain. We employ Tomographic Atomic Force Microscopy (T-AFM), progressively measuring nanoscale photocurrents during tip-induced surface milling, in order to three dimensionally reconstruct the photoconduction network. Specifically, results are presented for perovskite based solar half cells, engineered with continuous layers of SnO2-x or NiOx between a MAPbI3 absorber and a conducting back electrode. This isolates electron or hole conduction, respectively, with a clear reversal in the sign of the biased photocurrents and even when directly mapping nanoscale short circuit currents. PCBM and Spiro additives concentrated at grain boundaries are further employed, in order to elucidate benefits or disadvantages of interfaces for distinct carrier types. Local, ensemble, and depth dependencies of photocurrents for grains and grain boundaries are thus uniquely considered, thereby informing optimal microstructures for future hybrid perovskite solar cell designs.

EN04.08.24

Directly Probing the Effects of Defect Passivation on Ion Migration in Wide Bandgap Perovskites Justin Pothoof, Rajiv Giridharagopal and David S. Ginger; University of Washington, United States

Wide bandgap halide perovskite (~1.7 eV) materials are the most promising active layers being studied for use in tandem solar cells utilizing silicon (~1.1 eV) as its bottom light harvesting layer. Being solution processible and having an easily tunable bandgap, perovskites can be tailored to fit the already well optimized and established silicon photovoltaic cell to maximize power conversion efficiency. While perovskites are known to be defect tolerant when discussing device performance, those same defects allow for ionic transport through the crystal lattice leading to device instability in the form of phase segregation, hysteresis, and active layer degradation at interphases or electrodes. In wide bandgap perovskites in particular, this ionic motion is exacerbated by the mixed halide composition necessary to achieve a larger energy gap needed in the tandem architecture. Understanding the phenomenon of ion migration and our ability to control it is paramount to the reproducible fabrication of high efficiency and operationally stable photovoltaics. Here, we use a combination of multimodal scanning probe microscopy and photoluminescence characterization to observe the migration of ions in wide bandgap perovskite films. Importantly, we also use this combination of methods to show the benefits of defect passivation schemes in reducing this deleterious ion migration. Defect passivation, often through chemical post-treatment of the perovskite active layer, has been reported to reduce nonradiative recombination. Here we show that passivation also can reduce ion migration and therefore enhance long-term stability. To measure this effect, we utilize electrical and optoelectronic scanning probe microscopy, such as scanning Kelvin probe microscopy and surface photovoltage, to probe ion motion locally and correlate these measurements with photoluminescence lifetimes and intensity. These results enable future investigations of multiple facets of post-processing treatments on optoelectronic properties, such as carrier lifetimes, photoluminescence enhancement, mitigation of ionic migration, and changes in device metrics among other measurements.

EN04.08.26

Direct Observation of Light-Induced Halide Diffusion in 2D Lateral Heterostructures Halide Perovskite Crystals Yanqi Luo[1], Shuchen Zhang[2], Jia-Shiang Chen[1], Xuedan Ma[1], Junjing Deng[1], Yi Jiang[1], Luxi Li[1], Barry Lai[1], Si Chen[1], Sarah Wieghold[1] and Letian Dou[2]; [1]Argonne National Laboratory, United States; [2]Purdue University, United States

Two-dimensional (2D) halide perovskites with enhanced stability and radiative recombination properties are promising for photovoltaic and light-emitting diode (LED) applications. Recent progress in fabricating lateral heterojunctions of 2D halide perovskites provides a unique platform for creating LEDs with large structural and compositional tunability. However, an improved understanding of the origins of degradation and the interactions with external stimuli within lateral heterostructures needs to be established to overcome stability barriers. In this study, we monitor the evolution of halide diffusion using non-destructive synchrotron-based nanoprobe X-ray fluorescence (Nano-XRF) within various dimensional phenylethylammonium (PEA) based 2D crystals. Upon continuous UV light exposure, the iodine-rich region undergoes rapid sublimation or related photooxidation reactions, while bromine is relatively stable and gradually diffuses/migrates to the previously iodine-rich junction. The degree of bromide diffusion as a function of dimensionality is revealed experimentally in the lateral heterostructures perovskite system for the first time. Understanding the ionic transport mechanism and its driving force is essential for engineering long-lived halide perovskite devices.

EN04.08.30

Assessing *n*-Type Dopability of the Low-Dimensional Metal Halide $Cs_3Cu_2I_5$ Young-Kwang Jung[1] and Aron Walsh[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Imperial College London, United Kingdom

Low-dimensional metal halides are emerging materials for light-emitting applications due to their unique optical properties (e.g. high photoluminescence quantum yield and giant Stokes shift) [1-4]. Even though their use in other applications including memristors [5] and thermoelectrics [6] has been suggested, fundamental understanding of those compounds is still lacking. For instance, whether we can tune physical properties of low-dimensional metal halides from doping is not known yet. Herein, we identify complex intrinsic defect chemistry of $Cs_3Cu_2I_5$ — the most well known example of low-dimensional metal halides — and further assess *n*-type dopability of the material using first-principles calculations. We will discuss how different defect properties of $Cs_3Cu_2I_5$ is from other conventional materials and what dopant will be most effective to make it *n*-type.

EN04.08.31
Chiral Nonlinear Optics of Halide Perovskite Under Light-Matter Strong Coupling Daichi Okada and Fumito Araoka; RIKEN Center for Emergent Matter Science, Japan

Light-matter strong coupling is the hybridized state of light and matter, which can be achieved by coherent coupling between an excitonic transition and a resonant optical mode of a cavity, generating two new split exciton-polaritonic energy states, that is the so-called Rabi-splitting. In past years, it has been seen strong coupling can manipulate and enhance various types of materials properties, such as photochemical reactivity, conductivity, rate of energy transfer, nonlinear optical effect, and so on. Because of such interesting quantum nature and potential, many scientists are investigating to deepen the understanding of strong coupling and develop it to various types of materials and physical properties. However, chirality related physical properties has yet been scarcely studied.
In this work, we study nonlinear optical effect in thin films of chiral halide perovskite that are placed either in the strong coupling condition inside a Fabry-Perot (FP) cavity or not (uncoupled condition). Due to the strong excitonic oscillator strength, chiral halide perovskite shows clear Rabi-splitting with a large separation energy of about 0.25 eV. The formation of the strong coupling gives rise to an enhancement of second harmonic generation (SHG) activity by about one order of magnitude at the higher-energy polaritonic band (the so-called, upper polariton). Furthermore, the dissymmetric factor (g-value) of SHG circular dichroism is also modified and improved under the strong coupling, showing inversed and enhanced g-values at upper polaritonic band as well as enhancement of SHG itself. These modifications are linked with changes in the linear circular dichroism and subsequent enhancement of nonlinear electronic/magnetic susceptibility due to the strong coupling. The fact reveals that strong coupling is an effective way to manipulate also the chiral nonlinear optical effect.

2D Perovskite—Exciting Playgound for Excitation Studies Paulina Plochocka[1,2]; [1]CNRS, France; [2]Wroclaw University of Science and Technology, Poland

High environmental stability and surprisingly high efficiency of solar cells based on 2D perovskites have renewed interest in these materials. These natural quantum wells consist of planes of metal-halide octahedra, separated by organic spacers. The unique synergy of soft lattice and opto-electronic properties are often invoked to explain superior characteristic of perovskites materials in applications. At the
same time such unique synergy creates fascinating playground for exciton physics which challenges our understanding of this elementary excitation. I will demonstrate that even after decade of intense investigation the notation ”unique” so often used in case
of perovskites deserves serious scrutiny.
First, I will show that in 2D perovskites, the distortion imposed by the organic spacers governs the effective mass of the carriers. As a result, and unlike in any other semiconductor, the effective mass of the carriers in 2D perovskites can be easily tailored. Secondly, I will highlight controversy related to exciton fine structure in different perovskite compounds and demonstarte that the soft lattice can suppress relaxation of excitons to dark state making 2D perovskites great light emitters.

9:00 AM EN04.09.02
Mobile Trions in Two-Dimensional Hybrid Perovskites Sophia Terres[1], Jonas D. Ziegler[1], Yeongsu Cho[2], Matan Menahem[3], Takashi Taniguchi[4], Kenji Watanabe[4], Omer Yaffe[3], Timothy C. Berkelbach[2] and Alexey Chernikov[1]; [1]Technische Universität Dresden, Germany; [2]Columbia University, United States; [3]Weizmann Institute of Science, Israel; [4]National Institute for Materials Science, Japan

Two-dimensional hybrid perovskites are a highly intriguing class of materials. They represent natural quantum well systems composed of alternating inorganic and organic molecular layers. Interesting from the perspectives of both fundamental science and applications, they combine an efficient coupling of electrons to a soft lattice with strong Coulomb interactions between the charge carriers. The latter lead to the formation of tightly bound excitons that are shown to be excellent light emitters and absorbers as well as to determine the transport of optical excitations. Consequently, the physics of excitons in 2D perovskites are currently one of the highly active areas of contemporary research. What remains very difficult to access, however, is the interaction of excitons with free charge carriers – a scenario that is commonly encountered in optoelectronic devices and presents an intriguing case of composite Bose-Fermi quasiparticle mixtures.
Here, we report experimental realization of electrically doped, ultrathin 2D perovskite layers, studied in ambipolar field-effect transistor geometries. We

demonstrate the formation of three-particle charged exciton complexes, known as trions, by detecting photoluminescence spectra as function of gate voltage. In addition, by measuring time- and spatially-resolved profiles of the exciton emission we reveal the impact of exciton-carrier interaction on the exciton mobility. The trion binding energies are found to be in the range of 30 – 50 meV, depending on the sample thickness. Such extremely large values are a direct consequence of strong Coulomb interaction and scale with the exciton binding energies, as shown by theoretical calculations. Moreover, we show that trions can be both localized at cryogenic temperatures but also feature thermally activated, efficient transport already at 50 K. The experimental realization of both tunable and mobile trions brings the topic of exciton-carrier mixtures into the realm of 2D perovskites. It opens up avenues for fundamental research of interacting electronic states in hybrid semiconductors and encourages potential applications involving electrically guided charged exciton currents.

Exciton Diffusion in 3D Halide Perovskite Nanocrystal Assemblies Michael F. Lichtenegger[1], Andreas Bornschlegl[1], Jan Drewniok[1], Carola Lampe[1], Nina Henke[1], Andreas Singldinger[1], Maryna Bodnarchuk[2], Maksym V. Kovalenko[2] and Alexander S. Urban[1]; [1]Ludwig-Maximilians-Universität München, Germany; [2]ETH Zurich, Switzerland

Halide perovskite nanocrystals (PNC) have attracted the scientific community for over a decade, but there are still open questions addressing research not only for academic purposes. Among these are PNC stability, maximizing quantum yields, and improving transport performance in thin films. Especially excited-state transport is of tremendous importance for light emission and light-harvesting devices. Surrounded by organic ligands, charge transport is nearly nonexistent in PNC films, rendering energy transfer of excitons the dominant transport mechanism.
We investigate exciton diffusion in films of PNCs cubes and quantum-confined nanoplatelets around room temperature (15-50 °C). Here, diffusion takes advantage of the individual NC size, yielding threefold diffusivity for the largest NCs compared to the smallest ones. Surprisingly, the diffusion process worsens with increasing temperature (up to 50 °C) for all NCs systems. This rate at which this happens differs among the NCs; consequently, the 3 ML NPLs outperform the other NC systems for high temperatures. These two phenomena can be explained by different exciton/free charge carrier ratios present in the NCs. Larger free electron/hole pair ratios decrease the transport efficiency with charge transport irrelevant.
Furthermore, we present unprecedented exciton diffusion results in perovskite nanocrystal films. We investigate an unordered film consisting of 14 nm cubes and highly ordered superlattices comprising either 5 nm or 9 nm large cubes within the range of 9-220 K. Surprisingly, exciton diffusion is higher in the larger PNCs film, irrespective of order for almost all temperatures. Within this temperature range, initially, the diffusivity increases with increasing temperature, reaches a maximum, and drops with increasing temperature for both film types.[2] We detect three effects whose interplay is responsible for this novel trend. 1) Thermally activated FRET hopping, 2) size-dependent exciton fine level splitting between dark and bright states, and 3) exciton/free charge carrier ratios varying with exciton binding energy (PNC size). This study offers deeper insights into exciton diffusion processes, especially at low temperatures.

Unconventional Exciton Transport Phenomena in $CsPbBr_3$ Nanocrystal Solids William Tisdale; Massachusetts Institute of Technology, United States

In some ways, the properties of colloidal $CsPbBr_3$ nanocrystals resemble those of conventional semiconductor nanocrystals. In other ways, $CsPbBr_3$ is wholly unique. In this talk, I will present experimental results from our lab using time-resolved emission microscopy to probe the spatiotemporal dynamics of exciton transport in disordered $CsPbBr_3$ nanocrystal films and nanocrystal superlattices. $CsPbBr_3$ nanocrystals exhibit a range of novel and unconventional transport behavior, including excitation memory effects, collective phenomena, and record-high values of exciton diffusivity.

Ultra-Narrow Room-Temperature Emission from Single $CsPbBr_3$ Perovskite Quantum Dots Gabriele Raino[1,2], Nuri Yazdani[3], Simon C. Böhme[1,2], Chenglian Zhu[1,2], Marta D. Rossell[2], Rolf Erni[2], Vanessa Wood[3], Ivan Infante[4] and Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]ETH Zürich, Switzerland; [4]Istituto Italiano di Tecnologia, Italy

Semiconductor quantum dots (QDs) have long been considered artificial atoms, but despite the overarching analogies in the strong energy-level quantization and the single-photon emission capability, their emission spectrum is far broader than typical atomic emission lines. Here,[1] by using ab-initio molecular dynamics for simulating exciton-surface phonon interactions in structurally dynamic $CsPbBr_3$ QDs, followed by single quantum dot optical spectroscopy, we demonstrate that emission line-broadening in these quantum dots is primarily governed by the coupling of excitons to low-energy surface phonons. Mild adjustments of the surface chemical composition allow for attaining much smaller emission linewidths of 35 - 65 meV (vs. initial values of 70-120 meV), which are on par with the best values known for structurally rigid, colloidal II-VI quantum dots (20 - 60 meV).
Ultra-narrow emission at room temperature is desired for conventional light-emitting devices and paramount for emerging quantum light sources.

Highly Pure Single-Photon Emission from Single Perovskite QDs Chenglian Zhu[1,2], Malwina Marczak[1,2], Leon Feld[1,2], Simon C. Böhme[1,2], Caterina Bernasconi[1,2], Anastasiia Moskalenko[1,2], Ihor Cherniukh[1,2], Dmitry N. Dirin[1,2], Maryna Bodnarchuk[1,2], Maksym V. Kovalenko[1,2] and Gabriele Raino[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Attaining pure single-photon emission is key for many quantum technologies,[1] from optical quantum computing[2] to quantum key distribution[3] and quantum imaging.[4] The past 20 years have seen the development of several solid-state quantum emitters, but most of them require highly sophisticated techniques (e.g., ultra-high vacuum growth methods and cryostats for low-temperature operation). The system complexity may be significantly reduced by employing quantum emitters capable of working at room temperature. Lead-halide perovskite $APbX_3$ (A=Cs or organic cation; X=Cl, Br, I) quantum dots (QDs) are one of the desired materials, of particular interest due to their low-cost synthesis, solution processability, tunability of the emission wavelength via size and composition, narrow-band emission, short radiative lifetime (~ns at RT) as well as high photoluminescence quantum yield (QY).[5,6] Here, we present a systematic study across ~ 170 photostable single $CsPbX_3$ (X: Br and I) colloidal QDs of different sizes and compositions, unveiling that increasing quantum confinement is an effective strategy for maximizing single-photon purity due to the suppressed biexciton quantum yield. Leveraging the latter, we achieve 98% single-photon purity ($g^{(2)}(0)$ as low as 2%) from a cavity-free, non-resonantly excited single 6.6 nm $CsPbI_3$ QDs, showcasing the great potential of $CsPbX_3$ QDs as room-temperature highly pure single-photon sources for quantum technologies.

Coherent Exciton Transport in Perovskite Quantum Dot Superlattices Libai Huang; Purdue University, United States

The performance of quantum dot (QD) devices in optoelectronic and quantum information applications relies on not only the properties of the individual QDs but also the collective properties arising from interactions between QDs within a solid. The interactions between QDs determine whether long-range coherence and transport can be achieved. Due to their large oscillator strengths, perovskite QD superlattices (SLs) have the potential for exciton superradiance. However, the ultrafast dephasing processes can limit their coherence lengths. We provide a detailed study on the key factors that control exciton delocalization and transport in perovskite QD SLs. Through temperature-dependent and time-resolved photoluminescence microscopy measurements, we demonstrate coherent exciton propagation in highly ordered SLs. We unravel the effect of disorder by comparing SLs with varying degrees of inhomogeneity. Our results point to the exciting opportunities in engineering exciton coherence in perovskite solids.

Effects of Symmetry Breaking Due to the Bounding Facets of Halide Perovskite Nanocrystals Peter C. Sercel; Center for Hybrid Organic Inorganic Semiconductors for Energy, United States

Halide perovskite nanocrystals are a promising platform for optoelectronic devices such as light sources and displays, and are currently being considered for potential applications in quantum information processing. Such applications hinge on our understanding and control of the exciton fine structure. We begin by reviewing the electron-hole exchange theory for the exciton fine structure in cesium lead halide nanocrystals, which has been shown experimentally to govern the exciton fine structure in these systems [1]. We elaborate on the particular role of the nanocrystal shape in conjunction with long range exchange: To date, models for the fine structure in cuboidal perovskite nanocrystals (e.g., Refs. [1,2]) and in lead halide perovskite nanoplatelets (e.g. Ref. [3]) have assumed the bounding facets in these structures are comprised of the lowest index orthorhombic crystal planes. However, recent studies indicate that, to the contrary, the bounding facets of cuboidal perovskite nanocrystals [4] and cesium lead halide nanoplatelets [5] correspond to the pseudocubic {100} crystal planes. We show that this situation, in general, causes a breaking of the orthorhombic symmetry of the nanocrystals.

In this talk we explore the impact of this facet-related symmetry breaking on the exciton fine structure and optical properties. One consequence is the creation of a bright exciton “fine-structure gap” which can be observed in ensemble-level transient absorption measurements [6]. We predict the existence of chiro-optical effects, which are a manifestation of “extrinsic chirality”, notwithstanding the existence of inversion symmetry in these structures. We will discuss generalizations to other perovskite systems such as two-dimensional hybrid organic/inorganic perovskites.

Manipulating Chirality of 2D Lead Perovskites via Achiral Isomer Cations Hao Li, Ibrahim Dursun and Qiuming Yu; Cornell University, United States

Hybrid organic-inorganic perovskites have emerged as an important family of materials for optoelectronics with broader applications in solar cells, photodetectors, light-emitting diodes (LEDs), and lasers. As ionic semiconductors, the flexible crystal structures and tunable compositions make it possible to rationally design hybrid perovskites with desired properties. Chiral perovskites demonstrate such possibility and the breakthrough with respect to the development of a new class of chiral semiconductors, which opens up new applications of hybrid perovskites to chiroptoelectronics, ferroelectrics, and

spintronics. One type of chiral perovskites is based on two-dimensional (2D) hybrid organic-inorganic perovskites by incorporating chiral organic ligands between achiral inorganic single layers composed of corner-sharing metal-halide octahedra. As a new class of chiral semiconductors, the chirality of hybrid 2D perovskites is attributed to the symmetry-breaking in the inorganic framework induced by the enantiopure chiral organic cations via asymmetric hydrogen bonding interactions, which transfers the structural chirality across the organic-inorganic interface. In this work, we introduced achiral alkyl isomer cations, n-butylammonium (n-BA^+) and iso-butylammonium (iso-BA^+) into the organic layer with chiral organic cations (R/S-MBA^+). Single phase 2D (R/S-$MBA_xnBA_{1-x})_2PbI_4$ and (R/S-$MBA_yisoBA_{1-y})_2PbI_4$ were obtained with x = 0.5 and y = 0.7. The CD signals became strong, and the polarity was flipped by the incorporation of nBA in (R/S-$MBA_{0.5}nBA_{0.5})_2PbI_4$. We performed density functional theory (DFT) calculations to understand the interaction between organic and inorganic layers and its impact on electronic band structure and band gap. We performed temperature dependent powder XRD and pair distribution function (PDF) measurements using NSLS-II synchrotron at the Brookhaven National Laboratory to investigate structural variations with temperature to help understanding the observation of the unique behavior exhibited in the temperature dependent circular polarized photoluminescent (CPPL) measurements. We also conducted conventional and circular polarized transient absorption spectroscopy (TAS) to understand the photophysics embedded in these new chiral perovskites. Unlike $(R/S\text{-}MBA)_2PbI_4$ that exhibit red-shifted and broaden CPPL spectra with the increasing of temperature, (R/S-$MBA_{0.5}nBA_{0.5})_2PbI_4$ and (R/S-$MBA_{0.7}isoBA_{0.3})_2PbI_4$ show non-shifted CPPL peak and conserved peak width from 10 K -300 K. DFT calculations show stronger hydrogen bonding and more tilted octahedron due to the asymmetric cations on the opposite sides of the inorganic framework. While many phenomena are unknown and needed further investigations, this work provides a new way to manipulate chirality of 2D perovskites, which could lead to broader applications.

Characterizing the Circular Polarization-Dependent Refractive Index of Low-Dimensional Chiral Perovskites Shunran Li, Peijun Guo, Conrad Kocoj, Joseph Bennett and Xiaobin Wang; Yale University, United States

Hybrid organic-inorganic perovskites (HOIPs) have recently emerged as promising materials with remarkable light-absorbing and luminescent properties. In two-dimensional hybrid perovskites (2DHPs), chiral ligands can endow the chirality to perovskites and further enable chiral optoelectronic applications such as chiral photoluminescence and chiral photodetection. Currently, the degree of chirality in 2DHPs is represented by their circular dichroism (CD), defined as difference in absorption between left-handed (A_L) and right-handed (A_R) circularly polarized light. However, such characterizations are typically performed on thin film samples in transmission measurements, and the results can be blurred by material thickness and film morphology. Here, we propose and demonstrate the use of chiral complex refractive index (n and k) as a more intrinsic parameter to evaluate the degree of chirality of 2DHPs. From reflectance spectroscopy and the transfer matrix method, we characterize the chirality-dependent n and k for archetypal chiral 2DHPs. Our study provides fundamental insights regarding how chiral ligands impact the intrinsic material optical property and provide guiding principles for the design of chiral perovskites optoelectronic devices.

Synthesis, Characterization and Optical Properties of Chiral Metal Halides Ali Azmy[1], Alissa Anderson[1], Alexander Fyffe[1], Nourdine Zibouche[2], Lukasz Wojtas[1], Minh Tuan Trinh[1] and Ioannis Spanopoulos[1]; [1]University of South Florida, United States; [2]University of Bath, United Kingdom

Halide perovskites pose as a versatile class of semiconductor materials with exceptional optoelectronic properties and unique structural versatility. They are very competent in applications such as solid-state solar cells and LEDs, but their potential in non-traditional perovskite related research directions such as spintronics is not yet explored. Despite their performance, traditional lead-based perovskites are not suitable for real applications due to toxicity and instability related issues. Double perovskites and lead-free metal halides can eliminate the need for lead, while producing a greener material with equally exquisite optoelectronic features.
Towards this end we synthesized a lead-free metal halide compound based on a chiral linker (L1). Utilization of chiral linkers allows the acquisition of non-centrosymmetric crystalline materials, highly sought after for their nonlinear optical properties (NLO). We present here the synthesis of $(L1)_2Sb_2Br_{10}$, along with its structural, and optical properties. The material is a wide band gap semiconductor, it crystallizes in the $P2_1$ space group, and exhibits asymmetric broad light emission at RT. Second Harmonic Generation (SHG) measurements verify the non-centrosymmetric nature of the structure, while the in-plane azimuthal SHG plot reveals a strong anisotropic signal. This new material poses as an excellent candidate for spintronic applications where important structure-property relationships in terms of spin lifetimes can be extracted.

Controlling Charge, Spin and Light in Lead-Halide Inspired Hybrid Semiconductors Matthew C. Beard; National Renewable Energy Laboratory, United States

In this presentation I will discuss our studies of controlling the charge carrier dynamics, light/matter interactions, and spin populations in metal-halide organic/inorganic hybrid systems. In one effort we are exploring the use of novel organic hybrid systems at and near interfaces to control the carrier dynamics and reduce surface recombination but also to protect grain boundary surfaces from degradation. With respect to controlling spins we have recently studied and developed a novel class of chiral hybrid semiconductors based upon layered metal-halide perovskite 2D Ruddlesden-Popper type structures. These systems exhibit chiral induced spin selectivity whereby only one spin sense can transport across the film and the other spin sense is blocked. From these systems we can achieve a high degree of spin current polarization and injection when used as a contact layer. We have developed novel spin-based LEDs using mixed NCs as the light emitting layer that promotes light emission at a highly spin-polarized interface. The LED spin-polarization is limited by spin-depolarization within the MHP NCs. In a separate effort we have explored the use of chiral copper-halide hybrid systems for circular light polarized detection. Chiral based copper-halide systems combined with highly conductive carbon nanotube networks can be employed to detect circular polarized light with the use of polarizers. Our chiral heterostructure shows high photoresponsivity of 452 A/W, a competitive anisotropy factor of up to 21%, a current response in microamperes, and low working voltage down to 0.01 V. Finally, we have developed novel photocatalyst based upon the unique properties of metal-halide semiconductor nanocrystals and show that such systems can drive multiple electron reactions. These results demonstrate that the emergent properties of organic−inorganic hybrid systems offer unique opportunities in controlling light, charge and spin.

Composition Gradient-Enabled Circular Photogalvanic Effect in Epitaxial $CsPbBr_xCl_{(3-x)}$ Film Ru Jia and Jian Shi; Rensselaer Polytechnic Institute, United States

Inversion symmetry breaking could lead to the creation of Rashba-Dresselhauls magnetic field which plays the key role in spintronic devices. In this project, we propose and develop a composition gradient engineering approach that breaks inversion symmetry in inorganic halide perovskite with strong spin-orbit coupling. We synthesize epitaxial $CsPbBr_xCl_{(3-x)}$ with Br/Cl composition gradient by a two-step chemical vapor deposition (CVD) approach. Through optoelectronic measurements, we show the presence of circular photogalvanic effect (CPGE) evidencing a Rashba-like spin polarized band structure. By spatially resolved photoluminescence spectra, we find that the observed CPGE is likely a cumulative result of inversion symmetry-broken interfaces featured by abrupt and stepwise composition gradient between the pristine and separated daughter phases. Our work suggests an avenue in engineering the spintronic property of halide perovskite for information processing.

4:00 PM EN04.10.07
Local Symmetry Breaking Drives Spin Accumulation in a Polycrystalline Metal Halide Perovskite Arjun Ashoka, Sascha Feldmann and Akshay Rao; University of Cambridge, United Kingdom

Photoinduced spin-charge interconversion in semiconductors with spin-orbit coupling could provide a route to optically addressable spintronics without the use of external magnetic fields. A central question that remains is whether the resulting spin-associated charge currents are robust to structural disorder, which is inherent to polycrystalline semiconductors, desirable for device applications. Using femtosecond circular polarization-resolved transient absorption microscopy on polycrystalline metal halide perovskite thin films, we observe the formation of micron-scale spin domains on picosecond timescales through spin-associated lateral charge currents. We show that local symmetry breaking, evidenced by micron-scale variations in second-harmonic generation intensity and ferroelectric domains, induces spatially varying Rashba-like spin textures that drive spin-momentum locked currents, leading to local spin accumulation. Local symmetry breaking is only enhanced by increased local structural disorder and our observations suggest that the simultaneous presence of spin-momentum locking will always lead to local spin accumulation. Such structurally disordered Rashba-like materials could provide a new optically addressable platform for ultrafast nanoscale spin-device physics.

4:15 PM EN04.10.08
Tuning the Thermoelectric Properties in Vacuum Deposited Cesium Tin Iodide Thin Films Paz Sebastia-Luna[1], Unnati Pokharel[2], Bas A. Huisman[1], Lambert Jan Anton Koster[2], Francisco Palazon[1,3] and Henk J. Bolink[1]; [1]University of Valencia, Spain; [2]University of Groningen, Netherlands; [3]Universidad Politécnica de Cartagena, Spain

Thermoelectric generators (TEGs) represent a very promising source of renewable energy, as they directly convert (waste) heat into electricity. Most current thermoelectric materials have important drawbacks, such as toxicity, scarceness, and peak operating temperatures above 300 ^{0}C. Herein, we report the thermoelectric properties of different crystalline phases of Sn-based perovskite thin films. A novel 2D phase, Cs_2SnI_4, is obtained through vacuum thermal deposition and easily converted into the black β phase of $CsSnI_3$ (B-β $CsSnI_3$) by annealing. B-β $CsSnI_3$ is a *p*-type semiconductor with a figure-of-merit (ZT) ranging from 0.021 to 0.033 for temperatures below 100 ^{0}C, which makes it a promising candidate for applications such as the Internet of Things (IoT). The B-β phase is stable under an inert atmosphere but spontaneously oxidizes to Cs_2SnI_6 when exposed to air. In-detail thermoelectric study for both compounds is presented, showing potential for implementation in low temperature operating TEGs.

4:30 PM EN04.10.09
Dielectric Effects in Halide Perovskites Doru C. Lupascu[1], Andrei Karabanov[1], Young Un Jin[1], Niels Benson[1], Kristina Winkler[1], Bernd Marler[2], Vladimir Shvartsman[1] and Miriana Vadala[1]; [1]University of Duisburg-Essen, Germany; [2]Ruhr University Bochum, Germany

The soft nature of the crystal lattices in halide perovskites and related compounds offers a magnificent new realm of properties to these crystals. Among these is the outstandingly large dielectric constant reaching up to very high frequency values. In this contriution we will summarize the state of the art in this field and options to develop new compounds. We will revisit the charge types forming in this class of crystals, the paraleelctric and/or ferroelectric contributions. It will be displayed that ferroelectricity is a very rare effect and in most cases is just a misinterpretation of experimental data. Ways to further tune charge carrier mobility will be outlined.

4:45 PM EN04.10.10
Trifluorinated Substitution Strategy to Induce In-Plane Ferroelectricity in Ruddlesden-Popper Layered Hybrid Perovskites Haining Zheng and Kian Ping Loh; National University of Singapore, Singapore

Two-dimensional (2D) organic-inorganic hybrid perovskites (HOIPs), which possess outstanding optical characteristics, unique structural tunability and customizable elemental composition, have elicited tremendous attention in a wide range of optoelectronic and energy storage applications. One of the most remarkable applications is ferroelectricity-driven non-volatile memory devices. Ferroelectricity, i.e. the characteristic of a material that possesses spontaneous polarization that can be switched by applying external electric fields, has been reported in a number of layered hybrid perovskites, for instance, $[2\text{-fluorobenzylammonium}]_2PbCl_4$ [1], $(4,4\text{-difluoropiperidinium})_2PbI_4$ [2] as well as the quasi-2D perovskites $[n\text{-butylammonium}]_2(methylamine)Pb_2Br_7$ [3] and $(ethylammonium)_4Pb_3Br_{10}$ [4]. Nevertheless, on account of the complexity of metal-organic interaction, the precise design and prediction of hybrid perovskite ferroelectrics is still a challenge. In this talk, I will introduce the recently reported design strategy to synthesize perovskite ferroelectrics, including H/F substitution, quasi-spherical theory, homochirality [5] and intercalation-driven strategy [6][7], and also propose a novel trifluorinated substitution strategy that can induce robust in-plane ferroelectricity in Ruddlesden-Popper-phase (RPP) layered hybrid lead chlorine perovskites. The trifluorinated modification of organic ligands can provide additional intermolecular F...F interactions to enhance the strength of the dipole moment and facilitate perovskites to crystallize in ferroelectric space groups. Furthermore, this trifluorinated substitution strategy can also achieve a large spontaneous polarization (P_s) of 8.0 μC cm^{-2} and a high phase transition temperature (T_c) of 415 K, which has been experimentally proved by differential scanning calorimetry (DSC), second harmonic generation (SHG), polarization-electric field (P-E) hysteresis loop and piezoresponse force microscopy (PFM) measurements. This unique trifluorinated substitution strategy offers the possibility to design manipulable memory devices with high operation temperature, shedding the light on multifunctional ferroelectric optoelectronic devices.

10:30 AM EN04.11.03
Carrier Equilibrium in 2D Hybrid Perovskites Thin Crystals Probed with Tandem Ultrafast Optical Spectroscopy Angelica Simbula[1], Luyan Wu[1], Fang Liu[1], Riccardo Pau[1,2], Federico Pitzalis[1], Stefano Lai[1], Daniela Marongiu[1], Andrea Mura[1], Francesco Quochi[1], Michele Saba[1] and Giovanni Bongiovanni[1]; [1]Università degli Studi di Cagliari, Italy; [2]University of Groningen, Netherlands

2D hybrid perovskites (HP) are playing a major role in emerging photovoltaics, thanks also to their long-term stability and high-power conversion efficiency. Despite their outstanding success, the dynamics of photogenerated carriers in these materials, from which their conversion efficiency stems, still needs to be assessed. We can get useful information on photocarrier dynamics thanks to "tandem" ultrafast optical spectroscopy setup, combining transient absorption spectroscopy and time resolved photoluminescence in the same excitation conditions [1]. We report results of tandem spectroscopy applied for the first time to thin crystals of 2D HP (phenethylammonium $(PEA)_2PbI_4$) in different configurations, both with resonant and non-resonant excitationation, and compared with their thin-films counterparts. We believe that our results provide important insights in the photophysics laying under the exceptional optoelectronic properties of these materials.

Alkyl-Aryl Cation Mixing in Chiral 2D Perovskites Liang Yan[1], Manoj K. Jana[2], Peter C. Sercel[3], David B. Mitzi[2,2] and Wei You[1]; [1]University of North Carolina at Chapel Hill, United States; [2]Duke University, United States; [3]Center for Hybrid Organic Inorganic Semiconductors for Energy, United States

We report 2D hybrid perovskites comprising a blend of chiral arylammonium and achiral alkylammonium spacer cations (1 : 1 mole ratio). These new perovskites feature an unprecedented combination of chirality and alkyl-aryl functionality alongside non-covalent intermolecular interactions (e.g., CH—π interactions), determined by their crystal structures. The mixed-cation perovskites exhibit a circular dichroism that is markedly different from the purely chiral cation analogs, offering new avenues to tune the chiroptical properties of known chiral perovskites, instead of solely relying on otherwise complex chemical syntheses of new useable chiral cations. Further, the ability to dilute the density of chiral cations by mixing with achiral cations may offer a potential way to tailor the spin-based properties in 2D hybrid perovskites, such as Rashba-Dresselhaus spin splitting and chirality-induced spin selectivity and magnetization effects.

11:00 AM EN04.11.06
Survey of acceptor dopants for inorganic halide perovskites John L. Lyons and Michael W. Swift; Naval Research Laboratory, United States

All-inorganic lead halide perovskites, such as cesium lead bromide ($CsPbBr_3$), are expected to be high-performing light emitters, with potential applications including lighting, displays, and quantum information. All of these applications would benefit from having fully controlled electrical conductivity. However, it has proven difficult to achieve high *p*-type carrier concentrations in these materials. In this work, a wide variety of possible acceptor dopants are evaluated in the halide perovskites, using first-principles calculations based on a hybrid functional with spin-orbit coupling. This approach not only leads to accurate predictions for band structure and band offsets, but also provides a better description of dopant properties. We connect our results with prior work on native defects which are expected to act as compensating species. We show that *p*-type doping is difficult because of two related effects: the moderately high formation energies of acceptor impurities, and compensation by native defects, particularly the lead–cesium antisites (Pb_{Cs}) and bromine interstitials (Br_i). Among the dopants considered, sodium and silver are identified as the most promising acceptors for overcoming these challenges to achieve p-type conductivity, and optimum chemical potential conditions for these dopants are identified.

11:15 AM EN04.11.07
Strain-Induced Structural Distortion, Octahedral Tilting and Bandgap Non-Linearity of 2D Butylammonium Tin Iodide Perovskites—A GGA+SOC Approach Mehreen Javed, Maamar Benkraouda, Noureddine Amrane and Atif Sattar; United Arab Emirates University, United Arab Emirates

Global sustainability challenge requires an immediate shift toward renewable energy resources. Two-dimensional perovskites with long-life stability can be tuned by strain engineering to modulate the structural and electronic properties thus achieving higher solar power conversion efficiency. Herein, we have investigated the influence of biaxial strain (±3% and ±6%) on structural distortion, octahedral tilting, and bandgap tuning of monolayer Butylammonium Tin Iodide (BA_2SnI_4) perovskite through first-principles density functional theory calculations. The prototype structure has a single sheet of corner shared inorganic SnI_4 metal cages sandwiched between Butylammonium (*BA*) organic spacer cations offering an optically favorable direct bandgap of 1.457eV, centered at Γ-point. Equivalent biaxial strains (ε_{xx} and ε_{yy}) are applied along with the directions [100] and [010] of x- and y-axes respectively, by fractions starting from ε = −6% to ε = +6% using a step size of 3%. The lattice parameters *a* and *b* of BA_2SnI_4 are constrained to various values different from their equilibrium lattice parameters, keeping the *c* parameter invariant. Both tensile and compressive strains (±3% and ±6%) applied along the x-axis result in smaller bandgaps than strains oriented along the y-axis. The cationic and anionic dominance at conduction and valence bands support the defect tolerant tendency, with no trap states in the bandgap. The organic components constitute a larger bandgap than the inorganic part with satisfied quantum and dielectric confinement. Spin-orbit coupling is explored as a more influential phenomenon than the strain effect to tune electronic properties. The strain-induced competing effects of octahedral tilting and structural distortion with bandgap bowing and spin-orbit coupling provide a systematic strategy to tune bandgaps of different optoelectronic device applications.

Critical Currents of Lithium Anode Solid-State Batteries with Ceramic Electrolytes Ziyang Ning[1], Dominic Spencer Jolly[1], Dominic Melvin[1,2], Guanchen Li[1], Jitti Kasemchainan[1], T. James Marrow[1], Charles Monroe[1,2] and Peter Bruce[1,2,3]; [1]University of Oxford, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]The Henry Royce Institute, United Kingdom

Solid-state batteries using a lithium anode and a ceramic electrolyte promise to improve the energy density and safety of cells. However, there are significant challenges to cycling lithium anode solid-state batteries at practical current densities of several mA cm^{-2}. Critical currents occur on discharge (stripping) above which cells fail due to voiding at the Li/solid electrolyte interface. Such voiding depends on Li creep rates, which depend on temperature and stack pressure. Dendrites (Li filaments) penetrate the solid electrolyte on charge (plating). Using X-ray computed tomography we have followed in detail how Li dendrites crack Li_6PS_5Cl electrolytes and how the dendrite-cracks propagate across the solid electrolyte. We model the process based on our observations including the process of dry crack propagation. The relationship between cycling conditions, stack pressure and the properties of the solid electrolyte will be discussed. The findings help to inform routes for realising solid-state batteries that avoid short-circuits.

11:00 AM EN05.01.02
Mechanics of Lithium Metal at Nanoscale by EBSD Coupled Nanoindentation Jack Aspinall, David E. Armstrong and Mauro Pasta; University of Oxford, United Kingdom

The fracture of ceramic solid electrolytes, driven by the plating of lithium within cracks, has been identified as one of the fundamental issues to resolve to successfully develop solid-state batteries[1]. Understanding the mechanics of lithium at the nanoscale is therefore essential. In this work, the elastic and plastic properties of lithium are measured by Berkovich nanoindentation within an enclosed argon glovebox system. Lithium is particularly challenging to study due to its high reactivity and softness, preventing the use of traditional surface preparation methods. Using a novel surface preparation methodology, lithium metal samples are characterised by electron backscattered diffraction (EBSD) before and after indentation to allow the dependence of the mechanical properties on crystallographic orientation to be measured, and the stiffness tensor components, moduli and poisons ratio to be independently determined using a method first proposed by Vlassak and Nix[2]. The measured stiffness tensor components are C_11 = 13.3 GPa, C12 = 11.2 GPa and C44 = 8.8 GPa. These values agree with earlier acoustic works on lithium single crystals within 2%[3]. Hardness measurements show anisotropy according to Schmid's law, with a clear size effect which may explain observed lithium filament propagation. The experiments were repeated across lithium magnesium solid solution alloys from 5 to 20 atomic percent to investigate the change in elastic and plastic properties with solute content.

11:15 AM EN05.01.04
Designing the Ion Exchange Process to Optimize the Tradeoff Between Induced Residual Stress and Ion Transport to Prevent Lithium Filament Growth in Solid Electrolytes Harsh D. Jagad[1], Stephen Harris[2], Brian W. Sheldon[1] and Yue Qi[1]; [1]Brown University, United States; [2]Lawrence Berkeley National Laboratory, United States

Lithium filament propagation in solid state electrolytes (like Lithium Lanthanum Zirconium Oxide LLZO) is stymieing the widespread adoption of Lithium anodes secondary batteries. Sub-surface isovalent Ion Exchange (IX) with a larger cation radius was proposed to prevent the filament propagation by inducing residual compressive stresses (RCS) in the electrolyte. However, several thermodynamic and kinetic tradeoffs need to be optimized. For example, larger ion size induces larger chemical strain and higher RCS but may require higher ion exchange temperature to overcome the large ion substitutional free energy and slow diffusion process. On the other hand, smaller ion size (albeit, still larger than Li+) may require higher exchange concentrations to achieve similar vales of RCS, while the high concentration may block Li ion diffusion pathways. Another key challenge is the diffusivity of the exchanged cations in LLZO, which should be sufficient enough to penetrate 1~20 microns in order to suppress crack growth; while being immobile at battery operation conditions. Furthermore, the Li ion diffusivity is also reduced by the ion exchange process, setting an upper limit for the ion exchange concentration and RCS. We compare these tradeoffs for K^+, Na^+, Ag^+ cations to guide the optimization of ion exchange process. Using Density Functional Theory (DFT) informed thermodynamic calculations, a variety of commonly existing precursors (oxides, halides, nitrides, pure metal, etc). were screened to give the suitable substitutional free energy. The preferred site occupied by the exchanged species in the LLZO is compared for the three cations at various ion-exchange concentrations to understand their impact on diffusion. Molecular Dynamics simulations are then carried out to compare the stress and concentration dependent cation diffusivity. Extrapolating these results to a continuum scale thin film, the macroscopic RCS and the corresponding increase in fracture toughness are evaluated and compared for the various cations. For example, in the case of K^+, at 3.4% exchange, the RCS induced is close to 1.1 GPa while lowering the Lithium diffusivity by less than a factor of 0.8 at 300K. In summary, the integrated multiscale modelling approach allowed us to optimize the exchange cation size, concentration, ion exchange depth, to balance the increase of RCS and fracture strength while maintaining sufficient Li+ diffusivity to alleviate the lithium filament growth problem in solid state electrolytes.

Deflection and Arrest of Metal Dendrites—Using Engineered Stresses to Prevent Short-Circuit Failures in Solid Electrolytes Cole D. Fincher[1], Christos E. Athanasiou[2,1,3], Brian W. Sheldon[2], W. C. Carter[1] and Yet-Ming Chiang[1]; [1]Massachusetts Institute of Technology, United States; [2]Brown University, United States; [3]Georgia Institute of Technology, United States

Metal penetration and electrolyte failure at low current densities threaten the viability of high energy solid-state batteries with metal anodes. Whether metal filaments are driven by mechanical failure or electrochemical degradation of solid electrolytes remains a topic of debate. If internal mechanical forces drive failure, superimposing an external compressive load on the system should balance internal stress buildups and mitigate penetration. Here, we investigate this hypothesis. In-operando microscopy reveals the response of propagating metal filaments to applied loads and electrochemical stimuli. Compressive loads alter the direction of filament propagation, deflecting filament growth and averting cell failure. We develop a simple linear elastic fracture mechanics model which captures many aspects of this behavior. Based upon this analysis, we estimate the impact of applied stack pressure and in-plane stresses on filament propagation within conventional symmetric and full cells. We then chart the in-plane stresses required to prevent dendrite-induced short circuits. Lastly, we outline cell configurations and processing conditions which result in sufficient residual stresses to deflect metal filaments in solid electrolytes via processing, Overall, this work shows experimentally that it is possible to force metal dendrites to follow a tortuous path, thus increasing the time and amount of capacity plated before failure.

SESSION EN05.02: High Energy Solid-State Batteries Enabled by Anode Design

Monday Afternoon, November 28, 2022
Hynes, Level 3, Room 304

1:45 PM *EN05.02.01
Interfacial Dynamics in Anode-Free Solid-State Batteries Neil P. Dasgupta; University of Michigan, United States

Solid-state batteries (SSB) have seen a dramatic increase in research in recent years because of their ability to address safety challenges associated with flammable liquid electrolytes, and the potential to enable Li metal anodes. Recently there has been an increase in attention paid to anode-free SSB configurations, where all of the lithium inventory in the battery is supplied from the cathode. Accordingly, Li metal is plated out at the interface between a solid electrolyte and a metallic current collector. This enables a N:P ratio of 1, representing a significant increase in the theoretical energy density compared to cells with excess Li metal in the anode. The anode-free configuration unique physical phenomena with regards to chemo-mechanics at the interface, and also represents a valuable platform to quantify the stability and reversibility of Li plating and stripping at solid-solid interfaces.

To probe the dynamic evolution of anode-free solid-state batteries, in this talk, I will present results using a complimentary set of *in situ/operando* methodologies. First, we will explore quantify the impacts of electrochemical cycling conditions and external variables on the voltage signatures and reversibility of anode formation. Comparisons will be made between anode-free cells using state-of-the-art metal oxide and sulfide solid electrolytes. *Operando* video microscopy will be used to study the morphological evolution of the interface, including 3-dimensional analysis using focus variation microscopy. The chemical evolution of SEI formation during the initial anode formation cycle will be explored using *operando* x-ray photoelectron spectroscopy (XPS). The results of these investigations point towards unique processes that occur in anode-free SSBs, including transitions in reaction pathways between SEI formation and Li plating, as well as mechanical evolution of both the Li metal and current collector during nucleation and growth.

2:15 PM EN05.02.02
Uncovering the Effects of Alloy Interfacial Layers in Anode Free Solid-State Batteries Through Cryogenic Focused Ion Beam Characterization Stephanie E. Sandoval, John Lewis and Matthew T. McDowell; Georgia Institute of Technology, United States

In both liquid and solid-state electrolyte (SSE) battery systems, there is growing interest in developing “anode-free” architectures. Anode-free systems feature no active material at the anode current collector and therefore substantially increase the volumetric energy density compared to standard Li-ion batteries. This configuration additionally simplifies manufacturing by removing the need to process lithium metal. During charging of an anode-free cell, Li^+ ions are removed from the lithiated cathode and electrodeposited as lithium metal on the anode current collector. Upon discharge, lithium is stripped and intercalated back into the cathode. Since there is no excess lithium at the anode, it is essential that deposited lithium is entirely removed to achieve high

Coulombic efficiencies (CE). Thus, it is critically important to understand the nucleation and growth behaviors of lithium in anode-free configurations while exploring methods to spatially control lithium growth. Previous work which probed the effects of alloy interlayers in liquid electrolyte systems using *operando* optical microscopy has found that silver thin films enable higher CE than bare current collectors and cause different deposition and stripping dynamics[1]. Silver layers have also shown beneficial effects in enabling long-term cycling of solid-state batteries (SSBs)[2]. Here, we investigate the structural and morphological evolution of alloy interlayers in SSBs using cryogenic focused ion beam (cryo-FIB) methods correlated with electrochemical measurements. Improved CEs are observed using silver and gold thin films compared to bare copper. Performance improvements are investigated using cryo-FIB to probe the Cu| electrodeposited Li| SSE interface. Samples are cooled to -145 °C to stabilize the electrodeposited lithium and minimize interactions between lithium and the gallium ion beam. Once cooled, ~25 mm x ~25 mm x ~25 mm trenches are milled to reveal the solid-solid interface of interest. We observe non-uniform growth on bare copper while uniform lithium growth is observed in silver- and gold- modified interfaces. Interestingly, we observe distinct morphological evolution comparing both alloy interlayers, which also affects cycling behavior. Electrochemical impedance spectroscopy during deposition and stripping is further used to understand and investigate the influence of the alloy interlayers and correlate to morphology evolution. This work provides new understanding of interfacial modification at solid-solid interfaces in SSBs, which will be important for engineering anode-free SSBs.

Alloy Anodes for Solid-State Batteries Yonglin Huang, Bowen Shao and Fudong Han; Rensselaer Polytechnic Institute, United States

The serious challenges of utilizing Li metal anodes with solid electrolytes have motivated the research on alternative anodes. Alloy-based anodes have been gaining great interest recently due to their high capacities. Nevertheless, the utilization of alloy anodes cannot prevent Li plating and subsequent cell shorting. In this presentation, we aim to provide our initial understanding of the dendrite formation in alloy-based solid-state batteries by evaluating the dendrite suppression capability of commonly Li alloys including Li-Zn, Li-Si, Li-Sn, and Li-Al. Our results indicate that Li-Al outperforms other alloys in preventing cell shorting. A possible mechanism for the superior performance of Li-Al based on its mechanical properties will also be introduced. While the slightly higher potential of alloy anodes helps to improve the interfacial stability with solid electrolytes, our recent results show that apparent decomposition of thiophosphate-based solid electrolytes occurs when used with Si anodes. The decomposition of solid electrolytes not only leads to a decrease in the first cycle coulombic efficiency which can complicate cell balancing, but also affects the reaction mechanisms in the subsequent cycles. The utilization of cathodic stable electrolytes, for example, hydrides, is therefore important for alloy anodes. Our work highlights that the properties of both the alloy itself and the solid electrolyte should be carefully studied for the future development of alloy anodes for solid-state batteries.

2:45 PM BREAK

3:15 PM EN05.02.05
Initial Coulombic Efficiency of Hard Carbon in All-Solid-State Sodium-Ion Battery Jin An Sam Oh[1,2], Grayson Deysher[1], Phillip Ridley[1], Long Hoang Bao Nguyen[1] and Y. Shirley Meng[1,3]; [1]University of California, San Diego, United States; [2]Agency for Science, Technology and Research, Singapore; [3]The University of Chicago, United States

All-solid-state sodium ion batteries are highly sought after stationary energy storage systems which can integrate renewal energy into the existing power grid. Among different sodium-ion anodes, hard carbon has a low redox potential, reasonable capacity, and is low cost making it a good candidate in a large-scale format. However, the implementation of hard carbon is hindered by its low initial Coulombic efficiency (ICE) due to formation of solid electrolyte interphase and irreversible sodium trapping. In this study, hard carbon compatibility with a solid-state electrolyte and its initial Coulombic efficiency were studied in detail using X-ray photoemission spectroscopy, electrochemical impedance spectroscopy, and electron microscopy. Additionally, we exploit a method presodiate of the hard carbon to significantly improve the initial Coulombic efficiency. Consequently, the assembled all-solid-state sodium-ions battery with presodiated hard carbon exhibits a higher initial energy density with good reversibility.

3:30 PM *EN05.02.07
Li Metal Solid State Battery Safety Assessed with Calorimetry and Modeling of Large-Format Cells Paul S. Albertus, Nathan Johnson and Bhuvsmita Bhargava; University of Maryland, United States

It is commonly assumed that the introduction of solid-state electrolytes implies the improved safety of high-energy batteries due to the removal of the combustible organic solvents in present Li-ion cells. However, safety is a multifaceted issue that involves thermal runaway onset temperature, self-heating rates, total heat production, maximum temperature, gas or other material release from a cell, thermal runaway prevention mechanisms, and other factors.[1-3] In addition, the use of lithium metal anodes (which melt at 180°C) for high energy density cells may introduce previously unconsidered safety issues due to the presence of molten and reactive lithium metal during a thermal runaway.

This talk will present results on the modeling of thermal runaway in a Li metal solid state battery, under both thermal ramp (e.g., in an oven) and short circuit conditions, with quantitative assessments of the mole fractions of key species in the cell and the temperature.[3] Key assumptions and parameter sensitivities will be shared, to clarify the most important areas for attention and analysis regarding Li metal solid state battery safety. In addition, results from differential scanning calorimetry (DSC) measurements of mg-scale quantities of solid state battery material sets will be presented, which provide quantitative information on onset temperatures and heat flows of key reactions. These experimental results will focus on cells with Li metal, an LLZO-based solid electrode, and metal oxide cathodes.

Finally, perspectives will be given on the early-stage (e.g., for materials and single-layer coin and pouch cells) evaluation of safety for prospective high-energy cells, for which commercial-scale cells (e.g., multi-layer cells of at least several Ah) are not yet available.

SESSION EN05.03: Solid Electrolytes Design for Next Generation Solid-State Batteries I
Session Chairs: Alex Bates and Juner Zhu
Tuesday Morning, November 29, 2022
Hynes, Level 3, Room 304

8:30 AM *EN05.03.01
Residual Compressive Stress as a Proposed General Solution to Dendrite Penetration in Solid Electrolytes Stephen J. Harris[1], Yue Qi[2], Brian W. Sheldon[2], Harsh D. Jagad[2], Chunmei Ban[3], Remi Dingreville[4], Scott Monismith[5], Jianmin Qu[5] and Sydney Morris[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]Brown University, United States; [3]University of Colorado Boulder, United States; [4]Sandia National Laboratories, United States; [5]Tufts University, United States

Rapid filament growth of lithium is limiting the commercialization of solid state lithium metal anode batteries. Recent work demonstrates that lithium filaments grow into pre-existing or nascent cracks in the solid electrolyte, suggesting that increasing the fracture toughness of the solid electrolytes will inhibit filament penetration. We previously suggested that introducing residual compressive stresses at the surface of the solid electrolyte can provide this additional fracture toughness. In this talk we will discuss ion exchange and ion implantation as methods for introducing residual compresses near the surface of solid electrolytes.

9:00 AM EN05.03.02
Pressure Dependent Studies on Site-Disordered Lithium Superionic Argyrodite Li6PS5Br Vasiliki Faka, Matthias T. Agne and Wolfgang Zeier; University of Münster, Germany

The understanding and development of Li^+ solid ionic conductors is important for solid-state batteries. In the search for novel solid electrolytes for solid-state batteries, lithium argyrodite ionic conductors have been in recent focus owing to their high ionic conductivities and processability. Although atomic site disorder has been systematically studied in these materials, the influence of internal strain resulting from microstructural defects such as dislocations has not. Characterizing the effects of internal strain on ion transport is particularly important given the prevalent use of high energy ball milling in the synthesis and processing of solid-state electrolytes for solid state batteries. In this work, we systematically study the effects of internal strain on the bulk ionic transport of the Li_6PS_5Br argyrodite. We are able to reproducibly induce internal strain by applying uniaxial pressures of 250 – 1500 MPa. Quantification of the bulk internal strain occurs in parallel with a local structural analyses by pair distribution function analysis. The changing ionic conductivity of the different materials is assessed by electrochemical impedance spectroscopy and the lithium-ion mobility is probed by NMR spectroscopy. Together, these results show that the high lithium-ion mobility in Li_6PS_5Br is quantifiably affected by external pressure that results in straining of the material. Not only does this work show that strain engineering may be a new methodology for tuning ion conductors without changing the composition of the material itself, it also shows that the external pressures during solid state battery formation may affect the solid electrolyte permanently.

9:15 AM EN05.03.03
Crystallographic Design of Battery Materials Ananya Renuka Balakrishna; University of Southern California, United States

Solid-state batteries have the potential to enhance energy density and offer greater safety when compared with conventional Li-ion batteries. However, a bottleneck with using a solid-state electrolyte lies in mechanically integrating the solid-state electrolyte with the active materials (electrodes). For example, inserting and extracting Li into electrode lattices expands electrode materials up to 10% in volume. These chemo-mechanical strains in the electrode induce misfit stresses at the electrode/electrolyte interfaces, which weaken the structural integrity and electrical conductivity of the battery material composite. In today's talk, we will show how epitaxial strains in thin-film electrodes can be engineered to deter delamination. We develop a continuum model to explore the interplay between phase-transformation microstructures and substrate strains in thin-film electrodes. We apply this model to the vanadium-oxide system and show how tensile straining of electrodes deters delamination and enhances the reversible cycling of electrode materials. I will also discuss some recent work on crystallographically designing electrode microstructures to mitigate volume changes and fatigue. In this latter project, we draw inspiration from shape-memory alloys to stabilize microstructures that have minimum volume changes and high reversibility. Broadly, our work provides a battery design framework to mechanically engineer electrodes and enhance battery safety and lifespan.

9:30 AM *EN05.03.04
Interfaces and Scaling Relations in Solid-State Batteries Wolfgang Zeier; University of Muenster, Germany

The advent of solid-state batteries has spawned a recent increase in interest in lithium conducting solid electrolytes. However, many open questions remain when trying to optimize electrolytes and understand solid state battery chemistries.
In this presentation, we will explore the current focus of halide-based ionic conductors in solid state batteries and discuss stability limitations in solid state battery cells at the anode as well as the cathode composites.
In a second part, we show the influence of Si type anode materials on the effective transport and behavior of solid-state batteries
Finally, we will discuss that it is not only important to find fast ionic conductors but that for an effective thermal battery management the thermal transport properties of solid ionic conductors need to be explored and understood. Here we will show the diffusive thermal transport nature of solid electrolytes and their different scaling relations that put in question the assumption of Bruggeman transport in solid state batteries.

10:30 AM *EN05.04.01
Structure and Ion Dynamics in Solid Electrolytes Observed by NMR Spectroscopy Sylvio Indris; Karlsruhe Institute of Technology–Institute for Applied Materials, Germany

The correlation between structure and dynamics in different Li and Na solid electrolyte materials was investigated by a combination of different nuclear magnetic resonance (NMR) techniques, including magic-angle spinning NMR, temperature-dependent NMR lineshape analysis, NMR relaxometry, and field-gradient NMR. We are thus able to investigate the dynamics of Li or Na ions on different time scales from some nanoseconds to a few seconds, and thus we can observe the local hopping of these charge carriers as well as the long-range transport over several micrometers.
Some examples will be given for Li_3PS_4, Li_6PS_5Cl, $Li_{0.29}La_{0.57}TiO_3$, and NASICON-type structures for Li and Na electrolytes [1-12]. In order to obtain insights into the diffusion pathways inside the crystal structures and the energy landscapes probed by the mobile ions, the NMR results are compared to those obtained by impedance spectroscopy and different diffraction techniques.

Lithium Deposition Behavior of Anode-Free Solid-State Lithium Secondary Batteries with Carbon-Based Composite Layer Da Young Ko, Donghan Youn, Ji Young Kim and Hansu Kim; Hanyang University, Korea (the Republic of)

Anode-free solid-state lithium secondary batteries are one of the most promising next-generation energy storage systems to improve gravimetric and volumetric energy density. Among various types of solid electrolytes, inorganic sulfide solid electrolytes have drawn attention due to their high ionic conductivity and good scalability. However, low Coulombic efficiency because of its absence of excess lithium source and poor cycle life caused by high chemical reactivity between lithium metal and sulfide solid electrolyte are key issues to be solved. In this work, we compared lithium plating and stripping behaviors of current collectors with and without amorphous carbon-containing composite layer by using various electrochemical and analytical characterization methods. We demonstrate types of material, ratio, or microstructure of the composite layer could affect overall electrochemical performance of the battery. The corresponding morphological difference of deposited lithium will be discussed further in the presentation.

11:15 AM EN05.04.03
Increase in Critical Current Density Due to Mn Rich Secondary Phase Formation in Li Stuffed Garnets Sebastian J. Altus[1,2], Innes McClelland[1,3,2], Denis Cumming[4,2] and Edmund J. Cussen[1,2]; [1]University of Sheffield, United Kingdom; [2]The Faraday Institution, United Kingdom; [3]ISIS Neutron and Muon Source, United Kingdom; [4]The University of Sheffield, United Kingdom

Increasing interest in the commercialization of solid-state batteries as an energy source has emphasised the inherent problem of Li dendritic growth.[1] This fundamental mechanism hinders solid state electrolytes from operating at required critical current densities for electric vehicles.[2,3] In a concerted effort to identify the source of Li dendrite growth researchers have identified high electronic conductivity as the origin for Li dendrite formation in solid electrolytes.[4]
Here we investigated the isovalent doping of Garnet type $Li_{6.4}La_3Zr_{1.4}Ta_{0.6}O_{12}$ with the Mn^{4+} cation to enable mixed ionic electronic conduction (MIEC). The ability to introduce small amounts of electronic conductivity would allow for controlled investigations into electrochemical performance and degradation as well as characterize the nucleation and propagation of Li dendrites in a variable electronic conductor. Diffraction analysis following solid state synthesis of $Li_{6.4}La_3Ta_{0.6}Zr_{1.4-x}Mn_xO_{12}$ (x = 0.035, 0.07, 0.105) revealed successful stabilisation of the target cubic phase . However, the presence of Ruddlesden popper impurity compound $LiLa_4MnO_8$ was also identified. To further investigate the affect of grain boundary located compound on the electrochemical properties, AC impedance and DC polarisation analysis were undertaken. Subsequent measurements revealed only a negligible change in electronic and ionic conductivity with only x=0.105 displaying a significant decrease in its ionic conductivity. To elucidate the stability of cycling Li through the solid state electrolyte composite, galvanostatic cycling was performed in a Li|Li symmetrical cell. Here it was found that increasing the dopant level reduced the resistance, thus increasing the critical current density. This was observed up to x=0.07 whereupon the secondary compound counteracted the effect and the critical current density decreased. Impedance spectroscopy analysis of Li in contact with the electrolyte revealed the formation of an interphase contribution. This may also be visually seen by a discolouration of the pellet. This work shows that the creation of a composite, where the secondary compound, even at low dopant levels, holding different electrochemical properties to the parent compound may affect important electrochemical attributes of the parent compound.

Can We Utilise Phonons to Enhance Li-Ion Diffusion? Benjamin A. Williamson and Sverre Magnus Selbach; Norwegian University of Science and Technology, Norway

Solid state electrolytes offer the potential to drastically increase the overall stability of rechargeable lithium batteries as well as provide the means to realise the use of Li-metal anodes maximising the charge capacity of a device. At present, batteries use liquid electrolytes such as $[LiPF_6]^-$ which although they possess high ionic conductivities of $1x10^{-2}$ S cm^{-1} limit the safe temperature ranges a battery can be operated at as well as forbidding the use of Li-metal anodes due to dendrite formation leading to short circuiting and “thermal runaway”. At present, however, there is a dearth of materials suitable for the role

of a highly conductive, stable, solid electrolyte. Current highly conductive materials such as the agyrodites (Li_6PS_5X; X=Cl,Br) or LGPS ($Li_{10}GeP_2S_{12}$) typically possess stability issues, whilst more stable materials show low conductivities, e.g. tetragonal LLZO ($Li_7La_3Zr_2O_{12}$). Understanding the fundamental processes that govern ionic conductivity in such materials has long been a focus of research, however limited information is available on how the intrinsic lattice dynamics of a material influence this, and whether it is a governing factor. In this work we look at understanding the phonon processes between the bulk crystal lattice and a vacanncy migration event in the Li-rich antiperovskites (Li_3OX ; X=Cl,Br,I). In studying the phonons in this way, we aim to question how phonon-based descriptors can be applied to materials discovery and whether diffusion processes can be enhanced via external stimuli.

The Formation of Residual Li Compounds on Ni-Rich NCM Cathodes and Their Effect on the Electrochemical Performance in LPSCl-Based ASSBs Burak Aktekin, Anja Henss and Jürgen Janek; Justus-Liebig-Universität Giessen, Germany

$LiNi_xCo_yMn_{(1-x-y)}O_2$ (NCM) type lithium transition metal oxides with high nickel concentrations have attracted a significant interest as a cathode material in lithium ion batteries due to their high energy density and low cobalt content, however, their reactivity with air during storage/handling and how this affects the electrochemical performance had been overlooked until the recent years. Exposure to H_2O and CO_2 during air storage/handling can lead to formation of LiOH, Li_2CO_3 and also transition metal hydroxides/carbonates.[1,2] The formation of such Li-compounds can also cause structural changes near the surface of cathode particles.[3] Therefore, it is very important to understand how these residual Li compounds are formed and how they affect the electrochemical performance. In all-solid-state batteries (ASSBs), the presence of Li_2CO_3 may improve the electrochemical performance in sulfide-based solid electrolytes,[4,5] however, there has been no dedicated study aiming to understand relationship between the cell performance and the presence of specific residual Li compounds. In this study, we prepare single crystal $LiNi_{0.83}Mn_{0.06}Co_{0.11}O_2$ powders with different residual Li amounts and compositions by either carefully controlling the washing, post-annealing, the ambient air exposure (e.g. humidity and CO_2 concentrations) conditions, or applying coatings with an external Li source. Characterization of these powders will be presented with valuable insights gained from a number of analytical techniques such as XPS, TOF-SIMS, TGA-MS, FIB-SEM, acid titration and XRD. In the next step, the relationship between the residual Li type/amount and the electrochemical performance will be evaluated in ASSB cells with Li_6PS_5Cl solid electrolyte and In-Li alloy counter electrode.

Mechanistic Interrogation of Thermal Stability in Solid-State Batteries Partha P. Mukherjee and Bairav Sabarish Vishnugopi; Purdue University, United States

Solid-state batteries (SSBs), consisting of an inorganic solid electrolyte and a lithium metal anode are promising next-generation energy storage devices that can deliver high energy and power densities. However, the development of practical SSBs still requires overcoming fundamental challenges related to morphological evolution, transport-kinetics interaction, and electro-chemo-mechanical failure. While a wide range of candidate mechanisms leading to interface instability and failure onset have been studied, their mechanistic implication on the thermal stability at solid-solid interfaces is not understood yet. Due to various factors including the high reactivity of lithium metal, potential for oxygen liberation in the cathode, spatio-temporal evolution of thermal hotspots (e.g., during fast charging) and the propensity for internal short-circuit, the safety of SSBs needs to be critically evaluated. In this presentation, we assess the mechanistic role of thermo-electrochemical interactions, interface stability and interphase growth characteristics that can affect the thermal stability in SSBs.

2:00 PM EN05.05.02
The Role of Anisotropy on the Chemo-Mechanical Failure of Secondary NMC Particles Embedded in a Sulfide-Based Solid Electrolyte Avtar Singh[1], Wei Li[1], Trevor Martin[2], Donal Finegan[2] and Juner Zhu[3,1]; [1]Massachusetts Institute of Technology, United States; [2]National Renewable Energy Laboratory, United States; [3]Northeastern University, United States

Lithium-Nickel-Manganese-Cobalt-Oxide (NMC) is being extensively applied as the cathode for solid-state batteries to match the high energy density of metallic anodes. In practice, NMC particles are embedded in the solid electrolyte (SE), forming a composite structure. One of the fundamental challenges for characterization is the co-existence of multiple failure mechanisms. Cracks can initiate and propagate along the grain boundaries between primary particles, through the primary particles, through the SE, or debonding the interface between particles and SE. Therefore, a thermodynamically consistent multi-physics modeling framework was developed to capture all these mechanisms. In order to consider the initiation and propagation of fracture, a regular phase-field fracture variable was employed. A diffused phase-field parameter was introduced to define the transition of chemo-mechanical properties between the grains, grain boundaries, electrolyte, and electrolyte-electrode interfaces. Inspired by the recent experimental evidence that clearly showed that morphological regulation can help mitigate the internal cracks, our model considered two sources of anisotropy, i.e. morphological orientation and crystal orientation. In addition, the concentration-dependent transport and mechanical properties were considered. The present model was implemented in the open-source FEM package MOOSE for solving three state variables: concentration, displacement, and phase-field damage parameter. Various parametric studies were performed to explore the effect of grain morphology and crystal orientation on the chemical-mechanical response of electrode material. The simulation results of this parametric study agreed well with experimental observations that regulated NMC811 particles have significantly fewer cracks than the randomly-oriented NMC532 particles. Ultimately, we applied this model of a polycrystalline particle embedded in a sulfide-based SE to study the

pressure effect on the crack formation and particle fragmentation. Bayesian optimization was used to find the optimal distribution of external pressure on the SE to study three different objectives under the same current density: minimizing the total amount of cracks, minimizing the volume of primary particles that are isolated from Li pathways, or maximizing the coulombic efficiency. Results demonstrated that controlling external pressure can change the electrochemical failure patterns.

Towards a Molecular Understanding of the Interfacial Li-Ion Dynamics in Composite Solid-State Electrolytes Under High Polymer Confinement—the Case of Polyethylene Oxide—$Li_7La_3Zr_2O_{12}$ Composites Mauricio R. Bonilla[1], Fabián García Daza[2], Henry A. Cortés[1], Javier Carrasco[3] and Elena Akhmatskaya[1,4]; [1]Basque Center for Applied Mathematics, Spain; [2]The University of Manchester, United Kingdom; [3]Centre for Cooperative Research on Alternative Energies (CIC energiGUNE), Basque Research and Technology Alliance (BRTA), Spain; [4]IKERBASQUE, Basque Foundation for Science, Spain

Composite solid-state electrolytes (CSSEs) comprising a conductive, flexible polymer matrix embedding ceramic filler particles have emerged as a promising option for all-solid-state Li-ion batteries. Understanding the interfacial diffusion of Li^+ as a function of filler content is crucial to formulating high-performance and cost-efficient CSSE. By considering as a case study a CSSE constituted by ion-conducting Ga^{3+} doped-$Li_7La_3Zr_2O_{12}$ (LLZO) garnet fillers embedded within a poly (ethylene oxide) and lithium bis(trifluoromethanesulfonyl) imide polymer matrix (PEO(LiTFSI)), we study the interfacial distribution and dynamics of Li^+ at conditions of high polymer phase confinement in fully amorphous PEO above the melting point, T_m. Such confinement scenario aims to simulate the interstitial space between filler particles in close proximity, which is tantamount to the percolation conditions at which conductivity enhancement has been experimentally observed. By combining classical umbrella sampling calculations, molecular dynamics simulations, and hybrid Monte Carlo methods, we show that the free energy profile associated with the extraction of a Li^+ ion from the garnet surface is site-dependent and highly asymmetric, suggesting a strong thermodynamic drive towards Li^+ adsorption onto the garnet phase. Adsorbed Li^+ is stabilized by exposed oxygens on the garnet surface and oxygens from bound PEO. Only beyond 0.35 nm from the garnet surface, the polymer coordination shell reaches its typical bulk density of 5 oxygens per Li^+, leading to a slight decrease in the free energy. We also find that this thermodynamic drive towards Li^+ uptake is counteracted by a kinetic barrier: free polymer chains in the bulk are significantly more mobile than garnet–bound chains. Hence, they can rapidly adapt to coordinate and stabilize incoming Li^+ ions, dramatically reducing the probability that a Li^+ ion approaches within 0.35 nm of the garnet surface. Under high polymer confinement (i.e., high filler volume fraction), the overlapping of bound polymer shells from opposite surfaces reduces the availability of free chains, leading to a significant decrease in Li^+ diffusivity within the interstitial space.

We put forward that understanding Li^+ diffusion in LLZO:PEO (LiTFSI) CSSEs above T_m, and at conditions of high polymer confinement provides valuable insights to interpret the variation of ionic conductivity with volume fraction *below* T_m (at typical operating conditions). This is because filler particles are surrounded by a layer of amorphous polymer even at room temperature (RT), as filler particles disrupt structural regularity. Based on this premise, we are able to qualitatively describe the experimental variation of RT conductivity with filler content reported in recent experimental work.

2:30 PM EN05.05.04
Unraveling the Grain Boundary Effects in Lithium Lanthanum Titanate (LLTO) Solid Electrolyte Hyungjun Kim[1], Patrick Conlin[2], Matthew E. Bergschneider[2], Hayoung Chung[3], Sung Youb Kim[3], Suk Won Cha[1], Maenghyo Cho[1] and Kyeongjae Cho[2]; [1]Seoul National University, Korea (the Republic of); [2]The University of Texas at Dallas, United States; [3]Ulsan National Institute of Science and Technology, Korea (the Republic of)

To meet the high energy density and safety requirements of next-generation batteries, all-solid-state batteries (ASSBs) are promising candidates. A lithium metal anode with a high theoretical specific capacity (3860 mAh g^{-1}) and the lowest electrochemical potential (-3.04 V vs. standard hydrogen electrode) is proving to be an essential component in ASSBs. However, solid electrolytes (SEs) in ASSBs still have hurdles to overcome such as lithium metallic phase accumulation, interfacial instability, and unsatisfactory ionic conductivity. Furthermore, solid electrolytes are generally powder-sintered into the polycrystalline phase, and the nature of grain boundaries (GBs) affects the overall performance of solid electrolytes. The polycrystalline solid electrolytes and the effects of GBs are not fully understood yet. In this work, we present a first-principles calculation-based theoretical study that discovers the effect of grain boundaries on ionic and electronic properties in perovskite $Li_{3x}La_{(2/3)-x}TiO_3$ ($0 < x < 0.167$) (LLTO). Since the grain boundaries of SEs have various microstructure configurations, we consider the experimentally observed grain boundary configurations: i) grain boundaries without pore and ii) grain boundaries with pore space. The density functional theory (DFT) studies have uncovered the following properties of LLTO GBs. In pore-free grain boundaries, lithium-ion can enter the grain boundary region without an energy barrier in the aspect of thermodynamics. Moreover, the grain boundary region has an electron insulating feature comparable to bulk LLTO, even differences in A-site composition ($0 < x < 0.167$) have a negligible effect on electronic conductivity for stoichiometric grain boundaries. Besides, when the A-site distortion occurs at grain boundaries, the grain boundary region exhibits a p-type conductive property but has a high energy barrier for lithium-ion to cross into the grain boundary region. These findings show that the internal lithium metallic phase nucleation does not occur at the interface of firmly connected crystalline grains. On the contrary, in the grain boundaries with pore structure, the pore space has a p-type conductive feature and lithium-ion tends to reside in the pore space in a neutral charge state. This indicates that the nucleation of the lithium metallic phase begins at the intergranular pore space of solid electrolytes. Based on the thorough investigation of the ionic and electronic properties of various LLTO grain boundaries, consequently, we confirm that the lithium metallic phase nucleates in the solid electrolytes crystalline grains interface rather than at the densely connected solid electrolyte grain boundaries. Our understanding provides an essential insight into the effect of grain boundary on the electrochemical performance of solid electrolytes as well as the crucial properties to be considered in the manufacturing of high electrochemical performance and safety improved solid electrolytes for advanced secondary batteries.

Effects of Li Defects on Moisture Stability and Li-Ion Transport Properties on $Li_{10}SiP_2S_{12}$ Solid Electrolyte—A First-Principles Study Hou Jen Lai and Jyh-Chiang Jiang; National Taiwan University of Science and Technology, Taiwan

All-solid-state batteries (ASSBs) are expected to replace liquid electrolyte-based lithium-ion batteries (LIBs) as the next-generation rechargeable battery technology to meet the increasing demand for advanced energy storage systems because of their high energy density and safety. Solid electrolytes (SEs) with high Li-ion conductivity are required for ASSBs. Over the years, $Li_{10}SiP_2S_{12}$ (LSPS) has attracted attention as a promising new Li-ion conductor, as it has the high Li-ion conductivity (2.3 mS/cm). However, the poor chemical stability of sulfide-based electrolytes in the presence of moisture causes the hydrolysis reaction on the LSPS surface, resulting in the formation of toxic H_2S gas. This disadvantage necessitates handling of the LSPS in an inert gas environment, limiting large-scale commercialization. Therefore, improving moisture stability without compromising ionic conductivity of LSPS-based SEs is a critical issue in the development of ASSBs. In this study, we used density functional theory (DFT) calculations to understand the reaction mechanisms of the hydrolysis reaction on the perfect and defective LSPS (101) surface. Furthermore, we investigated the effect of Li vacancy on the Li-ion conductivity of LSPS using ab initio molecular dynamics (AIMD) simulations and statistical thermodynamic methods. The low energy barrier of the hydrolysis reaction on the defective LSPS surface indicated that Li vacancy would decrease the moisture stability of the LSPS surface. On the other hand, the presence of Li vacancy increased Li inter-cage migration, which increased Li ionic conductivity in the LSPS. Our findings show that the Li vacancy has a significant impact on the moisture stability and Li-ion conductivity of LSPS.

The Complex Mechanisms that Create High Li-ion Mobility in Oxides and Sulfides Gerbrand Ceder[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The exciting development of solids with extremely high Li-ion conductivity, higher than that in traditional liquid electrolytes, in the last decade has forced us to rethink the processes that make cations move in solids. Super-ionic Li conductors typically have very high Li concentration so that their conductivity behavior cannot be explained with simple point defect mechanisms. Instead, ideas of concerted motion or highly correlated motion have been proposed. I will discuss our current understanding of the mechanisms that provide high Li-ion conductivity. We find that due to the high screening power of S^{2-} Li mobility in sulfides is mostly determined by local anion coordination and its variation along the migration pathway, making anion topology the main determinant of Li-ion conductivity. As a result, we find that there is little coordinated or concerted motion in sulfides. In contrast, due to the lower screening power of oxides and their lower Li-Li distances, Li-ion conductivity is much more determined by the electrostatic interaction with the other cations, setting the stage for possible concerted motion of multiple ions. I will show how this leads to very specific, but precise rules for selecting structures that may accommodate very fast Li-ion motion.

4:00 PM EN05.05.07
Ion Transport and Interfacial Stability in Fluorine Containing Lithium Argyrodite Electrolytes for Solid-State Lithium-Sulfur Batteries Varun Shreyas, Saransh Gupta, William Arnold, Hui Wang and Badri Narayanan; University of Louisville, United States

Rechargeable solid-state lithium-sulfur batteries (SSLSBs) offer tremendous promise as a safe and energy-dense storage technology for use in electric transportation, robotics, and portable electronics. Lithium argyrodites (e.g., Li_7PS_6, and its halogen-doped derivatives) have emerged as a lucrative class of solid-state electrolytes (SSEs) for SSLSBs owing to their high Li-ion conductivity (~10^{-3} S/cm), good elastic stiffness (~30 GPa), and low flammability. Despite their promise, SSLSBs based on sulfide electrolytes remain far from commercialization due to lack of atomic-scale understanding of ion-conduction, charge transport, structural evolution, and interfacial reactions (e.g., dendrite growth, electrolyte decomposition etc.). Here we employ a combination of density functional theory calculations, and ab initio molecular dynamics simulations to address this challenge for fluorinated argyrodites. Specifically, using accurate materials modeling, we design fluorine-containing argyrodite electrolytes that simultaneously offer enhanced (a) Li-ion conduction facilitated by unique Li-disorder induced by fluorine and other halogen co-dopants, and (b) stability against Li-anode owing to formation of a stable solid-electrolyte interface containing conductive species (Li_3P), alongside LiCl and LiF. We will discuss these results in the context of accelerating design of novel solid-state electrolytes for long-lived, stable, and high-energy density SSLSBs.

4:15 PM EN05.05.08
Thermodynamic and Kinetic Stability of Cathode Electrolyte Interface in All Solid-State Li-S Batteries Manas Likhit Holekevi Chandrappa, Swastika Banerjee, Ji Qi, Chi Chen and Shyue Ping Ong; University of California San Diego, United States

Despite the advancements in the Li-S batteries (LSBs), the issues of polysulfide shuttling continues to be a major roadblock it's commercialization. Polysulfide shuttling results in an irreversible loss of active material which results in capacity fading. Replacing liquid electrolyte with solid state electrolytes (SE) holds the promise to mitigate this issue. However, the interfacial stability of these SE/cathode interfaces remains largely unknown. Here, we present a comprehensive evaluation of stability of the SE/cathode interfaces of all the major classes of SEs (oxides, sulfides, nitrides, and halides). Except sulfides SE interfaces all other SE interfaces are predicted to be (electro)chemically unstable. The known Li ion battery (LIB) oxide buffer layers were not found to be suitable to stabilize the oxides and nitride SE interfaces. However, a few sulfide buffer layers such as $LiAlS_2$, Sc_2S_3, Y_2S_3 can potentially be used as buffer layer for the unstable oxide and halide interfaces. We developed an accurate moment tensor potential (MTP) to study the dynamic stability of SE/cathode interface by taking β-Li_3PS_4 and α-S_8 interfaces as representative example. MD simulations of realistic large-scale interface (>1000s atoms) simulations indicate that this interface is unstable over longer timescales (several ns). Using bond connectivity-based clustering the interface reaction products were analyzed which showed a steady increase in the concentration of several short and long S chains (S_x) at the interface over nanosecond timescales. The presence of several Li polysulfide (Li-S_x) resembling molecules was also detected at the interface. We also confirm that the Li polysulfides are localized at the interface and shows no diffusion into the β-Li_3PS_4.

4:30 PM *EN05.05.09
Effects of Aliovalent Doping on Structure and Properties of Na_3SbS_4 Type Superionic Conductors Selim Halacoglu, Yang Li, Varun Shreyas, Badri Narayanan and Hui Wang; University of Louisville, United States

Aliovalent doping is a promising strategy to further enhance the ionically conductive properties of solid-state ion conductors. Beside the conductivity, the aliovalent dopants also affect the synthesis mechanism, crystalline structure, as well as the electrochemical stability of the doped conductors. In this talk, we will present Na_3SbS_4 as a model material to introduce different types of aliovalent anion or cation dopants, and discuss the doping chemistry in sulfide-based solid electrolytes. On the structural studies, we tracked the synthetic process of doped Na_3SbS_4 by in situ neutron diffraction and examined the phase purity and structural stability after different doping treatment. Besides, we also evaluated the ionic conductivity of doped Na_3SbS_4 conductors and established the correlations between dopants and ion transport, as well as the interface stability between the doped Na_3SbS_4 conductors with metallic Na anode. We will also discussion a few strategies for interface stabilization in sulfide-based solid state Na batteries.

EN05.06.02
Phase Evolution and Thermodynamics of Al-Doped Cubic LLZO Studied by High-Temperature X-Ray Diffraction Øystein Gullbrekken[1], Maria Tsoutsouva[2], Daniel Rettenwander[1], Mari-Ann Einarsrud[1] and Sverre Magnus Selbach[1]; [1]Norwegian University of Science and Technology, Norway; [2]Onera, France

$Li_7La_3Zr_2O_{12}$ (LLZO) is a promising solid-state electrolyte for advanced Li-ion batteries due to its high ionic conductivity, non-flammability and high electrochemical stability against Li anodes and high voltage cathodes. However, synthesis of phase pure LLZO is challenging due to easy formation of secondary phases, such as the pyrochlore $La_2Zr_2O_7$, that are detrimental to the performance of a LLZO electrolyte. Although many studies have been performed on the electrochemical performance of LLZO, the understanding of the thermodynamics of the synthesis of LLZO is still lacking.

Here we report on high-temperature X-ray diffraction (HTXRD) following the crystallization of a gel of Al-doped LLZO. Gels with 0, 10 and 20 mol% excess Li were prepared and calcined at 500 °C to remove the volatile components before HTXRD. The powders calcined at 500 °C consisted primarily of $La_2Zr_2O_7$ with trace amounts of Li_2CO_3 and $La_2O_2CO_3$ and were used as starting materials to study the formation of the cubic LLZO phase. During HTXRD the samples were heated from 500 °C to 700 °C in steps of 20 °C, and further to 1000 °C in steps of 50 °C. Upon heating the pyrochlore phase gradually transforms to cubic LLZO. In all samples, cubic LLZO first appears around 600 °C and the pyrochlore phase disappears around 750 °C in the samples with 0 % and 20 % excess Li. We performed two analyses of the sample with 10 % excess Li by HTXRD, one with normal deposition thickness and another with thinner deposition thickness. In the thin sample, cubic LLZO appears at a lower temperature of 560 °C compared to the other experiments. The pyrochlore phase does not fully disappear but instead reappears and crystallizes at the highest temperatures investigated, indicating extensive Li loss from the thin sample. These observations suggest that atmospheric exposure and the relative surface area of powder are important factors for LLZO formation.

To understand the thermodynamics of LLZO formation, we propose the following reaction to take place based on the identified reactants and products:
$6.25\ Li_2CO_3 + 0.25\ Al_2O_3 + 2\ La_2Zr_2O_7 + La_2O_2CO_3 \rightarrow 2\ Li_{6.25-x}Al_{0.25}La_3Zr_2O_{12-0.5x} + 7.25\ CO_2(g) + x\ Li_2O(g)$.
The enthalpy, entropy and Gibbs energy of the reaction were calculated from literature values and DFT calculations and agree with the experimental observations. Finally, we discuss the significance of the highly disordered Li sublattice for the entropy of cubic LLZO. We believe our findings will contribute to improved understanding of LLZO formation and facilitate the synthesis of high-performance phase pure LLZO electrolytes.

EN05.06.03
Multi-Functional Interface for High-Rate and Long-Durable Garnet-Type Solid Electrolyte in Lithium Metal Batteries Sangwook Han, Kyeongsu Lee and Kisuk Kang; Seoul National University, Korea (the Republic of)

Lithium dendrite growth in solid electrolytes is one of the major obstacles to the commercialization of solid-state batteries based on garnet-type solid electrolytes. Herein, we propose a strategy that can simultaneously resolve both the interface and electronic conductivity issues via a simple one-step procedure that provides multi-layer protection at low temperature. We take advantage of the facile chemical conversion reaction, showing the wet-coated SnF_2 particles on the solid electrolyte effectively produces a multi-functional interface composed of LiF and Li–Sn alloy upon contact with lithium. We demonstrate multi-function enables the remarkably high critical current density up to 2.4 mA cm^{-2} at 25 °C and the stable galvanostatic cycling for over 1000 hours at 0.5 mA cm^{-2} in the lithium symmetric cell. Moreover, the full cell delivers robust cycle life of more than 600 cycles at 1.0 mA cm^{-2}, which is the highest performance at room temperature reported to date.

EN05.06.05
Hybrid Electrolyte Films Incorporating Interfacial-Barrier-Free Garnet-Type Oxide Electrolytes for High-Power-Density Solid-State Batteries Dong Ok Shin, Myeong Ju Lee and Young-Gi Lee; Electronics and Telecommunications Research Institute, Korea (the Republic of)

The key requirement for realizing solid-state batteries where permeable liquid electrolytes (LEs) are replaced with rigid and fragile solid electrolytes, is to form an intimate interface between electrodes and electrolyte layers. To achieve this goal, a hybrid solid electrolyte (HSE) fully using the advantages of both organic and inorganic materials has been considered a promising component. While the inorganic part could contribute to enhancing total conductivity, the organic part could offset the intrinsic drawbacks such as brittleness and fragility of common solid electrolytes. As a proof of concept, a garnet-type $Li_7La_3Zr_2O_{12}$ (LLZO) ceramic solid electrolyte was employed as a Li-ion conductive filler to construct the HES. However, a formidable challenge facing the LLZO solid electrolyte is its intrinsic surface layer which was inevitably formed in the course of the synthesis process, potentially acting as a resistant interfacial barrier to Li-ion transport. In this work, we demonstrate for the first time that the highly conductive polyvinylidene fluoride (PVDF)-based HSE film incorporating LLZO fillers without the resistive layer through a reliable dry etching process. Such a thin layer mainly consisting of amorphous lithium carbonate has been removed without damaging the core LLZO during the etching process. With optimized the content of LLZO (30 wt% vs. weight of PVDF matrix), the etched LLZO-based HSE film showed the ionic conductivity of 4.05×10^{-4} S cm^{-1}, which was around two times higher than that of the non-etched LLZO-based HSE film. Cycling results with Li symmetric cells of Li/LLZO-PVDF HSE film/Li verified the superior stability of HSE film with etched-LLZO. Particularly, full cell results with SSBs of $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$/LLZO-PVDF HSE film/Li identified that a high-power-density feature could be obtained in the cell with the HSE film based on etched-LLZO. Moreover, it is revealed that the formation of the chemically modified region at the PVDF/LLZO interface and the resulting promoted Li-ion transport can be furthered in HSEs with etched-LLZO fillers.

EN05.06.06
Stabilization of Cycling Performance of $Li[Ni_{0.95}Co_{0.04}Al_{0.01}]O_2$ Cathode Using Thin Film Solid Electrolyte Interlayer Jeon Kim, YeSung Kim, GiMun Han and ChongSeung Yoon; HanYang University, Korea (the Republic of)

The expanding usage of commercial lithium batteries in newer application fields has led to significant attention towards solid electrolytes due to the safety issue with flammable and volatile organic electrolytes. It is expected that practical application of the lithium secondary batteries (LIBs) with the solid electrolytes in order to solve this problem. All-solid-state lithium thin-film batteries (TFBs) are expected to apply to many electrical applications, because of their advantage of safety, long cycle life and form factor based on the solid electrolyte. However, the electrochemical performance of TFBs has been limited by various factors and the interface between the electrolyte and the electrode is one of the key factor of high performing rechargeable all solid state batteries. In this study, we investigated the influence of Solid Electrolyte thin film on cell characteristics and also tried to improve the battery performance compared with liquid electrolytes. Various types of ceramic electrolytes have been employed for improving the performance of LIBs. Among various oxides, NASICONs (NA-Super-Ionic-CONductor) have lower ionic conductivity but are comparatively stable in ambient conditions as well as against commonly used cathode materials. In this work, NASICON-type $LiSnZr(PO_4)_3$ (LSZP, hereinafter) ceramics is used for solid state electrolyte material in our experiment. A $Li[Ni_{0.95}Co_{0.04}Al_{0.01}]O_2$ (NCA95, hereinafter) system with a high specific capacity was selected as the cathode and LSZP as the solid electrolyte coating. Li was chosen as the anode material. To evaluate the electrochemical properties of the solid electrolyte interlayer, LSZP thin films on the NCA95 Cathode were prepared by RF magnetron reactive sputtering method for Solid electrolyte material in our experiment. The sputtering power and argon pressure of LSZP films have been optimized and are kept constant to reduce interference factors. In this study, We are trying to enhance the cycling performance of discharge capacity by coating thickness of the LSZP. A cells were fabricated in a glove box with Ar atmosphere and investigated by electrical and electrochemical properties at room temperature. In addition to demonstrating the microstructure and the structural changes during the lithiation of the thin film deposited cathode were followed by ex situ transmission electron microscopy (TEM) to provide structural changes of the microstructure observed between Electrolyte and cathodes. The electrochemical performances of the solid electrolyte interlayer were evaluated using 2032

coin-type half-cells with a lithium (Li) metal anode. The coin cells were cycled between 2.7 and 4.3 V at 30°C. We also investigated the influence of interlayer thickness on cell characteristics and tried to improve the discharge properties. Introducing the thin film solid electrolyte interlayer could improve the battery discharging performance and high stability. The capacity loss rate was decreased with interlayer about 2.3% after 50 charge-discharge cycles. Here, We show that thin film solid electrolyte interlayer process can be considered the practical for commercial applications because of the capacity retention. The batteries with an interlayer revealed better capacity retention and rate characteristics than the pristine one during the charging/discharging, which indicates a promising strategy for the development of ASSBs.

EN05.06.07
Rational Design of Hybrid Electrolytes for All-Solid-State Lithium Batteries Jungdon Suk; Korea Research Institute of Chemical Technology, Korea (the Republic of)

Rechargeable Li-ion batteries have led to a remarkable revolution in consumer electronics, electric vehicles (EV), and energy storage systems (ESS). Especially, EVs are one of the good options for autonomous vehicles and to reduce CO_2 emissions. Rechargeable Li-ion batteries which have been successfully applied to potable electronics are widely used for EVs. However, shot driving range due to the limited energy density of Li-ion batteries and safety issues should be overcome to meet a requirement for EVs.
Solid polymer electrolytes (SPEs) and hybrid electrolytes with oxide electrolytes are considered promising electrolytes for next-generation all-solid-state lithium batteries because they have much better safety, flexibility, and mechanical stability in the design of the cells, compared with the liquid electrolytes. Current research on solid polymer electrolytes has focused on poly(ethylene oxide)(PEO)-based polymers, but they are restrictively allowed for practical applications because of their weaknesses such as low ionic conductivity at room temperature and poor electrode/electrolyte interface characteristics.
In this presentation, the semi-interpenetrating polymer network PEO-based polymer electrolyte and hybrid electrolytes with oxide electrolytes were used to investigate the performance of Li-polymer batteries by using Ni-rich NMC such as $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ (NMC811) as cathode materials and carbon-silicon composite or lithium metal as anode materials. All-solid-state batteries are successfully operated at room temperature and 45ºC with high rate capability and enhanced cycle performances.

EN05.06.08
High-Temperature Discharge Characteristics of Salt-Coated Solid Electrolyte Hae-Won Cheong, Minu Kim, Tae-Young Ahn, Chaehyeok Han, Kiyoul Kim, Seung-Ho Kang, Yusong Choi and Jang-Hyeon Cho; Agency for Defense Development, Korea (the Republic of)

High-temperature thermal batteries, also called molten-salt batteries, are primary batteries that can be reserved for a long period of up to several decades. The molten salt electrolyte for the thermal battery is a solid insulator that thoroughly prevents self-discharge before activation, but once instantly melted by the pyrotechnic heat source, it becomes an excellent ionic conductor and can supply high-power electricity. Usually, fine MgO powder is added as an inorganic binder to prevent the molten-salt electrolyte from flowing down. Although it is desirable to add a large amount of MgO to hold the liquid electrolyte even under severe acceleration conditions, but if it is excessive, the internal resistance of the cell will increase due to its electrically insulating nature of MgO. Meanwhile, all-solid-state batteries characterized by solid electrolytes have received great attention for their high safety and improved energy density even with high-voltage cathodes. Considering the use for thermal batteries, high-temperature stability and long-term storage properties as well as excellent ionic conductivity of the solid electrolyte are crucially important. The densely sintered body can have high ionic conductivity, however, the poor contact between solids deteriorates the output power capability. In this study, we proposed composite electrolytes that significantly improved the contact area and ionic conductivity by coating the surface of the solid electrolyte with molten salt. It has been shown that the soft salt film coated on the hard surface can also prevent self-discharge and increase the compaction strength. The solid electrolyte used in this study is $Li_7La_3Zr_2O_{12}$ (LLZO). Discharge performance was tested using disk-shaped $LiSi/FeS_2$ cells.

EN05.06.09
Highly Stable Solid Hybrid Electrolytes Based on Li-Ion Conductive $Li_{6.4}La_3Zr_{1.4}Ta_{0.6}O_{12}$ Framework for All-Solid-State Lithium Batteries with High Energy Density and Long Cycle Life Leiwu Tian, Ji-Wan Kim and Dong-Won Kim; Hanyang University, Korea (the Republic of)

All-solid-state lithium batteries (ASSLBs) are one of the best candidates for improving energy density and enhancing battery safety. However, many properties such as ionic conductivity, electrochemical and mechanical stability need to be improved for practical application. In this work, a vertically aligned $Li_{6.4}La_3Zr_{1.4}Ta_{0.6}O_{12}$ (LLZO) framework composed by three different layers (dense layer, vertical aligned layer and finger liked layer) was prepared by phase inversion method. A framework-based solid hybrid electrolyte (F-SHE) was then obtained by penetrating poly(ε-caprolactone) (PCL)-based polymer electrolyte into LLZO framework. The resulting flexible F-SHE exhibited a high ion conductivity of 1.03×10^{-4} S cm^{-1} at 25 °C, which was attributed to the vertical aligned lithium-ion conductive LLZO framework that provided fast conduction pathway for lithium ions. The lithium symmetric cells assembled with F-SHE showed a long cycling life more than 700 h at 0.3 mA cm^{-2}, indicating the solid electrolyte promoted a uniform flux for lithium stripping/plating and suppressed the growth of lithium dendrite. The solid-state Li/NCM cell employing F-SHE exhibited good cycling performance in terms of discharge capacity and cycling stability. Our results demonstrate that the F-SHE can be a promising electrolyte for practical application in ASSLBs with enhanced safety and long cycle life.

EN05.06.10
Design of Pyrrolidinium-PEG Ionic Copolyesters for Li-Ion Transport Channels in Polymer Network Gel-Polymer Electrolytes Younggyun Choi and Jong Hyeok Park; Yonsei University, Korea (the Republic of)

Since electric vehicle (EV) accidents from flammable lithium-ion batteries (LIBs) continue to increase, solving the safety issue of LIBs has emerged as an important task. Highly volatile liquid solvents that help solvate and transport Li^+ are the major cause of the flammability of LIBs. Therefore, replacing liquid electrolytes with solid electrolytes may overcome this safety issue. Even though solid-state electrolytes have advantages over liquid electrolytes, restricted ion transportation in solid-state electrolytes causes poor room temperature ionic conductivity ($\approx10^{-5}$ to 10^{-2} mS cm^{-1}), which makes solid-state electrolytes difficult to apply to commercial LIBs.

In this work, ionic liquid-based linear polyesters were adapted on solid-state electrolytes. Several ionic polyesters prepared from imidazolium ionic liquid monomers have been previously reported. Imidazolium-polyethylene glycol (Imidazolium-PEG) copolyesters have also been researched, and their electrical and thermal properties are dependent on the length of the PEG segment. However, because pyrrolidinium ionic liquids are more stable and show wider electrochemical windows than imidazolium ionic liquids, pyrrolidinium ionic liquid based polyesters have been prepared and used for solid-state electrolytes. To fabricate a solid-state semi-IPN polymer electrolyte system, a UV-crosslinkable polymer matrix of ethoxylated trimethylolpropane triacrylate (ETPTA) and tailored linear pyrrolidinium-PEG copolyester with carbonate liquid electrolyte were mixed. Well-dispersed pyrrolidinium-PEG copolyester (P_NPEG, N: average molecular weight of PEG) could accelerate Li^+ transportation between the cathode and anode in the polymer matrix. To optimize battery performance, P_NPEG was synthesized from PEGs with different average molecular weights and pyrrolidinium Bis(trifluoromethanesulfonyl)imide (pyrrolidinium-Tf_2N) ionic monomers. The PEG backbone in P_NPEG promotes Li^+ transportation through the

interactions between ether groups and Li^+ ions. In addition, ionic liquid monomers in P_NPEG contribute to ion solvation and selective cation transport. In summary, we reported an in situ UV-cured gel polymer electrolyte (GPE) incorporating novel pyrrolidinium-PEG copolyester materials to promote lithium ion transport properties. Well-dispersed P_{1000}PEG in the GPE formed ion channels, which were confirmed by SEM images and electrochemical tests. The amorphous polymer structure and low *T*g of P_{1000}PEG-GPE supported the higher ion conductivity results obtained by XRD and DSC analysis, respectively. In addition, MD simulations showed a lower coordination number between P_NPEG and Li^+ than between pure PEG1000 and Li^+. As the optimized proportion of P_{1000}PEG improved the ion conductivity and stability of the solid-state electrolytes, this study is expected to support advances in solid-state batteries applying P_{1000}PEG-based ion channels beyond liquid electrolytes.

EN05.06.11
Study on Mechanical Strength Measurement and Strength Improvement of Sulfide-Based Electrodes Kiyoul Kim, Tae-Young Ahn, Chaehyuk Han, Haewon Jung and Yusong Choi; Agency for Defense Development, Korea (the Republic of)

The thermal battery is a primary battery that is used in special fields such as defense due to its high power and high reliability characteristics. In the thermal battery, a lithium or lithium compound negative electrode and a metal sulfide-based positive electrode system are used. There is always a demand for reducing the weight of the system and a need for the increasing area of electrode. Therefore, it is essential to study the mechanical strength of the electrode and improve its strength. In this research, the strength of the compaction of the positive electrode material was quantitatively measured, and research was conducted to improve the strength for weight reduction and large area. Two methods of measurement were proposed for quantifying the mechanical strength of the electrode of the disk-shaped green compact electrode. The fracture strength of the green compact was measured by the "Monotonic equi-biaxial flexural strength test" method proposed by ASTM C1499-09, and the fracture toughness was measured by the double cantilever beam (DCB) test. In order to improve the mechanical strength, the strength according to the powder particle size and the compression pressure was measured. Higher fracture strength and fracture toughness more than double that of green compacts with reference powder grain size and differentiation smaller than 45μm were measured. The effect of powder particle size and compression pressure on strength was analyzed through powder characterizations and microstructure observations. In addition, actual electrodes were fabricated and the possibility of battery utilization was verified through discharge tests

EN05.06.13
Investigating Chemo-Mechanical Phenomena in All-Solid-State Lithium Metal Batteries Using *In Situ* Curvature Measurements Sydney Morris[1], Jung Hwi Cho[1], Kunjoong Kim[2], Srinath Chakravarthy[3], Xingcheng Xiao[4], Jennifer L. Rupp[2] and Brian W. Sheldon[1]; [1]Brown University, United States; [2]Massachusetts Institute of Technology, United States; [3]Samsung Semiconductor, Inc., United States; [4]General Motors Research and Development Center, United States

With increasing interest in the use of solid electrolytes (SE) for lithium-ion and lithium metal batteries, it is important to understand their chemo-mechanical properties and failure mechanisms. A key failure mechanism in the garnet-type solid electrolyte lithium lanthanum zirconium oxide (LLZO) are short circuits caused by Li penetration through the SE once a critical current density (CCD) is reached. Such Li penetration is known to cause fracturing of the SE, highlighting the need to investigate the combined chemo-mechanical phenomena that affect the performance and lifetime of all-solid-state batteries. The unique challenge of evaluating the mechanical driving forces behind this mechanism and how the stresses within the SE evolve during Li plating require careful in situ measurements. This work investigates the evolution of such phenomena within the LLZO using in situ curvature measurements, in both a traditional symmetric Li cell configuration and a novel anode-free configuration. Data was then analyzed in the context of a Finite Element Model (FEM) to quantitatively evaluate stress evolution in the solid electrolyte. Results show that Li metal plating within a surface flaw leads to an accumulation of stress prior to short-circuiting. The combined results of experiments and the FEM suggest that it is critical to minimize surface defects and flaws during the manufacturing of LLZO.

EN05.06.14
A Study of Fabrication and Characterization of Na_xMnO_2 as a Cathode Material for Sodium-Ion Battery Zia Uddin Mahmud and Kartik Ghosh; Missouri State University, United States

The necessity for electrochemical energy storage technologies is promptly boosted due to the spread of renewable energy sources and the promising market for net-scale battery applications. Sodium-ion batteries (SIB) are a novel battery class due to Na materials' abundance and low cost compared to lithium. Na_xMnO_2, a sodium-based material is one of the promising candidates for large-scale SIB applications due to the diffusion of Na-ion providing high power density. In the present study, $Na_{0.44}MnO_2$ is being prepared by hydrothermal method and investigated Structural, Electrical properties, and describe electrochemical properties of materials. The Materials were characterized using various techniques including X-ray diffraction (XRD), Raman spectroscopy, scanning electron microscopy (SEM), and UV-VIS. The Rietveld refinement performed on the respective XRD pattern led on orthorhombic structure with space group Pmc2_1. We have observed by altering anode materials with graphite, graphene, and a different portion of graphite-graphene mixture affects the efficiency and cycle life. In addition, electronic and structural properties have been modeled employing density functional theory. This synthesis process can be useful for sodium-ion battery applications.

EN05.06.15
Heterogeneous Ion Transport Dynamics in an Organic Ionic Plastic Crystal—With Point Vacancies or at Grain Boundaries Hyungshick Park and Bong June Sung; Sogang Univ., Korea (the Republic of)

Organic ionic plastic crystals (OIPCs) are a class of solid electrolyte materials. In OIPCs, the interactions between ions are strong enough to form a translationally ordered structure, while the interactions are still weak enough to allow rotational motions of ions. Due to this unique characteristic, dopant ions such as lithium ions can show fast dynamics in the OIPCs. Therefore, OIPCs can be utilized as matrix materials for solid electrolytes. Various ion transport mechanisms through defects have been proposed. However, it is very hard to track ions at the molecular level and understand how these defects facilitate the dynamics in OIPCs via experimental techniques. Hence, the dominant ion transport mechanism in OIPCs is still in debate. In this work, we perform atomistic molecular dynamics simulations to understand the transport mechanisms of matrix and lithium ions in 1,3-dimethylimidazolium hexafluorophosphate ([MMIM][PF_6]) in the presence of defects. We employ two kinds of defects: 1) a point vacancy and 2) a grain boundary. We calculate mean squared displacements (MSDs) and self-part of van Hove correlation functions of ions. We find that both defects facilitate the dynamics of matrix ions and increase the dynamic heterogeneity. However, we observe the anisotropy of structures and dynamics of ions at grain boundaries. Moreover, we calculate non-Gaussian parameters to estimate the timescale (τ_{max}) at which heterogeneous dynamics become maximum. τ_{max} of grain boundary systems are approximately more than 100 ns, while that of point vacancy systems are 10—50 ns. We infer that the difference between these two ion transport mechanisms are the difference in timescales of heterogeneous dynamics.

EN05.06.16
Nanostructure-Designed Interlayer for Anode-Less All-Solid-State Batteries Seunggoo Jun, Yong Bae Song and Yoon Seok Jung; Yonsei University,

Korea (the Republic of)

Owing to their potential of improved energy density and safety compared to conventional lithium-ion batteries, all-solid-state batteries (ASSBs) are considered a promising alternative to accelerate the electrification of power trains. Adopting Li metal anodes for ASSBs has been the Holy Grail as it can maximize the energy density, considering the highest specific capacity (3860 mA h g^{-1}) and the lowest potential (-3.04 V vs. the standard hydrogen electrode (SHE)) for Li metal. However, penetrating growth of Li metal occurs in ASSBs, and various factors, such as grain boundary, defect, and byproduct formation by side reactions of Li-SE, complicates the design of SE/Li interfaces. Recently, Samsung reported the innovative strategy of anode-less ASSBs enabled by the use of carbon-silver layer that prohibits a direct contact between SE and in situ grown Li metal. However, preparation and processability of silver nanoparticles is a potential risk for the practical applications.
In this presentation, we report nanostructure-designed interlayer for anode-less ASSBs. The developed interlayer is intact in ambient atmosphere and facilitates reversible deposition/dissolution of Li metal during charge-discharge.

Development of Next Generation Solid-State Batteries and the Path to Manufacturing Steven J. Visco; PolyPlus Battery Company, United States

A critical difference between conventional rechargeable batteries and solid-state batteries is the substitution of a solid electrolyte for the volatile (and typically flammable) liquid electrolyte. However, this substitution is non-trivial and has significant implications for the structure, performance, manufacture, and cost of solid-state batteries. The scaling and manufacture of polymer electrolytes is relatively straightforward but their low ionic conductivity at room temperature precludes widespread adoption. A number of polycrystalline solid electrolytes have excellent room temperature ionic conductivities, however the difficulty in maintaining solid-solid contacts in composite electrodes is challenging, and the scaling of polycrystalline ceramic sheet is also nontrivial and likely expensive. Oxide glasses have been used successfully in commercial solid-state micro-batteries, but these batteries are made by physical vapor deposition and therefore very expensive to produce. Sulfide glass solid electrolytes have the advantages of being relatively soft and therefore easier to establish solid-solid contacts, and can be scaled using conventional thin glass processing technology. However, sulfide electrolytes are sensitive to moisture which introduces its own complexity in manufacturing. In this presentation we will examine the merits and challenges of each approach and potential paths to commercialization of high energy density solid-state batteries.

9:15 AM EN05.07.03
First-Principles Study on Selenium-doped $Li_{10}GeP_2S_{12}$ Solid Electrolyte—Effects of Doping on Moisture Stability and Li-Ion Transport Properties Santhanamoorthi Nachimuthu and Jyh-Chiang Jiang; National Taiwan University of Science & Technology, Taiwan

All-solid-state lithium-ion batteries (ASSBs) are currently at the forefront of the search for next-generation energy storage technologies. ASSBs use solid-state electrolytes (SSEs) rather than the liquid electrolyte, allowing for greater safety, higher energy density, and higher output power. Among the different SSEs, the ceramic-sulfide-based solid electrolyte, $Li_{10}GeP_2S_{12}$ (LGPS) has attracted considerable attention because of its comparable ionic conductivity of 12 mS/cm with current organic liquid electrolytes. However, one of the most significant challenges in LGPS is the hydrolysis reactions at the interface, which are intrinsically unstable in ambient humidity, resulting in the release of toxic gas H_2S and, as a result, a significant decrease in ionic conductivity. Hence, improving moisture stability without degrading the ionic conductivity of LGPS-based SSEs is one of the key issues in developing efficient ASSBs. Herein, we report the reactivity of the LGPS surface towards H_2O, subsequent hydrolysis reactions for the H_2S formation, and effective methods to suppress the H_2S evolution on the LGPS surface using density functional theory (DFT) calculations. The pristine LGPS surface is highly unstable towards H_2O at room temperature, where H_2O dissociation occurs spontaneously. However, the H_2O adsorption and its activation are weakened upon the Se substitution on the LGPS surface. By doping the Se atom on LGPS, the H_2S evolution can be suppressed and significantly improve the chemical stability of the LGPS surface. In addition, we predict the Li^+ ion transport properties of both pristine and Se-doped LGPS compounds using ab initio molecular dynamics (AIMD) simulations. The Se-doped LGPS material has a similar bandgap to pristine LGPS; it can have similar decomposition products and low electronic conductivity. The predicted ionic conductivity of Se-doped LGPS is found to be slightly lower than the pristine. These findings suggest that replacing sulfur atoms in LGPS with Se atoms could be an effective strategy for improving moisture stability.

Solid-State Lithium-Metal Battery Technology Niall Donnelly; QuantumScape, United States

The advancement of the battery industry plays a critical role in meeting consumer demand on the performance and efficiency of electric vehicles, however, today's EVs lack the performance, safety and cost required for mass-market adoption of zero-emissions vehicles.
QuantumScape developed the industry's first anode-free cell design, using a nonflammable, noncombustible solid-state separator that will enable extended range, faster charging and safer operating than today's EVs and gas-powered vehicles. Join the session presented by QuantumScape Vice President of Research and Development Niall Donnelly to learn more about QuantumScape and its solid-state lithium-metal battery technology.

10:30 AM EN05.07.06
Ultrafast High-Temperature Sintering of Solid-State Electrolytes Qi Dong and Liangbing Hu; University of Maryland, United States

The synthesis of high-quality solid-state electrolyte membranes is challenging due to the lack of fine control over the grain growth by conventional sintering methods. Herein, we report a unique high-temperature (1500 K) and rapid sintering (2-30 s) process called ultrafast high-temperature sintering (UHS) that can tailor the grain growth and densification toward high-quality, high-performance solid-state electrolyte membranes for Li battery applications. In this technique, the high temperature promotes grain growth and removes impurities during sintering. Meanwhile, the short sintering

duration in seconds ensures good tunability from porous to dense microstructures, as well as accurate control on the grain size, distribution, and composition. Using Ta-doped $Li_7La_3Zr_2O_{12}$ (LLZTO) garnet as a model system, we demonstrate sintering dense solid-state electrolyte membranes with nearly identical grain size and distribution compared to the powders before sintering, along with reduced defects and high relative density. These features contribute to high ionic conductivity (6.4×10^{-4} S cm^{-1} at room temperature) and excellent electrochemical stability during Li striping/plating (over 300 h under 0.2 mA cm^{-2}). We further demonstrate sintering solid-state electrolyte with volatile fillers (e.g., LLZTO with Li_3N) toward a dense microstructure, as well as 3D porous solid-state electrolyte scaffolds on various substrates, both showing excellent electrochemical performances. This UHS approach can be further extended to a variety of ceramic conductors for solid-state battery applications.

10:45 AM EN05.07.07
Solid-State Electrodes and Electrolytes with Tunable and Low-Tortuosity Micro-Architected Structures from Nonequilibrium Processing Anton Resing and Joerg G. Werner; Boston University, United States

The miniaturization of electronics and development of the internet of things (IOT) demands dense and solid-state energy storage on the square millimeter scale, as well as the ability to supply energy over a spectrum of response times. These goals require reimagined processing methods that move beyond planar architectures to create free-standing and active material dense architectures which can serve as the backbone for energy and power dense solid-state batteries (SSBs). Here we introduce a material-agnostic hybrid inorganic phase inversion (HIPI) process as an advanced scalable manufacturing method that results in free-standing solid-state low-tortuosity architectures with anisotropic through-plane material orientation. Critical to their deployment as an active framework in SSBs is the accessible porosity present in the HIPI architectures, resulting from the use of an oligo(ethylene oxide)-based organogel support. The HIPI process can enable both interdigitated electrodes and low-tortuosity solid electrolytes whose relevant feature sizes between 1-20 µm can be tailored by tuning the gelation temperature and nucleation density of the inorganic suspension during the nonequilibrium HIPI process. By tailoring these architectures, the pitch and areal enhancement factor can be adjusted within a multiparameter space to meet both shape constraints and performance demands of specific energy storage applications.

11:00 AM EN05.07.08
Ultimate Design Principles and Fabrication Process for High Energy Density Solid State Pouch Cells Based on Solid Polymer Electrolytes Jinsoo Kim; Korea Institute of Energy Research, Korea (the Republic of)

Solid-state lithium batteries have become promising alternatives to the conventional lithium-ion chemistries for pursuing enhanced safety and higher energy density. Owing to the advancement in the solid electrolytes and the active materials, its energy-storing characteristics are getting evolved in the lab-scale environment, but it is still far from the practical cell engineering perspectives. Here, we are proposing an ultimate design principle for building practically energy-dense solid-state batteries from the microstructure of electrodes to the entire cell architecture. The impact of multiscale parameters on the cell energy density was mathematically evaluated such as 1) gravimetric/volumetric composition, 2) apparent density, 3) areal loading amount in the electrode level, 4) the types of anode materials, 5) the thickness of solid electrolyte membrane, 6) the electrode sheet stacking number, and 7) the cell size. Not only just designing the electrochemical cells, but the fabrication process developments are also quite important to demonstrate the design methodology. To validate our design logic, we also suggest adequate processing methods and made double-layer stacked 200 mAh scale solid-state pouch cells based on the solid polymer electrolyte with PVDF-HFP conjugated to lithium salts and plasticizer as a model system. Thanks to the NCM622-based high active material composition (94 wt%), the areal capacity (> 4 mAh cm−1) using WIP (warm isostatic press) densification with the freestanding thin lithium metal anode (40 µm), we could verify the energy density as high as 227 Wh kg−1 including the whole-cell package, which was certified by the third-party organization. This design principle and the developed process can be applied to the various kind of solid-state batteries, so it might guide the research community to rationally achieve the practical high energy density milestone.

11:15 AM EN05.07.09
On the Use of Photoelasticity for Operando Dendrite-Induced Stress Quantification in Ceramic Electrolytes Christos E. Athanasiou[1], Cole D. Fincher[2], Colin Gilgenbach[2], W. C. Carter[2], Huajian Gao[3], Yet-Ming Chiang[2] and Brian W. Sheldon[4]; [1]Georgia Institute of Technology, United States; [2]Massachusetts Institute of Technology, United States; [3]Nanyang Technological University, Singapore; [4]Brown University, United States

The measurement of stress fields around lithium metal protrusions in solid electrolytes in operating conditions is critical for the design of next-generation, dendrite-resistant solid electrolytes. However, such stress measurements entail inherent experimental difficulties associated with acquiring accurate data at small scales in thin ceramic electrolytes.

By employing the principle of photoelasticity combined with electrochemical cycling in a plan-view cell the aforementioned challenges are bypassed, allowing not only to follow the progression of the dendrite, but also to obtain full field stress information on a propagating dendrite in semi-transparent LLZTO electrolyte. This new experimental methodology will be presented together with a relevant fracture mechanics analysis demonstrating the importance of engineering stress in dendritic propagation at high current densities.

SESSION EN05.08: Solid-State Battery Fabrication—From Materials to Novel Cell Architectures II
Session Chairs: Dominika Buchberger and Yue Qi
Wednesday Afternoon, November 30, 2022
Hynes, Level 3, Room 304

1:30 PM EN05.08.01
Stabilizing the Solid Electrolyte in Inert Atmosphere for Solid-State Battery Fabrication Through Co-Sintering Process Hari Raj[1], Timothée Fabre[2], Marlu C. Steil[3], Renaud Bouchet[2] and Valerie Pralong[1]; [1]CRISMAT Laboratory, ENSICAEN, Unicaen, CNRS, France; [2]Universite Grenoble Alpes, University Savoie Mt Blanc, CNRS, Grenoble INP, LEPMI, France; [3]Universite Grenoble Alpes, CNRS, Grenoble INP, SIMAP, France

Climate change due to excessive emission of greenhouse gases has impacted society and ecological life. Therefore, it is an urgent requirement to find alternative renewable (solar and wind) energy sources to replace conventional fossil fuels. Here, low cost, safe and high energy storage devices are required to ensure a continuous energy supply. However, current Li-ion batteries are facing challenges to fulfil the safety and high energy demands of fast-growing market of electric vehicles (EVs) and hybrid electronic vehicles (HEVs). In particular, liquid organic electrolytes used in conventional LIBs have raised the safety issues due to serious fire risk because of its flammability and volatility [1-3].
Therefore, extensive research is being focused to replace liquid electrolyte with suitable solid electrolyte for next-generation (SSBs) [4]. The inorganic

solid electrolytes are well-known for their realistic industrial manufacturing due to higher stability against ambient air and high temperature [5]. The NASICON type $Li_{1+x}Al_xTi_{2-x}(PO_4)_3$ (LATP) has shown very promising properties in terms of chemical/thermal stability and low cost. The ionic conductivity of LATP has been reported upto 10^{-4} to 10^{-3} S cm^{-1} at room temperature [6]. If fabrication of SSB is considered by co-sintering process of LATP solid electrolyte and phosphate based cathode materials such as $LiFePO_4$, $Li_3V_2(PO_4)_3$, sintering can only be possible in inert atmosphere (Ar/N_2) because these cathode materials are not stable in air at high temperature.
Therefore, by considering more practical approach for SSB fabrication through co-sintering process, present work focuses on sintering behavior of $Li_{1.4}Al_{0.4}Ti_{1.6}(PO_4)_3$ (LATP) solid electrolyte in argon atmosphere as a function of particle size and sintering conditions. The structural analysis of LATP was done by XRD, morphological study by SEM, particle size analysis by granulometry and densification of pellets was determined by dilatometry techniques. The conductivity measurement of sintered pellets is carried out by AC impedance spectroscopy techniques. At the end of study, we have not only stabilized the LATP in argon atmosphere but also achieved the high conductivity of 8.77×10^{-4} S cm^{-1} at 25 °C for pellets sintered at just 800 °C in argon. The electrochemical study of LATP was also conducted in symmetric cell and with $Li_3V_2(PO_4)_3$ cathode.

1:45 PM EN05.08.02
Investigation Of Nitrogen Doping Of Amorphous Lithium Aluminate As Thin-Film Solid Electrolyte Riccardo Taormina[1,2] and Fabio Di Fonzo[1]; [1]Italian Institute of Technology, Italy; [2]Politecnico di Milano, Italy

Solid electrolytes, or fast ion conductors, are characterized by a high ionic conductivity, sometimes comparable to the one of liquid electrolytes. The isotropic and non-periodic structure of amorphous ceramics have shown to contribute to increase the overall ionic conductivity of the material by decreasing the grain-boundary resistive contribution. The formation of high-density phases is responsible for the fast ionic conductivity in polycrystalline electrolytes, but this implies the use of high temperature processing (sintering), limiting the employment of amorphous materials. Current thin-film electrolytes technologies relies mostly on lithium phosphate oxynitride LiPON (σ_{Li} = 10-6 S/cm,), which demonstrated that the absence of grain boundaries, allows the formation of lithium small dendrites which can grow inside the material without cracking it, avoiding short life cycle of the battery over high current densities. Gao et al. addressed the limited ionic conductivity of LiPON to the strong bond between the PO 4- group with Li+: for this reason, elements with weaker electronegativity than P, such as Al, can generate an ionic bond with O with weaker electrostatic force, regulating the kinetics of Li+ transport and speeds up the diffusion process. Lithium Aluminate (LiAlO2) and Nitrogen-doped Lithium Aluminate (LiAlON) result in a competitive position for the development of an innovative amorphous electrolyte: very few studies have been conducted on the development of lithium aluminate based solid electrolytes at the present time, mainly due to its low processability at the amorphous phase and the low ionic conductivity of the crystalline phase, more common in the traditional sintering processes.
In this preliminary work, it is presented for the first time the possibility to obtain with Pulsed Laser Deposition (PLD), a completely amorphous $LiAlO_2$ solid electrolyte with a room temperature ionic conductivity of 10-10 S/cm. Thanks to the PLD processing, the grade of polymorphism can be easily controlled as well as film thickness range (10nm up to 10um) and film porosity. By controlling the atmosphere of the process, different content of nitrogen doping has been achieved, promoting the formation of the highly ionic conductive and electronically insulating LiAlON. Electrochemical analysis such as DC polarization and Impedance Spectroscopy, revealed the wide electrochemical voltage stability against lithium metal and the high ionic conductivity of the solid electrolyte. A setup for the direct deposition of the thin film over lithium metal surface is proposed, allowing the realization of symmetric cell test and plating/stripping test. Good protection of Lithium metal substrate has been observed from the $LiAlO_2$ SSE over 24h in atmosphere, hindering oxidation and degradation of the sample.

Doped NaSICON-Type Solid Electrolytes for Sodium-Ion Batteries from Scalable Spray-Flame Synthesis Mohammed-Ali Sheikh[1], Leon Müller[1] and Hartmut Wiggers[1,2]; [1]University of Duisburg-Essen, Germany; [2]Center for Nanointegration Duisburg-Essen (CENIDE), Germany

Solid-state sodium ion batteries are a viable alternative to lithium ion batteries, especially for use in stationary devices, due to the high availability of raw materials and low costs [1] and Sodium Super Ion Conductors (NaSICON) are promising candidates for solid electrolytes in solid-state sodium-ion batteries. They exhibit good mechanical properties, high ionic conductivity and compatibility with sodium metal based anodes enabling high energy density [2]. One of the best studied NaSICON materials is $Na_3Zr_2Si_2PO_{12}$ (NZSP) with a high ionic conductivity in the order of 10^{-3} Scm^{-1} at room temperature [3, 4]. Conventional synthesis methods of this class of materials such as solid-state reaction and liquid-phase synthesis have several drawbacks due to time-consuming process steps such as milling, high temperature sintering, precipitation, washing and drying steps to obtain the final product [5]. We present spray flame synthesis (SFS) as a new approach for the synthesis of nanosized NaSICON materials. Recent studies have shown that sintering of nanoparticular NZSP precursors offers several advantages: A high specific surface area, which increases the sintering activity, and short atomic diffusion paths, allowing high homogeneity and phase purity to be achieved at comparatively low sintering temperatures [6].
In SFS, metal salts dissolved in organic solvents are combusted resulting in fine metal oxide particles. They are characterized by transmission electron microscopy (TEM), X-Ray diffraction (XRD) and Raman-Spectroscopy for structural and morphological investigation. Elemental information is obtained via energy-dispersive X-Ray spectroscopy (EDX) and X-Ray photoelectron spectroscopy (XPS). Ionic conductivities of sintered NZSP pellets are measured by impedance spectroscopy.
In our approach, nanoparticles with a median diameter of around 5 nm are obtained. The pristine particles consist of crystalline ZrO_2, homogeneously covered with an amorphous layer consisting of the elements Na, Si, P and O. After a short annealing step for 1h at 1000°C, this mixture can be converted almost quantitatively into the desired rhombohedral NZSP phase. Moreover, aliovalent dopants were successfully added for the synthesis of $Na_{3+2x}A_xZr_{2-x}Si_2PO_{12}$ with A = Mg or Ca. Pressed pellets sintered at 1100°C for 3h to a relative density of ~90% showed - for a material sintered for such a short period of time - a surprisingly high ionic conductivity of up to 10^{-4} Scm^{-1} (Mg-doped).
In conclusion, a novel approach for the preparation of NZSP allowing the phase formation at relatively low temperatures is demonstrated. Spray flame synthesis is an elegant and promising possibility for the scalable production of solid electrolytes, which also holds great potential, especially with regard to further improvement of ionic conductivity through targeted doping.

Cathode Optimization for All-Solid-State Lithium Sulfur Batteries Yi Lin[1], Rodolfo I. Ledesma[2], Vesselin I. Yamakov[2], Ji Su[1], Donald A. Dornbusch[3], James Wu[3] and Rocco Viggiano[3]; [1]NASA Langley Research Center, United States; [2]National Institute of Aerospace, United States; [3]NASA Glenn Research Center, United States

Future electric aircrafts will require energy storage systems with high specific energy (ideally > 500 Wh/kg) but non-flammable, for which all-solid-state lithium-sulfur (Li-S) batteries are a top choice. However, one of the major bottlenecks in attaining the full potential of all-solid-state Li-S batteries is achieving high S utilization while maximizing energy density by using higher S content and higher cathode mass loadings. Since S is electrically non-conductive, the increased loading of S would reduce both ion and electron transport throughout the composite cathode, and thus detrimental to S utilization. Therefore, the composition and the interfaces within the cathode need to be optimized to achieve a balance between increased S content and maximal utilization. In this presentation, we discuss our strategy in preparing cathode composites with various compositions while fine tuning the interfaces of active material S with the solid electrolyte and the carbon additive. By evaluating the cathode performance differences, key parameters and processes in optimizing S utilization for balanced energy density performance may be identified.

Mechanistic Analysis of Void Formation in Solid-State Batteries Bairav Sabarish Vishnugopi and Partha P. Mukherjee; Purdue University, United States

Despite the theoretical promise of solid-state batteries (SSBs) to deliver high energy and power densities, various challenges related to electro-chemo-mechanics, transport and morphological growth at different solid-solid interfaces still need to be addressed. Among the various challenges, the formation and growth of voids in the lithium metal anode during stripping has a critical implication on performance and failure onset. In this presentation, we examine the competing nature of interfacial mechanisms including electrodissolution, lithium mechanics, vacancy diffusion and ion transport interaction, and the underlying role of heterogeneities on void formation and the evolution of solid-solid point contacts. The mechanistic effect of interfacial roughness, external pressure and temperature on the interface stability, contact area evolution and electrochemical performance will be studied.

3:45 PM EN05.09.02
Evolution of Diffusion-Induced Stress in Lithium Metal Anodes Kurt Hebert; Iowa State University, United States

Stresses in lithium metal anodes determine their stability during inevitable volume changes experienced upon cycling. Lithium deformation in response to stress changes during cycling can initiate surface morphological instabilities which lead to capacity loss, e. g. dendrites, moss, dead lithium etc. Such instabilities are particularly important for solid state batteries where anode-electrolyte interfacial integrity must be maintained. There exist to date limited experimental studies of stress evolution in Li metal anodes, and the mechanistic origins of stress generation are controversial. I will present a model for stress evolution in Li metal anodes during plating and stripping cycles, and detailed comparison of the predictions to an experimental study by J. H. Cho et al. where stress was inferred from measurements of curvature changes during litihium plating and stripping on silicon wafers (Energy Storage Mater. 24 (2020) 281). The model assumes that stress changes originate from grain boundary diffusion of Li atoms into the anode during plating and out of the anode during stripping. Diffusion-induced strain is coupled to viscoplastic deformation of lithium, calculated using an elastic-viscoplastic model due to Narayan and Anand (Extreme Mech. Lett., 24 (2018) 21) The model predictions demonstrate detailed quantitative agreement with experimental transients of wafer-curvature during both plating-open circuit and plating-stripping cycles in a liquid cell. Similar diffusion-induced plastic deformation of lithium anodes may occur in solid-state batteries, where it could contribute significantly to interfacial instabilities.

4:00 PM EN05.09.03
A Thermodynamically Consistent, Phase-Field Electro-Chemo-Mechanical Theory with Account for Damage in Solids—Application to Metal Filament Growth in Solid-State Batteries Donald Bistri and Claudio V. Di Leo; Georgia Institute of Technology, United States

Solid-state batteries (SSBs) present a promising technology and have attracted significant research attention owing to their superior properties including increased energy density (3860 mAh), wider electrochemical window (0-5V) and safer electrolyte design. From a safety standpoint, SSBs are particularly appealing in that replacement of flammable conventional organic electrolytes with highly conductive, mechanically stiff inorganic solid-state electrolytes (SSEs) can alleviate failure due to short circuit or ignition. However, operation of SSBs is hampered by numerous chemo-mechanical challenges, the most critical one associated with metal filament growth across the SSE.

Filament protrusions can initiate at perturbations of the interface or microstructural heterogeneities and subsequently grow through the SSE, causing the battery to short-circuit. It is critical to understand from both an experimental and modeling perspective the interplay of various mechanisms including morphology of the SSE microstructure, elastic-viscoplastic behavior of Li-metal, critical current density and stack pressure on the morphology of filamentary protrusions across the SSE. While much has been done to understand the interplay of aforementioned mechanisms from an experimental standpoint, theoretical frameworks on modeling of filaments growth in SSBs are still at their infancy and typically simplify dendrites as pressurized cracks under a linear-elastic fracture mechanics (LEFM) approach.

In this work, we propose a thermodynamically consistent phase-field reaction-diffusion-damage theory to investigate the morphology of filament growth across the SSE under varying chemo-mechanical operational conditions. The theory is fully coupled with electrodeposition at the Li metal-SSE interface impacting mechanical deformation, stress generation and subsequent fracture of the SSE. Conversely, electrodeposition kinetics are affected by mechanical stresses through a thermodynamically consistent, physically motivated driving force that distinguishes the role of various chemical, electrical and mechanical contributions. Concurrently, the theory captures the interplay between crack propagation and electrodeposition phenomena by tracking the damage and reaction field using separate phase-field variables such that metal growth is preceded by and confined to damaged regions within the SSE

accessible by Li-metal. This is a critical feature of the theory and confirms experimental observations that the crack front propagates ahead of Li. We specialize the theory and study the role of variations of chemo-mechanical properties (i.e. applied electric potential, SSE fracture energy) on the morphology of metal filament growth and map operational conditions to distinguish between domains of i) stable vs. unstable growth ii) intergranular vs. transgranular growth mode. In doing so, the proposed framework provides a quantitative understanding on mechanisms dictating metal filament growth in SSEs and identifies mitigation strategies to employ in future SSB designs for successful operation.

4:15 PM EN05.09.04
Electro-Chemo-Mechanical Phenomena Governing Dendrite Formation in Solid-State Batteries Sundeep Vema, Dipayan Mukherjee, Joe Stallard, Supreeth Nagendran, Vikram Deshpande, Norman A. Fleck and Clare Grey; University of Cambridge, United Kingdom

Solid electrolyte-based Li-ion batteries can enable energy storage devices with high energy and power densities due to their compatibility with high voltage cathodes (>5 V vs Li/Li^+) and Li metal anode. Among numerous solid electrolytes, doped Lithium Lanthanum Zirconium Oxide (LLZO) has a high room temperature ionic conductivity (~10^{-3} mS cm^{-1}) and electrochemical stability. LLZO when cycled with Li metal in a symmetrical cell configuration (Li-LLZO-Li), continuous stripping and plating results in the formation of Li metal filaments (dendrites) which nucleate on the cathode, propagate through the solid electrolyte, and short-circuit the cell. The exact phenomena governing the dendrite formation are unclear.

In this work, we have optimized the synthesis and sintering conditions of doped LLZO (both Al and Ga doped) and achieved low interfacial resistance between Li metal and solid electrolyte (<20 Ω cm^2). By cycling under constant pressure and temperature, and careful unidirectional plating, we have estimated the true critical current density (CCD) at which a dendrite nucleates and short-circuits the cell. We have also developed an electro-chemo-mechanical model for the nucleation and propagation of dendrites and have corroborated the model with experiments. We show that the process of Lithium ion (Li^+) transfer from solid electrolyte to Li metal (Li^0) in a prefilled crack can break open a hard ceramic solid electrolyte and thus create a pathway for Li^0 to plate inside the crack. We also hypothesize the conditions that dictate whether a dendrite grows in a filled mode, i.e., when a dendrite and crack grow together or in a dry mode, i.e., where the crack grows much faster than the dendrite.

SESSION EN05.11: Solid Electrolytes Design for Next Generation Solid-State Batteries II

Design of Novel Solid Electrolytes and Fabrication of High-Performance Solid Batteries Hailong Chen; Georgia Institute of Technology, United States

In recent years, a good number of fast ionic conductors have been studied as solid electrolytes for Li-ion or Na-ion batteries. Here we will present our understanding on the advantages and disadvantages of different types for solid electrolytes, including their electrochemical properties, synthesizability, and compatibility in solid cells. Specifically, we will share our recent progresses on rational design of novel sulfide and halide solid electrolytes based on in-depth characterization and understanding of their crystal structure and structure-property relationship. Sulfides commonly offer high room temperature conductivity and good anode compatibility, but their syntheses are tricky and relatively expensive. Halides commonly show lower room temperature conductivity than sulfides, but they are easy to synthesize and stable against air. We will report the crystal structure characterization of sulfide and halide solid electrolytes with using ex situ and in situ high resolution synchrotron X-ray and neutron diffraction and pair distribution function analysis, coupled with variable temperature electrochemical impedance spectroscopy. The design of long-lasting, high-performance solid cell with using the novel electrolytes will also be discussed, including materials selection, cell fabrication and electrochemical testing conditions and protocols.

9:00 AM EN05.11.02
High-Performance and Cost-Effective All-Solid-State Conversion-Type Iron Fluoride Cathode Bowen Shao[1], Sha Tan[2], Yonglin Huang[1], Lifu Zhang[1], Jian Shi[1], Xiaoqing Yang[2], Enyuan Hu[2] and Fudong Han[1]; [1]Rensselaer Polytechnic Institute, United States; [2]Brookhaven National Laboratory, United States

The large-scale deployment of lithium-ion batteries requires next-generation cathodes to not contain toxic and expensive elements such as Ni and Co, as well as to provide a higher energy density than existing cathodes. Conversion-type iron fluorides can fulfill these requirements and are being actively pursued by many research groups. Despite being discovered about two decades ago, the commercialization of cost-effective and energy-dense iron fluoride cathodes was obstructed by its low first-cycle redox reversibility, poor cycling stability, and large voltage hysteresis. Here, we demonstrated that these challenges are promising to be overcome by applying halide-based solid electrolytes (SEs). Through detailed ex-situ X-ray diffraction and X-ray absorption spectroscopy investigation, our results showed that halide-based SEs realize the complete intrinsic conversion and reconversion of FeF_2 because of their extinguished electrochemical stability, which cannot be achieved by sulfide SEs. The halide-SE-based all-solid-state FeF_2 cathode demonstrated extraordinary electrochemical performance compared with FeF_2 electrodes in liquid electrolytes, including a high specific capacity (~ 600 mAh/g), a long cycle life (over 100 cycles), a high first-cycle coulombic efficiency (~100%), and high-rate performance. The superior performance can be attributed to the reduced and reversible electrolyte decomposition, avoidance of cation dissolution, and mechanical lockage of electrode particles. Our study also revealed amorphization of FeF_2 cathode with halide SE enhanced the electrode kinetics. Our results demonstrate solidifying the batteries can be used as an effective approach to address the key challenges of iron fluoride cathodes for their practical application.

9:15 AM EN05.11.03
High-Performance All-Solid-State Li-S Batteries Through Advanced Carbon Fiber Decorated with 2D Transition Metal Sulfide Xiao Sun, Daxian Cao and Hongli Zhu; Northeastern University, United States

All-solid-state Lithium-sulfur batteries (ASSLSBs) are considered to concurrently deliver high energy density and safety. Considering the poor electronic conductivity of sulfur, porous carbon has been widely used as the host sulfur and serve as conductive additive to boost the sulfur mass loading and rate performance. However, the conventional porous carbon used in liquid cells exhibits low efficiency in ASSLSBs because it is challenging for the immobile solid electrolytes (SEs) to reach the sulfur confined in the pores distributed in the depth of carbon. The pore structure and distribution highly impact the electrochemical performance of ASSLSBs. Herein, for the first time, we designed a novel carbon fiber with a core-shell structure that processes a layer of micropores located only at the surface via activation by solid potassium hydroxide (KOH). The carbon fibers were fabricated through scalable

electrospinning of polyacrylonitrile followed by carbonization and activation. The obtained polyacrylonitrile-derived porous carbon fibers (named PPCF) possessing an ultrahigh specific surface area of 1519 m^2/g provide sufficient sites to host sulfur. Since the porous carbon layer is at the surface, the sulfur within the surface pores has excellent contact with SE; Meanwhile, the dense core provided excellent electron conduction. Therefore, this structurally designed carbon fiber boosted the utilization of sulfur due to enhanced electron and ion accessibilities, accelerated charge transfer, and dramatically promoted the reaction kinetic in the ASSLSBs.
However, the employment of carbon additives can improve the electrical conductivity but accelerate the decomposition of SSEs. Herein, we designed a highly conductive carbon fiber decorated with hybrid 1T/2H MoS_2 nanosheets and applied it in ASSLSBs. The chemical and electrochemical compatibility among MoS_2, sulfur and sulfide SSE can greatly improve the stability of the cathode and therefore maintain pristine interfaces between the different compositions for stable ion and electron transport. The presence of electrical-conductive metallic 1T MoS_2 and its uniform distribution on carbon fiber without aggregation benefit the electron transfer between carbon and sulfur. As a result, our ASSLSB delivered an ultrahigh initial discharge and charge capacity of 1456 mAh g^{-1} and 1470 mAh g^{-1} at 0.05 C individually with ultrahigh initial coulombic efficiency and maintained high capacity retention of 78 % after 220 cycles. The extremely high initial coulombic efficiency is attributed to the elimination of shuttle effects through SSE and stable interface. The batteries also obtained a remarkable rate performance of 1069 mAh g^{-1} at 1 C. This study pioneered the new idea that fabricating the high performance ASSLSBs through developing surface functionalized and stabilized conductive carbon additives in metal sulfides based ASSLSBs.

9:30 AM DISCUSSION TIME

9:45 AM EN05.11.05
All-Solid-State Garnet Type Lithium-Sulfur Battery Enabled by Inorganic Interfacial Engineering and 3D Electrolyte Architectures Changmin Shi, Griffin Godbey and Eric D. Wachsman; University of Maryland, College Park, United States

Current progress in Lithium-Sulfur (Li-S) batteries using garnet electrolytes have involved use of flammable liquid or polymer catholytes to achieve stable cycling due to poor ionic conduction properties of sulfur and the poor interface between sulfur cathodes and LLZO. However, this compromises the safety of "solid-state" batteries. In this work, we propose a novel design which coats our sulfur cathode (Li-S redox material: sulfurized polyacrylonitrile, SPAN) with lithium bis(fluorosulfonyl)imide (LiFSI) to improve SPAN/SPAN and cathode/LLZO interfaces and to provide ionic conductivity in the composite cathode. The LiFSI salt has an ionic conductivity of 1.2×10^{-4} S/cm at 60 Celsius degree and 1.9×10^{-5} S/cm at 22 Celsius degree, and it is stable in the charge/discharge electrochemical window of SPAN. LiFSI creates Li+ ionic conductive pathways which enhance Li^+ ion transport kinetics through the cathode and its interface with LLZO. With our thin bilayer LLZO architecture[1,2] we are the first to demonstrate an all-solid-state garnet Li-S batteries that achieved an average discharge capacity of 1400 mAh/g at 0.167 mA/cm^2 for over 40 cycles and 437 mAh/g at a discharge current density of 0.84 mA/cm^2 for over 200 cycles both at 60 Celsius degree, using a sulfur mass loading of 1 mg/cm^2. With a new 3D column architecture, we extended sulfur loading to $7mg/cm^2$ and achieved an exceptionally high discharge capacity of 1569 mAh/g at 0.03C (~0.35 mA/cm^2) at 60 Celsius degree using our all-solid-state garnet Li-S battery design, which corresponding to an energy density of 338 Wh/kg and 797 Wh/L.

10:00 AM BREAK

10:30 AM *EN05.11.06
Semi-Solid-State Batteries and Their Path to Commercialization Joanna Burdynska; Factorial Energy, United States

As vehicle electrification advances, the need for high-energy, high-power energy storage solutions increases. The lithium-ion battery (LIB) has emerged as the technology of choice to meet these challenges. Nonetheless, with the ever-increasing battery capacity of cars to increase range, future systems will need to have significantly higher energy densities. At the same time, consumers are pushing for faster charging times [1].
Future lithium-ion batteries may not be able to meet these requirements, especially since their energy density is limited by the given electrode configuration, in particular by the graphite anode. On top of this, safety concerns arise for such high energy systems, as the liquid, organic electrolyte is potentially flammable. To counter such concerns, next generation batteries are intended to employ solid or semi-solid electrolytes (SEs). Those novel electrolytes possess higher thermal stability, thus increase safety, and reduce leakage in the event of fire or crash.
At the same time, those novel electrolytes are intended to allow substitution of the conventional graphite anode with a lithium metal anode. Elemental lithium being light-weight and possessing the most negative electrode potential is the ideal anode material choice and considered the holy grail of batteries. The use of lithium metal would significantly increase the cell energy density and allow electric vehicles to further increase their driving range, while simultaneously allow for faster charging times.
As the prerequisite technologies for the practical solid-state batteries (SSBs) are reported and developed at quicker pace, its commercialization looks very promising. However, there are still problems to be solved.
Highly conductive SEs, high voltage compatible cathodes and high-capacity anodes are good examples of these, however, they still must be verified by applying them to practically large format cells. At the same time, all these components of ASSBs should satisfy requirements of not only the high performance of each material, but also the compatibility between materials, mass production processability, and overall cost.
Along with the cell design-related technology, multi-stacking and cell size upscaling is also crucial. Developed materials and cell technologies must be suitable for mass production not only in terms of materials, but also cells. In general, SSBs using inorganic SEs are more difficult for mass production rather than SSBs using polymer-based and/or semi-solid electrolytes.
Factorial Energy is a leader in the field of semi-solid electrolytes. Prototype cells employing the proprietary Factorial Electrolyte System Technology (FEST™) have demonstrated over 550 cycles when using a state-of-the-art nickel-rich cathode material and a lithium metal anode. Importantly, due to the semi-solid nature of the electrolyte, the cells have shown to perform well at ambient conditions, unlike other solid-state batteries, which require elevated temperatures to operate. After demonstrating the of high performance of semi-solid-state electrolytes Factorial Energy entered into development programs with three major OEMs, Mercedes Benz, Stellantis and Hyundai Motor Corporation. We believe that deep collaboration between battery companies and OEMs will help to accelerate the commercialization of next generation batteries.
The successful commercialization of SSBs strongly relies on the development of the key technologies of its constituents (SEs having high ionic conductivity with high cathodic/anodic stabilities, cathodes having high specific capacity and stable to high oxidation potential, protected thin lithium metals). Also, it should come with the advanced processing including the techniques for upscaling, and cell optimization (i.e. chemical/electrochemical reactivity minimization and interfacial bonding control at the interfaces).

High-Energy and Long-Lasting Lithium Metal Batteries Lithium Employing Garnet Solid Electrolytes and Interlayers Jusik Kim[1], Gabin Yoon[1], Sewon Kim[1], Michael Badding[2], Zhen Song[2], Jaemyung Chang[2] and Dongmin Im[1]; [1]Samsung Advanced Institute of Technology, Korea (the Republic of); [2]Corning Incorporated, United States

Lithium metal batteries (LMBs) are considered the most promising next-generation battery system because of their high energy density and safety. Significant research effort has been devoted to developing more stable and energy-dense LMBs than the state-of-the-art Li-ion batteries. However, the LMB performance remains unsatisfactory for commercialization, primarily owing to the inability of solid electrolytes to block Li dendrite propagation. Herein, we report that the compatibility between LLZO and lithium metal is crucial for the long-term stability, which can be accomplished by regulating bulk dopants and the corresponding dopant-specific interfacial treatment using protonation/etching. It is demonstrated that LMB using tailored garnet-type $Li_{7-x}La_{3-a}Zr_{2-b}O_{12}$ (LLZO) solid electrolytes shows remarkable stability and energy density, meeting the lifespan requirements of commercial applications (cumulative capacity : > 4000 mAh cm^{-2} at 3mA cm^{-2}).
We further demonstrate highly stable LMB even at room-temperature (25ºC) employing garnet-type oxide electrolyte by introducing a carbon-based interlayer with careful interface engineering. It is theoretically and experimentally demonstrated that our design effectively regulated Li deposition away from the solid electrolyte, preventing dendrite penetration. Overall, our garnet-type oxide-based LMB exhibited a high energy density of ~680 Wh/L for over 800 cycles at 25ºC without using external pressure, which could meet the cycling requirements and the operating conditions of smartphone batteries, which are represented by: (i) 400 cycles @88% cycle retention without Li metal shorting at the operating current density of 1.6 mA/cm^2 (0.5 C-rate charging/discharging) and (ii) room-temperature operation under the condition of no external pressure. Moreover, we successfully developed a tape-cast solid electrolyte with a large area (1 inch × 1 inch) and demonstrated excellent cycling performance at 25 °C in a 10-mAh-capacity cell beyond a coin-size cell (~1 mAh).

Guiding Principles for Fast Lithium-Ion Diffusion in Oxides KyuJung Jun[1], Yihan Xiao[1], Yan Eric Wang[2] and Gerbrand Ceder[1]; [1]University of California, Berkeley, United States; [2]Samsung Research America, United States

Inorganic lithium conductors are one of the most critical components for all-solid-state batteries. While superionic Li-ion conductivity can be found in many materials classes, oxides have the apparent advantage of better electrochemical stability and enhanced safety as compared to sulfide materials. However, achieving high lithiu- ion conductivity in oxides has been significantly more challenging due to the lower screening power of the oxygen anions. In contrast to the wide variety of sulfides structures with fast Li-ion motion, oxide frameworks that result in high Li mobility are mostly limited to NASICON-type structures, garnets and perovskites. Moreover, the highest lithium ionic conductivity achieved in oxides is on the order of 1 mS/cm, which is at least one order of magnitude lower than that of the best sulfides.

In this talk, we will present our recent findings [1][2] that let us rationalize how we can achieve high ionic conductivity in oxides and explain why designing oxide lithium superionic conductors requires a conceptually different approach from that in sulfide materials. We find that corner-sharing frameworks of non-Li cations provides high distorted lithium environment as well as sparse cation distribution that allow lithium percolation with minimal electrostatic repulsion, thereby resulting in low activation energies for lithium-ion motion[1]. By embedding the lithium diffusion network into graph representations we demonstrate that an activated local environment is a key feature of compounds with low activation energies[2]. Using these findings, we discover 16 new oxide lithium-superionic conductors and show experimental verification of the high conductivity for one of these materials. Finally, we present an oxide material that is computationally predicted to exhibit ultrafast lithium-ion conductivity over 150 mS/cm at room temperature; the highest ionic conductivity predicted in any inorganic material so far. Our study vastly expands the structural prototypes of oxides with high lithium-ion conductivity and allows the consideration of a more diverse structural and chemical space for solid electrolytes to be used in all-solid-state batteries.

Lithium-Argyrodite Based Solid-State Battery Design and Fabrication Jagjit Nanda; SLAC National Accelerator Laboratory, United States

Lithium-metal based solid-state batteries (SSB) are considered to the *holy-grail* of the next generation battery technology for their promise of higher energy density (500 Wh/Kg), safety and providing a flexible platform for integrating a number of solid-electrolytes (SE) and high capacity cathodes to achieve the end goal for users. The talk will highlight on various *state-of-the art* solid-electrolytes and their key physical and electrochemical attributes for enabling stable electrode-electrolyte interfaces and integration with high capacity cathodes The design rule for achieving high energy and fast charge SSB will be discussed with specific focus on sulfide based solid-electrolytes. Most of the sulfide-based SE compositions such as Li_3PS_4 and Argyrodite ($LiPS_5X$; X= Cl, Br) are thermodynamically unstable against high voltage cathodes such as NMC. Multiple approaches to limit the undesired decomposition of SE at the cathode-SE interfaces and improve capacity retention using interfacial coating and optimizing the cathode composition and architecture. Finally, issue related to anode free configuration using argyrodite based SE will be discussed.

Interfacial Stability Study of Argyrodite and Nb_2O_5-coated Ni-Rich NMC Under Electrochemical Cycling by Transmission Electron Microscopy Paul Naillou, Adrien Boulineau, Julien Lavie, Eric De Vito and Philippe Azaïs; CEA Grenoble, France

Interfacial phenomena in all-solid-state lithium-ion batteries are extensively studied since they are considered as the main limiting factor for performances and lifetime [1]. Among all electrolytes, Li_6PS_5Cl argyrodite receives great attention due to its high ionic conductivity and its convenience in technological integration [2]. On the other hand, high Ni content in NMC layered oxide cathode materials are known to offer best specific energy density and higher lithium utilization despite higher surface reactivity [3]. Hence, coating materials have been developed in order to inhibit surface degradation and lithium loss through stable SEI formation, such as Niobium-based coatings. However, all solid-state composite electrode based on argyrodite and cathode materials present complex chemical and structural changes that are not yet fully understood. Several approaches have been adopted to enhance comprehension of argyrodite reactivity such as X-ray photoelectron spectroscopy (XPS) [4], electrochemical impedance spectroscopy (EIS) [5], time-of-flight secondary ion mass spectrometry (TOF-SIMS) [6] and ultimately, Transmission Electron Microscopy (TEM) studies have excelled to provide comprehensive and spatially resolved chemical and structural data.

In this context the spontaneous and the electrochemical reactivity of argyrodite Li_6PS_5Cl electrolyte material toward single-crystal Ni-rich NMC cathode material has been investigated. The impact of the Nb_2O_5 coating over the cathode material has also been deeply studied. Most of the characterizations have been led with the help of state of the art TEM-related technics, such as energy-dispersive X-ray spectroscopy (EDX), electron energy loss spectroscopy (EELS) and selected area electron diffraction (SAED). Great care has been taken to work in conditions in which the materials are not altered.

Preliminary study of Nb_2O_5 coating provides details on its crystallinity, thickness, coverage on cathode material, and stability toward lithium diffusion. Cathode material / coating interface has been notably observed on a thin specimen with high resolution imaging coupled with EDX and remarkable details on lithium diffusion through a few nanometers in the coating have been recorded on spectroscopic measurements. With and without this coating, NMC / argyrodite mixture does not show any spontaneous interface generation. However, under electrochemical solicitation, several species have been identified and characterized such as LiCl, P_2S_5, P_2O_5, Li_3PS_4, NiS, and S^0. The correlation with XPS allowed to point out unrevealed subtleties until now and to discuss degradation mechanisms. The segregation of LiCl toward Li_3PS_4 has been directly observed, validating the theoretical predictions of argyrodite degradation depending on stability window.

Moreover, a novel *operando* TEM characterization technique has been developed to study the interfacial modifications of argyrodite / NMC cells during electrochemical cycling within the TEM. This is the first time such original setup is proposed inside the electron microscopy community: it allows the direct *operando* characterization of the battery while keeping it always prevented from air exposure from the device preparation to the characterization inside the TEM.

A Polycationic Substituted Lithium Argyrodite Superionic Solid Electrolyte Lin Jing[1], Gennady Cherkashinin[2], Mareen Schäfer[1], Georgian Melinte[1], Sylvio Indris[1,3], Aleksandr Kondrakov[1,4], Jürgen Janek[5,1], Torsten Brezesinski[1] and Florian Strauss[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Technical University Darmstadt, Germany; [3]Helmholtz Institute Ulm (HIU), Germany; [4]BASF SE, Germany; [5]Justus-Liebig-University Giessen, Germany

Solid-state batteries are attracting great attention because of potentially higher energy and power densities than conventional Li-ion batteries based on liquid electrolytes. Yet, they are plagued by the development of advanced solid electrolytes, mainly lacking in ionic conductivity and electrochemical stability; thus, the ongoing quest for exploration of new materials and compositions. Despite increasing research interests in high-entropy materials, the effect that configurational entropy has on the charge transport properties remains largely elusive. Recently, we have shown that high-entropy argyrodites can be achieved via polyanionic/cationic substitution, showing a low activation energy (E_A = 0.22 eV) and moderate r.t. ionic conductivity (~1 mS/cm). However, the possibility of polycationic substitution and the resulting structure-property relationships have not been explored yet.
Within this context, we herein report about the influence of polycationic substitution on the Li-ion conductivity in argyrodite superionic conductors. Using electrochemical impedance spectroscopy and ^{7}Li pulsed field gradient nuclear magnetic resonance (NMR) spectroscopy, it is found that polycationic substitution leads to a very low activation energy (E_A = 0.19 eV) for Li-ion conduction and a high r.t. ionic conductivity of ~13 mS/cm. These findings are rationalized via neutron powder diffraction (at 298 K and 10 K) in combination with magic angle spinning NMR spectroscopy. A high S^{2-}/I^- anion site disorder (up to ~10 %) and redistribution of Li lead to shortened jump distances and therefore facilitated long-range ion diffusion. Finally, it was implemented as SE in bulk-type SSBs. Using XPS analysis we reveal the (electro)chemical degradation upon cycling related to specific elemental constituents. Overall, our results show the possibility of polycationic substitution in lithium argyrodites, thereby opening up large compositional space for the development of novel superionic conductors with improved properties.

Amorphous Sodium Chloride Solid Electrolytes with High Ionic Conductivity Phillip Ridley[1], Long Hoang Bao Nguyen[1], Grayson Deysher[1], Jin An Sam Oh[1], Jihyun Jang[1] and Y. Shirley Meng[2,1]; [1]University of California, San Diego, United States; [2]The University of Chicago, United States

Due to the lack of appropriate solid electrolytes possessing a wide electrochemical window that is compatible with both the anode and cathode, separate anolytes and catholytes have been proposed as an approach to realize high performing solid-state batteries. Chloride-based solid electrolytes have emerged as promising catholyte due to their great deformability, excellent electrochemical stability at higher voltages, and good ionic conductivities. While lithium-based chloride solid electrolytes have shown high ionic conductivities (10^{-4} – 10^{-3} S cm^{-1}), the sodium analogues have been scarcely reported and their ionic conductivities significantly lag (10^{-6} – 10^{-5} S cm^{-1}). Consequently, sodium solid-state batteries using chloride catholytes exhibit poor kinetics and lackluster cycling performance at room temperature. Herein, we explore the “Composition−Structure−Conduction property” relationship in the Na−Y−Zr−Cl solid electrolyte system. Experimental observations show that a reduction in crystallinity leads to a significant improvement in the room-temperature ionic conductivity to 10^{-4} S cm^{-1}, which is one of the highest reported in the literature. This high ionic conductivity ultimately translates to improved room-temperature reversible capacity in the battery performance.

Revealing Li Dynamics in Mixed Ionic-Electronic Conducting Interlayer of All-Solid-State Batteries Daxian Cao[1], Kenneth Burch[2], Michael Geiwitz[2], Kang Xu[3], Tongtai Ji[1] and Hongli Zhu[1]; [1]Northeastern University, United States; [2]Boston College, United States; [3]CCDC Army Research

Laboratory, United States

Lithium-metal (Li^0) anode is considered the holy grail of all-solid-state batteries owing to their exceedingly high energy density; in practice, their stability remains unsatisfactory because of the incompatibility between Li^0 and solid-state electrolytes (SEs). One strategy is to introduce an interlayer, which often consists of a mixed ionic-electronic conductor (MIEC), to stabilize the Li^0. However, how Li ions (Li^+) transport within MIEC remains unknown. Herein, we investigate the Li, including Li^0 and Li^+, dynamics in a graphite interlayer, a typical MIEC, using *operando* neutron imaging and Raman spectroscopy. Our study reveals the Li evolution during mechano-chemistry and mechano-electrochemistry reactions. During cell assembly, intercalation–extrusion-dominated mechano-chemical reactions transform the graphite into a Li-graphite interlayer consisting of SE, Li^0, and diluted graphite-intercalation compounds. During battery operation, dictated by the lowest nucleation energy, Li^0 plating preferentially occurred at the Li-graphite|SE interface and then transferred into the Li-graphite interlayer without intercalation. Upon further plating, Li^0-dendrites formed, inducing short circuits and reverse immigration of Li^0 from the anode to the cathode during charging. Continuum modeling was conducted to explain the Li dynamics. We concluded that with the MIEC interlayer, a lowest nucleation barrier at the Li^0 side is necessary to drive the Li^+ to transport across the MIEC and preferentially deposit onto the Li^0.

High Capacity Lithium Metal Stripping Dynamics in Solid State Batteries Kelsey B. Hatzell; Princeton University, United States

All solid-state batteries (ASSB) can potentially meet the energy density threshold (900 Wh. L^{-1}) for next-generation batteries by employing Lithium metal anode and solid electrolyte (SE). However, there is a lack in critical understanding of interfacial chemo-mechanics and ion transport in solid-state batteries which leads to poor cycling performance and dendrite-induced shorting. In this work, we investigate polycrystalline garnet $Li_7La_3Zr_2O_{12}$ (LLZO), a model solid electrolyte which is psuedo-non-reactive against Li metal. However, Li-LLZO interfaces at high current density initiate substantial void growth, which causes dendrite formation during plating. Stack pressure and temperature are effective means to initiate creep-induced void filling and decreasing charge transfer resistance to enable stable cycling. Applying stack pressure enables Li to deform and creep above yield stress during stripping at high current densities but is not sufficient to prevent cell shorting during plating. We employed a 3-electrode setup to understand the kinetic limitations and morphology changes in Li-LLZO interface during long-term stripping (5 mAh. cm^{-2}). The role of cathode-LLZO interfaces was also studied which dictates cyclability and capacity retention in full cells. This work elucidates the role of cathodic and anodic interfacial chemo-mechanics which will contribute to our further understanding electrochemical instability of solid-state batteries.

Lithium Metal Morphology & Performance Informed by Micro-Computed Tomography Lara Dienemann[1], Ahmed Al-Obeidi[2], Adrien Stejer[3], Iryna Zenyuk[3] and Matthew Panzer[1]; [1]Tufts University, United States; [2]Ionic Materials, United States; [3]University of California, Irvine, United States

Alone, *ex-situ* analysis and *postmortem* teardowns often convolute interpretations of lithium metal cell failure modes. In this study, micro-computed tomography renders lithium metal interfaces in various conditions and formats throughout cycling to assist in better understanding the morphology of cycled lithium and its relationship with cycling performance. *Operando* studies link cycling performance with morphology with greater resolution and provide insight into physical phenomena such as deformation of the separator imposed by the lithium metal volume changes. Rolled lithium foils, stack pressure, inorganic-organic hybrid coatings, electrolyte solvent types, and polymer separator morphology is investigated. With this methodology, hairy nanoparticle-based artificial SEIs are found to promote uniform and dense lithium cycling, and their chemo-mechanical interplay which supports this mechanism is studied. Finally, the findings inform best practices in fundamental lithium metal cell design.

4:30 PM EN05.13.04
Interdiffusion Induced Cathode-Electrolyte Interface Instability of Single-Crystalline LLTO Solid Electrolyte Hanseul Choi[1], Hee-Dong Kwak[1], Celesta S. Chang[2], Min-Ju Choi[1], Jae Young Kim[1], Sangwook Han[1], Sunyoung Lee[1], Mingi Moon[1], Sewon Kim[1], Ho Won Jang[1], Kisuk Kang[1], Jeehwan Kim[2] and Yun Seog Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

All-solid-state battery using solid electrolyte is promising for next generation energy storage device due to its potential for stability and high energy density. In particular, $Li_{3x}La_{2/3-x}TiO_3$ (LLTO) ($0.05 < x < 0.167$), a perovskite type solid electrolyte, has shown an ionic conductivity as high as 10^{-3} S/cm at a x of 0.11 as well as air-stability. However, a high interfacial resistance when in contact with an electrode and interfacial instability between the electrode and solid electrolyte caused by electrochemical degradation make it difficult to put LLTO into practical use. Although various efforts including adding an artificial solid electrolyte interface layers such as Al_2O_3 have been employed to mostly mitigate the interface of lithium-metal anodes, the degradation issue at the electrolyte-cathode interface still remains. The interdiffusion of metal-ions between polycrystalline LLTO pellet and $LiCoO_2$ (LCO) has been reported, however the bulk diffusion without grain boundaries is desirable to evaluate the interdiffusion phenomena and investigate its effects on the Li-ion transport properties of LLTO.
In this study, we investigate the instability of the single crystalline LLTO electrolyte-cathode interface induced by the interdiffusion of metal cations in conventional cathode materials, LCO and $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ (NCM). We deposit single crystalline LLTO (100) solid electrolyte thin films to exclude the effect of grain boundaries and structural defects of LLTO. Single crystalline LLTO (001) thin-films are deposited by using pulsed laser deposition (PLD) technique epitaxially on $SrTiO_3$ (001) substrates having a lattice mismatch of 0.8%. The LCO or NCM thin-films are also stacked on LLTO/STO. The structure and the diffusion dynamics between the cathode and the electrolyte are characterized by scanning transmission electron microscopy and X-ray photoelectron spectroscopy with a depth profiling. The interdiffusion of metal cations at the LLTO-LCO interface are measured to be more rapid than that of the LLTO-NCM interface, even with lower deposition temperature. The interfacial resistance of the resulting interfaces from each cathode and the electrolyte are measured through electrochemical impedance spectroscopy. Furthermore, approaches using diffusion barrier layers to mitigate the interdiffusion of ion conductors and cathodes are also discussed.

Role of Electronic Passivation in Stabilizing the Lithium LiPON Solid Electrolyte Interphases Yuheng Li[1], Pieremanuele Canepa[1] and Prashun Gorai[2]; [1]National University of Singapore, Singapore; [2]Colorado School of Mines, United States

The solid-electrolyte interphase (SEI) is crucial to the electrochemical performance of all-solid-state batteries (ASSBs). Theoretical characterization of SEI properties will help understand the origin of interfacial stability (and instability) between solid electrolytes and electrodes. Among solid electrolytes for Lithium(Li)-ion ASSBs, the lithium phosphorus oxynitride $Li_xPO_yN_z$ (LiPON) is one of the most stable against Li metal anode. However, it has been shown that LiPON reacts with Li metal and forms SEIs. The SEI formation stops after a thin layer is formed, but the mechanism that enables this apparent stabilization is unclear. Thermodynamics underpins the defect formation in materials and in turn, creation of electronic charge. Materials for energy storage, including solid electrolytes, are no exception to this fundamental process. Here, we computationally evaluate the electronic passivation of SEIs and its role in stabilizing the Li-LiPON interface. Specifically, we determine the defect and charge carrier concentrations in Li-LiPON SEIs, including Li_2O, Li_3N, Li_3P, and Li_3PO_4. The defect and charge carrier concentrations were calculated from defect thermodynamics. We then predicted the electronic conductivity of the SEIs under different electrochemical conditions, which correspond to varying potentials to the Li metal anode. Our results reveal that the stoichiometrically abundant and uniformly distributed Li_2O has expectedly negligible electronic conductivity, while the electronically conducting components, such as Li_3N and Li_3P, show preferential distribution in the SEI. We posit that the overall electronically insulating nature of the SEI is responsible for the stability of the Li-LiPON interface. The computational approach adopted here can be extended to reveal the origin of the interfacial stability in other ASSBs.

SESSION EN05.14: Solid Electrolytes Design for Next Generation Solid-State Batteries IV

8:30 AM *EN05.14.01
Solid Electrolytes for All-Solid-State Batteries Linda Nazar and Laidong Zhou; University of Waterloo, Canada

All-solid state lithium-ion batteries (ASSBs) have emerged as attractive alternatives to conventional liquid electrolyte cells for electrochemical energy storage, owing to their anticipated enhanced safety and higher energy densities. ASSBs are founded on high performance fast-ion conducting solid electrolytes, where the search for improved materials hinges on understanding their intrinsic nature and gaining comprehensive knowledge of the factors that dictate facile Li-ion transport. In turn, incorporating them into high functional ASSBs relies on mastering the interface of the solid electrolyte with the electrode materials.

These topics will be the focus of the presentation based on recent findings in our laboratory. Our correlation of structure with ionic conductivity in a range of newly developed fast ion Li conductors helps understand how cation disorder and a frustrated energy landscape impacts conductivity and activation energy. These considerations lead to exciting new classes of fast-ion conductors, including new argyrodite fast-ion conducting iodides and lithium metal halides. Promising all solid-state Li-ion batteries utilize “bare” NCM-type, Ni-rich lithium metal oxide cathodes coupled with high voltage-stable solid-state electrolytes. Low-resistance “clean” solid-solid interfaces enable room temperature cells with capacities close to their liquid Li-ion counterparts at practical discharge rates over very long-term cycling.

9:00 AM EN05.14.02
Bilayer Dense-Porous LLZO Membranes for High Performance Li-Garnet Solid-State Batteries Huanyu Zhang[1,2], Kostiantyn Kravchyk[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Currently, the replacement of liquid Li-ion electrolytes with their non-flammable and non-toxic solid counterparts based on $Li_7La_3Zr_2O_{12}$ (LLZO) with the garnet-type structure is pursued as a compelling approach to improve the energy density, cycling stability, and safety of Li-ion batteries (LIBs).[1-3] However, Li dendrites form in $Li_7La_3Zr_2O_{12}$ (LLZO) solid electrolytes due to intrinsic volume changes of Li and the appearance of voids at the Li metal/LLZO interface. [4] Bilayer dense-porous LLZO membranes make for a compelling solution of this pertinent challenge in the field of Li-garnet solid-state batteries (SSB). Lithium is thus stored in the pores of the LLZO, thereby avoiding (i) dynamic changes of the anode volume and (ii) the formation of voids during Li stripping due to increased surface area of the Li/LLZO interface. The dense layer then additionally reduces the probability of short circuits during cell charging. In this work, we report a method for producing such bilayer membranes utilizing sequential tape-casting of porous and dense layers. The minimum attainable thicknesses are 8–10 µm for dense and 32–35 µm for porous layers, enabling gravimetric and volumetric energy densities of Li-garnet SSBs of 230 Wh kg^{-1} and 830 Wh L^{-1}, respectively. Bilayer LLZO membranes in symmetrical cell configuration exhibit high critical current density up to 6 mA cm^{-2} and cycling stability of over 100 cycles at a current density of 0.1 mA cm^{-2} at an areal capacity limitation of 1 mAh cm^{-2}. The electrochemical performance of LLZO membranes is also assessed in combination with a $LiFePO_4$ cathode, delivering areal capacities of ca. 0.45 mAh cm^{-2} at a current density of 0.1 C.

CO_2-Derived Block Polycarbonate-Ethers for Accommodating the Volume Change in Solid-State Battery Composite Cathodes Hui Gao[1,2], Georgina Gregory[1,2], Boyang Liu[1,2], Xiangwen Gao[1,2], Mauro Pasta[1], Peter Bruce[1] and Charlotte Williams[1]; [1]University of Oxford, United Kingdom; [2]Faraday Institution, United Kingdom

All-solid-state batteries have gained increasing attention because of their high energy density and safety. Several inorganic solid electrolytes achieved the requirement of lithium-ion conductivity for all-solid-state batteries. However, the rigid and brittle nature of inorganics prevents good interfacial contact

with electrodes. The active materials are subjected to volume change upon charging/discharging. This leads to contact loss between active materials and electrolytes in the composite cathode (including the active material, inorganic solid electrolyte and carbon), resulting in poor cycling stability of the cells. To overcome the contact loss, the polymers can be introduced into cathode composites to improve the interfaces, cohesion and mechanical properties. Herein, we prepare the cathode composite of solid-state batteries by adding purpose-designed triblock polymers, poly(ethylene oxide)-*b*-poly(4-vinyl cyclohexene oxide carbonate)-*b*-poly(ethylene oxide) (PEO-*b*-PC-*b*-PEO). Triblock polymers are synthesised by hydroxyl telechelic PEO as a macroinitiator for CO_2/epoxide ring-opening copolymerization and a well-controlled Mg(II)Co(II) catalyst at 1 bar CO_2. The correlation of ion conductivity and mechanical properties with the block polymer composition is investigated. Three lead polymers are identified. These block polymers show high ionic conductivity (10^{-4} S cm^{-1}) at room temperature, lithium-ion transport (t_{Li+} 0.3-0.62), good electrochemical oxidative stability (> 4 V vs Li^+/Li) and elastomeric or plastomer properties (G' 0.1 -67 MPa). The solid-state batteries with the block polymer in the $LiNi_{0.8}Mn_{0.1}Co_{0.1}O_2$ cathode composite demonstrate greater capacity retention than equivalent cells featuring PEO homopolymer or without any polymer.

9:30 AM EN05.14.04
Increasing the Ionic Conductivity of Lithium Carbonphosphonitride Thermosets Through Plasticization and Increased Li Concentration Andrew Purdy, Brian L. Chaloux, Hunter O. Ford, Megan B. Sassin, Christopher A. Klug and Daniel M. Fragiadakis; Naval Research Laboratory, United States

Lithium dicyanamide ($LiN(CN)_2$) reacts with phosphorus cyanide ($P(CN)_3$) in a 2:1 or greater mole ratio in any anhydrous non-protic mutual solvent to form a resin. The resin solution is used to coat metal coupons or to impregnate silica fiber paper, which are then cured at temperatures of 200-300 °C, forming adherent, ion conducting films of a completely non-combustible material. When fully cured, those films have a low ionic conductivity, probably due to rigid crosslinking of the thermoset. We found previously that adding compounds to the resin, such as LiCN that contain a higher concentration of Li than $LiN(CN)_2$, increases the ionic conductivity. Post-cure treatment with diglyme also causes a dramatic conductivity increase, presumably by complexing the mobile Li ions and plasticizing the material. We will report our systematic efforts to increase Li^+ ion conductivity by introducing small amounts of non-volatile poly(oxoethylene) based plasticizers, and by copolymerizing the resin with other cyano Li monomers to increase the Li concentration. The ionic conductivity and chain motions of these films were characterized by impedance and dielectric relaxation spectroscopy, and test cells with Li foil were constructed and measured. Additionally, the bulk thermoset material was analyzed by solid state NMR. We evaluated how the composition, conductivity, and electrochemical stability of these materials depends on the solvents of preparation and the poly(oxoethylene) and Li cyano additives used. Additionally, combustibility was tested to determine how much plasticizer can be added without compromising the inherent non-flammability of the thermoset materials.

9:45 AM EN05.14.05
Highly Ion-Conductive, Elastic and Adhesive Zwitterionic Polymer Electrolyte for All-Solid-State Lithium Batteries Sangil Kim[1,2], Gang Cheng[1,2], Kun Wang[1], Yuechen Gao[1], Hyang Seol[1,2] and Anh Ngo[1]; [1]University of Illinois, Chicago, United States; [2]ZPore, LLC, United States

Currently, lithium-ion batteries (LIBs) are considered to be one of the most popular energy storage systems for electronic devices supported by high energy density, high operating voltage, and favorable cycling performance. However, commercial LIBs with the organic liquid electrolyte and lithium (Li) salts are associated with critical safety issues such as uncontrollable side reactions, toxic liquid electrolyte leakage, flammability of electrolytes, and poor thermal stability. Therefore, replacing the liquid electrolyte with solid electrolytes is quite necessary. Among several solid ion conductors, solid polymer electrolytes (SPEs) can offer excellent flexibility, interfacial compatibility with electrodes, good processibility, low cost, and light weights that can overcome the limitations of ceramic ion conductors. However, current SPEs often encounter limitations such as poor mechanical strength and dimensional thermal stability, inferior electrochemical stability, and low Li^+ ion conductivity at room temperature (~10^{-5} S cm^{-1} at room temperature).
Here we present a multifunctional solid polymer electrolyte based on zwitterionic polyurethanes (zPU-SPE) for all-solid-state LIBs (SLBs). Our zPU-SPE exhibits a great potential to overcome current technical limitations of conventional SPE materials in SLB applications (e.g., low Li^+ ion conductivity, inferior electrochemical/mechanical stabilities, unsatisfactory suppression of Li dendrite growth). We designed and synthesized a series of zPU [i.e., poly ((diethanolamine ethyl acetate)-co-poly(tetrahydrofuran)-co-(1,6-diisocyanatohexane))]. Our zPU-SPE can host an equal amount of lithium bis(trifluoromethanesulfonyl) imide (LiTFSI) without phase separation (up to 80 wt% of LiTFSI loading). The Li-ion conductivity value of zPU exponentially increases with the addition of LiTFSI and reaches 7.4×10^{-4} S/cm with Li^+ transference number of 0.6 at 25° C, almost 14 times higher than the conductivity of poly(ethylene oxide) (PEO) SPE with ethylene oxide/Li^+ ratio = 16. In addition, its superior adhesion energy (487.5 J/m^2 of zPU-SPE vs. 150 J/m^2 of commercial 3M Scotch Tape) can minimize interfacial resistance between electrode and SPE, and thus cell resistance of 100-µm-thick zPU SPE is as low as 280 W/cm^2 compared to 1230 W/cm^2 of the cell with a similar thickness of PEO SPE. Our zPU-SPE also showed an excellent elastic property with a tensile break of 1700% owing to its high density of inter- and intra-molecular hydrogen bonding in polymer matrix. The SLB battery performance of PEO and zPU-SPEs was evaluated using a solid-state Li/SPE/$LiFePO_4$ cell; the assembled SLB cell was cycled at a constant current rate of 1 C at 25 °C. After a discharge capacity of the cell with zPU-SPE stabilized at 100 mAh g^{-1} after 15 cycles, there is a negligible capacity decrease (only 3% capacity decrease after 700 cycles), delivering a discharge capacity of 97 mAh g^{-1} with stable Coulombic efficiency (100%) over entire cycles. However, the discharge capacity of Li/PEO/$LiFePO_4$ cells drops rapidly to 3 mAh g^{-1} after 100 cycles. These results demonstrate that the SLB cell assembled with PCB-PTHFU shows high discharge/charge capacity and excellent capacity retention with stable Coulombic efficiency. The good electrochemical performance of the zPU SPE can be attributed to good compatibility with electrodes, low charge transfer resistance at the interface of electrode/electrolyte, and high Li-ion conductivity, strongly suggesting that zPU SPEs are potential candidates for development of high performance of SLBs.

10:30 AM EN05.14.06
Tunable Conformal Electrodeposition of Ultra-Thin Polymeric Films for Electrolyte Interphases Wenlu Wang, Anton Resing, Zhaoyi Zheng and Joerg G. Werner; Boston Univeristy, United States

Interfaces between materials of various functionalities are omnipresent in solid-state energy-storage devices and partially determine the device performance and degradation due to interfacial incompatibility, instability, resistance, and loss of contact over cycling. Designer three-dimensional (3D) electrolyte-type interphases that bridge battery components and materials with disparate functions, such as the active electrode materials and solid electrolyte, could overcome some of these compatibility detriments and the increase in contact resistance over long-term operation. Additionally, 3D thin-film solid-state batteries as promising candidates for high-performance microscale power sources require 3D ultrathin solid electrolyte interphases, as they take advantage of both short ion diffusion distances for high rate capability with low heat generation, as well as the third dimension for high material loading and energy density. Important characteristics of such electrolyte-type interphases are their capability of electronic insulation and the physical separation of incompatible materials while allowing for ion transport. However, a key challenge of obtaining such functional interphases in batteries is their conformal deposition as thin and uniform coatings on 3D electrode architectures. In this work, we design multifunctional electrochemically active molecules that combine the capability of ionic conduction and molecular permeability with conformal electrodeposition into polymeric thin films that can be uniformly applied to porous electrodes with arbitrary 3D structures. We present an exhaustive exploration of their material-processing-structure-property relationships that reveals the multi-scale control over the ultrathin-film properties. For example, the uniform film thickness is tunable from 10 to 100s of nanometer

through molecular design and electrodeposition conditions, while their molecular permeability and electronic resistance can be tailored from pervious to fully blocking. We show that the electrodeposited functional interphases fully coat complex 3D electrode architectures with retention of their functionality in a battery. This work demonstrates that rational molecular design enables the conformal electrodeposition of ultrathin functional coatings with solid polymer electrolyte properties on 3D structured electrodes that will enable designer interphases in various solid-state battery architectures and chemistries.

10:45 AM EN05.14.07
Gradient Ceramics in Polymer Hybrid Electrolyte with Improved Electrochemical Performance for Solid State Li-Ion Batteries Md Yusuf Ali[1], Gerrit Michael Overhoff[2], Hartmut Wiggers[1,3] and Gunther Brunklaus[2]; [1]Institute for Combustion and Gas Dynamics—Reactive Fluids, University of Duisburg-Essen, Germany; [2]Helmholtz Institute Münster, Germany; [3]CENIDE, Center for Nanointegration, University of Duisburg-Essen, Germany

Solid-state Li-ion batteries have been regarded as one of the most promising candidate for future green energy storage devices due to their safety, low cost, and high energy density properties. Polymer and ceramics electrolytes are attractive candidates to boost the application of lithium metal batteries. Single-ion conducting polymers can reduce polarization and lithium dendrite growth, though these materials are eventually mechanically overly rigid, thus requiring mobilizers such as organic solvents to transport Li ions. Inhomogeneous distribution of the solvent and resulting preferential Li transport pathways might yield favored spots for Li plating, imposing additional mechanical stress and even premature cell short-circuits. On the other hand, ceramic e.g., $Li_{1.3}Al_{0.3}Ti_{1.7}(PO_4)_3$ (LATP) NASICON based electrolytes are known for better dendrite growth inhibitor, high temperature applicability. Here, we explored a ceramic-in-polymer hybrid electrolyte consisting of a polymer blend of single-ion conducting polymer and PVDF-HFP, including EC:PC as swelling agent, and silane-modified (3 Aminopropyltriethoxysilan (APTES)) LATP particles. The hybrid electrolyte features an oxide-rich layer that notably stabilizes the interphase toward Li metal, enabling single-side lithium deposition for over 700 hours at a current density of 0.1 mA cm^{-2}. Also, the incorporated oxide particles significantly reduce the natural solvent uptake from 140 to 38 wt.% despite maintaining reasonably high ionic conductivities. Its electrochemical performance was evaluated in $LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ (NMC622)||lithium metal cells, exhibiting impressive capacity retention over 300 cycles. Notably, the very thin $LiNbO_3$ coating of the cathode material further boosts the cycling stability, resulting in capacity retention of 78 % over more than 600 cycles, clearly highlighting the potential of the hybrid electrolyte concept.

Polycarbonate Solid Electrolytes for Structural Batteries with Enhanced Mechanical Properties Gerald Singer, Cheng-Tien Hsieh, Yanjun Guo and Yuan Yang; Columbia University, United States

Polymer electrolytes are of increasing importance to replace flammable liquid electrolytes, that can lead to leakage and safety concerns in modern lithium-ion batteries (LIB). Besides the elimination of solvents, polymer electrolytes are light-weight and possess excellent processing, which makes them a great choice for large-scale applications. Most polymers show good mechanical properties but very low intrinsic ion conductivity, which is essential for an electrolyte in batteries. Therefore, a great effort is being made to increase its ion conductivity by adding plasticizers to the polymer matrix to reasonable values (>0.2 mS/cm), which usually leads to a significant reduction in the mechanical performance. Consequently, only a few examples with reasonable modulus and ion conductivity have been demonstrated so far.
In this study, a polycarbonate-based solid polymer electrolyte (SPE) that shows a combination of good electrochemical and mechanical performance is presented. The SPE can be in-situ polymerized thermally with a glass fiber separator and demonstrates good cycling performance with $LiFePO_4$/Li cells at room temperature. High modulus and strength of the SPE along with good ion conductivity of ca. 0.3 mS/cm enables a strong connection and efficient ion diffusion between the two electrodes. This exceptional combination can be used to improve the mechanical properties of structural batteries on the material-level.

11:15 AM EN05.14.09
***In Situ* Thermo-Mechanical Characterization and Strain Engineering of LiPON Thin Films** Truong Cai[1], Andrew S. Westover[2], Sergiy Kalnaus[2], Jung Hwi Cho[1], Christos E. Athanasiou[1], Nancy Dudney[2] and Brian W. Sheldon[1]; [1]Brown Univerisity, United States; [2]Oak Ridge National Laboratory, United States

High temperature multi-optical-stress sensor (HTMOSS) has been used to characterize the coefficient of thermal expansion (CTE) and yield stress of 1-micron thick LiPON films. Six fully dense, amorphous films were deposited on glass and sapphire substrates. The films were then annealed at temperatures ranging from 80 to 200 C for 3 hours. The CTE of LiPON is found to be approximately 4.1e-6, and argued to be independent of the substrate type. Because of this intermediate CTE value, by varying the substrate, we could impose either tension and compression due to thermal mismatch to the film. We observed further that the yield stress of the film is approximately 60 MPa under compression and 100 MPa under tension. Using constant-load hold at and beyond yield point, the films were found to relieve the stress developed during heating with visco-plastic deformation, which led to permanent residual stress during cooling as high as 120 MPa in either tension or compression depending on substrate type. We also found that at annealing temperature higher than 140 C LiPON lost ductility which could be due to composition changes as indicated by XPS measurement. The stress-relief mechanism at constant-load indicates that LiPON may be beneficial as a protective layer against dendrites penetration. Moreover our experimental platform proves that it's an effective method to engineer strain into thin-film solid electrolytes that could be extended to other materials like LLZO or sulfide electrolyte.

Fragility and Ion Transport in Silica-Based Ionogels Patricia E. McNeil[1], Thibaud Guillemin[2], Jean Le Bideau[2] and Bruce S. Dunn[1]; [1]UCLA, United States; [2]Université de Nantes, France

The design of electrolytes exhibiting liquid like transport properties with the form and structure of a solid separator is a promising direction for the development of solid-state electrochemical devices, especially solid-state batteries. In recent years, pseudo solid-state electrolytes known as ionogels have emerged as a group of solid phase materials that exhibit the properties of ionic liquids. These materials, which are comprised of two interpenetrating phases, are synthesized using well-known room temperature sol-gel synthesis methods which produce complex open microstructures with various dimensionalities. Ionogels are macroscopically rigid but exhibit liquid-like transport properties due to an ionic liquid (IL) being confined in the nanoscale pores of a sol-gel derived silica matrix. Typically ionogels range from 60-90% IL volume which, in contrast to sol-gel materials that use volatile solvents (e.g., alcohols), are retained in the final material because of the extremely low volatility of ILs. By confining the IL in the mesoscale pores of the sol-gel matrix, ionogels take full advantage of ionic liquid utility, including good chemical stability, high ionic conductivity, thermal stability, and a wide electrochemical window, in combination with a rigid solid backbone.

The present study examines the transport properties for ionic liquids confined within mesoporous materials. The fragility index was determined for several samples with varying microstructures and used to characterize performance as a pseudo-solid electrolyte. Fragility is a measure of the thermal sensitivity of the liquid structure and is described by the fragility index, D. A fragile liquid collapses under weak perturbations and leads to structural re-arrangement. Thus, a fragile liquid exhibits fast dynamical re-arrangement characterized by short relaxation times and non-Fickian diffusion, giving rise to non-Arrhenius behavior. A low D value corresponds to weak molecular interactions, while a high value corresponds to strong molecular interactions. In this

way, fragility is related to molecular mobility with its correlative effect on ionic conductivity and viscosity. In applying these concepts to ionogels, as the complexity of the matrix increases, the fragility index also increases, leading to lower conductivity materials. In our study, the microstructural features influencing conductivity were examined using Archie's law, assuming that the silica matrix conductivity was negligible. This type of analysis is validated for rock matrices and in the current work was extended to pseudo-solid electrolyte materials. Utilizing the concepts presented here, we demonstrate how ionogel samples can approach the conductivity of the unconfined ionic liquid. These conclusions are applicable to a variety of pseudo-solid electrolyte systems and have important implications for the design of solid-state electrochemical devices.

Hybrid Quasi-Solid-State Electrolytes—Structure, Dynamics, and Their Effects on Ionic Conductivity Nyalaliska W. Utomo, Minori G. Kitahata, Yue Deng, Xiaotun Liu, Qing Zhao, Tian Tang and Lynden A. Archer; Cornell University, United States

The shift from liquid to solid-state electrolyte has been the focus of many battery electrolyte systems. Solid polymer electrolytes (SPEs) offer advantages such as the suppression of dendrite growth, good electrochemical stability, and low flammability and toxicity. SPEs formed inside an electrochemical cell from monomers and initiators is a strategy employed to overcome electrolyte wetting to active electrode components. The addition of SiO_2 nanoparticles with PEG_{5kDa} tethers hairy nanoparticles (HNPs) modifies the $Al(OTf)_3$-initiated polymerization of poly(1,3-dioxolane) (poly(DOL)). Time-dependent rheology measurements during polymerization indicate altered macrokinetics and structure. Curiously, the commonly observed soft glassy dynamics in self-suspended hairy nanoparticles (HNPs) are significantly reduced due to the strong interaction between PEG tethers and poly(DOL) chains. This strong interaction leads to co-crystallization –anchoring the nanoparticles to their poly(DOL) host. This anchoring not only enables good dispersion of nanoparticles in the matrix but also opens up more pathways for Li-ion transport as the ether oxygens of both PEG tethers and poly(DOL) chains provide sites for Li-ion hopping. Making use of this regulated Li-ion motion, we are able to increase the room-temperature conductivity of self-suspended HNPs from nS/cm-scale up to 4 mS/cm, four times higher than the golden standard for ether-based SPEs. This favorable ion transport is also reflected in good electrochemical performance in Li||Cu and Li||sPAN (sulfur/poly(acrylonitrile) cells. Bare, larger microparticles, on the other hand, reduces ionic conductivity in a way predicted by the Maxwell conductivity model up to core volume fractions as high as 40 vol.%. Curiously, at this high core volume fraction, electrolytes have high moduli comparable to solid electrolytes while still possessing liquid-like dynamics.

Toward Improved Conductivity and Electrochemical Stability of Halide Superionic Conductors for All-Solid-State Batteries Hiram Kwak, Juhyoun Park, Yeji Choi, Mu Chang Lee and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

While lithium-ion batteries using conventional liquid electrolytes have been widely used from portable electronic devices to large-scale applications, such as electric vehicles and energy storage systems, their serious safety concerns have remained unsolved. Moreover, alternative electrode chemistries such as Li metal have not been stabilized by using liquid electrolytes. In this regard, all-solid-state batteries employing inorganic solid electrolytes (SEs) are considered a promising alternative.
Recently, halide SEs, such as Li_3YCl_6, are newly emerging due to their prestigious advantages of excellent electrochemical/chemical oxidation stability and processability. However, a criticism of most halide SEs developed thus far is the use of costly central metal elements, such as Y, Sc, and In, with the only exception of Zr. Several descriptors affecting ionic conductivity of halide SEs have been identified: i) charge carrier concentration which is controlled by aliovalent substitution; ii) structural framework, such as trigonal, orthorhombic, and monoclinic structures; iii) structural disorder, such as disorder of Li^+ and central metal cation disorder and stacking faults. Meanwhile, the critical drawback of halide SEs, i.e., poor cathodic stability, prohibits their use for negative electrodes, such as Li metal. In this regard, all-solid-state batteries using hybrid SEs using halide and sulfide SEs together would be practically reasonable. However, their compatibility has not been extensively investigated yet.
In this presentation, we report on our recent results of our strategies to develop new halide SEs with improved ionic conductivities and electrochemical/chemical stability. Also, the results of all-solid-state batteries employing developed SEs are discussed.

Mapping and Modeling Physicochemical Fields in Solid-State Lithium Metal Batteries Shou-Hang Bo; Shanghai Jiao Tong University, China

The safety and energy density of solid-state batteries can be, in principle, substantially increased compared with conventional batteries. However, the use of solid-state electrolytes introduces pronounced complexities to the solid-state system because of the strong coupling between different physiochemical fields. This necessitates the development of experimental and theoretical methods to directly trace the evolution of electrochemical, stress, crack and thermal fields upon battery cycling, to fully understand the electrochemical processes. In this talk, I will discuss imaging tools that are developed in our group to track the electrochemical reaction fronts (i.e., electrochemical deposits of lithium metal), stress and crack evolution in 3D during processing and cycling of solid-state lithium metal batteries. We show that the crack formation and stress distribution in solid-state electrolytes are extremely sensitive to the preparation conditions, which, in turn, affect the electrochemical performance of batteries. Further, these imaging data can be combined with theoretical efforts to develop electromechanical and/or electrothermal models for solid-state lithium metal batteries. These works provide a strong basis to understand the strong coupling between different physiochemical fields, a prerequisite to fully unlock the potential of solid-state lithium metal batteries.

9:00 AM EN05.15.04
Investigating the Effects of Doping Layered Lithium Nickel Oxide Lavan Ganeshkumar; University College London, United Kingdom

Lithium-ion batteries have long been established as the leading technology for energy storage devices due to their high energy density and longevity 1. Common cathode materials for these batteries are layered oxides. LiCoO2 (LCO) is a popular layered oxide which is commonly used within the electronic

industry. Yet, due to increasing environmental impacts tied with the price of the cobalt, there has been a substantial push for cobalt-free cathode materials, especially for the automotive application 2. The isostructural compound LiNiO2 (LNO) has been identified as the ideal replacement for LCO. LNO, with more earth-abundant Ni sources, has the theoretical capacity and voltages comparable to LCO 1. However, the material cannot fully utilize its theoretical energy density due to its mechanical and thermodynamical instabilities. Recent work has demonstrated that substitution strategies can cater for the instabilities whilst also minimising the reduction in
capacity during battery cycling. Still, the underlying chemistry of the improved stabilities of the substituted LNO remain challenging to be elucidated, which has been hidden behind the false ground state structure of R-3m space group. Recently, owing to the Jahn-Teller (JT) distortion, LNO has been found to have the ground state structure with the P21/c space group 3,4,5. Density functional theory (DFT) calculation, with its ability to predict the ground state structures and charge compensation mechanisms, have been an effective
tool for investigating solid-state materials with dopants. In this study, we implement DFT in order to fully understand the doped structure with the aim to find a stable nickel-rich cathode with a high theoretical capacity. Using the JT distorted structure, intrinsic point defects have been investigated in these cathode materials. This reveals insight into the experimental observations for LNO and gives an understanding for the charge compensating mechanisms within the pristine system. In addition, by comparing the present results with previous studies, the study will reveal insight into the charge compensating mechanisms as has been established for the pristine system. Lastly, the study explores Mg and W as dopants for LNO due to their notable success established in previous experimental studies 6,7. In turn, this will explain the observations of improvements in stability upon addition of the dopants.

Sn-Substituted Sulfide Solid Electrolyte Prepared by Liquid-Phase Synthesis for All-Solid-State Batteries Jehoon Woo, Yong Bae Song, Yeji Choi, Jun Pyo Son, Jong Seok Kim and Yoon Seok Jung; Yonsei University, Korea (the Republic of)

Sulfide solid electrolytes (SEs) are widely regarded as one of the most promising candidates for practical all-solid-state batteries (ASSBs) owing to their high ionic conductivities and excellent deformability. However, sulfide SEs are vulnerable to moisture, resulting in the release of toxic H_2S gas and degradation in Li^+ conductivity when exposed to ambient air. To improve the moisture stability, various compositions have been explored, and their common preparation method has been solid-state synthesis. While liquid-phase synthesis has the potential advantage for mass production, the poor solubility of metal chalcogenides (e.g., SnS_2 and GeS_2) has restricted the available composition to only metal-free ones. Recently, our group developed amine-thiol chemistry enabling liquid-phase syntheses of metal-containing sulfide SEs.
In this presentation, we report Sn-substituted sulfide SEs derived via amine-thiol chemistry. The product SEs exhibit improved air-stability compared to conventional metal-free SEs. Mechanical properties of Sn-substituted sulfide SEs are also discussed. Finally, all-solid-state cell performances under practically meaningful conditions such as low pressures are presented.

Anodes Made of Multicoated Nano-Silicon and Graphene Nanoplatelets in Li-Ion Batteries Pin-Yi Zhao, Antonio R. Gonzalez, Bing Li, Yuhan Liu, Robert Palgrave and Kwang-Leong Choy; University College London, United Kingdom

Silicon anodes are regarded as a near-term practical application by virtue of their high theoretical specific capacity. Despite this, when high-capacity silicon anodes are cycled, they show poor electrical conductivity, considerable volume variation, and severe aggregation. In this study, multicoated anodes are fabricated based on the layered deposition of nano-silicon and graphene nanoplatelets. An innovative, simple, non-vacuum, and cost-effective aerosol-assisted chemical deposition (AACD) technique is designed to deposit a homogeneous composite coating. The multicoated anodes are processed with an organic solvent and deposited on the spacers as current collectors. A fundamental investigation is conducted on critical aspects such as the solvent and nano-silicon concentration. The gaps between the layers accommodate the volume expansion of silicon for superior cycle performance, while the plane of the layers promotes high-rate capability. After 500 discharge/charge cycles, the multicoated composite anode (with 10 wt.% silicon) demonstrates promising capacity retention of 85.8% in Li-ion batteries. The AACD technique combines the benefits of atmospheric pressure chemical vapour deposition and aerosol-assisted chemical vapour deposition, providing an appealing research setting for initial laboratory studies in rechargeable batteries. Furthermore, two ways for presenting cyclic discharge/charge patterns are proposed with generalised algorithms in linear algebra.

Li-Garnet Solid-State Batteries—Status, Challenges and Prospects Kostiantyn Kravchyk[1,2] and Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Solid-state Li-ion batteries based on Li-garnet $Li_7La_3Zr_2O_{12}$ (LLZO) electrolyte have seen rapid advances in recent years. These solid-state systems are poised to address the urgent need for safe, non-flammable, and temperature-tolerant energy storage batteries that concomitantly possess improved energy densities and the cycle life as compared to conventional liquid-electrolyte-based counterparts. In this presentation, we will review present research pursuits and discuss the limitations in the employment of LLZO solid-state electrolyte (SSE) for solid-state Li-ion batteries. Particular emphasis will be given to the discussion of pros and cons of current methodologies in the fabrication of solid-state cathodes, LLZO SSE, and Li metal anode layers.[1] Furthermore, we will discuss the contributions of the LLZO thickness, cathode areal capacity, and LLZO content in the solid-state cathode on the energy density of Li-garnet solid-state batteries, summarizing their required values for matching the energy densities of conventional Li-ion systems.[2], [3] Finally, we will highlight challenges that must be addressed in the move towards eventual commercialization of Li-garnet solid-state batteries.

9:40 AM EN05.15.09
Atomic-Scale Origin of the Low Grain-Boundary Resistance in Perovskite Solid Electrolyte $Li_{0.375}Sr_{0.4375}Ta_{0.75}Zr_{0.25}O_3$ Ji Qi and Shyue Ping Ong; University of California, San Diego, United States

Oxide solid electrolytes (OSEs) have the potential to achieve improved safety and energy density for lithium-ion batteries, but their high grain-boundary

(GB) resistance is a general bottleneck. In the most well studied perovskite OSE, $Li_{3x}La_{2/3-x}TiO_3$ (LLTO), the ionic conductivity of GBs is about three orders of magnitude lower than that of the bulk. In contrast, the related $Li_{0.375}Sr_{0.4375}Ta_{0.75}Zr_{0.25}O_3$ (LSTZ0.75) perovskite exhibits low GB resistance for reasons yet unknown. Here, we used an active learning moment tensor potential, to reveal the atomic scale structure and composition of LSTZ0.75 GBs. We found that Li depletion, which is a major reason for the low GB ionic conductivity of LLTO, is absent for the GBs of LSTZ0.75. Instead, the low GB resistivity of LSTZ0.75 is attributed to the formation of a nanoscale defective cubic perovskite interfacial structure that contained abundant vacancies, supported by electron energy loss spectroscopies. Our study provides new insights into the atomic scale mechanisms of low GB resistivity and shade light on using machine learning interatomic potentials to study complex GB structures in solid electrolyte materials.

Investigating Dry Room Compatibility of Sulfide Solid-State Electrolytes for Scalable Manufacturing Yu-Ting Chen[1], Maxwell A. T. Marple[2], Darren H. Tan[1], So-Yeon Ham[1], Baharak Sayahpour[1], Wei-Kang Li[1], Hedi Yang[1], Jeong Beom Lee[3], Hoe Jin Hah[3], Erik A. Wu[1], Jean-Marie Doux[1], Jihyun Jang[1], Phillip Ridley[1], Ashley Cronk[1], Grayson Deysher[1], Zheng Chen[1] and Y. Shirley Meng[4]; [1]University of California, San Diego, United States; [2]Lawrence Livermore National Laboratory, United States; [3]LG Energy Solution, Ltd., Korea (the Republic of); [4]University of Chicago, United States

ll-solid-state batteries (ASSBs) are viewed as promising next-generation energy storage devices, due to their enhanced safety by replacing organic liquid electrolytes with non-flammable solid-state electrolytes (SSEs). The high ionic conductivity and low Young's modulus of sulfide SSEs make them suitable candidates for commercial ASSBs. Nevertheless, sulfide SSEs are generally reported to be unstable in ambient air. Moreover, instead of gloveboxes used for laboratory scale studies, large scale production of batteries is usually conducted in dry rooms. Thus, this study aims to elucidate the chemical evolution of a sulfide electrolyte, Li_6PS_5Cl (LPSCl), during air exposure and to evaluate its dry room compatibility. When LPSCl is exposed to ambient air, hydrolysis, hydration, and carbonate formation can occur. Moreover, hydrolysis can lead to irreversible sulfur loss and therefore LPSCl cannot be fully recovered in the subsequent heat treatment. During heat treatment, exposed LPSCl undergoes dehydration, decomposition of carbonate species, and reformation of the LPSCl phase. Finally, LPSCl was found to exhibit good stability in a dry room environment and was subject to only minor conductivity loss due to carbonate formation. The dry room exposed LPSCl sample was tested in a $LiNi_{0.8}Co_{0.1}Mn_{0.1}O_2$ | LiIn half-cell, exhibiting no significant loss of electrochemical performance compared with the pristine LPSCl, proving it to be compatible with dry room manufacturing processes.

Evaluating the Auger Recombination Temperature Dependence in Crystalline Silicon and the Implication on the Device Efficiency Jorge F. Ochoa Bueno, Simone Bernardini and Mariana Bertoni; Arizona State University, United States

As the bulk quality and surface passivation of silicon devices improve, the intrinsic recombination processes become increasingly crucial to the performance of solar cells. With higher lifetimes, the operating maximum power point slides to higher injection levels, and the intrinsic Auger lifetime represents the next boundary to the overall device performance.
Recently, several authors have proposed revisions to the Auger charge carrier recombination parametrization based on reports of measured lifetimes exceeding previously accepted models. However, these revisions are restricted to room temperature, ignoring solar cell operational temperatures on the field.

We revisit the Auger regime by making the corrections proposed by Black and Niewelt framework and, through the thickness method, analyze the Auger temperature dependence. It is well known that Auger recombination cannot be measured directly; its contribution must therefore be separated from the total measured recombination. By varying the substrate thickness systematically, we experimentally determine the surface recombination, and the bulk lifetime is taken by subtracting the former from the measured effective lifetime. This procedure is conducted at different temperatures. We show that as the temperature increases, the bulk lifetimes significantly exceed those predicted by the recently revised Auger parametrization, which points out the inadequacy of the parameterization to satisfactorily describe the Auger lifetime temperature dependence. These results suggest a strong temperature dependence of the Auger recombination and the need for its characterization at the device operating conditions. The latter is of great importance for calculating the fundamental limiting power conversion efficiency.
In the present work, we experimentally evaluate the Auger lifetime in high-quality float-zone n-type silicon material across a range of temperatures from 300 to 500 K and carrier injection levels representative of the device operating at maximum power point and open-circuit conditions. The radiative recombination is calculated using the widely accepted current values, and by modeling the contributions from the Shockley-Read-Hall recombination, the Auger is separated from other bulk recombination mechanisms. We calculate an ambipolar Auger coefficient $C_{amb}=2.12 \times 10^{-30}$ cm^6s^{-1} in excellent agreement with the most up-to-date parametrization at room temperature. The Auger temperature-dependence experimentally observed can be explained following the quantum mechanical approach proposed by Hangleiter and Häcker. Their approach described the Auger recombination in silicon as enhanced by the presence of scattering and bound states, i.e., excitons, due to the Coulombic interaction among charge carriers. We propose that the enhancement factors g_{ech} and g_{ehh} exhibit an exponentially decrease with increasing temperature due to the increasing disturbance to the e-h bound states introduced by thermal agitation. Thus, the Auger recombination rate is expected to decrease exponentially with increasing temperature validating the Auger lifetime increment observed. Finally, we evaluate the impact of the experimental Auger temperature dependence on the limit imposed by the intrinsic lifetime on the implied voltage within the analyzed range of injection levels and temperatures and compare it to the results obtained by applying the recently adopted Auger parameterization.

3:45 PM *EN06.01.04
Hot-Wire Chemical Vapor Deposition Techniques for High Efficiency Silicon Heterojunction Solar Cells Kaining Ding; Forschungszentrum Jülich GmbH, Germany

In this contribution we will review the usage of hot-wire chemical vapor deposition (also called catalytic chemical vapor deposition) in crystalline silicon solar cell manufacturing and introduce new approaches how to use this technique to further improve the efficiency of high efficiency silicon heterojunction solar cells. Hot-wire chemical vapor deposition is a plasma-free chemical vapor deposition process, which differs from plasma-enhanced chemical vapor deposition, the current mainstream technology to grow silicon thin-films. This difference allows for a larger extend of decoupling of gas dissociation and film growth, which opens additional possibilities. For example, the deposition rate can be very high without the risk of plasma damage to the surface. Also, material compositions like highly stoichiometric nanocrystalline silicon carbide can be grown. In this contribution we will discuss the growth mechanisms, innovative processes, and industry application of hot-wire chemical vapor deposition.

Evaluation of PID Characteristics of Bifacial p-PERC Silicon Photovoltaic Modules by Encapsulant Types Jang Hongjun, Solhee Lee, Sang-Won Lee, Donghwan Kim, Yoonmook Kang and Hae-Seok Lee; Korea University, Korea (the Republic of)

As global warming is getting worse recently because of fossil fuel, renewable energy is getting much attention. Although there are many renewable energies like solar cell, wind power and hydropower, solar cell is becoming main energy source among renewable energy because of economical aspects. Among solar cells, bifacial solar cells composed of glass on both side can receive more light than monofacial solar cells. Therefore, bifacial solar cells are installed about 20GW, which is an increase of about 10 times from 2018. Bifacial p-passivated emitter and rear cell(p-PERC) solar cells are being recording high efficiency so it is mass-produced worldwidely. Solar cells are connected to form solar modules, and the modules are connected in series to form strings, and in this process, potential difference occurs between frames and solar cells. When potential difference occurs between the frame of the solar module and the solar cell, potential induced degradation (PID) occurs. If solar cells are (-) biased than frames, then alkaline ions in module glass(soda-lime glass) enter to solar cell, which causes large reduction in power of the solar modules. There are two main mechanisms of PID in p-PERC. First in front side, stacking faults formed and grown by Na^+ ions damage p-n junction of solar cell and result in leakage current and we call this as PID-shunting(PID-s). Second in rear side, Na^+ ions also move to rear side and reduce field effect passivation of AlO_X layer. We call this mechanism as PID-polarization(PID-p). Due to development of wafer process and other passivation skills PID-s is getting decreased, so PID-p in rear side is main cause of power loss. Exact mechanism of PID-p in bifacial p-PERC rear side is not proved yet, so we focused on the PID-p by analyzing change of charges like Na^+ ions. Currently, ethylene vinyl acetate(EVA) is mainly used as an encapsulant for a photovoltaic module because of economical reasons, but in the case of EVA, leakage current flows much due to low volume resistance. And because of high water transmissibility, more moisture moves to solar cells, resulting in more serious PID. Recently, polyolefin elastomer(POE) has been researched as a material that replaces EVA, and POE has high volume resistance, making it more efficient to prevent PID. PID is known to be serious with humid and high temperature conditions. Therefore we fabricated bifacial p-PERC modules with two types of encapsulant(EVA, POE) and applied 85°C/85%RH/1000V condition. After that, we analyzed degree of degradation of two types modules by utilizing Electroluminescence images (EL) and LIV(Light I-V).

EN06.02.02
Field-Induced Radial Junction for Dopant-Free Crystalline Silicon Solar Cells with an Efficiency of over 20% Deokjae Choi and Kwanyong Seo; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Radial junctions on crystalline silicon (c-Si) microwire structures considerably reduce the diffusion length of photo-induced minority carriers required for energy generation by decoupling light absorption and carrier separation in an orthogonal spatial direction. Hence, radial junctions mitigate the need for high-purity materials and thus reduce the fabrication cost of c-Si solar cells. In this study, the formation of dopant-free radial junctions from atomic layer deposition (ALD) of Al_2O_3 on an n-c-Si microwire surface is reported. ALD-Al_2O_3 generates a p^+ inversion layer, which eventually forms the radial junction on the n-c-Si surface. The width of the depletion region induced by the p^+ inversion layer is calculated from PC1D simulation as 900 nm. The

fabricated dopant-free radial junction c-Si solar cells exhibit a power conversion efficiency of 20.1%, which is higher than those of previously reported microwire-based radial junction solar cells. Notably, internal quantum efficiencies of over 90% were obtained in the 300–980 nm wavelength region, thereby verifying the successful formation of radial junctions.

EN06.02.04
A Study of Reflected Light Effect from Module Component with MATLAB Ji-Seong Hwang, Yoonmook Kang, Donghwan Kim and Hae-Seok Lee; Korea University, Korea (the Republic of)

The Paris climate agreement aims to keep the average global temperature rise below 2 °C, and strive to not exceed 1.5 °C. According to a report by the world meteorological organization(WMO), carbon dioxide concentrations reached new highs in 2021, and the global average annual temperature rise was about 1.11 °C (±0.13 °C). Intergovernmental panel on climate change (IPCC) has released its 6th report that forecast 1.5 degree rise between 2021 and 2040. In order to achieve the goal of reducing greenhouse gas emissions, solar energy industry should aim to grow rapidly.

In manufacturing process of photovoltaic module, it is important to reduce cell-to-module power loss(CTM loss). A simulation program Fraunhofer ISE, SmartCalc.Module is the only program to estimate CTM loss. However, this program showed a meaningful error when calculating a mini-module consisting of a single string.

In this research, we studied an effect of reflected light from the area containing non-active component like backsheet and string interconnector. We applied open source MATLAB codes to shingled solar modules that use electrical conductive adhesives to interconnect between cells.

EN06.02.05
Passivation and Carrier Lifetime of Ultra-Thin Film Silicon with Tandem Niobium Oxide and Attached Organosilane Emma J. Pellerin, Julia Martin, Ronald Grimm and Lyubov Titova; Worcester Polytechnic Institute, United States

Tandem junction solar cells with silicon and a dissimilar absorber material pose unique challenges for minimizing interfacial defects between those absorbers. Organic layers would enable flexible, soft, carrier-selective contacts, but silane attachment chemistry to silicon presents its own interfacial defects that must be minimized. A focus on silicon substrates in tandem with deposited niobium oxides, and silane-based organic layers has potential to minimize electronic defects and improve efficiencies. Here, atomic-layer deposition (ALD) deposited ultra-thin niobium oxide layers and wet-chemical processing yielded organosilane monolayers on silicon substrates. Photoelectron spectroscopy quantified surface coverages while microwave-based transient photoconductivity measurements established carrier recombination velocities for these surfaces. Ongoing studies are quantifying the resulting solar energy conversion of the resulting soft-interface tandem junction solar cells.

EN06.02.07
Energy Yield Comparison Between the Mono Facial Module and the Bi Facial Module at the Carport System During 4 Seasons Sungho Hwang[1], Woncheol Jeong[1], Hae-seok Lee[1], Dongchul Suh[2], Yoonmook Kang[1] and Yongseok Jun[1]; [1]Korea University, Korea (the Republic of); [2]Hoseo University, Korea (the Republic of)

Both Mono facial and bi facial modules have been major products in the current PV market. Recently, ITRPV predicts the bi facial module's market share will be over than 60% in 2023 because the bi facial module is well known for more power than mono facial module due to light absorption from both sides (not only from front side, but also from rear side). Many researches have shown the yield comparison for both products by simulation or field data from the utility system. In this paper, the yield data analysis for both products has been compared at the carport system in the climate over Korea peninsula during 1 year (4 seasons).
The cell structure is based on the PERC cells with the M4 size wafer. In case of bi facial cell, the rear metal line design is different with the mono facial cell in order to absorb the light from the rear side. Aluminum(Al) paste covers full area of the rear side in case of the mono facial cell and Al covers the part of the rear side with the finger design as like the front design at the bi facial cell. The dielectric structure of the bi facial cell is the same with the mono facial cell which is optimized for maximizing the absorption from the front side. The module BOM (Bill Of Material) of the bi facial module is different with that of the mono facial module, for example, the glass thickness is 3.2 mm for the mono facial module and two glasses with 2.0 mm thickness are used for the bifacial module. EVA thickness is also different. 400um thick EVA for the bi facial module and 500 um EVA for mono facial module are used. In case of the rear glass of the bifacial module, there is no white grid between cells. The average module powers at STC are 422.4 watt on mono facial module and 414.9 watt on bi facial module. Each 15 modules are installed for the each type on the side; thus the climate effect is same. The carport had 5 degrees for north direction and the albedo is Asphalt, but most of time, there are parked cars under the modules, which can bring different albedo.
The annual energy yield is 933.73 kWh/kWp on the mono facial module and 956.98 kWh/kWp on the bi facial module. The bifacial module shows higher energy yield by 23.25 kWh/kWp. All months do not show same phenomenon. For example, May and June data show higher yield value by around 6 kWh/kWp because the large irradiance value on the May and June brings more light absorption from the rear side. From the July, the irradiance value begins to decrease and the temperature shows the highest during 1 year in Korea peninsula climate. At this condition, the delta of July shows decreasing trend. This trend continues up to the Dec(Sprint to Fal). From Jan to March (winter season), the delta of energy yield is almost similar or even minus, which means the yield of the mono facial module shows higher value.. Only 3 months(winter) shows this trend.
Most the dominant parameter for the delta value is the irradiance value at this carport system. The energy yields as the absolute value for both modules show lower value compared with the published values respectively because the Albedo value is low due to the carport structure for the bifacial module and the direction of the carport is to the north for both modules, thus all modules receive relatively lower irradiance. In case of the bifacial module, the delta value of the energy yield between both types is less than the expectation because some parameters such as lower bi-facility value (68.2%) are lower on the bifacial module because both cell types are optimized for absorbing the front light.

EN06.02.08
Effective Near-Infrared Light Management in Silicon Heterojunction Solar Cells for Perovskite/Silicon Tandem Solar Cell Application Yoshio Ohshita[1], Hyunju Lee[2,3] and Atsushi Ogura[2,3]; [1]Toyota Technological Institute, Japan; [2]Meiji Renewable Energy Laboratory, Japan; [3]Meiji University, Japan

Perovskite/silicon tandem solar cells are intensively being investigated as a promising candidate for next generation solar cells combining low costs and high efficiency. Currently, the silicon heterojunction (SHJ) bottom cell technology, which provides high open-circuit voltage values of up to 750 mV, dominates in perovskite/silicon tandem research, and also the latest perovskite/silicon tandem world records are based on SHJ bottom cells [1]. Despite this exciting performance, the tandem solar cell was still limited not only by a relatively low top cell voltage output but also by the bottom-cell photocurrent. For instance, the total photocurrent density of the world record perovskite/silicon tandem solar cell was only 39.6 mA cm^{-2} [1]. For comparison, 42.7 $mAcm^{-2}$ were reached in the world record SHJ cell [2], which is very close to the theoretical maximum for silicon of about 43.3 $mAcm^{-2}$ [3]. An important optical loss mechanism in this tandem cell, in comparison to an optimized single-junction silicon cell, is the increased reflection and reduced absorption in

the near infrared (NIR) part of the spectrum, hence reduced photocurrent in the silicon bottom cell. In particular, on the rear side of SHJ solar cells, an unoptimized transparent conducting oxide (TCO)/metal reflector is the origin of significant losses in the NIR part of the spectrum. These losses come from plasmonic absorption at the TCO/metal interface and from free carrier absorption in the TCO [4,5]. Therefore, the NIR light management becomes increasingly important as short-circuit current in the NIR region has to be incereased owing to the increasing interest of using SHJ solar cells as bottom cells in perovskite/silicon tandem solar cells. This contribution demonstrates an improved NIR response of the tungsten-doped indium oxide (IWO)/Ag rear contact in rear-junction SHJ solar cells. The free-carrier concentration and the thickness of the rear IWO layer are optimized in order to minimize the free-carrier and the plasmonic absorption losses without detrimentally affecting the selectivity and the electrical transport properties of SHJ solar cells. In detail, the NIR reflectance of IWO/Ag rear contacts deposited on random pyramid textured silicon wafers can be enhanced by increasing the thickness of IWO layers because of reduced plasmonic absorption at a IWO/Ag interface by increasing the thickness of IWO layers. In addition, 160-nm-thick IWO layers fabricated with an O_2-rich O_2/Ar process gas during remote plasma deposition of the IWO layers, demonstrate the largely reduced free-carrier and plasmonic absorption and the enhanced NIR reflectance of IWO/Ag rear contacts. Furthermore, measured SHJ solar cell parameters such as open-circuit voltage, short-circuit current and fill factor, are shown to be impacted by free-carrier concentration in IWO layers within the investigated ranges. As a result of these optimizations, a significant reduction of the parasitic absorption loss in the NIR part of the spectrum is obtained, leading to a champion SHJ solar cell with a short-circuit current density of up to 40.8 mA/cm^2 and an efficiency of 22.4%. This work was supported by NEDO.

8:30 AM *EN06.03.01
Performance and Degradation in Silicon PV Systems Under Outdoor Conditions in Relation to Reliability Aspects of Silicon PV Modules Angèle Reinders[1,2]; [1]Eindhoven University of Technology, Netherlands; [2]University of Twente, Netherlands

The degradation of silicon photovoltaic (PV) modules is one of the key factors to reduce the cost of PV electricity produced by increasing the operational lifetime of PV systems installed in outdoor conditions. To capture degradation in the field, an performance analysis has been executed of monitoring data of over 8400 PV systems. These PV plants are small residential systems with silicon PV modules with a median installed capacity of 6 kWp, primarily installed in Europe, with an average lifetime of 30.5 months. The monitoring data have been stored in the Pearl PV database as time series with 10 min resolution ranging from one to four years from 2010 to 2016 also covering the following metadata: installed capacity, latitude, longitude, azimuth, and tilt angle of the PV modules. ERA5 reanalysis data are used as irradiance data. From the analysis it is found that the annual mean performance ratio across all systems was 76.7 %; and the average yield is 954.9 kWh/kWp per year [1]. On the basis of an analysis of monitoring data, average performance losses between 0.74 %/year and 0.86 %/year were calculated depending on the method used.
To reduce these degradation rates, it is imperative to know the degradation and failure phenomena. Hence, in this presentation an overview is given of the state-of-the-art knowledge on the reliability of silicon PV modules [2]. This overview consists of three parts: firstly, a brief contextual summary about reliability metrics and how reliability is measured. Secondly, a summary of the main stress factors and how they influence module degradation. Finally, a detailed review of degradation and failure modes is presented, which has been partitioned by the individual components within a silicon PV module. This connects the degradation phenomena to the performance of installed PV systems.
From this perspective and through extensive testing and failure analysis, researchers in the field of silicon for photovoltaics could investigate silicon materials in order to reduce stressors and their impact on the long term stability of silicon PV modules installed in the field.

A Novel Pixelation Approach to Integrate PV for Urban Architecture Conservation Gavin P. Raharjo, Min H. Saw, Shin W. Leow and Mauro Pravettoni; National University of Singapore, Singapore

Conservation of heritage buildings in high density urban context such as Singapore has shifted its paradigm from purely physical preservation to making them functionally relevant for the age through constant redevelopment and repurposing. This opens opportunity for the adoption of modern and innovative technological solutions, such as building-integrated photovoltaics (BIPV), to be a novel approach to value-add these living artefacts; transforming them from energy consumer to clean energy provider. However, integration of standard photovoltaic (PV) module is still deemed inappropriate when it comes to respecting the aesthetics of these conserved buildings, yet it is necessary to populate as much surface as possible to meet the energy demand. Without a

better solution in terms of aesthetics and colour, PV integration on conserved buildings, and even modern structures are limited to the areas out of the public eye. Colourful PV panels for better aesthetic integration are becoming more prevalent. However, it comes with a compromise on PV performance: the ink and frit pigments will absorb and reflect the solar spectrum in particular wavelengths to achieve the desired colour. The light transmittance differs for different colours, and this could cause two issues: i) mismatch losses and ii) potential formation of hot-spots during operation of the PV module. In view of that, in our previous work, we have developed two novel design principles to mitigate mismatch losses and the risk of hot-spot formation in colourful PV modules. The first principle applies a repetitive design across the PV module to achieve uniform cell to cell shading. Secondly, we have studied extensively the relationship between colours, printing parameters and transmittance. By choosing the appropriate colour combinations, as well as printing parameters (e.g. ink thickness) for each colour, different colour areas would have the same amount of transmittance, thus mitigating hot-spots. This lifts the constraints of using repetitive patterns and allows for higher design flexibilities. In this work, the design principle based on colour science is further synthesized into two "pixelation-based" design schemes: (1) Stippling effect: contrasting color tones (eg. dark blue and white) are designed to produce the same level of irradiance transmission under AM 1.5G spectrum. Gradations of light and shade can then be produced by applying the stippling technique to produce an image, while maintaining uniform irradiance on the underlying PV cells.; and (2) Pointillism: a progression of scheme (1), color variation is achieved by extending the equivalent light transmission principle to the design of pixels containing multiple colors. Custom algorithm translating generic raster images to fit this pixel design scheme is also developed. These "pixelation-based" design schemes offer two-fold benefits: (1) allows higher light transmittance to the solar cells and hence improve the electrical efficiency of colourful PV modules; and (2) allows for more flexible image translation for a harmonious BIPV integration on the façade to support urban conservation effort.

Terawatt Scale Sustainability with Silicon PV Silvana Ovaitt; National Renewable Energy Laboratory, United States

We have very ambitious goals and need for decarbonization at the US and World level, which will drive a fast growth in Solar PV manufacturing and deployment. In this talk I'll cover some priorities to de-risk this energy transition, based on module reliability and sustainable materials and energy considerations through the lifetime of solar PV modules. Circular economy is an important concept to start implementing as an industry; some key findings are the importance of striving for long lifetimes, and prioritizing circularity paths tailored for the PV community.

Will Pinholes for SiO_x/poly-Si Passivating Contacts Enhance the Passivation Quality? Guangtao Yang, Remon Gram, Paul Procel, Can Han, Zhirong Yao, Yifeng Zhao, Luana Mazzarella, Miroslav Zeman and Olindo Isabella; Delft University of Technology, Netherlands

Poly-Si carrier-selective passivating contacts for c-Si solar cells provide outstanding passivation quality and carrier selectivity as demonstrated in many high-efficiency solar cells architectures [1-12]. Their unique structure consists of two layers. An ultra-thin SiO_x layer chemically passivates the c-Si surface and builds up a potential barrier for the carriers' transport through it [13]. Then, a heavily doped poly-Si layer sits on top of the ultra-thin SiO_x layer. Owing to an optimized doping level, higher within the poly-Si layer and the c-Si surface than in the c-Si bulk, an electrical field is built up at the c-Si interface, enabling field effect passivation and carrier selectivity. The optimization of the doping tail inside the c-Si surface induces an efficient separation of carriers inside the c-Si bulk before they reach the c-Si surface where the defect density, D_{it}, is high. Practically, the doping tail is affected by the thermal diffusion budget (TB) [14] and the properties of the ultra-thin SiO_x layer [15]. However, when annealed at high temperature, the ultra-thin SiO_x layer can be locally broken to form pinholes, which will affect the doping tail and the D_{it} at the c-Si surface [13]. Consequently, the formation of pinholes will influence the passivation quality of the poly-Si passivating contacts. In poly-Si processes one thermal process is conventionally used to activate/diffuse the dopants and to form pinholes in SiO_x, if any. This makes it difficult to study the effect of the SiO_x pinhole formation on the passivation quality. In order to investigate this topic, one needs to decouple these steps.
In this contribution, we effectively decoupled the process of forming pinholes from dopants diffusion by means of a two-step annealing process during the fabrication of our ion-implanted poly-Si passivating contacts. A pre-annealing step before ion-implantation is used to form the pinholes in the SiO_x layer. A second post-annealing step with different TB is used to activate the ion-implanted doping species and enable their diffusion. With a selective etching process based on TMAH [13,16], we monitored the density of the formed pinholes in the pre-annealing step. This enabled us to evaluate the influence of the presence of pinholes and the TB of dopants on the passivation quality of poly-Si passivating contacts.
It is found that, for both n^+ and p^+ poly-Si samples, the existence of pinholes can enhance their passivation quality, as long as the pinhole density and the post-annealing TB are not too high (~$1x10^7$ cm^{-2} and ~$2x10^{12}$ cm^2, respectively). Also, we found that the sensitivity of passivation quality on the pinhole density for n^+ poly-Si samples is much higher than that for p^+ poly-Si samples. The enhanced passivation quality is due to the strengthening of the electrical field passivation, owning to the local diffusion of dopants through the pinholes.

Silicon Microwire Arrays with Nanoscale Spacing for Radial Junction c-Si Solar Cells with an Efficiency of 20.5% Namwoo Kim[1], Deokjae Choi[1], Hyungwoo Kim[1], Han-Don Um[2] and Kwanyong Seo[1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Kangwon National University, Korea (the Republic of)

Structural optimization of microwire arrays is important for the successful demonstration of the practical feasibility of radial junction crystalline silicon (c-Si) solar cells. In this study, we investigated an optimized design of tapered microwire (TMW) arrays to maximize the light absorption of c-Si solar cells, while minimizing the surface recombination, for simultaneously improving the open-circuit voltage and short-circuit current density (J_{sc}). Finite-difference time-domain simulations confirmed that controlling the spacing between the TMWs at the nanometer scale is more effective for increasing the light absorption than increasing the TMW length. The photogenerated current of a c-Si TMW array with a 200 nm spacing was calculated to be 42.90 mA/cm^2, which is close to the theoretical limit of 43.37 mA/cm^2 in the 300–1100 nm wavelength range. To experimentally demonstrate the TMW arrays with a nanometer-scale spacing of 200 nm, which cannot be realized by conventional photolithography, we utilized a soft lithography method based on polystyrene beads for patterning a c-Si wafer. The solar cells based on optimized TMW arrays exhibited a J_{sc} of 42.5 mA/cm^2 and power conversion efficiency of 20.5%, which exceed those of the previously reported microwire-based radial junction solar cells.

11:00 AM EN06.04.03
Enhancement of Light Absorption in Transparent Crystalline Silicon Solar Cells Using Light-Harvesting Film Kangmin Lee, Jeonghwan Park and Kwanyong Seo; UNIST, Korea (the Republic of)

A light-harvesting film is considered as a means to improve the power conversion efficiency (PCE) of solar cells. However, when a light-harvesting film is applied to transparent solar cells, it is difficult to maintain the transparency of transparent solar cells due to the high haze ratio of the film (>95%). In this study, we apply a light-harvesting film onto the selective area, which is the light absorption region of the transparent *c*-Si solar cells. As a result, the transparent *c*-Si solar cells with light-harvesting film exhibited a current density (J_{SC}) increase of 2.6 mA/cm^2 compared with the transparent *c*-Si solar cells without a light-harvesting film. Therefore, the best device showed a PCE of 15.8% (J_{SC} = 31.7 mA/cm^2, open-circuit voltage (V_{OC}) = 638 mV, and fill factor (*FF*) = 78.3%) at an average visible transmittance of 20%, while maintaining a low haze ratio (0.95%). Furthermore, the transparent *c*-Si solar cells with the light-harvesting film have the advantage of minimizing the PCE degradation depending on the angle of light incidence. The transparent *c*-Si solar cells with light-harvesting film change the J_{SC} are under 4% for incident angles below approximately 50°, whereas that of the reference cells (conventional planar *c*-Si solar cells) loses over 30% in the same angle range. Hence, the proposed transparent *c*-Si solar cells present a unique opportunity to develop next-generation transparent solar cells, which would satisfy high efficiency and minimize PCE degradation according to the angle of light incidence.

11:15 AM EN06.04.04
25 cm^2-Sized Glass-Like Transparent Crystalline Silicon Solar Cells with an Efficiency of 14.5% Jeonghwan Park, Kangmin Lee and Kwanyong Seo; UNIST, Korea (the Republic of)

Forming light-transmitting structures on c-Si photovoltaics to transmit visible light without wavelength dependency is a promising strategy to realize neutral-color transparent c-Si photovoltaics (c-Si TPVs). However, dry etching, which is used to form a light-transmitting structure on c-Si, inevitably causes nanoscale surface damages such as scallops and plasma-induced damage in c-Si. This aggravates carrier recombination, which decreases the power conversion efficiency (PCE) of c-Si TPVs. Here, we propose an effective chemical treatment method for removing nanoscale surface damage from c-Si microholes. A large-sized neutral-color c-Si TPV after the chemical treatment exhibited a high PCE of 14.5% at a transmittance of 20%. The chemical treatment also enabled systematic control of the hole size (167 nm/sec), and thus, the transmittance was easily tuned from 10% to 70%. Notably, the proposed chemical treatment satisfies the three development factors of 1) high PCE, 2) scaling up, and 3) easy light transmittance tuning of c-Si TPVs.

11:30 AM EN06.04.05
Utilizing Three Terminal IBC-Based Si as a Platform to Study the Durability of Photoelectrodes for Solar Fuel Production Darci Collins[1,2], Nathan T. Nesbitt[1], Daniel Tune[3], Valentin D. Mihailetchi[3] and Emily Warren[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States; [3]International Solar Energy Research Center (ISC) Konstanz, Germany

Three terminal (3T) Si solar cells based on interdigitated back contact (IBC) structures are growing in popularity for the fabrication of tandem solar cells.[1] 3T devices also have potential application in photoelectrochemical fuel-forming applications. The vast majority of photoelectrochemical devices are based on two terminal (2T) semiconductor electrodes. Under illumination, these devices can drive fuel-forming electrochemical reactions coupled to an appropriate catalyst (e.g., the hydrogen evolution reaction or CO_2 reduction). While these devices are still at early stages of research, eventually they will need to operate for long periods of time (years) under diurnal illumination. The operation of photoelectrodes in dark or under diurnal cycling has only received a limited amount of research focus, but may present a problem, as many p-type semiconductor materials and solar cells used as photocathodes oxidize or corrode when not "protected" by the cathodic current present under illumination.[2] Generally, it is assumed that photocathode devices will sit at open circuit (not passing any current) when not illuminated, but this does not allow the same cathodic protection provided by illumination. Providing cathodic protection to the electrode surface can improve the long-term durability of fuel-forming photocathodes. However, in the dark, 2T p-n junction devices cannot pass appreciable amounts of current in the same direction without going into reverse bias or breakdown.

Using 3T devices as photocathodes can potentially overcome some of these challenges, by providing an alternative pathway to pass current to the electrode surface. We are studying the benefits that a three-terminal (3T) photoabsorber structure can provide for the stability to diurnal cycling and selectivity of solar-driven CO_2R. Using a 3T nuIBC structure (an n-type IBC cell with a conductive n-type front contact fabricated at ISC Konstanz)[3] we can operate the device as a standard 2T photocathode when connecting the p^+ back contact (R) to drive electrochemistry at the front of the cell (F). Additionally, we can also connect the n^+ back contact (Z) to drive electrochemistry in the dark without needing to drive current backward through the p-n junction. In this talk, will discuss the electrochemical characterization of 3T Si IBC devices for electrochemical fuel production. We show the performance of these 3T devices in both a standard photovoltaic configuration and as a 3T photocathode for both regenerative and fuel forming reactions. We will show preliminary stability data for these devices and discuss the potential for using a 3T structure for active repair of a photoelectrochemical system.

Interconnection Configurations for Silicon-Based Hybrid Tandem Photovoltaics Kirstin M. Alberi; National Renewable Energy Laboratory, United States

Hybrid tandem solar cells, in which two different photovoltaic absorbers are combined, are increasingly considered as a viable option for extending the efficiency of single junction Si solar cells. Silicon is a natural choice for the bottom sub-cell due to its near-ideal bandgap energy for high tandem power conversion efficiency and its compatibility with both monolithic and mechanically stacked integration approaches. One important yet open design consideration is how the top and bottom sub-cells are connected. Two-terminal, three-terminal and four-terminal interconnection schemes are all options at the cell level. The choice will be dictated in part by the specific top sub-cell absorber material, the ease of fabricating a tunnel junction with the bottom Si sub-cell, and the preferred or established top sub-cell manufacturing methods that are already in place. This talk will cover these interconnection approaches, including voltage matching options at the module level, their benefits and drawbacks, and specific challenges of implementing them with different top sub-cell technologies. Future prospects and near-term research needs will also be discussed.

2:00 PM EN06.05.02
Potential of Si Tandem Solar Cells for PV-Powered Vehicle Applications Masafumi Yamaguchi, Kyotaro Nakamura, Ryo Ozaki, Nobuaki Kojima and Yoshio Ohshita; Toyota Technological Institute, Japan

PV-powered vehicle applications are very attractive for reducing CO_2 emission and creation of new market [1]. Development of high-efficiency (> 30%) and low-cost solar cell modules is very important. Although Toyota Prius and Nissan eNV 200 demonstration cars installed with Sharp's high-efficiency III-V 3-junction solar cell modules with an efficiency of more than 30% have demonstrated longer driving range of 26km/day average compared to 16km/day average for Sono Motors Sion installed with Si back contact solar cell modules with an efficiency of 21.5%, cost reduction of MJ solar cells is necessary for PV-powered vehicle applications. Development of Si tandem solar cells [2] is very promising for cost reduction.
This paper compares analytical results for PV-powered installed with various solar cell modules and actual driving distance of the Toyota Prius demonstration car and Sono Motors Sion. In addition, analytical results for driving distance of PV-powered vehicles installed with various candidate Si tandem solar cells and multi-junction solar cells are shown in this paper.
Solar cell module efficiency impact on driving distance of PV-powered vehicles was calculated. In the calculations, 4kWh/m^2/day as solar irradiance, 3m^2 as module installation area and the charging system efficiency of 73.9% composing of cell temperature correction, maximum power point tracking, DC/DC conversion, and DC charging were assumed. Table 1 shows estimated potential and actual data for driving distance DD of vehicles powered by current solar cell modules. Good agreement between calculated and actual data shows validity of analytical procedure as shown Table 1. Table 2 shows estimated potential of driving distance DD of vehicles powered by candidate Si tandem solar cells including our results and multi-junction solar cells. The III-V 3-junction and Si 3-junction tandem solar cell modules with an efficiency of more than 35% are shown to have potential of driving distance of more than 30 km/day average and more than 50 km/day on a clear day as shown in Table 2.

Table 1. Estimated potential and actual data for driving distance DD of vehicles powered by current solar cell modules

Modules	Efficiency (%)	Estimated DD (km/day)	Actual DD(km/day)
III-V 3-J	32.65	27.0	
III-V 3-J (Prius)	30.9	25.6	25.6
GaAs	25.1	20.8	
Si	24.4	20.2	
Si (Sion)	20	16.6	16
CIGS	19.2	15.9	
Perovskite	17.9	14.8	

Table 2. Estimated potential of driving distance DD of vehicles powered by candidate solar cells

Solar cells	Efficiency (%)	Estimated DD (km/day)
III-V 3-J	39.5	32.8
III-V/Si 3-J	35.9	29.8
III-V/Si 3-J (our study)	34.0	28,2
III-V/Si 2-J	32.8	27.9
III-V/CiGS 3-J	29.3	24.3
Perovskite/Si 2-J	29.8	24.7
Perovskite/perovskite 2-J	28.0	23.2
Perovskite/CIGS 2-J	24.2	20.1

Several losses such as non-radiative recombination, optical and resistance in Si tandem solar cells are discussed in this paper.

Novel Technique to Characterize Minority and Majority Carrier Contact Resistivity Dirk Steyn[1], Matthew Hartenstein[1], William Nemeth[2], San Theingi[2], David L. Young[2], Sumit Agarwal[1] and Pauls Stradins[2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory,

United States

In this work we report a novel method of measuring both majority and minority carrier contact resistivities. In the pursuit of highly efficient silicon solar cells, a great deal of research has been done on passivating and selective contacts [1-3]. The contacts of these cell must be well passivating and conductive, and the accurate characterization of contacts is of great importance to silicon PV. The transfer length method (TLM) is widely used to characterize the contact resistivity of PV devices. However, TLM can only be used to measure the majority carrier contact resistivity. To measure the minority carrier contact resistivity with TLM, a contact must be created on the same type of wafer as the minority carrier contact to avoid blocking diode effects. It is not clear that this contact will have the exact same properties as a contact on the original wafer. Our technique can be used to measure the resistance of electrons and holes separately on the same type of wafer used in the final cell, allowing for the accurate characterization of both contacts.

In our method, a thin tunneling oxide is grown on n-Cz silicon. Then heavily doped polysilicon of the same type, either n or p-type, is deposited on both sides of the device to create carrier selective contacts (either electron or hole selecting). The devices have a metal grid on the front, and a full back metal contact (the typical metallization scheme of a bipolar solar cell device). By increasing illumination, the apparent resistance (measured between the front and back metal) of the bulk silicon substrate will approach zero due to increasing wafer conductivity from the high injection of photocarriers, and only the resistance of the contacts will be detected. Under illumination, the effect of the blocking diode is decreased due to increased minority carrier density and a weaker field in the diode. Since the contacts are carrier selective, practically only electrons or holes will conduct through the contact, depending on the contact used, and allows for the measurement of both types of contacts as they would behave in practice. We can then plot the total resistance measured against the inverse of illumination. This gives a very distinct plot that approaches the total contact resistance at the y-intercept. The value of contact resistivity measured in this way has been verified with TLM measurements for n-type contacts on an n-type wafer. We have also characterized the resistivity of p-type contacts on an n-Cz wafer. Unlike the TLM method, we can observe the effects of spreading resistance caused by contact geometry without any additional calculations. This is seen as the total resistance levels out as the inverse of illumination approaches infinity. While this value should ideally correspond to the bulk resistance of the underlying wafer, we observe it to be higher than expected, likely due to spreading resistance between the two contacts.

This technique can give more accurate insight into the causes behind problematic series resistance than TLM and can be used to optimize contact design as well as contact geometry. In addition to the work mentioned above, we will present extensive simulations of this measurement done in Quokka 3, show how this can be used to characterize full devices, and demonstrate how this technique can be used in calculating contact selectivity [1]. We suspect that this method can be used to expand the definition of contact selectivity and will present our investigation of material property effects on selectivity.

Electrically Detected Magnetic Resonance (EDMR) Spectroscopic Determination of Bulk Defects in *n*-type Cz Silicon Chirag M. Mule[1,2], Vincenzo LaSalvia[1], William Nemeth[1], Fedor Sharov[3], Elijah Allridge[3], Harvey Guthrey[1], Patrick Lenahan[3], Sumit Agarwal[2] and Pauls Stradins[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States; [3]The Pennsylvania State University, United States

We have produced minicells that exactly replicate the performance of the large area poly-Si/SiO_2 passivated contact cells and measure the Electrically Detected Magnetic Resonance spectroscopic (EDMR) response of the bulk defects in the *n*-type Cz silicon wafer on them. High efficiency *n*-type monocrystalline silicon cells with passivated contacts are rapidly gaining global PV market share and are expected to dominate by 2031 [1]. In the current high-performance *n*Cz wafers with lifetimes ~ 20 ms, as little as 10^{10} cm^{-3} defects can degrade the cell efficiencies. Electron Paramagnetic Resonance (EPR) can be used for sensitive detection of the bulk defects however the detection limit for EPR is ~10^{11} cm^{-3}. The EDMR can be performed directly on the devices, structures with passivated contacts, fragments of a module, is > 100x more sensitive than the EPR, and senses only the current/performance affecting defects in a cell. The high sensitivity allows EDMR measurements at the room temperatures, avoiding expensive cryogenic equipment. Thus, EDMR has a high potential for the application to advance the Si PV industry.
The high lifetime *n*Cz wafers are prone to various Process-Induced Degradation defects (PIDs) due to thermal processing – oxygen precipitates, vacancies, voids, interstitials etc. We characterize them using EDMR spectroscopy with our unique minicell design and the EDMR at the Penn State University. We use the specific thermal budgets to induce bulk defects: 1) Boron diffusion and deep drive-in (~980ºC 10 hr) to induce oxygen precipitates and 2) Tabula Rasa (10 min. 1100ºC) in N_2 to induce vacancies in *n*Cz minicell bulk and study them by the EDMR, correlating with the performance loss of the PID-degraded minicells. In the only attempt from the literature by Lang et al [2] the bulk signal intensities are weak, and it is uncertain whether the Pb_0 & Pb_1 signal is coming from the surface or the bulk.
We laser-scribe the *n*Cz Si to 1 mm x 1 cm minicell precursors, which undergo saw damage removal and wet-chemical cleaning. Further, we thermally grow ~1.5 nm tunneling SiO_x and then deposit a-Si: H. We add the doped n^+ and p^+ layers through mechanical masks with 10-micron precision and anneal at 850ºC to drive the dopants into the a-Si:H layer and crystallize to poly-Si layers. This is followed by Al_2O_3 deposition and Forming Gas Anneal. the minicells are finally metallized with TiAg pads and grids and inserted into the EDMR resonant cavity. The cell process mimics our large area passivated contact cell.
The EDMR were performed both using radiofrequency/low field (prototype of Penn State startup Blue Spin desktop spectrometer) and high field, microwave X-band Bruker system adapted for EDMR. These initial data were taken at room temperature, showed a signal at *g*-value of 2.006 which corresponds to the Si-dangling bond, likely from the Si wafer surface. This demonstrates the viability of the minicell design, cell processing and the EDMR capabilities.

Architectures for High-Efficiency Crystalline Silicon Solar Cells Miroslav Zeman, Yifeng Zhao, Manvika Singh, Luana Mazzarella, Arthur Weeber and Olindo Isabella; Delft University of Technology, Netherlands

At present, crystalline silicon (c-Si) based solar cells dominate the PV market. There is a continuous effort to improve the conversion efficiency of c-Si solar cells by developing and optimizing different c-Si solar cell architectures.

Front/back-contacted silicon heterojunction (FBC-SHJ) solar cells have exhibited efficiencies well above 26% [1]. To achieve such high efficiencies, the material quality of (*i*)a-Si:H passivating layer is critical, ensuring excellent surface passivation and facilitating charge carrier collections in SHJ solar cells. Fourier-transform infrared spectroscopy (FTIR) was used to study the quality of (*i*)a-Si:H layers deposited in the range from 140°C to 200°C. FTIR results showed that (*i*)a-Si:H films were less dense when deposited at lower temperatures, thus hindering their surface passivation capabilities. However, with additional hydrogen plasma treatments (HPTs), the (*i*)a-Si:H layers deposited at lower temperatures the passivation qualities was significantly improved in contrast to their counterparts deposited at higher temperatures. Further, for monofacial solar cells with screen-printed Ag contacts we observed highest V_{OC}s for cells with (*i*)a-Si:H deposited at the lowest temperature (140°C), however, the related *FF*s are poorer as compared to their higher temperature counterparts. The optimum trade-off between V_{OC} and *FF* for the SHJ cells was found with temperatures ranging from 160°C to 180°C. Based on our FTIR study, this trade-off reveals two critical requirements for optimizing the (*i*)a-Si:H layers in high-efficiency SHJ solar cells: (i) excellent surface passivation quality to reduce losses induced by interface recombinations and (ii) less-defective (*i*)a-Si:H bulk to not disrupt the charge carrier collections.

Moreover, reducing indium (In) and silver (Ag) consumption is a crucial challenge for scaling up SHJ solar cell technology towards terawatt level implementation. We performed optical modelling and electrical studies to optimize TCO thicknesses [2]. Instead of standardly used 75-nm-thick tin-doped indium oxide (ITO) on the illumination side, we applied 50-nm-thick tungsten-doped indium oxide (IWO) plus 100-nm-thick SiO_x forming a double-layer antireflection coating (DLARC), which concurrently reduces the thickness of the TCO and improves the optical response of the monofacial SHJ solar cells. To reduce Ag use, we utilized electroplated Cu for forming the front metal grid [3]. The best monofacial SHJ solar cell fabricated in this study achieved V_{OC} of 726.0 mV, J_{SC} of 39.97 mA/cm^2, *FF* of 83.3% and efficiency of 24.18%. We demonstrated Cu-plated bifacial SHJ solar cells with DLARCs exhibiting efficiencies > 22% (*n*-side illumination) by applying 25-nm-thick IWO and ITO for *n*- and *p*- contact, respectively [2]. This represents a 78% reduction in TCO use as compared to our lab-standard 75 nm plus 150 nm TCO utilization in monofacial SHJ solar cells.

High-thermal budget carrier selective passivating contacts (CSPCs) based on poly-SiO_x [4],[5],[6], are another excellent candidates for high-efficiency c-Si solar cells. We obtained 690 mV i-V_{oc} on poly-SiO_x / textured c-Si surfaces using the 2-step annealing approach. High passivation quality was achieved for both p and n type poly-SiOx CSPCs. With the developed poly-SiOx CSPCs, we fabricated 4-cm^2 large, screen-printed single side textured (SST) single junction c-Si solar cell with a certified efficiency of 20.47%. Likewise, a certified efficiency of 18.57% was obtained for a double side textured (DST) cell with poly-SiOx CSPC.

This work was supported by Dutch NWO Joint Solar Program III.

The Critical Role of TCO Deposition on Solar Cell Performance Monica Morales-Masis; University of Twente, Netherlands

Transparent Conducting Oxides (TCOs) are widely accepted transparent electrodes in a variety of solar cells employing passivating and selective contacts, such as silicon heterojunction (SHJ) solar cells and thin film technologies such as CIGS and perovskite solar cells. Among all possible ways to deposit TCOs, sputter deposition is the most employed technology, both in academia and industry. However, the high kinetic energies of the arriving species during sputtering may damage sensitive functional layers beneath, affecting interface formation, passivation and ultimately device performance. This has motivated the search for alternative sputter system designs or deposition techniques, allowing low damage growth of TCOs on the sensitive layers. Here we explore pulsed laser deposition (PLD) as an alternative low-damage physical vapor deposition technique. PLD is operated at high deposition pressures, promoting thermalization of particles, and therefore reducing the kinetic energy of ablated species. Broadband transparent and high mobility TCOs were developed using wafer-scale (4-inch) PLD with deposition rates on par with lab-scale RF sputtering[1]. To investigate the effects of the deposition pressure, we developed ITO with identical sheet resistance (50 Ohm/sq) at deposition pressures three orders of magnitude apart, and applied them as a front TCO in SHJ cells and as rear-contact in semitransparent perovskite cells. The role of the deposition pressure on TCO properties, absorber carrier lifetime and its link to SHJ and perovskite solar cell parameters such as series resistance and fill factor (FF) will be discussed. Strategies to mitigate damage, for each type of cell will be furthermore discussed.

Exceptional Surface Passivation and Carrier Transport in Pyramidically Textured N-Type Silicon by Organic Molecules with Sulfonic Acid Head Groups and Perfluoroalkyl Tail Groups Milad Ghasemikashtiban, Konstantin Tsoi, Gorkem Gunbas and Selcuk Yerci; Middle East Technical University, Turkey

Improving the passivation quality of the surface in silicon (Si) solar cell is one of the main strategies for enabling higher performance. Excellent passivation schemes have been recently developed, with lifetimes reaching 0.5 sec using, for example, Al_2O_3 and SiN_x dielectric layers with proper (i.e.,

negative and positive for p- and n-type Si, respectively) fixed charges. However, one of the main disadvantages of such dielectrics is the deposition methods requiring vacuum and, possibly, high-temperature annealing steps. Eliminating these steps has the potential to reduce the fabrication costs of silicon solar cells considerably. One family of materials that potentially can provide high passivation of silicon is organic materials. Due to the simplicity of their deposition methods (often fabricated in the room ambiance without subsequent thermal annealing), and the capacity to inherently possess high dipole moments and fixed charges, organic materials might deliver the same level of performance as inorganic dielectrics but at a reduced cost. In this regard, we present an investigative study of organic materials with sulfonic acid head groups and perfluoroalkyl tail groups.
We demonstrate minority carrier lifetime values of over 8 ms (an implied open circuit voltage (iV_{oc}) of > 730 mV) with organic materials on textured Czochralski n-type Si wafers, comparable to the passivation level of high-performance inorganic dielectrics. Moreover, we show that only 5% of organic material dissolved in a solution of deionized water (DI) and isopropanol (IPA) is sufficient to passivate the silicon surface. IPA/DI water provides much higher performance compared to alternative solvents (DMSO, ACN, Ethanol, and IPA without water). The critical role of DI water is elucidated.
Si surfaces coated with organic materials were investigated using Attenuated Total Reflectance (ATR), Fourier Transform Infrared spectroscopy (FTIR), and X-ray Photoelectron Spectroscopy. Initial results indicate that passivation is mainly provided by the field effect, resulting in a favorable energy band bend bending at the surface of Si. Due to the chemical structure of organic materials and their similarity to those of self-assembling monolayers, we hypothesize that these organic materials form dipoles at the interface generating an electric field and resulting in a favorable band bending. This hypothesis is also supported by contact angle measurements, which reveal high hydrophobicity for surfaces treated with organic materials.
These organic materials provide good passivation together with good carrier transport properties. A contact resistance as low as 106 $m\Omega/cm^2$ is achieved through n-Si – organic materials – aluminum stacks, which can be further reduced to 15 $m\Omega/cm^2$ with a thin layer of LiF_x deposited under Al metal.
Lastly, we discuss the stability of organic materials and demonstrate that keeping the samples under nitrogen ambient, at low temperatures (2 °C), or adding PCBM ([6,6]-Phenyl C_{61} butyric acid methyl ester) into the solutions improves the stability considerably. A very first proof-of-concept solar cell with organic materials deposited at the rear of the solar cell demonstrated an efficiency of ~17%, only 3% lower than the PERC type silicon solar cell produced in the same batch.
Our results prove that organic materials with a head group that anchors to pyramidally textured Si and a tail group that provides a high dipole with a cost-effective, low-temperature fabrication can provide good passivation and charge transport and thus have great potential for providing high-performance solar cells.

Pushing Solar Energy Conversion Beyond Today's Efficiency and Cost Limits Rutger Schlatmann[1,2]; [1]Helmholtz-Zentrum Berlin, Germany; [2]HTW Berlin, Germany

In this talk, we will discuss the detailed material science and engineering aspects of Perovskite/silicon tandem solar cells, that led to a 1 cm2 sample with 29.8% efficiency. We will focus on adaptations to the standard Silicon Heterojunction bottom cell that enabled high-efficiency tandem values. More in particular, we will discuss optical measures to optimize the bottom cell response in the infrared part of the spectrum. Closely connected to the engineering of the optics, we will discuss the interplay between bottom cell and subsequent top cell optimization. Consequences and potential modifications for industrial implementation will be discussed.
We will also briefly discuss the complicated dynamics, involving both degradation and recovery mechanisms, that are observed in combined indoor and outdoor stability measurements on encapsulated perovskite based tandem cells, which we have monitored for well over a year.

8:30 AM *EN06.07.02
Towards Large Area 4-Terminal Hybrid Perovskite-Silicon Tandems Using Scalable Processing Arthur W. Weeber[1,2]; [1]TNO, Netherlands; [2]Delft University of Technology, Netherlands

Co-authors from Solliance partners TNO, TU/e, TU Delft and imec will be added to the final paper.

The current PV market is dominated by crystalline silicon solars with so-called PERC architecture (Passivated Emitter and Rear Cell). However, the PERC technology is approaching its efficiency limit of about 24% and to maintain the overall 0.5-0.6% absolute annual efficiency improvement, TOPCon (Tunnel Oxide Passivating Contacts) and silicon heterojunctions (SHJ) are seen as the follow-ups. Efficiencies close to and beyond 26% have been achieved in an industrial environment for TOPCon [1] and SHJ [2] respectively. Several large manufacturers are already producing TOPCon and SHJ solar cells and modules. The current world record silicon solar cell is a fully back-contacted SHJ one with an efficiency of 26.7% [3].
For the next step and reaching efficiencies beyond 30% crystalline silicon solar cells can be combined with perovskite solar cells. With a stack of these solar cells in a so-called tandem configuration the solar spectrum can be better utilized. The current world record for a perovskite-silicon tandem is 29.8% and obtained by HZB [4].
Tandem architectures with 2-, 3- or 4-terminals are being researched, and all these configurations have advantages and drawbacks. In this paper we will focus on so-called 4-terminal (4T) perovskite-silicon tandems. The advantage of 4T tandems is that current matching is not required because the component solar cells can operate independently of each other which can result in a higher annual yield. Another advantage of 4T tandems is that bottom cells with different architectures (PERC, TOPCon, SHJ, back-contacted) can be integrated more or less independent of the top-cell layout. A drawback for 4T tandems will be that additional electronics are needed.
We will present our latest results for 4T tandems for small area lab cells, but also for large area cells and modules (area matched). Results of stability and reliability, outdoor monitoring and annual yield modelling will also be shown. So far, we have obtained over 29.5% efficiency for small area tandems with different silicon bottom cell architectures (internal measurements). For large area cells upscaling from spin-coating to slot-die-coating was carried out for the perovskite solar cell. Modules of 100 cm^2 were made using P1, P2 and P3 laser scribing and an efficiency above 16% was obtained for 1.6 eV bandgap perovskite material. Applying this 1.6 eV perovskite solar cell with a SHJ bottom cell and integrating both component cells in an area matched module (100 cm^2) resulted in an efficiency of 25.6% [5].
For lab size perovskite solar cells huge progress has been made with respect to stability and reliability. Several accelerated lifetime test have been passed successfully. Performing outdoor monitoring tests is crucial for tandem PV. At TNO we installed an outdoor facility dedicated to tandems. First results show good outdoor stability over a period of almost a year for the best tandem module configurations [6].
With respect to conventional monofacial PV, the annual yield can be increased by applying bifacial technology. As stated above, in 4T tandems the

component cells can operate independently and with advanced annual yield modelling we have shown a significant higher average generated photocurrent for 4T tandems compared to its 2T counterpart [7].
More details and recent progress will be presented during the conference.

This work has been carried in different Dutch and European project.

From Three Terminal Tandem Solar Cells to Modules Henning Schulte-Huxel, Robert Witteck, Susanne Blankemeyer and Marc Köntges; Institute for Solar Energy Research in Hamelin (ISFH), Germany

Three terminal tandem (3TT) solar cells require an adapted module integration scheme in order to explore their full efficiency potential. The three terminals allow to extract the power of the top and bottom cell separately. In a string, the wide bandgap top cells are interconnected in parallel to multiple bottom cells, resulting in parallel/series interconnection. This special interconnection has implications for the operation of the subcells, the resulting current path between the subcells, the layout of the cell interconnects and for the system level. Here, we analyze by simulations and experiments the various aspects resulting from the module integration of 3TT depending on the voltage ratio of the top and the bottom cell and their relative orientation, either the sub cells are connected in series and allow a two-terminal (2T) operation (s-type) or they are reverse orientated (r-type). The aim is to present approaches and relevant aspects for modules and systems based on 3T devices, including the integration of bypass diodes as well as the interconnection of modules and their impact on string end losses. The findings also serve as a guide for the design and construction of future 3TT solar cells for optimal module integration.
The interconnection is formed by a combination of a typical front-to-back manner and the contacting of back contacted solar cells. For the 1:2 r-type 3TT devices, one interconnect connects the contacts of three adjacent solar cells, resulting in a short length of the interconnect and thus low series resistance losses. All s-type devices and voltage ratios that differ from 1:2 result in longer current paths with the need to pass an intermediate solar cell without contacting it. This requires additional insulating layers on the cells' rear side and causes additional resistive losses as well as material costs.
Starting from the cell level perspective, the independent operation of the top and bottom cell is restricted in a string by the requirement of voltage matching of the subcells. However, this type of matching is robust in efficiency with respect to variations in the current of the individual subcells. Apart from the resilience to spectral changes, this also means that 3TT strings can be operated bifacially, unlike 2TT strings that are sensitive for illumination inhomogeneities, allowing a significant increase in energy yield. Furthermore, the series/parallel interconnection provides unique possibilities to protect sensitive perovskite top cells from too high reverse voltages, thus avoiding significant cell degradation. Due to the parallel current path in the interconnection scheme of voltage-matched 3TT cells, they are more robust with respect to partial shading compared to strings of 2T devices. Nevertheless, bypass diodes are required to protect the cells from too high power dissipation in case of shading. For strings with a finite number of cells, string-end losses occur due to the requirement to combine the contacts of the end cells in one terminal. These losses account for at least the power of about one 3TT cell for devices with a 1:2 voltage ratio of the subcells and an r-type configuration. All other 3TT devices have higher string-end losses. One could terminate the strings to integrate the bypass diode, resulting in these string-end losses as will be discussed in detail in the final contribution. However, the 1:2 r-type configuration allows to integrate a bypass diode in parallel to a continuous string, shifting the string-end loss from the substring level of a module to the end of the module string on system level. This means that the string-end loss in a PV system with 20 modules of 72 cells each (1000 V system) accounts to 1/1440 of the power of one r-type 1:2 3TT device, instead of 1/24 as for the module's substring.

9:30 AM *EN06.07.04
Challenges in the Realization of Perovskite/Si Tandem Solar Cells Stephanie Essig; University of Stuttgart, Germany

No doubt commercial Si solar cells will soon be upgraded by combining them with wider bandgap (1.6-1.9 eV) top cells. Such tandem devices allow the reduction of thermalization losses and an efficiency enhancement beyond 30%. While there is a clear trend towards top cells based on low-cost metal halide perovskites, the optimum tandem cell architecture, ideal fabrication process, subcell interconnection, and module integration are still under debate. Furthermore, there is a multitude of interconnection schemes: Most appealing is the monolithic 2-terminal (2T) tandem device architecture with serially connected cells, as known from established (but costly) III-V technology. However, 3-terminal (3T) and 4-terminal (4T) designs also have their pros and cons.
Realization of high-efficiency 2T perovskite/Si tandem cells requires matching the photo currents generated in top and bottom cells. Yet, more technological advancements, like large-scale perovskite cell deposition on textured Si and the development of suitable cell interconnection layers, are needed. The ideal Si bottom cell must be optimized for efficient absorption of the infrared solar radiation. In addition, it features an optically transparent, electrically conductive, and passivating front contact which does withstand subsequent top cell processing. Bottom cell front contacts with similar properties are needed for 3T tandem devices featuring Si cells with interdigitated back contacts (IBC). In contrast to 2T, the 3T configuration does not require current-matching of the subcells. Consequently, and as known from stacked 4-terminal tandems, the energy yield of 3T tandems is more tolerant towards spectral variations and dissimilar degradation behavior of the perovskite top and Si bottom cells.
At the Institute for Photovoltaics (ipv) we investigate various tandem cell architectures and work on the building blocks needed for tandem solar cells. Hence, we develop strategies to implement established c-Si technology into high-efficiency perovskite/Si devices.

High-Efficiency Both-Sides-Contacted Silicon Solar Cells—Requirements and Design Options Armin Richter, Ralph Müller, Jan Benick, Bernd Steinhauser, Christian Reichel, Andreas Fell, Martin Bivour, Martin Hermle and Stefan W. Glunz; Fraunhofer Institute for Solar Energy Systems ISE, Germany

The photovoltaic industry is dominated by crystalline silicon solar cells. While interdigitated back contact cells have yielded the highest efficiency, both-sides-contacted cells are the preferred choice in industrial production due to their lower processing complexity. Typically, such industrial cells feature a pn junction at the front surface. In order to identify an ultimate design for both-sides-contacted cells, we have studied here different cell designs at a very high performance level. We demonstrate a very conversion efficiency of 26.0% for a both-sides-contacted silicon solar cell, which exhibits the pn junction at the back surface in form of a full area passivating contact based on poly crystalline silicon. One key feature of this advanced cell structure is the highly transparent front surface based on dielectric passivation layers without any lateral conductivity. A detailed power loss analysis reveals that this cell balances electron and hole transport losses as well as transport and recombination losses in general. On the base of this analysis we performed a systematic simulation study for a variety of different solar cell designs, which led to some fundamental design rules for future >26% efficiency silicon solar cells. We discuss further requirements and design options for these solar cells to improve the device performance even further.

11:00 AM EN06.08.02

Interface Treatments for High-Efficiency MoO_x Based Silicon Heterojunction Solar Cells Liqi Cao[1], Paul Procel[1,2], Luana Mazzarella[1], Yifeng Zhao[1], Engin Özkol[1], Jin Yan[1], Can Han[1], Guangtao Yang[1], Zhirong Yao[1], Miroslav Zeman[1] and Olindo Isabella[1]; [1]TU Delft, Netherlands; [2]San Francisco de Quito University, Ecuador

Silicon based solar cells dominate the market of photovoltaics, which hold the highest potential for green electricity production. A front/back-contacted architecture combined with the silicon-based heterojunction (SHJ) concept realized a world record efficiency of 26.3%[1]. However, conventional silicon-based doped layers, which work as carrier selective transport layers, are not optically transparent.
Transition metal oxides are promising candidates for SHJ solar cells due to their advantageous opto-electronic properties. Molybdenum oxide (MoO_x) with high work function (WF) has achieved highly efficient solar cells with 23.5% efficiency[2]. However, depositing high quality MoO_x thin film on top of a-Si:H is challenging due to highly reactive surfaces[3]. This interaction may result in interfacial oxidation, lower Mo oxidation states and reduced WF[4,5]. In turn, electrical performances of solar cells featuring MoO_x are poorer[3] than standard SHJ devices.
Several attempts have been made to prevent the reaction between MoO_x and (*i*)a-Si:H. Pre-annealing[4] of a-Si:H and pre-growth of SiO_x layer[6] have been proposed as effective ways to prevent the degradation of MoO_x. Nevertheless, those approaches require extra process steps that make MoO_x integration not immediately viable in industrial environment. In our previous work, we proposed a plasma treatment (*PT*) at MoO_x/(i)a-Si:H interface that demonstrated to mitigate dipole effect and resulted in improved cell performance[7]. After optimizing the interface treatment, even thinner MoO_x layer could be applied.
The solar cells were fabricated using 260±20 µm 4-inch double-side textured n-type <100> FZ wafers. (*i*)a-Si:H was deposited by plasma-enhanced chemical vapor deposition on both sides, while (*n*)a-Si:H only at the rear side. We carried out two different plasma treatments on the (*i*)a-Si:H interface prior MoO_x deposition: one called *PT* from a mixture of SiH_4, H_2 and CO_2 and another called *PTB* from a mixture of SiH_4, H_2, CO_2 and B_2H_6. One sample without plasma treatment (*noPT*) was used as reference to evaluate the efficacy of the proposed method. A thickness series from 1 to 4 nm of MoO_x was thermally evaporated from MoO_3 powder at the pressure of 5×10^{-6} mbar. After that, optimized 50-nm and 150-nm thick tungsten-doped indium oxide (IWO) layers were sputtered through a hard mask at front and rear side, respectively, defining six 2×2 cm^2 solar cells per wafer. As metal contact at the front side, we used room temperature Cu plating[8] with a metal coverage fraction of 1.575%; at the rear side, 500-nm thick Ag layer was sputtered on the full device area.
We studied the impact of different plasma treatment conditions on MoO_x film quality and cells' performance. MoO_x film quality was assessed based on O vacancies inside the film[4]. The samples with interface treatments contain less O vacancies than the sample without treatment. It is noticeable that the cell precursors endowed with *PTB* yield higher fill factor (*FF*) than other types of precursors. Instead, *PT* and *noPT* samples benefitted from high short-circuit current density (J_{SC}). Ultimately, *PTB* and *PT* samples achieved similar conversion efficiency. For the variation of MoO_x thickness, we observed that even a slightly change in its thickness influences the solar cells' electrical performance drastically. An ultra-thin, ~1.7-nm thick MoO_x layer could provide sufficient field passivation (open circuit voltage, V_{OC} = 721.4 mV) and good opto-electrical properties (*FF* = 82.18% and $J_{SC\text{-illuminated-area}}$ = 40.20 mA/cm^2). With our approach we demonstrate word record cell with ISFH-certified conversion efficiency of 23.83%.

Investigation of Local Parameters of PERC Solar Cells Metallized with Screen Printed Cu-Paste Suchismita Mitra[1], Steve Johnston[1], Steve Harvey[1], Harvey Guthrey[1], Ruvini Dharmadasa[2], Kevin Elmer[2], Apolo Nambo[2], Thad Druffle[2], Sandra Huneycutt[3], Abasifreke Ebong[3] and Pauls Stradins[1]; [1]NREL, Golden, United States; [2]Bert thin films, United States; [3]University of North Carolina at Charlotte, United States

We report on copper (Cu) screen print metallization of silicon (Si) solar cells and analyze the performance loss factors due to this new metallization process by mapping of local parameters for large area Passivated Emitter Rear Contact (PERC) solar cells. In order to reach about 40 TW of PV required to transition our planet to renewables, the silver (Ag) should disappear from PV production and get replaced with more abundant and cheaper material. Cu is an excellent alternative to Ag; being cheap and exhibiting similar electrical resistivities. But there are challenges associated with it like easy oxidation, diffusion into the Si cell and recombination activity. Most of the work that has been carried out in case of Cu involves electroplating to get a high aspect ratio metal contact, but it requires additional masking steps like photolithography. Thus, screen printing, a dominant metallization technology, is a potentially inexpensive solution for Cu metallization on c-Si solar cell. The selective emitter PERC cells were developed on M6 sized monocrystalline p-type wafers with a front grid screen-printed with Cu paste and partial Al contacts at the rear side. Although the champion cells have a fill factor (FF) ~77%, we have investigated the solar cells with very low FF (62% to 68%) in order to understand the reason behind the low FF. FF loss analysis indicates that there is ~13.35% loss due to series resistance (Rs), ~4.5% loss due to J_{02} and a negligible loss of ~0.07% due to shunt resistance (R_{sh}). Our primary motivation for mapping these parameters is to investigate whether the low FF is a result of non-uniformity or overall low value of these parameters. Photoluminescence (PL) imaging was performed at different load conditions including short circuit and open circuit conditions under 1 sun illumination with source excitation of 808 nm and exposure time of 0.5sec. Electroluminescence (EL) imaging was also carried out at different applied voltages in the dark. The PL and EL images at different bias conditions are used to generate the R_s maps. Dark Lock-in Thermography (DLIT) using a thermal camera was measured at a reverse bias and three forward biases (0.508V, 0.547V, 0.631V) which were subsequently used for local IV analysis based on 2-diode model to generate maps for R_{sh}, J_{01} and J_{02}. Even at short-circuit conditions, the PL images show some bright patches, which indicate that contact formation has

not taken place in those areas. At open circuit conditions, the PL images still show those bright patches at the edges but is very uniform over most the surface. In the EL images, the non-contacted regions are dark, while the remaining areas are quite uniform. Thus, from the PL and EL images at different bias conditions, it is observed that the overall contact formation is uniform barring a few places at the edges indicating that the series resistance is uniform but high over the entire surface. The reason behind the high R_s can be high contact resistance at Cu/Si interface which needs further investigation. The DLIT image in the reverse bias is also mostly uniform and dark over the entire surface supporting our FF loss analysis of low R_{sh} loss. But the DLIT images in the forward biases show non-uniform spots in the interior of the cells which become prominent as higher bias voltages are applied. These spots, which were not visible in EL or PL images indicate non-uniformity of J_{01} and J_{02}. Further studies to investigate the interfaces will be done to understand the source of non-uniformity of J_{01} and J_{02}, diffusion of Cu atoms and the role of the barrier layer between Cu and silicon. We intend to study the diffusion of Cu into Si by SIMS, XRD, TEM, Raman spectroscopy and AFM and present it at the conference.The use of screen printable Cu pastes can reduce the cost of PV production processes to a great extent and hence, is of extreme relevance to the PV community.

11:30 AM EN06.08.04
Electron Transport Layer Design Considerations for Si-based Photocathodes for CO_2 Reduction Joel W. Ager[1,2], Rajiv R. Prabhakar[2], Raphaël Lemerle[2] and Elif N. Dayi[2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Use of charge-selective, passivating contacts is responsible much of the recent progress in improving the efficiency of Si-based photovoltaic cells [1]. Designing such contacts for the photoelectrochemical (PEC) environment (i.e. electron transport layers for photocathodes and hole transport layers for photoanodes) has some commonalities with PV but also brings additional challenges and constraints [2]. Focusing on ETLs, materials used for this purpose much be stable in the PEC environment and either be catalytic for the desired reaction (e.g. hydrogen evolution, HER, or CO_2 reduction, CO_2R) or be compatible with a co-catalyst that is. For Si photocathodes used for HER, TiO_2 is widely used: it is stable in the low pH conditions which are typically employed and provides a conductive path to typically used catalysts such as Pt [3].
However, although TiO_2 ETLs appear to be stable at the near-neutral pH conditions used in PEC CO_2R, they also appear to be highly active for the competing HER reaction, which motivates a search for materials which will be more catalytically inert. Consideration of thermodynamic stability rules out many candidates that are used in PV applications (e.g. ITO). We will show that TaO_x synthesized by pulsed laser deposition and RF sputtering has promise as an ETL for PEC CO_2 reduction. Control of the oxygen vacancy concentration enables tuning its conductivity and hence improving its photocurrent densities under CO_2 reduction conditions. Initial work show that while the photovoltage of p-Si/TaO_x junctions is smaller compared to p-Si/TiO_2, TaO_x is catalytically less active for HER. As a result, p-Si/TaO_x/Ta/Au and p-Si/TaO_x/Cu photocathodes produce CO and C1 and 2 products (faradaic efficiencies > 50%), as expected.
As many PV absorber materials are themselves thermodynamically unstable under the strong reducing conditions of PEC CO_2 reduction, investigation of chemically compatible ETLs which also provide surface passivation is warranted. In this context, materials selection strategies, including the use of engineered and multifunctional layers (inspired by those used for PEC HER [4]), will be discussed.

Gettering and Passivation of Impurities and Defects in High Efficiency Silicon Solar Cells Daniel Macdonald, AnYao Liu, Kelvin Sio, Sieu Pheng Phang and Rabin Basnet; Australian National University, Australia

Impurities and defects continue to play an important role in limiting the efficiency of both laboratory and industrial silicon solar cells. In this work, we review recent progress in reducing the impact of some of the most important of these limiting defects through impurity gettering and passivation steps, which occur coincidentally during device fabrication. Since the dominant defects in a material depend very strongly on the crystal growth conditions, we categorise them by the three common silicon crystal growth techniques – Czochralski-grown mono-crystalline silicon, Cast-grown silicon (including both multicrystalline and cast-mono silicon), and Float-Zone silicon.

Czochralski-grown monocrystalline silicon (Cz-Si)
The primary defects in Cz-si, whether p- or n-type, are oxygen-related. In boron-doped p-type silicon, the very well-known Light-Induced Degradation (LID) caused by boron-oxygen defects dominates. Although in principle it is not affected by gettering, hydrogen is widely thought to play a key role in the permanent regeneration of this defect, which is a crucial step in stabilising the high efficiency p-type PERC cells that now dominate the PV industry.
In n-type Cz-Si, which is the preferred substrate for IBC, SHJ and poly-silicon passivating contact solar cells, an important class of defects that sometimes occur during high-temperature processing are the oxygen-related ring defects. These consist of oxygen precipitates, and sometimes their associated dislocations and decorating metallic impurities. Under certain conditions, they can be partially mitigated by impurity gettering and hydrogenation steps. These ring defects can also occur in p-type Cz-Si wafers.
Industrial Cz-Si wafers often also contain traces of dissolved metals such as Fe, which can significantly affect the carrier lifetime, if not removed during processing by gettering. Such gettering can be achieved by phosphorus or boron diffusion, aluminium alloying, doped-poly-silicon layers, and even deposited dielectric films such as silicon nitride and aluminium oxide.

Cast-grown silicon (HP mc-Si and cast-mono Si)
Cast high-performance multicrystalline silicon (HP mc-Si), by design, contains many grain boundaries. Fortunately the recombination activity of these grain boundaries can be significantly reduced after hydrogenation, such as via fired silicon nitride films during cell metallisation. Cast-monocrystalline silicon (cast-mono Si), on the other hand, tends to be dominated by dislocation clusters. These are much more difficult to negate through hydrogenation,

which reduces the achievable efficiency and yield for devices made on such wafers. Both HP mc-Si and cast-mono wafers also contain significant quantities of metallic impurities, some of which are precipitated at structural defects, whilst others remain dissolved. Under the right conditions, they can be gettered to a significant extent during phosphorus or boron diffusions, or by deposited films. This provides a convenient method to identify the metallic species present in these materials.

Float-Zone silicon (FZ-Si)
Although not used in industrial solar cells, Float-Zone silicon (FZ-Si) is often used in research laboratories, partly due to its immunity to oxygen-related LID and ring defects, and very low metallic impurity concentrations. However, due to the addition of nitrogen during crystal growth to control dislocations, they are subject to the formation of nitrogen-vacancy complexes. Once formed, these defects are highly recombination active. However they can be partly mitigated by hydrogenation.

Finally, although hydrogen is helpful in passivating some defects in silicon, it can also cause recombination-active defects when present in excess, such as the widely-researched Light and elevated-Temperature Induced Degradation (LeTID). Since these defects are caused by firing hydrogen-containing dielectric films, they can be found in all three types silicon wafer described above, whether n- or p-type.

7:00 PM *EN06.09.02
High Effiency Perovskites and Perovskite Tandems via Passivation and Charge Transport Engineering Kylie Catchpole; Australian National University, Australia

Combining perovskites with well-established photovoltaic materials such as silicon is an attractive approach for producing cheap, high efficiency and high voltage solar cells. Perovskite/silicon tandems have the potential for further progress in increasing the efficiency to 30% and beyond provided high efficiency perovskite cells can be demonstrated. We demonstrate a 4-terminal tandem perovskite/silicon configuration in which the efficiency is as high as 27.7% through a passivation approach using 2D perovskites. We also demonstrate efficiency above 22% and fill factor of 86% for a 1cm2 single junction perovskite cell using a titanium oxynitride electrode transport layer. We also discuss how high efficiency can contribute to lowering the cost of photovoltaics and to decarbonization, as well as some emerging research challenges as solar transitions to become one of the world's major energy technologies.

7:30 PM *EN06.09.03
Future of Silicon Heterojunction Solar PV Technologies Akira Terakawa[1,2]; [1]Panasonic Corporation, Japan; [2]Photovoltaic Power Generation Technology Research Association (PVTEC), Japan

A-S/c-Si heterojunction (SHJ) solar cells have been invented in 1990 by Sanyo, which are regarded as a candidate of the main streams of Si solar cells. The history and future prospective of SHJ technologies and applications will be reviewed.

8:00 PM EN06.09.04
Generation Mechanism of Dislocations During Cast Growth of High-Performance Multicrystalline Si Ingots Yutaka Ohno[1], Hideto Yoshida[2], Tatsuya Yokoi[3], Katsuyuki Mtsunaga[3], Koji Inoue[1], Yasuyoshi Nagai[1] and Noritaka Usami[3]; [1]IMR, Tohoku University, Japan; [2]SANKEN, Osaka University, Japan; [3]GSE, Nagoya University, Japan

Silicon ingots grown by cast-growth techniques, such as high-performance multicrystalline silicon (hp-Si), have a high productivity at low cost, even though dislocation clusters are frequently generated during the directional solidification. The clusters would degrade the macroscopic electric properties around them, which is much inferior to that in monocrystalline Si solar cells. One important issue to fabricate high quality cast-Si ingots for photovoltaic and electronic applications is, therefore, to control the dislocation generation. The dislocation sources are, however, hardly determined in commercial-scale Si ingots with complicated crystal structure. In the present work, we have found that dislocation clusters are effectively generated at Σ3 grain boundaries (GBs) in a commercial hp-Si ingot and discussed the origin of the dislocation generation.
We examined the generation sites on a multiscale by multimodal analysis using optical and electron microscopies, photoluminescence (PL) imaging, finite element stress calculations assisted by crystal growth simulation (CGSIM), and *ab-initio* calculations. A set of alkali-etched wafers cut from a hp-Si ingot was sequentially measured by PL imaging and optical microscopy (OM) [1], and three-dimensional distribution of dislocation clusters and GBs was visualized. The crystal orientation of the grains and GB characters were examined by machine learning using the OM data [2], and a Σ3 GB acting as dislocation source was selected. Macroscopic thermal stresses around the GB during the cast-growth was estimated by finite element calculations [3], with the parameters estimated by the relevant crystal growth simulations [4]. The atomistic structure of the GB was examined by transmission electron microscopy (TEM) and scanning TEM (STEM) [5], and local stresses at the GB was discussed by *ab-initio* calculations based on the STEM data.
Multiscale analysis of a commercial hp-Si ingot indicates that dislocation clusters can be generated at curved Σ3 GBs, around which high thermal stresses are concentrated. The GBs have a stepped structure composed of the symmetric Σ3 GB segments lying on {111} and {112}. TEM suggests dislocation generation at the stepped edges, and the Burgers vectors of the dislocations are parallel to the stepped edges. Finite element stress analyses indicate a high shear stress concentrated at the stepped edges. Also, *ab-initio* calculations with STEM data reveal large strains at the GBs, by which the critical stress needed for dislocation generation would be reduced.

Al-Catalyzed Si Nanowire Formation on Pre-Etched and Post-Polished Thin Si Substrates for Photovoltaic Application Wipakorn Jevasuwan and Naoki Fukata; National Institute for Materials Science, Japan

Thin silicon (Si) solar cells have been a candidate to suppress Si material consumption and utilize them as flexible and durable devices. However, the advantage has come with a trading-off in solar cell efficiency. Light absorption loss in thin Si wafers is an important issue to be overcome in order to improve the conversion efficiency. Systems made with one-dimensional (1D) nanostructures of inorganic semiconductors with high crystallinity such as Si nanowires (NWs) are promising to provide significant enhancement by increasing the light trapping and carrier collection area in thin cells owing to the unique NW physical properties [1,2]. From our report [2], vapor-liquid-solid (VLS) growth using aluminum (Al) catalyst of chemical vapor deposition (CVD) on bulk Si(111) wafers was proposed to create single-crystalline SiNWs that resolve the catalyst contamination problem. The developments of vertical-oriented, Al-doped, and smooth surface Al-catalyzed SiNW array formation together with the realization of high-performance SiNW-based

photovoltaic devices have been accomplished. In this study, thin SiNW-based solar cells were further demonstrated. Two different thin and bendable Al-catalyzed SiNW substrates were successfully prepared using simple techniques of pre-chemical etching in HF:CH_3COOH:HNO_3 solution before SiNW formation and post-mechanical polishing with diamond solution after SiNW growth. The formation of Al-catalyzed SiNWs on a pre-etched thin Si substrate was achieved as well as on a post-polished sample by applying optimized conditions from previous studies [2]. Although only one-half of SiNWs was vertically formed along [111] direction on pre-etched samples due to the Si surface roughness, low light reflectance (<10%) of both thin SiNW substrates is comparable. SiNW solar cells fabricated using an axial junction of p^+-p-n structure [2] on thin pre-etched and post-polished Si wafers could enhance the power conversion efficiency (PCE) up to 6.1% and 6.6%, respectively. Both thin SiNW substrates contribute light trapping qualities while the NW-shaped increases the carrier collecting area compared to thin planar cells. The ease of Al catalyst removal and the capabilities of Al existence as a p-type dopant in SiNWs are also advantageous. The problems of catalyst contamination could be avoided and the process is capable of being scaled up. The photovoltaic characteristics of the best SiNW sample and planar sample with optimizations will be discussed. Further necessitating improvements in SiNW quality and interface engineering is in progress. [1] W. Jevasuwan, et al., JJAP, 56 [8] (2017) 085201. [2] W. Jevasuwan and N. Fukata, Nanoscale. 13 [14] (2021) 6798-6808.

Fabrication of Highly Conducting Sc and Y Co-Doped ZrO_2 Solid Electrolyte Thin Film on a Porous Electrode Substrate via Facile Method for SOEC Applications Rinlee Butch Cervera and Dale Mhar Alfeche; University of the Philippines Diliman, Philippines

Scandium (Sc) and yttrium (Y) co-doped ZrO_2 (4Sc4YSZ) thin films were fabricated on a porous electrode substrate of NiO-YSZ using a facile drop-coating method. The 4Sc4YSZ powder was synthesized using sol-gel all alkoxide method while the 1:1 wt% composition of NiO and 8YSZ (NiO-YSZ) electrode substrate was synthesized via glycine-nitrate combustion method. The electrode substrate and solid electrolyte powders were characterized first before the half-cell fabrication. For the 4Sc4YSZ sol-gel derived powder, TG/DTA revealed that the powder stabilized at about 1000 degC which is complemented by FTIR results. From the FTIR spectra, the organic functional groups were completely removed after calcination at 1000 degC. The half-cell was then prepared via drop-coating of 4Sc4YSZ on a NiO/YSZ substrate and then characterized for its morphology and conductivity at intermediate temperatures. SEM-EDS revealed a well-distributed and homogeneous elemental composition of the 4Sc4YSZ solid electrolyte thin film on a porous Ni-YSZ electrode substrate. From the conductivity measurements done using electrochemical impedance spectroscopy (EIS), 4Sc4YSZ thin film can be a promising solid electrolyte material due to high total conductivity of about $1.2x10^{-1}$ S/cm at 700 ^oC with 0.73 eV activation energy

8:45 AM EN07.01.02
High-Throughput Discovery of Hydrogen Evolution Electrocatalysts in Different Complex Solid Solution Systems Based on Transition Metals Sabrina Baha[1], Simon Schumacher[2], Alan Savan[1], Corina Andronescu[2] and Alfred Ludwig[1,3]; [1]Materials Engineering, Germany; [2]Faculty of Chemistry and CENIDE Center for Nanointegration, Germany; [3]Center for Interface-Dominated High Performance Materials, Germany

The efficient production of green hydrogen is one of the most important steps towards the development of a sustainable hydrogen economy. However, in order to advance water electrolysis, new catalyst materials must be found that are ideally based on abundant and cheap elements and further reduce the energy consumption for the hydrogen evolution reaction (HER) [1]. These materials can be based on transition metals. Although individually less active for HER, as compositional complex solid solutions (CCSS) or also named as high entropy alloys (HEAs), their activity can be compared to commercial catalysts [2].
These alloys consist of five or more elements in a compositional range of typically 5-35 at.% and are stabilized by high mixing entropy in a single phase structure. Due to the large number of surface atomic arrangements, there are many different binding energies that can provide an increased density of

optimal or near-optimal binding energies for a given reaction after suitable optimization of the CCSS structure and composition [3]. CCSS have opened up almost infinite possibilities of compositions that need to be discovered in a systematic and material-saving manner [4].
For discovery of new catalysts, we used combinatorial fabrication and high-throughput characterization methods. A thin film with a concentration gradient of each element is deposited on a Si substrate by co-depositing individual elements from five sources, resulting in approximately 340 measurement areas (MAs) of different compositions. These are referred to as material libraries (MLs), which can then be screened using high-throughput methods. The structure and composition of the different MAs are investigated by energy-dispersive X-ray spectroscopy and X-ray diffraction. Using the electrochemical scanning droplet cell technique, we have explored the activity of the different catalyst materials present in the ML for alkaline HER. With only three different MLs in a compositional system, we can investigate more than 1000 different compositions and thus have identified in our work about 350 catalysts of the Cr-Co-Fe-Mo-Ni system with similar or higher electrocatalytic activity than recently reported for alkaline HER in this system [5]. The results show a complex interaction between composition and phases that affect the activity of HER. From these data, we can identify trends as a function of structure, elemental composition, and HER activity. Overall, we can conclude that high Fe and Co contents in the Co–Cr–Fe–Mo–Ni CCSS boost HER activity while an increasing amount of Cr has the opposite effect. In general, CCSS with higher HER activity have higher crystallinity. Still, the composition of the CCSS indicates a stronger influence than the crystallinity on the HER electrocatalytic activity.

Towards High-Performance, Low-Temperature Solid Oxide Cells with Vertically Aligned Nanocomposite Films Matthew Wells, Adam Lovett and Judith L. MacManus-Driscoll; University of Cambridge, United Kingdom

Low temperature micro solid oxide cells (μSOCs) represent a key technology in next-generation energy devices for portable applications, offering the highly efficient conversion of electrical to chemical energy (e.g. hydrogen), and vice versa. To date however, the widespread implementation of μSOCs, and therefore the effective use of hydrogen as a portable energy storage solution, has been prohibited by excessive polarisation resistances at the device electrodes, despite significant progress in materials design.

Vertically aligned nanocomposite (VAN) films have been a leading class of materials in recent performance enhancements in μSOC design, and in this work we further explore the growth and characterisation of such VAN films. State-of-the-art fluorite and perovskite materials are combined in each of the anode, electrolyte, and cathode layers and the enhancement rendered by the novel VAN structure quantified in each case by electrochemical impedance spectroscopy (EIS). Moreover, films are grown on both single-crystal and more commercially viable polycrystalline/amorphous substrates. This allows for a detailed study of the VAN growth mechanisms for materials of differing crystal structures, while also giving an improved understanding of the importance of crystalline perfection in thin-film μSOC device performance.

Future progress in low-temperature μSOC technology will rely heavily on a detailed understanding of the growth mechanisms of state-of-the-art nanostructured materials, such as VAN thin films. By building such an understanding and quantifying the performance enhancements resulting from a wide variety of VAN structures, this study represents an important step towards the realisation of efficient low-temperature μSOCs for portable applications.

9:15 AM EN07.01.04
Unconventional Highly Active and Stable Oxygen Reduction Catalysts Informed by Computational Design Strategies Ryan Jacobs[1,2], Jian Liu[1], Beom Tak Na[1], Bo Guan[1,3], Tao Yang[1,3], Shiwoo Lee[1], Greg Hackett[1], Tom Kalapos[1,3], Harry Abernathy[1] and Dane Morgan[1,2]; [1]U.S. Department of Energy National Energy Technology Laboratory, United States; [2]University of Wisconsin--Madison, United States; [3]NETL Support Contractor, United States

Discovering and engineering new materials with fast oxygen surface exchange kinetics and robust long-term stability is essential for the large scale, economically viable commercialization of solid oxide fuel cell (SOFC) technology. The perovskite catalyst material $BaFe_{0.125}Co_{0.125}Zr_{0.75}O_3$ (BFCZ75) was predicted to be promising from our recent density functional theory calculations but is unconventional due to its extremely high Zr content and low electronic conductivity.[1] However, we demonstrate that it exhibits oxygen reduction reaction surface exchange rates on par with $Ba_{0.5}Sr_{0.5}Co_{0.8}Fe_{0.2}O_3$ (BSCF) and excellent stability at typical operating temperatures.[2] We engineer new composite electrodes integrating BFCZ75 with commercial electrode materials $La_{1-x}Sr_xMnO_3$ (LSM) and $La_{1-x}Sr_xCo_yFe_{1-y}O_3$ (LSCF) and achieve high performance as measured by low area specific resistance (ASR) values, with the LSCF/BFCZ75 ASR values comparable to top performing non-composite electrode materials such as $SrCo_{0.8}Sc_{0.2}O_{3-d}$,[3] $BaNb_{0.05}Fe_{0.95}O_{3-d}$[4] and $BaCo_{0.7}Fe_{0.22}Y_{0.08}O_{3-d}$.[5] Considering this result was obtained with simple mixing of commercial LSM/LSCF and as-made BFCZ75 using standard processing methods, the performance of the electrode could be even further improved by optimizing the composition and microstructure. This study successfully demonstrates that modern computational-based materials discovery methods can point to unconventional and novel SOFC electrode design strategies which would have been either inaccessible to experimental techniques (e.g., too many compositions to examine) or ill-advised based on conventional wisdom (e.g., having too low electronic conductivity by virtue of low transition metal content). These novel design strategies can unlock new high-performing SOFC electrode materials with performance rivaling other state-of-the-art novel cathode materials, while also having improved operational stability and utilizing current commercial cathode material production lines, offering a promising path toward the widespread adoption of SOFC energy technology.

Solid-State Synthesis of Layered $KIrO_x$ for the Oxygen Evolution Reaction Rachael Quintin-Baxendale, Maria S. Sokolikova, Ifan E. Stephens and Cecilia Mattevi; Imperial College London, United Kingdom

The current climate crisis means that it is imperative to research new energy solutions, and using green hydrogen formed through electrocatalytic water splitting as a renewable energy storage system is an exciting prospect. Within water electrolysers, Iridium Oxide is commonly used as a catalyst for the Oxygen Evolution Reaction, the bottleneck reaction of the system on the anode, due to its high stability and activity. However, the low abundance and very high costs of Ir are hindering its commercial application for water electrolysis. Reducing the loading required of the iridium oxide could enable the commercial feasibility of this system, and various methods are gaining increased interest such as nano-structuring, doping and developing new support materials.
Nano-structuring rutile iridium oxide into two-dimensional (2D) nanosheets can offer extremely high surface areas, electron charge-transfer and conductivity abilities, allowing for a drastically reduced mass loading while preserving the catalytic activity. In this work, we synthesise a layered potassium iridate compound which is a precursor of 2D IrO_x. The compound was obtained through a high temperature solid-state reaction, followed by a shorter oxidative deintercalation step to remove potassium ions. Advanced structural characterizations have elucidated the crystal structure. The de-intercalated materials were then tested for oxygen evolution reaction. This approach can pave the way to increase the commercial viability of IrO_x as catalyst for water electrolysis.

Insight into the Synergy Between Silver Nanoparticles and Alkaline Anion Exchange Membranes for Power Output Konnie Duan[1], Quinton Geller[2], Helee Shukla[3], Haoyan Fang[4], Md Farabi Rahman[4], Aniket M. Raut[4], Sean Fang[5], Thomas Luong[6], Yuhao (Ben) Pan[7] and Miriam Rafailovich[4]; [1]Harvard-Westlake School, United States; [2]Los Alamos High School, United States; [3]New Hyde Park Memorial High School, United States; [4]Stony Brook University, The State University of New York, United States; [5]Maggie L. Walker Governor's School, United States; [6]Plano West Senior High School, United States; [7]Stuyvesant High School, United States

To develop innovative clean energy processes, scientists have been researching alkaline anion exchange membrane fuel cells (AEMFCs), which are currently expensive but can function in salt water and basic environments, unlike other hydrogen fuel cells. Previous studies on proton exchange membrane (PEM) fuel cells showed that monolayer sheets of nanoparticles (NPs) deposited onto Nafion PEMs via the Langmuir Blodgett Trough (LBT) were highly effective in increasing fuel cell power output. Density functional theory (DFT) calculations indicated the existence of a synergy between the surface of the Nafion membrane and the platelet shaped particles, which reduced the activation barrier for the CO oxidation reaction [1,2]. In AEMFCs, a different set of reactions determines the power generated, but a potential synergy between NPs and the membrane surface may still exist and lower the activation barrier. To explore this possibility, we evaluated silver (Ag) NPs, which have been shown to be effective in catalyzing these reactions [3]. We synthesized AgNPs using the Brust method and either deposited a monolayer using the LBT or sprayed AgNPs directly onto parts of the AEMFC. The AEMFCs were treated with dodecanethiol (C_{12})-protected AgNPs under five different conditions: (a) without AgC_{12} NPs, (b) with AgC_{12} NPs deposited using the LBT at 5 mN/m on both sides of the membrane, (c) with AgC_{12} NPs deposited using the LBT at 10 mN/m on both sides of the membrane, (d) with 1 µg/cm2 of AgC_{12} sprayed on both sides of the membrane, and (e) with 1 µg/cm2 of AgC_{12} sprayed on both electrodes. Each cell was tested for maximum power density. Approximately the same amount of AgNPs were applied via the LBT with the 10 mN/m surface pressure and each of the airbrush sprays. Each cell was operated with 0.76 mg/cm^2 Pt/C electrodes in ambient conditions at 60°C.

The AEMFC with AgC_{12} NPs sprayed onto the membrane exhibited the highest maximum of 0.556 W/cm^2 (39.7% increase) compared to the other test conditions, which include 0.469 W/cm^2 (17.8% increase) for AgNPs sprayed onto the electrodes, and 0.380 W/cm^2 (4.52% decrease) and 0.451 W/cm^2 (13.3% increase) for the 5 mN/m and 10 mN/m surface pressure depositions, respectively. The control cell had a peak power density of 0.398 W/cm^2 when operated. The membrane spray may have worked better than the electrode spray because of a yet-uncharacterized synergistic effect between the AgNPs and the membrane. The shape of the AgNP may also play a role in the observed effect, as shown by the reduced catalytic activity of deposited AgNPs, which are platelet-shaped after LBT application. The AEMFC with the monolayer deposited at 10 mN/m had a slightly greater maximum power density compared to deposition at 5 mN/m, likely due to the increased quantity of AgNP catalysts. These results clearly demonstrate that a synergy is established when AgNPs are deposited on the membrane for AEMFCs as well. The mechanism of action in AEMFCs, which is most enhanced by sprayed AgNPs on the membrane, appears to be different from that of PEM fuel cells, which showed enhancement when NPs were applied via LBT in previously published work. DFT calculations are in progress in order to elucidate the difference in mechanism.

We acknowledge the Morin Charitable Trust for funding.

Multiscale Simulations for Sorption-Diffusion Dynamics Within Polycrystalline Microstructures in the Hydrogen Storage Systems Younggil Song[1], Nathan D. Keilbart[1], Kyoung Eun Kweon[1], James Chapman[1,2], Yakun Zhu[1], Jennifer N. Rodriguez[1], Roger Qiu[1], Tae Wook Heo[1] and Brandon Wood[1]; [1]Lawrence Livermore National Laboratory, United States; [2]Boston University, United States

Within hydrogen storage systems, hydrogen travels various pathways to interact with metals. Metal oxide layers often form near the surface of the storage,

and hence hydrogen diffuses into the layers and find metals to form metal hydrides. In addition, metals and metal oxides are polycrystalline microstructures which have grains with different phases and grain boundaries located between them. The different phases and structural configurations lead to different hydrogen sorption and diffusion dynamics. Therefore, it is important to understand hydrogen sorption-diffusion dynamics within polycrystalline microstructures to enhance efficiency of hydrogen storages.

For the current study, we investigate hydrogen sorption-diffusion dynamics within polycrystalline TiO2 microstructures using simulations in various length scales and experiments. The TiO2 layer is typically observed at the surface of the Ti or Ti-based alloys for the hydrogen storage. This layer contains rutile and/or anatase grain structures, and amorphous phases are also existed at the grain boundaries. To identify the thermodynamic properties for the three phases, we use the atomistic simulations and experiments. A thermodynamic analysis of the hydrogen stability using density functional theory can characterize the variation of binding energy from the surface to the deep inside grains. In addition, the binding energy for the amorphous phase are analyzed as a function of the oxygen coordination which shows skew normal distributions. Additionally, we can obtain temperature-dependent hydrogen diffusivities within grains and grain boundaries from experiments and Kinetic Monte Carlo simulations, respectively. Those site-specific binding energies and temperature-dependent diffusivities are imposed into the mesoscale simulations to simulate the hydrogen sorption-diffusion dynamics within different microstructures. Our multi-scale simulations show that hydrogen adsorption is highly linked to the grain sizes within microstructures, which are also observed in experiments. We expect our multi-scale simulations and experiments can elucidate the relation between hydrogen adsorption and microstructures within hydrogen storage systems.

This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344.

Design Principles for Transition Metal Nitride Stability and Ammonia Generation in Acid Jiayu Peng, Juan J. Giner-Sanz, Livia Giordano, William Mounfield, Graham Leverick, Yang Yu, Yuriy Román-Leshkov and Yang Shao-Horn; Massachusetts Institute of Technology, United States

Transition metal nitrides have shown great promise for reducing/eliminating the use of expensive precious-metal-based catalysts (e.g., Pt) in proton exchange membrane fuel cells and electrolyzers, but the use of these nitrides in such technologies is still hindered by their dissolution at acidic pHs. Moreover, the decomposition of transition metal nitride catalysts in acid generates ammonia from the protonation of lattice nitrogen, giving rise to many false positives in previous reports of nitride catalysts for electrochemical nitrogen reduction to ammonia. To address these issues, it is essential to establish the stability descriptors of transition metal nitrides in acid. These stability descriptors can not only offer a fundamental understanding of nitride dissolution but also provide new guiding principles to optimize the intrinsic stability of nitrides for diverse acidic applications.

In this work, combining ab initio calculations with synchrotron X-ray spectroscopies, we identified electronic-structure-based design principles governing the extent and kinetics of nitride dissolution and ammonia production in acid. We found that lowering their nitrogen 2p band center with respect to the Fermi level leads to weakened metal-nitrogen bonds, increased labile metallic character, and a reduced barrier for the protonation of lattice nitrogen to produce ammonia, correlating with faster dissolution kinetics of nitrides in acid. Moreover, increasing the solubility of dissolved metal ions was found to be critical in preventing surface oxide passivation to ensure the complete conversion from transition metal nitrides to ammonia. Based on these observations, a mechanistic picture was proposed, where the protonation of lattice nitrogen is critical to trigger nitride dissolution, and this reaction scheme was supported by the pH-dependent dissolution kinetics of nitrides in acid.

These design principles and mechanistic insights for producing ammonia and dissolving metal ions from the decomposition of nitrides in acid are essential for a variety of applications. For example, these stability descriptors can be used to boost the stability of nitride catalysts for proton-exchange membrane fuel cells and electrochemical ammonia synthesis, where the dissolution of nitrides in acid has hindered their functions. Moreover, such descriptors for nitride dissolution and ammonia formation in acid provide emerging opportunities for designing nitride chemistries for distributed, on-demand ammonia generation. Lastly, as nitrides represent an exciting, yet markedly unexplored chemical space, this work provides a blueprint to design multinary nitrides in such a vast chemical space for various acidic applications, including electrocatalysis and beyond.

11:00 AM EN07.02.04
Facile Synthesis of Thiol-Decorated Ag Nanoparticles as Electrocatalyst for CO2RR Jinho Hyun and Chanho Pak; Gwangju Institute of Science and Technology, Korea (the Republic of)

Large amount of traditional fossil fuels has been consumed as energy resource with inevitably emitted carbon dioxide (CO2), one of the greenhouse gases, resulting in the global warming. Electrochemical catalysis is a cost-effective and energy-efficient way to convert CO2 into valuable products under ambient condition. However, the electrocatalytic reaction involved various pathways suffers from low selectivity and high overpotentials. Therefore, developing the electrocatalysts with the high selectivity and low overpotentials has been the focus of research.
Efficient carbon dioxide reduction reactions (CO2RR) is required to reduce greenhouse gases and obtain useful carbonaceous chemicals. Electrochemical carbon dioxide reduction (ECR) is one of the most effective methods to reduce carbon dioxide to carbon monoxide and/or other valuable chemicals. Coinage metals, i.e., gold, silver, and copper, are known as catalytic materials for ECR due to their appropriate binding energy for the intermediates (*COOH or *CO). Among them, silver-based catalysts showed high selectivity with relatively low overpotential and low cost. Morphology modification, size engineering and alloying have been conducted to improve ECR performance by promoting the reaction kinetics and selectivity. However, ECR can be improved by not only the enhancement of intrinsic activity but also extrinsic modification of interface.
Molecule-mediated electrocatalysts have been attracted attentions due to their unique electrochemical properties on interface between molecule and surface of electrocatalysts. The molecules around the electrocatalyst could adjust the electronic states of the surface resulting in improved activity and products selectivity. Conventional bulk metal electrodes after the modification of surface of electrodes by molecules showed enhanced ECR performance. We designed and fabricated a Thiol-decorated silver (Ag) nanoparticles on carbon support via simple acid reduction method. The as-prepared electrocatalyst has good dispersion and uniformity in particle size.

Hydrogen Infrastructure and Storage—U.S. DOE Hydrogen and Fuel Cell Technologies Office Perspectives Zeric Hulvey; U.S. Department of Energy, United States

Today there is rapidly increasing interest in utilizing hydrogen to provide clean, reliable power across a number of sectors, including transportation, power generation, energy storage, industrial applications, and chemical production. For many end uses, traditional methods of hydrogen storage and delivery—high pressure gaseous or liquefied hydrogen—will likely not be suitable for large-scale deployment. The U.S. Department of Energy (DOE) therefore remains interested in alternative methods of storage and delivery using materials-based technologies. This presentation will provide an overview of current hydrogen storage and delivery activities funded by DOE's Hydrogen and Fuel Cell Technologies Office (HFTO), with a focus on materials-based R&D. This will include current and future activities by the Hydrogen Materials – Advanced Research Consortium (HyMARC), a national laboratory-led consortium carrying out much of HFTO's materials-based efforts.

Fuel Cell Power—Toyota's Enduring Commitment Dallas Fox; Toyota Motor North America, United States

Toyota's enduring commitment to fuel cells is part of Toyota's broader "Environmental Challenge 2050" strategy. As ever, Toyota believes that the right powertrain for the right application is key to enabling a portfolio which is not only flexible, but also focuses on leveraging the individual strengths each option brings to the table. Whether it be hybrid, plug-in hybrid, battery-electric, or fuel cell, Toyota provides world class options that meet our customers' needs. When it comes to fuel cells, the advantages of high energy density, short refueling time, scalability, and low-to-no energy loss over time come to the fore. In this presentation, you will see how Toyota has explored the wide-ranging industries in which fuel cells can not only provide a marked performance advantage over established powertrains, but also show that better power and clean power don't have to be mutually exclusive. Reliable, powerful, and zero emissions: that's Toyota Fuel Cell.

3:30 PM *EN07.03.04
Design and Cost Analysis of a Liquid Organic Hydrogen Storage System for Enabling Wind and Solar Based Direct Iron Reduction Hanna Breunig[1], Fabian Rosner[1], Peter Valdez[2], Dionessius Papadias[3], Kriston Brooks[2], Rajesh Ahluwalia[3] and Thomas Autrey[2]; [1]Lawrence Berkeley National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States; [3]Argonne National Laboratory, United States

While steel recycling has proven to be energy efficient and low in carbon dioxide intensity, primary steel will still be necessary to meet growing demand for steel, and a recent evaluation of the industry by the IEA suggest new low-emission technologies such as hydrogen (H2) will be necessary to further lower emissions. Technologies for direct reduced iron (DRI) production using H2 have been successfully demonstrated with no adverse effects on steel quality. This presents the opportunity for renewably generated H2, from sustainable regional energy resources, to be coupled with the steel industry. Due to the fluctuations in the availability of renewable power and the continuous nature of the steel-making process, there is a need for H2 storage carriers to supply cheap, low-carbon emission H2 and energy continuously during operation. Based upon preliminary analyses of this coupling, it is clear that hydrogen storage is necessary to balance the continuous DRI process and intermittent electricity generation by renewables. Here, we present a concept and technoeconomic analysis of onsite H2 generation by way of renewable-powered electrolysis. To balance intermittencies, the H2 is stored using liquid organic hydrogen carriers (LOHCs), specifically methylcyclohexane (MCH) and dibenzyltoluene (DBT), and H2 can be regenerated on demand to serve reductant end uses at a steel mill.
We compare these LOHC-based storage systems, using MCH or DBT, with the use of compressed and liquid H2 for steel mill applications requiring up to 200 TPD H2 with and without a hypothetical price on carbon. Based on our process design, models and evaluation of the application, we estimate storage cost, storage duration, energy density, specific energy, charge and discharge rate, and efficiency for the storage system. We make recommendations on reasonable near-term values for performance targets based on the necessary requirements of the application and on the performance of business as usual (BaU) and incumbent ironmaking technologies.

EN07.04.03
Doping Effect in SnO_2 Nanoparticles for Catalysts in Polymer Electrolyte Fuel Cells Takeshi Fukuda and Seigo Ito; University of Hyogo, Japan

Recent energy issues require urgent efforts to realize a decarbonized society around the world. To proceed to the target, development of polymer electrolyte fuel cells (PEFCs) is a topic of great interest, which is related to fuel cell vehicles. Specially, improvement of the cathode catalysts (for oxygen reduction reaction: ORR) is a very important topic for the practical use. Basically, carbon has been utilized for the Pt catalyst due to the electrically conductivity and chemical stability. In this study, metal-doped tin oxide (M-SnO_2) was used as the cathode catalyst support, and the performance was evaluated by

electrochemical measurements irrespective the conductivity of M- SnO_2.
The SnO_2 nanoparticles were synthesized by a solvothermal method. Tin chloride pentahydrate, metal chlorides as doping materials, methanol, and tetramethylammonium hydroxide solution were mixed and stirred to form precursors, which were then placed in an Teflon-lined autoclave for solvothermal synthesis. The reactants were washed with solvent using centrifugation, and the M-SnO_2 powder was obtained. Platinum nanoparticles were deposited on M-SnO_2 by the polyol method using ethylene glycol, to be a platinum-tin oxide-supported catalyst (Pt/M-SnO_2). The resulting catalyst was coated on a rotating-disc glassy carbon electrode for the electrochemical evaluation. Cyclic voltammetry (CV) and linear sweep voltammetry (LSV) were performed, and the results were characterized based on the effective Pt surface area and the activity value of ORR per Pt mass.
Among the M-SnO_2 samples prepared in this study, the highest ECSA value was obtained for Pt/Cu-SnO_2, although the Cu-SnO_2 catalyst support shows no conductivity. In this conference presentation, we will report more detailed results based on the measurements of other samples.

EN07.04.04
Characterization of NaBH4 Powder Pellets with Heterogeneous Catalysts for Hydrogen-Based Power Systems of Urban Air Mobility Junseok Yoon[1], Byunghui Kim[2] and Indae Choi[3]; [1]Korea Institute of Materials Science (KIMS), Korea (the Republic of); [2]Changwon National University, Korea (the Republic of); [3]Gyeonggi University of Science and Technology, Korea (the Republic of)

Beyond the military purpose, Urban Air Mobility (UAM), commonly known as a drone, has recently become a significant device in the individual consumers and industrial sectors. In this study, to overcome the limitations of conventional battery systems, we investigate the characteristics of nanowire structures with different dimensional catalysts of Co and Ni through the hydrolysis reactions of NaBH4 powder pellets for the application of UAM. Among the ways to improve the hydrogen conversion rate of the pellets, a small amount of cerium is added to lead the higher hydrophilicity, enhancing the more significant surface contact coverage between catalytic nanowires and the solution in which pellets are dissolved. Compared with other hydrogen supply methods, the advantages of powder pellets with catalysts for hydrogen generation and storage lead to its lightweight and long-distance driving capability, following a wide range of coverage and easy refueling. The reactivity and stability are controlled by adjusting the hydrolysis reaction of NaBH4 material from the powder pellets, and non-precious metal catalysts are applied while maximizing the hydrogen conversion rate. The effects of influential factors on the improved hydrogen conversion rates are investigated by the optimization of variables (the amount of NaBH4 powder, the proportion of aqueous solution, the rate of precipitated sodium metaborate, recycling of the water generated from renewable power systems, and maintaining the temperatures during the hydrolysis reaction, etc.). With these results, a novel power generation system with fuel cell equipment using hydrogen gas from NaBH4 powder pellets is also developed for UAMs and applied for individual mobilities and mobile robots.

2D Sulfurized MoS2 To Reduce Hydrogen Crossover in PEMFCs Shanmukh Kutagulla, Benjamin Stacy, Isabel Caldinho, Nam Le, Brian Korgel and Deji Akinwande; University of Texas at Austin, United States

A fundamental challenge facing proton exchange membrane fuel cells (PEMFCs) is the tradeoff between fuel crossover and conductivity. 2D materials provide a potential avenue to break this relationship through performance increases with thinner membranes. Atomically thin materials are hypothesized to act as sieves to selectively shuttle protons while blocking hydrogen gas based on their crystal structure and resultant pore size.

MoS2 is a potentially promising material for this application due to a near-ideal pore size, as characterized by XRD, of 2.74 A based on the (100) d-spacing that sits between the kinetic diameters of water and hydrogen gas. In this study, we examine 2D MoS2 at various thicknesses (3nm, 6nm, 12 nm) and the resulting effect on H2 crossover in the cell. All MoS2 was grown via sulfurization of different thicknesses of molybdenum deposited on c-plane sapphire in a tube furnace and transferred onto a Nafion membrane (15 um). All MoS2 samples were characterized by Raman spectroscopy. Impedance and LSV crossover data were collected for 3 samples at each thickness.

The results show that trilayer, 3 nm MoS2 is the most effective hydrogen blocking membrane (54% improvement) while the thicker layers showed progressively lower hydrogen blocking ability. The results also show a surprising inverse relationship between MoS2 thickness and conductivity, as the thinnest trilayer MoS2 layer halved conductivity from baseline Nafion, while the thickest 12 nm film illustrated comparable conductivity to the NC700. This unexpected relationship is attributed to the growth dynamics of MoS2 at different precursor thicknesses, orienting itself from horizontal growth to vertical growth modes, thus changing the effective pore size from the in-plane gap (2.74 A) to the van der Waals gap (6.15 A).

Trilayer MoS2/Nafion MEA's showed superior crossover performance as compared to the baseline NC700, albeit halving conductivity, effectively performing similar to a much thicker membrane. This study thus illustrates the successful growth, transfer, and demonstration of a 2D material to improve the crossover characteristics of a Nafion membrane and provides a roadmap for further use of 2D coatings to enhance membrane performance.

EN07.04.06
Enhanced Photoelectrochemical Performance of WO_3 with Bi-Based Metal-Organic Frameworks and Glycerol Yoonsung Jung[1], Seungkyu Kim[2] and Sanghan Lee[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Energy Technology, Korea (the Republic of)

Photoelectrochemical (PEC) glycerol oxidation is an economical and nature-friendly energy conversion method that promotes hydrogen production and generates high value-added products using solar energy. Glycerol is a by-product of biodiesel manufacturing processes made from biological sources such as vegetable oils and animal fats. The need for biodiesel is increasing due to environmental problems and rising fossil fuel costs, and production of waste glycerol is also increasing.
On the other hand, glycerol is one of the three hydroxyl groups of alcohols. It is kinetically easily oxidized and thermodynamically requires less energy than water in the oxidation reaction. An oxidized products of glycerol are glyceraldehyde, dihydroxyacetone, glyceric acid, tartronic acid, glycolic acid, formic acid, and oxalic acid. Among them, glycolic acid is more valuable than glycerol and is used as a material for derivatives, degreasers, and skin care products.
Recently, research on PEC glycerol oxidation with various metal oxides has attracted attention. WO_3 is one of the suitable photoanodes for PEC glycerol oxidation owing to appropriate values of band gap (2.5-2.7 eV) and valence band edge position (3.0 V vs. reversible hydrogen electrode (RHE)). Nevertheless, studies on the selectivity and photocurrent improvement of PEC glycerol oxidation by WO_3 photoelectrodes are still insufficient. In order to improve the photocurrent of glycerol oxidation, a utilization of oxygen evolution cocatalysts (OECs) is one of the effective strategies owing to increasing the active area and promoting the charge transfer ability. Especially, Bi-metal organic frameworks (Bi-MOFs) is promising candidate of the OECs because Bi-MOFs is able to provide the high specific surface area, multiple active sites, and good catalytic stability.
We successfully fabricated Bi-MOFs/WO_3 via solvothermal synthesis. With adding glycerol to the electrolyte, the WO_3 photoelectrode shows improved photocurrent performance on the PEC glycerol oxidation reaction (1.14 mA/cm^2) than PEC water oxidation reaction (0.17 mA/cm^2) at 0.8 V vs. RHE under

1 sun. The main product by glycerol oxidation is a glycolic acid which is converted with selectivity of 80 % among products. Furthermore, the photocurrent is enhanced while maintaining the selectivity (82 %) in Bi-MOFs/WO_3 photoanodes (1.53 mA/cm^2 at 0.8 V vs. RHE).
This study highlights that an eco-friendly and sustainable hydrogen and high value-added product production system based on Bi-MOFs/WO_3 photoanodes which utilize solar energy and waste resulted from biodiesel.

EN07.04.07
Highly Active Cobalt Manganese Oxyhydroxide Added Pt/C Catalyst as ORR for PEFC Maito Tanabe and Seigo Ito; University of Hyogo, Japan

Problem of polymer electrolyte fuel cells (PEFCs) is the high cost and low durability of platinum-supported carbon catalysts (Pt/C). The cost issue is generally due to the high cost of platinum. This problem can be solved by adding other elements to Pt/C to increase the activity of Pt and reduce the amount of Pt used.[1] In this work, we focused on cobalt manganese oxyhydroxide (CMOH), because CMOH has been reported to be highly active as a catalyst for oxygen evolution reaction (OER) in alkaline water electrolysis.[2] In this study, CMOH was utilized to improve the oxygen reduction reaction (ORR) of Pt/C catalysts.

SnO_2 nanoparticles were utilized for the supporting material of CMOH. SnO_2 colloids were dispersed in H_2O. Potassium permanganate and cobalt acetate were added to the solution and stirred to coat CMOH on the SnO_2 surface (as CMOH-SnO_2). The obtained CMOH-SnO_2 was separated from the residue by centrifugation. The CMOH-SnO_2 was redispersed in water and ethanol, and Ketjen black (KB) was added and stirred. After heating, the solution was dried, and the obtaied CMOH-SnO_2/KB powder was grinded in an agate mortar. By heating the CMOH-SnO_2/KB powder at 300 °C for 2 hours, cobalt manganese oxide-SnO_2/KB (as CMO-SnO_2/KB) was obtained. Pt-CMOH-SnO_2/KB and Pt-CMO-SnO_2/KB were obtained by depositing platinum on these powders by the polyol method using ethylene glycol. For these electrochemical measurements, a three electrodes system cell was used with a rotating disk electrode coated with catalyst as the working electrode, a platinum wire as the counter electrode, and a reversible hydrogen electrode as the reference electrode with 0.1 M $HClO_4$ as the electrolyte solution.

Pt-CMOH-SnO_2/KB and Pt-CMO-SnO_2/KB showed lower ECSA values than Pt/KB. By TEM measurements, this is confirmed to be due to the agglomeration of platinum. However, both Pt-CMOH-SnO_2/KB and Pt-CMO-SnO_2/KB showed higher specific activity per Pt surface area. The interaction of CMOH or CMO with Pt may contribute to the enhanced catalytic activity. The improvement in specific activity was higher for Pt-CMO-SnO_2/KB than for Pt-CMOH-SnO_2/KB. This difference may be due to the presence or absence of hydroxyl groups in CMOH. As a result, Pt-CMO-SnO_2/KB successfully increased the oxygen reduction reaction activity (mass activity) per Pt mass compared to Pt/KB.

Hybrid Approach of Phase Separation and Selective Leaching Processes for Multicomponent Alloy Nanostructures and its Application to Hydrogen Storage Alloys Jinwoo Kim[1], So Young Lee[1,2], Ji Young Kim[2] and Eun Soo Park[2]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

In contrast to classical bulk alloying processes represented by melting and casting of metal mixtures, the fabrication of multicomponent alloy (MCA) nanostructures such as nanoparticles and nanofoams with more than three elements is often challenging. A few methodologies for directly synthesizing alloy nanostructures up to denary systems have been suggested recently. However, forming alloy nanoparticles inside another metal matrix, instead of inside aqueous media in wet solution-based chemical synthesis, is a fairly well understood strategy in terms of physical metallurgy. Extracting those alloy nanophases chemically from the matrix could provide an alternative way for fabricating novel MCA nanostructures. In this presentation, we introduce a hybrid approach of metallurgical bottom-up and chemical top-down processes for fabricating MCA nanostructures including nanoparticles and nanofoams. The former utilizes the liquid-state phase separation phenomenon that resembles “oil and water”, but occurs at nanoscale due to thermodynamic mixing relations among alloying elements and a rapid quenching process. Thermodynamic prediction of immiscible boundary in a temperature-composition space (miscibility gap) plays a key role in designing precursor alloys with MCA nanostructures. Selective leaching, the chemical top-down process for extracting the alloy nanostructures from the precursors, uses the chemical reactivity difference between the embedded nanostructures and the matrix phase against a certain chemical solution. We discuss here how the precise control of alloy composition and cooling rate based on thermodynamic assessments enables to prepare phase-separating precursor alloys for fabricating both nanoparticles and nanofoams with a broad size range. Depending on alloy systems, the atomic structure of alloy nanostructures could be controlled from fully amorphous to nanocrystalline and even into quasicrystalline structure. This unique approach for fabricating nanosized alloys provides an extended methodology to discover novel metallic nanomaterials with promising properties in diverse compositional spaces of MCA systems. We demonstrate how this approach can be applied to fabricate nanostructured alloys for reversible hydrogen storage (e.g. TiFe nanofoams). We also present how controlling the processing parameters influences the ligament size of the nanofoams and eventually manipulates their hydrogen adsorption and desorption behavior by nanoscale size effects.

Impact of Ion Exchange Capacity and Counterion Concentration on the Structure-Property Relationship of Pentablock Copolymer Ionomers Andrew White, Thivani Senathiraja and Chris Cornelius; Iowa State University, United States

Proton exchange membranes (PEMs) are becoming more prevalent in many industries as they are integral to many clean energy technologies. The ion transport and physical properties of PEMs can be fine-tuned by altering their morphology to allow a greater degree of efficiency in a wide range of applications. In this study, the impact of ion-exchange capacity (IEC) of pentablock copolymers (PBC(XX)) exchanged with different counterions was used in order to gauge their effects on the morphology and properties of these membranes. The counterions, $AlCl_3$ and LiCl, were directly introduced into the solvent and were combined with 5wt% PBC blends to produce homogenous solution-cast membranes. The FTIR analysis showed that, in the case of LiCl counterions exchanged with PBC, the interaction energy between the sulfonic acid groups and counterions increases with the concentration of counterions; however, it decreases with an increase in the concentration of sulfonic acid groups. In addition, in the case of PBC exchanged with $AlCl_3$ counterions, PBC (2.0) membranes showed no impact, while PBC (1.5) exhibited preferential interactions with the counterions. The ion conductivity measured using electron impedance spectroscopy (EIS) showed that, overall, as the concentration and size of counterions increased, the ionic conductivity dropped significantly. However, when the concentration of LiCl is 0.01M, both PBC (1.5) and PBC (2.0) had 38% and 62% higher conductivity values, respectively, when compared to the pure membranes except PBC (1.0). The enhancement in ion conductivity may be due to the rearrangement of the morphology of the PEM to facilitate ion conductivity. The thermal stability studies of PBC (1.5) and PBC (2.0) portrayed higher stability for membranes exchanged with $AlCl_3$ when compared to LiCl, while PBC (1.0) showed similar stability for both counterions. However, when the IEC of the PBC membranes increased, the thermal stability decreased by 5%. The decrease in the stability may be attributed to the acceleration decomposition due to the presence of sulfonic acid groups. Further studies may include a full morphological study to determine the extent of these changes.

Selenium-Incorporated Ruthenium Phosphide Nanotubes for Accelerated Hydrogen Evolution Reaction in Alkaline Media Eunsoo Lee and Kwangyeol Lee; Korea University, Korea (the Republic of)

Hydrogen production *via* electrochemical water splitting is a promising technology that can provide sustainable and eco-friendly energy resources. However, the hydrogen evolution reaction (HER) in alkaline conditions is still challenging owing to the sluggish reaction kinetics from the additional water dissociation step as a formidable hurdle. Due to the superior intrinsic activity of Ru-based electrocatalysts with phosphorous, we synthesized the selenium-incorporated ruthenium phosphides (Se-Ru_2P) nanotubes *via* alternating anion and cation exchange of $Cu_{2-x}S$ hexagonal nanorod templates. Interestingly, selenization of Ru_2P nanotubes could further improve the HER performance after an accelerated durability test (ADT), which might result from the newly formed anion vacant sites during the water electrolysis. Moreover, an in-depth X-ray photoelectron spectroscopic study demonstrated that the Ru-P bonds were more preserved in Se-decorated Ru_2P after ADT than in Ru_2P without Se decoration. Considering these advantages, the Se-Ru_2P nanotubes achieved superior hydrogen evolution catalytic properties with low overpotentials of 39 mV at a current density of 10 mA/cm^2 in 1.0 M KOH after 15,000 CV cycles. Furthermore, the Tafel slope of Se-Ru_2P nanotubes was only 32.8 mV dec^{-1}, indicating that the introduction of Se can positively alter the reaction kinetics toward the HER in alkaline media.

EN07.04.13
Mosaic CrO/Co_9S_8 Heterostructure with a Maximized Synergy Effect for Hydrogen Evolution in Neutral Media YeJi Park and Kwangyeol Lee; Korea University, Korea (the Republic of)

Generating hydrogen, an eco-friendly energy carrier, through electrochemical water splitting from the neutral media has attracted considerable attention due to the much less corrosion of the water electrolyzer and the feasibility of the direct usage of seawater sources without pH adjustment. To enhance the catalytic performance in neutral media by modulating the HER mechanism, electrocatalysts with dual-site were required for facilitating fast water adsorption/dissociation and sequential hydrogen desorption, respectively. Therefore, designing the well-defined heterostructures by integrating the H_2O adsorption-active materials with HER-active materials is a promising strategy to heighten the HER performance. Herein, we embedded the numerous oxophilic cluster into the metal sulfide matrix to synthesize the mosaic hetero-nanostructure with the maximized interface, increasing the active sites for hydrogen evolution reaction. The efficient charge redistribution at the interface is significantly enhanced the catalytic performance. This study provides a promising design strategy to synthesize the electrocatalysts with hetero-interface and a realization to understand the fundamental HER mechanism in neutral media.

EN07.04.14
Activating NiO Nanorods via Nitrogen Doping and Vacancy Engineering for Alkaline Hydrogen Evolution Reaction Jaerim Kim[1], Dong-Seok Kim[2], Jiye Kim[1], Hyeonwoong Hwang[1] and Jong kyu Kim[1]; [1]Pohang University of Science and Technology (POSTECH), Korea (the Republic of); [2]Korea Atomic Energy Research Institute, Korea (the Republic of)

Developing efficient and inexpensive electrocatalysts for oxygen evolution reaction (OER) and hydrogen evolution reaction (HER) in alkaline water-electrolysis is of paramount importance in the hydrogen economy to meet future energy demands. Earth-abundant transition metal oxide-based catalysts including NiO have emerged as the active OER catalysts with the advantages of compositional and structural diversity, low cost, easy synthesis, and eco-friendliness. However, they are generally considered inactive towards HER because of limited catalytic active sites, poor electrical conductivity, and inappropriate adsorption abilities. Herein, we show a strategy to activate NiO by using unique ion irradiation technology, which simultaneously creates the nitrogen dopants and oxygen vacancies. An array of three-dimensional (3D) NiO nanorods (NRs) was applied as the scaffold that provides abundant surface active sites and efficient channels for charge transfer and mass transport. Our experimental and theoretical results demonstrate the synergistic effect of nitrogen doping and vacancy engineering via nitrogen-ion irradiation to optimize the hydrogen adsorption and electrical conduction of NiO NRs, which results in the remarkably enhanced alkaline HER performance. Our approach can provide an effective and unique methodology for designing efficient electrocatalysts consisting of earth-abundant elements for electrochemical hydrogen production.

EN07.04.15
Highly Scalable Non-Noble Tri-Metallic Catalyst for Anion Exchange Membrane Electrolyzer Cell (AEMEC) Without Deactivation for Hundreds of Hours Demonstrated in Membrane Electrode Assembly Setup Ali Abdelhafiz[1], Sameh Elsaidi[2], Paul Kohl[3] and Ju Li[1]; [1]Massachusetts Institute of Technology, United States; [2]Illinois Institute of Technology, United States; [3]Georgia Institute of Technology, United States

Elevated pollution levels due to hydrocarbon fuels combustion and associated global warming effects escalate the necessity to find green alternative energy sources. Other CO2-free energy sources, such as nuclear energy, is hindered due to elevated costs of dumping the spent nuclear fuel and safety-related mitigation protocols. Thus, Water electrolysis is deemed the most prominent solution towards an economically feasible green hydrogen production. Water electrolysis results in the production of clean hydrogen and oxygen, without any associated carbonaceous emissions. Electricity used in water splitting can be supplied from intermittent and inexpensive sources, such as windmills, where such an electricity can't be stored for prolonged periods due to limited grid-scale battery capacity, for less than half a day. Electrochemical water splitting runs through two separate half reactions: hydrogen evolution reaction (HER) and oxygen evolution reaction (OER). Both reactions are sluggish in nature where an electrocatalyst is essential for the reaction to take place. Catalysts of choice for HER and OER, up to date, are based on noble metals (e.g., Pt, Ir or Ru). In addition to being very expensive, noble metal catalysts suffer from extremely short lifetime and poor efficiency. Therefore, many research efforts have been devoted to discovering efficient, prolonged, and cost-competitive catalysts. Transition metals (TM) have shown great potential in catalyzing HER and OER. OER is considered the bottleneck reaction in water electrolysis. Modulating the metal-oxygen covalency is considered a key to optimize the interaction between the catalyst materials and reaction intermediates. Alloying of different transition metals, heteroatom doping, and/or vacancy creation are prominent strategies to alter the electronic configuration of TM catalyst surfaces to enhance their electrocatalytic activity.
In the presented study, we are demonstrating the utilization of a versatile metal organic framework platform for OER in alkaline aqueous mediums. We carefully studied the effect of tri-metallic Fe, Ni and Co alloying, and their corresponding effect on OER activity and stability. Our synthesized MOF architecture showed a significant enhancement in OER activity due to dynamic chemical state perturbation during OER process, where tri-metallic MOF

turns from metallic to oxide, before converting to the super active oxyhydroxide phase at the OER onset. Catalyst electronic conductivity is a crucial factor to enhance its activity. Our developed synthesis strategy, beside being highly scalable to match industrial demands, successfully fabricated the tri-metallic MOF with a very high surface area and minute crystallite size. Catalytic activity towards OER have been demonstrated in a membrane electrode assembly (MEA) setup in an actual AEMEC device. Results showed a high stability and low overpotential, where catalysts subjected to 1000 mA/cm^2, recording a potential of 1.85 V. Performance remained stable for over 550 hours of continuous operation without noticeable decay in performance. The presented study is introducing an inexpensive, tremendously stable, and highly active catalyst without any noble metals, which can meet the industrial demands for green hydrogen production.

EN07.04.16
A Valuation Study of Membrane Thickness Selection and Load Cycling on Long-Term Value of PEM Water Electrolysis Systems Efat Mohammadi and Alexander J. Headley; The University of Memphis, United States

As the proportion of energy produced from intermittent renewable energy sources increases, the value of systems capable of storing large quantities of energy will increase as well. Hydrogen, being a very flexible energy storage medium with many end use applications, could play a pivotal role in the future. Polymer electrolyte membrane water electrolyzers (PEMWEs) have been gaining significant attention as a method of producing green hydrogen from intermittent renewable energy sources due to their simplicity, possibility to be designed as a compact system, and suitable dynamic response to the power fluctuations that will be inherent with fluctuating renewable power generation. The highest expenses for electrolysis systems are the membranes, noble metals for the electrocatalysts, as well as the bipolar plates and their coatings. Given the durability concerns for these systems in some conditions and the high upfront cost, they will need to be used in the right applications in addition to being sized and operated appropriately to make them cost-effective. For long term PEMWE performance the weakest component is the membrane, with membrane thinning being one of the most important degradation phenomena in water electrolysis. Though thinner membranes reduce ohmic losses, thereby increasing efficiency they are also more likely to fail more quickly than thicker membranes. Cell durability and safety issues regarding the mechanical strength of thinner membranes in PEMWE, as well as the permeability of gases through the membrane, are critical issues that must be considered. As a result of these two conflicting trends regarding membrane thickness, maximizing the long-term value of an electrolysis system will depend in part on the selection of the proper membrane specifications to maximize their life while minimizing the impact on efficiency.
This is a particularly important consideration for pairing with renewable energy as fluctuating power levels have an impact on PEMWE performance. However, primary studies on PEMWE degradation behavior have shown conflicting results as to how degradation is impacted by power fluctuations. While in some experiments cell voltage performance degradations are reported due to the current ripple, in the others, positive effects of current density switching on PEMWE durability are investigated. This makes valuation studies difficult as it is very unclear how the systems will be impacted by different operational characteristics. It has been suggested by some to leverage the available literature on PEM fuel cell (PEMFC) durability to evaluate electrolyzers as well, but these two technologies contain different materials, boundary and operating conditions which may not make the PEMFC literature useful for PEMWE systems.
Thus, in the present study the effect of membrane thickness selection on long-term value is considered with respect to various degradation trends reported in the literature. The reported performance of PEM electrolyzers are discussed to demonstrate how the value of a PEM electrolysis system could vary depending on the degradation phenomena that occur. Estimates for the effects of membrane thickness and load cycling on PEMWE longevity reported from various sources (including the PEMFC literature) are applied in conjunction with our suggested optimization software to highlight the PEMWE degradation issue. Here we hope to highlight the potential effects for system selection of the gap in PEMWE degradation data and determine the uncertainty that this knowledge gap brings to the realm of system sizing and valuation.

EN07.04.17
Study of the Use of Au-Nanoparticles and Mg Thin-Film Layer as Hole- and Electron-Selective Contacts in TiO_2-Based Photocatalytic Systems Oriol Segura[1], Eloi R. Costals[1], Cristobal Voz[1], Pablo R. Ortega[1], Magno Barcelos[2], Edoardo Maggi[1], Edgardo Saucedo[1], Jordi Llorca[1], Lluis Soler[1] and Joaquim Puigdollers[1]; [1]University of Politecnica-Catalunya, Spain; [2]Universidade Federal de São Carlos, Brazil

Photocatalysis is defined as the acceleration of chemical reactions under illumination and in the presence of a catalyst, which absorbs light and participates in the chemical transformation of the products present in the electrolyte. Under illumination, the photocatalytic system photogenerates charge carriers. The different electrochemical energies of these electrons and holes will be used to oxidize or reduce compounds, which translates into interesting applications, such as the generation of hydrogen or the elimination of pollutants. Since the light source comes from the sun, photocatalysis is considers a green technology to convert solar energy into chemical energy.

For the system to be efficient, these charge carriers (electrons and holes) must be physically and energetically separated. The energy separation must be adequate to be able to participate in the chemical reactions of reduction and oxidation, while the physical separation is necessary to avoid their recombination. As occurs in the manufacture of solar cells, the use of selective contacts of electrons and holes is a good strategy to achieve a physical and energetic separation of the photogenerated carriers.

In this work we optimize hydrogen generation from TiO_2 using selective contacts based on Au nanoparticles and thin layers of metallic Mg. Au np acts as a hole transport layer (allowing hole transport and blocking electrons) while Mg acts as an electron transport layer (allowing electron transport and blocking hole transport). Au incorporation is done by sol–gel dip coating method. While the deposition of Mg is carried out by thermal evaporation deposition in high vacuum. The use of shadow masks during the deposition of Mg allows obtaining an interdigitated structure, with TiO_2/Au np fringes and Mg fringes, in what we can call an Interdigitated Front Contact Photocatalytic system.

The global average hydrogen production was 2.8 µmol/(min g) *o*nly for the TiO_2 absorber, while in the sample with gold the global average production increases to 66.4 µmol/(min g) due to the catalytic effect. of gold nanoparticles. However, for the sample containing Au np plus the Mg layer, the hydrogen generation doubled the generation with respect to the TiO_2/Au sample, with an average total hydrogen production of 133.7 µmol/(min g)

This experimental result can be explained by taking into account the energy diagram of the different layers. The final conclusion is that the TiO_2/Au interface acts as a selective contact of holes, whereas Mg acts as a selective contact of electrons.
Additional characterization of the samples was performed by HRTEM, SEM and EDX.

EN07.04.18
Interfacial Band Alignment and Photoelectrochemical Properties of All-Sputtered $BiVO_4$/$FeMO_x$ (M = Co, Ni, Mn) *p-n* Heterojunctions Renato V. Goncalves[1], Andressa Correa[1], Lucas Rabelo[1], Washington Santa Rosa[1], Niqab Khan[2] and Sherdil Khan[2]; [1]University of Sao Paulo, Brazil; [2]Federal University of Rio Grande Do Sul, Brazil

$BiVO_4$ is a well-known *n*-type semiconductor with great potential for photoelectrochemical (PEC) conversion of solar energy into chemical fuels.

Nevertheless, photocurrent densities achieved for bare $BiVO_4$ photoanodes are still far from their theoretical maximum due to the sluggish water oxidation kinetics and severe electron-hole recombination. In this work, magnetron sputtering deposition was applied for depositing $FeMO_x$ (M = Co, Ni, Mn) cocatalyst layers to induce *p-n* heterojunctions and suppress charge recombination on $BiVO_4$ photoanodes. The all-sputtered $BiVO_4/FeMO_x$ (M = Co, Ni, Mn) films exhibited higher PEC performance on sulfite oxidation than the bare $BiVO_4$ photoanode. The *p-n* heterojunction $BiVO_4/FeMnO_x$ exhibited the highest photocurrent density (1.99 mA cm^{-2} at 1.23 V vs. RHE) and excellent chemical stability, indicating that the combination of Mn sites on Fe-based oxides provides promising novel cocatalysts materials for PEC applications. Experimental and theoretical techniques were used to investigate the interfacial band alignment and charge transport properties of $BiVO_4/FeMO_x$ (M = Co, Ni, Mn) heterojunctions. The results show that the naive alignment of the individual energy bands of semiconductors, both before and after equilibrium, results in significant potential barriers for the photogenerated charges on the $BiVO_4/FeMO_x$ (M = Co, Ni, Mn) photoanodes, which does not explain its enhanced PEC performance. Therefore, X-ray photoelectron spectroscopy, the Kraut method and the classical band bending model were combined to determine the valence band offsets, potential drops supported in the *n* and *p* layers, and the related depletion widths. Our results show that type II heterojunctions arise in the $BiVO_4/FeMO_x$ (M = Co, Ni, Mn) interface after equilibrium, eliminating the possible potential barriers. Furthermore, the $BiVO_4/FeMnO_x$ film showed a larger space charge region (SCR) characterized by a more intense built-in electric field than other heterojunctions, which explains its higher PEC performance. In summary, this work provides a viable technique for producing photocatalytic heterojunction systems based on metal oxide semiconductors and introduces simple tools for investigating interface effects on photoinduced charge carrier pathways for PEC applications.

EN07.04.20
Anti-Poisoning Carbon Shell-Encapsulated Pt-Based Nanoparticles for Selective Electrochemical Reactions in PAFCs Sourabh Chougule, Sreya Roy Chowdhury, Bathinapatla Sravani, Jiho Min, Yunjin Kim, Keonwoo Ko and Namgee Jung; Chungnam National University, Korea (the Republic of)

In phosphoric acid fuel cells (PAFCs), one of the significant issue is poisoning of Pt-based cathode catalysts by phosphate anions. It is well known that the fuel cell performance decreases by blocking the electrochemically active sites for oxygen reduction reaction (ORR) due to the strong adsorption of phosphate anions on the Pt surface. In this study, we attempt to reduce the poisoning effect by phosphate anions through encapsulating Pt-based nanoparticles by a molecular sieve layer. The structural control of the molecular sieve layer reduces the adsorption of anions and allows gas molecules to selectively penetrate into the Pt surface. In addition, the molecular sieve layer is expected to effectively prevent the dissolution of metal nanoparticles even under harsh conditions during the electrochemical reaction. The electrochemical analysis results suggest that metal nanoparticles coated with a molecular sieve layer having a better antipoisoning capability toward phosphate anion, high selectivity toward ORR with high durability in acid solutions. The durability of the molecular sieve layer-coated metal nanoparticles is demonstrated by accelerated degradation tests (ADTs). Inevitably, designing Pt-based catalysts with an antipoisoning carbon molecular sieve layer provides a highly effective way for use in PAFCs.

EN07.04.22
Understanding the Fundamentals of Hydrogen Degradation in Pipeline Steels Used for Large-Scale Storage and Transport Ting Yang[1], T. A. Venkatesh[2] and Ming Dao[1]; [1]Massachusetts Institute of Technology, United States; [2]Stony Brook University, United States

There is considerable interest in repurposing and reusing the multi-billion dollar pipeline infrastructure that is currently used for transporting natural gas for large-scale storage and transport of green hydrogen needed for the hydrogen economy. One of the key technical challenges in transitioning from natural gas networks to hydrogen networks is in understanding the effects of hydrogen on pipeline materials and identifying optimal operating conditions for the reliable and long-term use of the pipeline infrastructure. It is well known that hydrogen degradation (HD), a complex metallurgical phenomenon that combines chemical and physical processes that ultimately reduces material toughness and leads to catastrophic failure, is a key materials challenge to be addressed for enabling the hydrogen economy [1]. In particular, natural gas pipeline steels and pressure vessel steels, most of which are (BCC) ferritic steels, are susceptible to spontaneous failure in the field [2-6]. It is also observed that the hydrogen embrittlement effect is much more pronounced at relatively lower stresses and crack driving forces [7]. In this study, we focus on pure iron, which has a BCC crystal structure, as a model material and investigate the hydrogen embrittlement effect using several experimental approaches, including low cycle fatigue testing with the materials pre-charged with hydrogen and in-situ electrochemical nanoindentation testing of materials with in-situ charging of hydrogen. 304 stainless steel (FCC austenitic steel) is used as reference material. For the materials subjected to low cycle fatigue tensile experiments, fractographic analysis is conducted on the fracture surface to elucidate the effect of hydrogen on the microstructure and mechanical properties. For the materials subjected to in-situ electrochemical nanoindentation, microstructural analysis is conducted to understand the development of insipient plasticity events and dislocation microstructures in localized regions. The embrittlement effects due to hydrogen charging and the differences in dislocation and fracture characteristics are compared between pure iron and 304 stainless steel materials. The insights learned from the hydrogen embrittlement mechanism in pure iron could provide metallurgical design strategies for developing damage-resistant materials for pipeline steels in hydrogen storage and large-scale transport.

Graphene Oxide-Hydrogen Membrane Fuel Cells Using Ni-Zr Alloy Thin Films Young J. Cho, Shahjahan K. Chowdury, Sung B. Park and Yong-il Park; Kumoh National Institute of Technology, Korea (the Republic of)

Graphene oxide film (GOM) is an excellent proton conductor at room temperature under humidified conditions, but graphene oxide film fuel cells (GOMFC) exhibit lower maximum power densities compared to Nafion® due to fuel crossover, film degradation and loss of surface function. In this study, a double membrane composed of the GOM and a hydrogen permeable Ni-Zr alloy thin film was investigated as an electrolyte membrane for a hydrogen membrane fuel cell (HMFC). In this fuel cell, the graphene oxide-hydrogen film (GOHM) simultaneously serves as an anode catalyst and an electrolyte. A hydrogen-permeable metal thin film of about 40 nm was deposited by DC magnetron sputtering on a 20 μm-thick GOM using a $Ni_{64}Zr_{36}$ target to complete a double-layer GOHM electrolyte. The fuel cell performance of the fabricated Ni-Zr-based GOHMFC was compared with that of conventional PEMFC.

Controlling the Macrostructure of Chromophore Hydrogels for Enhanced Photocatlytic Hydrogen Evolution Jacob E. Kupferberg[1,2], Zois Syrgiannis[1,3], Luka Dordevic[1,2], Eric Bruckner[1], Adam Dannenhoffer[1], Evan Qi[1], Kristen Wek[1], Harry C. Fry[4], Liam Palmer[1,2,3] and Samuel I. Stupp[1,2,3]; [1]Northwestern University, United States; [2]Center for Bio-Inspired Energy, United States; [3]Simpson Querrey Institute for BioNanotechnology, United States; [4]Argonne National Laboratory, United States

Solar fuel generation is a promising method of producing stable storage molecules like hydrogen gas using abundant sunlight as an energy source. Self-assembling chromophore amphiphiles based on perylene monoimide (PMI) can form weak hydrogels capable of producing of H_2 in water under visible light illumination. However, the high diffusivity of these gels comes at the cost of poor mechanical stability. We report here on the use the natural biopolymer sodium alginate to both promote self-assembly and immobilization PMI in a robust hydrogel. The PMI-alginate matrix can entrap catalysts in close proximity to PMI photosensitizer to enhance H_2 evolution and enable long-term reusability for up to six days. By changing the diameter and the alginate loading of the PMI-alginate gel, we showed that hydrogen production could be enhanced by reducing the mass transfer distance of reagents through the gel.
The long-aspect ratio of the pi-pi stacked PMI assemblies also enables the formation of a percolation network for electrical conduction within the hydrogel network. In the hydrated state, the chromophore hydrogels displayed photoconductivity under visible light, enabling the application of these 3D hydrogels to electrodes. We then 3D printed this material on an FTO-NiO substrate to create 3D hydrogel photocathodes.

Highly Conjugated Covalent Organinc Frameworks for the Photocatalytic Generation of Hydrogen Jai-Ram Mistry and Iain A. Wright; Loughborough University, United Kingdom

The development of new conjugated covalent organic frameworks (COFs) designed specifically to maximise hydrogen adsorption and production has been a hot topic in recent years due to the desirable properties COFs possess. High thermal and chemical stability, tuneable pore sizes and charge transport properties as well as the molecular building block approach in their synthesis all make COF's excellent materials for hydrogen storage and production. This coupled with the lack of heavy metals within their structure and within their synthesis make COFs attractive in terms of sustainability.[1]

The specific design of compounds with a spiro core have been studied extensivley as componenets of conjugated oligomers and polymers, and their use as organic light emitting diode (OLED) and solar cells.[2] However, the use of spiro component in COFs has yet to be explored extensively. The C4 type symmetry in spiro compounds coupled with C2 symmetry in linkers would provide interesting topologies when considering the dihedral angel in spiro compounds. Varying the linker length also provides a greater insight into the effects this has on pore size and hence and H2 adsorption.

Furthermore, introducing electron rich donor type molecules within the linkers of the framework furthers the scope of application for these COFs thus allowing them to be used as photocatalysts for photocatalytic evolution of H2 from water. The high degree of crystallinity favours charge separation and transport, which provides COFs with promising catalytic activity.[3] This ties into the growing interest of organics polymeric photocatalyst as well as the growing market for new hydrogen storage and generation materials.

Herein we present a series of highly conjugated spiro core-based COFs designed with two main objectives, to increase hydrogen adsorption rates of COF materials and to further increase the hydrogen evolution rate (HER) seen in current COF photocatalyst materials.

Glycerol-Assisted Solar-to-Hydrogen Electrolysis in Simple Photoelectrochemical Integrated Systems Zebulon G. Schichtl, Robert H. Coridan, Hamed Mehrabi and Samuel K. Conlin; University of Arkansas, United States

Storing solar energy in the form of hydrogen from water splitting is an attractive replacement for fossil fuels for on-demand energy use. Unassisted solar-driven water splitting is difficult to achieve due to the overall thermodynamics of the reaction and the overpotentials required to drive water oxidation at appreciable rates. The ideal semiconductor material for water splitting would be capable of absorbing a substantial portion of the solar spectrum and generating hydrogen and oxygen at high rates, but this material does not exist yet. The voltage requirements of water splitting are met by designing complex, tandem photoelectrode systems in series but scalability and cost remain major concerns. Glycerol is a co-product of renewable biodiesel synthesis with a well-defined electrooxidation mechanism. The design of solar-to-hydrogen integrated photoelectrochemical (PEC) devices is simplified by replacing water oxidation with crude glycerol electrooxidation. Here, we describe the development of a trimetallic AuPtBi electrocatalyst with increased and sustained electrooxidation activity for crude glycerol. When paired with a hydrogen evolving cathode, the electrolysis system is capable of driving hydrogen evolution at low overall cell potentials (< 0.5 V). We demonstrate the capability for using a single semiconductor light absorber for solar-to-hydrogen production when the anode is performing glycerol oxidation rather than water oxidation. We demonstrate a photoelectrolysis approach using a monocrystalline Si and a GaAs single-junction photovoltaic (PV) in a traditional PV-electrolyzer system, and for an integrated PEC system driven by a copper bismuthate ($CuBi_2O_4$) photocathode. Finally, we will discuss technical and catalytic metrics that should be considered when comparing these glycerol-assisted integrated systems to other solar-to-fuels technologies.

9:15 AM EN07.05.05
H2 Production from Photocatalytic Assisted Electrolysis of Water Sang Youn Chae[1], Noyoung Yoon[2,3], Adeel Mehmood[1], Oh-Shim Joo[2] and Eun Duck Park[1]; [1]Ajou University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]Yonsei University, Korea (the Republic of)

Electrolysis of water can be a promising way of producing green hydrogen gaseous because of its zero-carbon emission during the electrolysis process. For green hydrogen production, the electrical power source for electrolysis also should be supplied from a renewable source such as solar light, this is one of

the reasons to increase the production cost of green hydrogen when compared to the production cost of grey hydrogen. Therefore it is important to increase electricity to hydrogen conversion efficiency. In this research, we utilized solar energy via WO_3 photocatalyst for water oxidation reaction and redox couple reduction. For efficient water oxidation and redox couple reduction, the noble-metal co-catalyst decorated WO_3 nanoparticle is designed. And then, the solar energy which is stored in the redox couple is subsequently used in the electrolysis process for hydrogen production reaction. This photolysis-electrolysis tandem system allows largely reduced operating voltage and also led to increased electrical power to hydrogen conversion efficiency.

Charge Transport in $SrTiO_3$:Rh and $BiVO_4$ Nanoparticle Photocatalysts for Z-Scheme Water Splitting Brian T. Zutter[1], Zejie Chen[2], Aliya S. Lapp[1], Kenta Watanabe[3], Luisa Barrera[4], Austin Bhandarkar[1], Akihiko Kudo[3], Rohini Bala Chandran[4], Shane Ardo[2] and A. A. Talin[1]; [1]Sandia National Laboratories, United States; [2]University of California, Irvine, United States; [3]Tokyo University of Science, Japan; [4]University of Michigan–Ann Arbor, United States

Solar-powered water splitting using nanoparticle photocatalyst suspensions is a promising route to economical, clean hydrogen production. In the Z-scheme approach, hydrogen and oxygen-evolving photocatalysts, such as $SrTiO_3$:Rh and $BiVO_4$, are coupled with a redox mediator to improve light absorption compared to single-photocatalyst systems. A key step in the water-splitting process is the separation and transport of photo-excited electrons and holes to the photocatalyst surface. Here we characterize charge transport in individual $SrTiO_3$:Rh and $BiVO_4$ nanoparticles using a nanoprobe within a scanning electron microscope, and directly map internal electric fields with electron-beam induced current. Charge transport in $SrTiO_3$:Rh particles is limited by bulk defect states within the nanoparticle, in contrast to nearly Ohmic conduction in $BiVO_4$ nanoparticles. $SrTiO_3$:Rh particles contain insignificant built-in E fields, while $BiVO_4$ nanoparticles contain built-in E field between different facets of the nanoparticle which can efficiently separate e-h pairs. Inefficient charge transport and lack of built-in electric field explain why the H_2-evolving $SrTiO_3$:Rh nanoparticles are the limiting component within this Z-scheme system.

Improving Hydrogen Storage in Metal-Organic Frameworks Michael Hirscher[1,2]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Advanced Institute for Materials Research, Tohoku University, Japan

Hydrogen storage in nanoporous materials has been attracting a great deal of attention in recent years, as high gravimetric H_2 capacities can be achieved at 77 K using materials with particularly high surface areas. Cryogenic storage by physisorption of hydrogen molecules will safely operate at low pressures, is fully reversible and has fast kinetics.
Experimental data of the gravimetric and volumetric hydrogen uptake have been analysed for many MOFs showing a linear correlation of the gravimetric absolute uptake with the specific surface area (Chahine's rule) [1]. Using the packing density of the powder as well as the single-crystal density, a linear relation is found between the volumetric absolute hydrogen uptake and the volumetric surface area [2]. The specific total volume occupied by a porous material, i.e. the inverse of its packing or single crystal-density, as a function of its specific surface area yields a linear relationship. Based on these results, a phenomenological model is developed for the volumetric absolute uptake as a function of the gravimetric absolute uptake [2]. The key for improving the volumetric storage capacity is closing the gap between the low-density powder towards the theoretical upper limit of the single crystal by either compaction, pelletizing or monoliths. Furthermore, interpenetrated frameworks show generally higher volumetric hydrogen uptakes [3]. Finally, for technical applications the key parameter is the usable or working capacity, which is the amount of hydrogen that can be delivered between the maximum tank pressure and the back pressure required by the end-user [4].
The presentation will give an overview of the current status and discuss future concepts [5,6].

Super Proton Conductivity Through Control of Hydrogen-Bonding Networks in Flexible Metal-Organic Frameworks Nam Ho Kwon, Seunghee Han, Jihan Kim and Eun Seon Cho; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

Due to the growing concern over climate change and its consequences, it requires the development of renewable energy storage and conversion systems. Fuel cells operating mainly based on hydrogen as a fuel have been considered as an attractive option for sustainable energy conversion. In particular, proton exchange membrane fuel cells (PEMFCs) are recognized as a promising candidate for transportation applications due to their mild operating conditions, high-power density and ultralow emission of pollutants. The design of proton exchange membrane with a high proton conductivity over a wide humidity range remains a challenge to improve the performance of PEMFCs. Moreover, the amorphous nature of the commonly used polymer exchange membrane materials hinders the investigation and control of the proton conduction behavior. Metal-organic frameworks (MOFs) have emerged as a new type of solid-state proton conductor, attributed to their high surface area and porosity as well as high crystallinity and structural tunability. The introduction of functional groups onto the frameworks and guest molecules into the pore spaces of MOFs allows the formation of hydrogen-bonding networks, facilitating proton conduction over a wide humidity range. Furthermore, the crystalline nature of MOFs enables the precise investigation of the hydrogen-bonding networks and the relevant proton conduction mechanism. However, it is still unclear about how the functional groups and non-aqueous proton carriers would simultaneously affect the formation of hydrogen-bonding networks within MOFs. In this regard, flexible MOFs which present a reversible dynamic structural transformation in response to external stimuli can be a suitable host material to unravel the aforementioned issues because of their

potential to control the proton transfer channels.

In this study, we designed a series of imidazole molecule-loaded flexible MOFs (Im@MIL-88B) to modify the hydrogen-bonding networks and the resulting proton conduction characteristics by controlling the breathing behavior. Imidazole molecules were selected as a proton carrier which possibly leads to a full breathing on the flexible framework through the strong host-guest interaction. The breathing behaviors of MIL-88B are tuned by varying the concentration of adsorbed imidazole molecules-Im@MIL-88B-SB (small breathing) and Im@MIL-88B-LB (large breathing)-and introducing functional groups onto MOF ligands-Im@MIL-88B-NH_2 and Im@MIL-88B-SO_3H, also investigating the pristine MIL-88B (no breathing) without the imidazole loading as a control. Im@MIL-88B-LB not only shows a larger breathing effect, but also accommodates a larger amount of encapsulated imidazole into the pore spaces. The proton conductivity of 8.93×10^{-2} S cm^{-1} at RH 95% and 60 °C for Im@MIL-88B-LB is achieved, which is the highest among N-heterocyclic molecules-loaded proton conducting MOFs reported so far to the best of our knowledge, in spite of mild operating condition. The computation results suggest that the breathing effect induces the pore opening in the frameworks and the mixed configuration of water and imidazole within the transfer channels, contributing to the formation of stable and continuous hydrogen-bonding networks. Interestingly, Im@MIL-88B-LB exhibits the higher proton conductivity than even functionalized Im@MIL-88B, which may be attributed to the high concentration of proton carriers through its large imidazole-dependent structural transformation and self-adaption, while the functional groups in the pores disturb such transformation Although the functional groups in the channels can facilitate the proton conduction, such effects are offset by the limited breathing behavior, suggesting that dense hydrogen-bonding network of proton carrier is a priority factor in proton conduction. Our investigation provides the promise about the design of hydrogen-bonding networks in proton carrier-loaded systems for facile proton conduction.

Structural Resolution and Mechanistic Insight into Hydrogen Adsorption in Flexible ZIF-7 Mike McGuirk; Colorado School of Mines, United States

Flexible metal–organic frameworks offer a route towards high useable hydrogen storage capacities with minimal swings in pressure and temperature *via* step-shaped adsorption and desorption profiles. Yet, the understanding of hydrogen-induced flexibility in candidate storage materials remains incomplete. Here, we investigate the hydrogen storage properties of a quintessential flexible metal–organic framework, ZIF-7. We use high-pressure isothermal hydrogen adsorption measurements to identify the pressure–temperature conditions of the hydrogen-induced structural transition in ZIF-7. The material displays narrow hysteresis and has a shallow adsorption slope between 100 K and 125 K. To gain mechanistic insight into the cause of the phase transition correlating with stepped adsorption and desorption, we conduct powder neutron diffraction measurements of the D_2 gas-dosed structures at conditions across the phase change. Rietveld refinements of the powder neutron diffraction patterns yield the structures of activated ZIF-7 and of the gas-dosed material in the dense and open phases. The structure of the activated phase of ZIF-7 is corroborated by the structure of the activated phase of the Cd congener, CdIF-13, which we report here for the first time based on single crystal X-ray diffraction measurements. Subsequent Rietveld refinements of the powder patterns for the gas-dosed structure reveal that the primary D_2 adsorption sites in the dense phase form D_2–arene interactions between adjacent ligands in a sandwich-like adsorption motif. These sites are prevalent in both the dense and the open structure for ZIF-7, and we hypothesize that they play an important role in templating the structure of the open phase. We discuss the implications of our findings for future approaches to rationally tune step-shaped adsorption in ZIF-7, its congeners, and flexible porous adsorbents in general. Lastly, important to the application of flexible frameworks, we show that pelletization of ZIF-7 produces minimal variation in performance.

Computational Study of Nanoscale Active Sites in PGM-Free Electrocatalysts for Proton Exchange Membrane Fuel Cells Guofeng Wang and Boyang Li; University of Pittsburgh, United States

Proton exchange membrane fuel cells (PEMFCs) can covert chemical energy stored in hydrogen fuels to electricity and produce environmentally benign product water. However, the emergent applications of PEMFCs is hindered by the present requirement of expensive Pt group metals (PGM) as their electrocatalysts. To advance PEMFC technology, it is of great interests to develop earth-abundant, non-precious metal based catalysts in replacement of Pt, especially for oxygen reduction reaction (ORR) occurring at the cathode of PEMFCs. In this regard, non-precious transition metal/nitrogen doped carbon (TM-N-C) catalysts have drawn much attention as a promising PGM-free ORR electrocatalyst due to its ORR activity approaching to Pt. However, the chemical structure of the active sites in these TM-N-C catalysts and their catalytic mechanism for ORR and electrochemical stability have not been fully understood. To gain insight into the nature of the nanoscale active sites in the TM-N-C catalysts, we have performed the first-principles density functional theory (DFT) calculations to investigate the progression of ORR on various types of TM-N_4 (TM = Fe, Mn, Co) moiety substitutionally embedded into a graphene layer. On each possible TM-N_4 active site, we calculated the adsorption energies of all the relevant chemical species, namely, O_2, O, OH, OOH, HOOH and H_2O, and the activation energies for O-O dissociation reactions involved in ORR using the DFT method. On FeN_4 and/or CoN_4 embedded in an intact graphene plane, our DFT calculations predicted that the ORR could happen through $4e^-$ associative pathway on the FeN_4 site, whereas follow a $2e^-$ pathway on the CoN_4 site due to high activation energy for O-O bond splitting and extremely weak adsorption of H_2O_2 on the CoN_4 site. Furthermore, we studied and compared the predicted activity and stability on an S1 type FeN_4 site with a porphyrinic architecture and an S2 site FeN_4 sites fully embedded in a graphene layer. Our computational results reveal that the S1 type FeN_4 site will catalyze ORR with the higher onset potential (i.e., higher ORR activity) than the S2 type FeN_4. However, the S1 type FeN_4 site is predicted to exhibit poorer electrochemical stability than the S2 type FeN_4. Our computational predictions are found to agree excellently with recent experimental measurements.

4:00 PM EN07.07.03
Oxygen Evolution Reaction (OER) of Precious-Metal-Free Perovskite Nanocatalysts Made by Spray-Flame Synthesis—Effect of A- and B-Site Substitutions and B-Site Doping Steven Angel[1], Adarsh Koul[2], Wolfgang Schuhmann[2], Christof Schulz[1,1] and Hartmut Wiggers[1,1]; [1]University of Duisburg-Essen, Germany; [2]Ruhr-University Bochum, Germany

The sustainable large-scale generation of hydrogen – *via* electrochemical water splitting – demands a large amount – and thus necessarily precious metal-free – active catalyst materials which allow the evolution of H_2 (HER) and O_2 (OER) at high rates while requiring low overpotentials.[1] Especially for the sluggish OER, cost-effective and abundant materials are sought as alternatives to RuO_2 and IrO_2 compounds which are scarce and poorly stable in alkaline electrolytes.[2] Perovskite-based materials (ABO_3) incorporating lanthanides (A-site) and 3*d* transition metal ions (B-site) have been identified as such

promising alternatives as their electronic structure and surface defects can be tuned by substituting/doping the A-and B-sites. The synthesis of such compounds is commonly done in time-consuming wet-chemical batch processes followed by a calcination step.[3, 4] Alternatively, the scalable spray-flame synthesis (SFS) allows the formation of functional high-surface-area doped/substituted perovskite nanoparticles in a single step.[5, 6]
Using the SFS method, we investigated the A-site ($La_{1-x}Sr_xCoO_3$, $x = 0 – 0.4$) and B-site ($LaCo_{1-y}Fe_yO_3$, $y = 0 – 1$) substitution, and the B-site doping ($LaCo_{0.94}M_{0.06}O_3$ (M = Cr, Mn, Fe, Ni, Cu) of the $LaCoO_3$ perovskite. XRD measurements indicated the formation of oxygen-deficient (e.g. $LaCoO_{3-d}$) trigonal R-3cR structures in the $La_{1-x}Sr_xCoO_3$ series, a transition from the rhombohedrally- to the orthorhombically-distorted perovskite structure at $y > 0.4$ in the $LaCo_{1-y}Fe_yO_3$ series, and the same rhombohedral $LaCoO_3$ structure in all samples from the $LaCo_{0.94}M_{0.06}O_3$ series. Investigations using XPS measurements revealed a surface enrichment of La^{3+} and Sr^{2+} ions and the presence of Sr-oxides in the $La_{1-x}Sr_xCoO_3$ series, an enrichment of La^{3+} at $y >$ 0.4 and the presence of iron in the oxidation state +3 regardless of the concentration (y) in the $LaCo_{1-y}Fe_yO_3$ series, and variable Co^{2+}/Co^{3+} ratios (e.g. ~0.57 and ~0.75 for the Cr- and Ni-doped samples, respectively) depending on the doping element in the $LaCo_{0.94}M_{0.06}O_3$ series. The nanoparticle products were further characterized using TEM/EDX, FTIR, and BET measurements. Selected samples were characterized *via* EXAFS, XANES, and XPS using synchrotron radiation.
For the oxygen-evolution reaction (OER) catalytic performance, the lowest overpotentials – 325, 345, and 397 mV vs. RHE at 10 mA cm^{-2} – were obtained using the $La_{0.7}Sr_{0.3}CoO_3$, $LaCo_{0.6}Fe_{0.4}O_3$, and $LaCo_{0.94}Ni_{0.06}O_3$ samples, respectively. These results point to the relevance of increasing the B–O covalency[7] and the electrical conductivity[8] of the perovskite structures and are comparable to the performance of commercial IrO_2 reference[9] materials (1.59 V vs. RHE at 10 mA cm^{-2}). Relationships between chemical composition, surface properties, and OER activity of the spray-flame synthesized catalysts will be discussed in detail.

Operando **STXM and Surface DFT Calculations of Manganese Oxide for Bifunctional Oxygen Electrochemistry** Evan Z. Carlson[1], William C. Chueh[1], Michal Bajdich[2] and J. Tyler Mefford[1]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

Limited supply of precious metals impedes the scale up of electrolyzer production. To enable 100s of GWs of PEM electrolyzer capacity by 2030, iridium supply must grow by more than 10x.[1] Even transition metal-based alkaline electrolyzers may face constraints as electric vehicles increasingly compete for nickel. Alternatively, catalysts made of cheaper, more abundant manganese could relieve these constraints, if engineered to have comparable activity and stability to the best performing precious metals. The unique bifunctional OER/ORR activity of Mn oxide could also enable electrolyzers that both produce and consume fuel with a single catalyst, achieving even greater material efficiency. Yet rational design of Mn oxide catalysts requires a better understanding of the structural and chemical motifs that lead to high bifunctional performance.

In this talk, we will discuss our investigation of the bifunctional OER & ORR activity of Mn oxide and its unusual pH dependence. Our model system, α-K_xMnO_2, is among the best reported Mn oxide catalysts for both the OER and the ORR, with ORR activity matching that of Pt. While the OER activity of Mn oxide has been shown to increase at higher pH, we will show that its ORR activity unexpectedly improves as well. We will discuss our attempts to understand this phenomenon with *operando* scanning transmission x-ray microscopy (STXM), which enables spectroscopic investigation of single catalyst particles during reaction with spatial resolution down to 25 nm. Complementary surface DFT calculations provide further evidence for identification of the active crystal facets and insights into the pH-dependency of the OER & ORR mechanisms. We will discuss the implications of this work on the design of bidirectional electrolyzers with low-cost, non-precious metal catalysts.

NiFe Nanoalloyed and Nanogranular Thin Films for Oxygen Evolution Reaction Catalysis Luca Ciambriello[1,2], Emanuele Cavaliere[1,2], Irene Vassalini[3,4,5], Ivano Alessandri[3,4,5], Matteo Ferroni[5,4,6], Rosaria Brescia[7], Luca Leoncino[7] and Luca Gavioli[1,2]; [1]Università Cattolica del Sacro Cuore, Italy; [2]Interdisciplinary Laboratories for Advanced Materials Physics (i-LAMP), Italy; [3]INSTM, Italy; [4]University of Brescia, Italy; [5]INO-CNR, Italy; [6]CNR-IMM, Italy; [7]Istituto Italiano di Tecnologia, Italy

The production of hydrogen (H_2), the best alternative to fossil fuels, can be achieved electrochemically through the water splitting, consisting in two half reactions: the oxygen evolution reaction (OER) and the hydrogen evolution reaction, where O_2 and H_2 are obtained from water molecules. The OER is the most thermodynamically demanding part, representing the bottleneck of the entire process. Nanoalloyed materials can overcome the water splitting limitations by serving as efficient OER catalysts with low fabrication costs, towards a large-scale development of H_2.
On nanostructured materials, the OER catalysis efficiency is mainly determined by the chemical composition and morphology, whose control during the electrode synthesis is of paramount importance.
From the chemical viewpoint metal alloying demonstrates a considerable activity enhancement with respect to pure materials, in particular for transition metals such as NiFe, presented here.
The electrode morphology (including surface roughness and porosity) as determined by micro/nano structures, may improve the efficiency by increasing

the electrochemical surface area. However, a relationship between the catalytic efficiency and the morphological behavior of NiFe electrodes as a function of thickness to unveil the role of porosity, surface area and roughness is missing.
A further fundamental point concerns the mass loading minimization in the electrodes by maintaining the same efficiency with the aim of reducing the synthesis costs. Despite the relevance of this aspect, a thickness dependent investigation of the catalytic efficiency has been limited to noble metals and few non-noble metal compounds.
A third point is the electrode stability in OER operation, influenced by the Ni/Fe oxy/hydroxides phases forming at the interface and by the evolution of the film stoichiometry and morphology during the electrochemical activity. At present, the identification and transformation of the active sites as well as the electrode morphological modifications are still debated.
Here we tackle these issues by synthesizing new nanoalloyed electrocatalysts with nanostructured morphology and high purity chemical composition, employing Supersonic Cluster Beam Deposition (SCBD). The electrodes consist in films with thickness in the 15-88 nm range (corresponding to 5-30 $\mu g/cm^2$ loading), composed of NiFe alloy nanoparticles (90%/10% weight fraction). AFM shows that the nanoclusters, having a trimodal size distribution ranging from 0.4 to 3.8 nm, assemble in a porous film with a thickness dependent surface roughness. XPS, reflection and transmission optical spectra reveal a partial NiFe oxidation/hydroxidation, in particular at the film surface, due to the air exposure. The SCBD films show excellent OER catalysis efficiency with a 380 mV overpotential. The electrochemical activity is independent of the film thickness, suggesting an excess of NiFe mass loading in the thicker electrodes and identifying the thinnest film (15 nm) as the most promising low-cost catalyst. Furthermore, a high stability over a set of 1000 accelerated electrochemical cycles is reported. The film OER activity determines considerable structural, morphological and chemical transformations, whose role in the catalysis is under investigation. The film shows an increase of oxide/hydroxide amorphous species, confirmed by a decrease of crystallinity from XRD and a decrease of metallicity from the optical spectra. The effect is accompanied by a film thickness growth measured by AFM, due to the incorporation of chemical species from the electrolyte solution such as $Ni(OH)_2$, resulting also from electrochemical current/potential curves. This work puts a crucial step toward the thickness optimization of thin films as OER catalysts and the investigation of their stability in electrochemical operation.

Optimized 2D Nanostructures for Catalysis of Hydrogen Evolution Reactions Caique Campos and Pedro A. Autreto; Federal University of ABC, Brazil

Hydrogen is one of the most promising energy carriers with energetic transport and storage advantages over fossil fuels. However, commercial H_2 production relies on Hydrocarbon reforming methods, emitting greenhouse gasses (GHG) such as CO2 [1]. H_2 can be produced without harmful emissions by water splitting in the electrochemical Hydrogen Evolution Reaction (HER). However, this mechanism is limited by the lack of cheap, abundant, and efficient catalysts. The search for new noble-metal-free catalysts has increasingly attracted researchers' interest in the last years, and several prospective materials have been proposed. The Transition Metal Dichalcogenides (TMD) emerged as prospect materials to catalyze HER. These materials exhibit interesting electronic and structural properties. Their catalytic activity can be optimized by increasing active site counting and tailoring electronic properties. Common strategies to optimize TMD catalytic activity comprehend phase engineering and doping [2]. $TiSe_2$ has emerged as a material with remarkable and extensively investigated properties. The stability of its 1T phase and sensibility of electronic properties to doping can be explored in catalysis. In this work, the catalytic activity of $TiSe_2$ in HERs is investigated via DFT calculations using the Quantum Espresso package. We employed the Computational Hydrogen Electrode model to conduct a thermodynamic study, evaluating the free energy variation of Hydrogen adsorption, which was reported as a good activity descriptor [3]. We found that the introduction of Pt dopants on the basal plane of the 1T-$TiSe_2$ enhances the activity of chalcogen sites.

Reversible H_2 Storage via High-Temperature Redox Cycling of Fe-Mo Lamellar Foams with High Structural Stability Jacob B. Mack, Samuel Pennell and David Dunand; Northwestern University, United States

Hydrogen storage using Fe-based redox materials represents a potentially inexpensive, environmentally friendly alternative to high pressure gas storage: hydrogen is stored through the reduction of Fe_3O_4, yielding steam and Fe, and hydrogen is formed via the reversible steam oxidation of Fe. At high temperatures (400-600°C) where the reaction kinetics are favorable, the large volumetric expansion and contraction of the Fe - Fe_3O_4 redox reaction (110%) drives sintering in Fe powder-bed systems, reducing and eventually choking gas access, and thus storage capacity. Unlike a packed bed of Fe powders, lamellar Fe foams, created by freeze-casting, provide free volume for the Fe lamellae to expand during oxidation without sintering to nearby material. However, upon oxidation, Kirkendall porosity develops within the lamellae due to the mismatch in diffusion between Fe and O. As Kirkendall pores coalesce inside lamellae, combined with fracture at lamellae tips from redox stresses, lamellar contact and densification persists. In the past, alloying with redox-inert elements (Ni, Co), has shown promise in stabilizing the Fe lamellae: as Fe is oxidized, a metallic core (Ni- or Co-rich) remains in each lamella, providing an interface that acts as a Kirkendall pore sink, and adhesion to the outer oxide layer to prevent fracture. Upon reduction, the lamellae re-homogenize due to extensive solid solution between Fe and Co/Ni, providing reversibility. Under accelerated cycling degradation studies at 800°C, repeated expansion and contraction of Fe-Ni and Fe-Co however triggers lamellar buckling, which leads to contacting and sintering of neighboring lamellae, and thus choking of the foams.
Here, we develop a strategy to counteract lamellar buckling during redox cycling, by using Mo as an alloying element for Fe foams, with the goal of improving lamellar mechanical strength and preventing their sintering. Freeze-cast Fe-25 at% Mo lamellar foams demonstrate strong sintering inhibition with a stable hierarchical porous structure, having porosity within each lamella, providing further volume for the Fe to expand into upon oxidation. As opposed to the solid solution Fe-Ni and Fe-Co foams studied before, a three-phase mixture of αFe-Mo, μFeMo, and Fe_3Mo_3C is present, further limiting diffusion, sintering and plastic deformation. Mo, like Fe, is oxidized by steam, leading to a three-phase composition of Fe_3O_4-MoO_2-$Fe_2Mo_3O_8$ at full oxidation. While the expansion from oxidation leads to the densification of the initially porous lamellae, the shrinkage upon reduction restores the internal lamellar porosity, achieving a reversibly porous lamella. Hydrogen reduction yields α-Fe(Mo) and a nanocrystalline Fe_2Mo phase, which produces a high surface area morphology, further increasing the oxidation rate for subsequent cycles. Buckling from metallic regions present during partial oxidation or reduction proceeds significantly slower, due to the lack of a percolating metallic network. Fracture of ceramic oxides does not cause significant lamellar widening, due to internal porosity, leading to a near constant foam density, without sintering, over the first 10 cycles, as compared to a loss of up to 40% porosity in Fe and 20% in Fe-Ni/Co foams. While lamellar buckling builds up over time in the new Fe-Mo foams, large scale densification is eliminated, since contacting lamellae sinter very slowly. By modifying the lamellar width and length, the extent of buckling can be lowered, further slowing densification. Thus, Mo alloying represents a significant improvement in structural stabilization and reversibility as compared to other Fe-foams.

Approaches to Dynamic Electric Model of Polymer Electrolyte Electrochemical Cell (PEEC) for Water Electrolysis Daichi Matsui[1], Katsushi Fujii[2], Satoshi Wada[2] and Atsushi Ogura[1,3]; [1]Meiji University, Japan; [2]RIKEN Center of Advanced Photonics, Japan; [3]Meiji University MREL, Japan

An energy supply system using hydrogen storage has been proposed with the use of renewable energy [1]. High performance and the toughness of the fluctuated energy are important for clean hydrogen production by using water electrolysis. A polymer electrolyte electrochemical cell (PEEC) is a suitable device for this renewable energy storage. In this report, we focused on this PEEC as devices that convert electricity into hydrogen.
The evaluated PEEC has an electrode area of 12.5 cm^2 with IrO_2 as the cathode catalyst and Pt as the anode catalyst. The electrolysis voltage is reported to be divided into four main parameters: open circuit potential, activation over potential, ohmic over potential, and concentration over potential [2,3]. The thermal dependences of the PEEC current-voltage characteristics are known to be relatively large. A device model explained with the fundamental electrochemical properties can be explained these static characteristics of PEEC including temperature dependence. However, this model has not been applied for the dynamic characteristics of the PEEC. Thus, the purpose of this report is to investigate the dynamic characteristics of PEEC by comparison with the results of the static device models and the evaluation results of the electrochemical impedance spectroscopy (EIS).
The equivalent circuit for PEEC is usually a single series resistor and double two components connected in parallel, that is, a resistor and a capacitor [4]. The comparison between the EIS results and the static device model was performed to evaluate the dynamic properties of PEEC. The EIS result at the imaginary part zero below the turn-on voltage indicates only the component of series resistance. The comparisons above the turn-on voltage indicate that the series resistance component of EIS is dominated by ohmic over potential and activation over potential in the chemical reaction-based device model. Since the activation over potential is known theoretically, the ohmic over potential can be estimated from the analysis. The two resistance components of EIS with the resistor and capacitor in parallel were found to show the activation over potentials of the anode and cathode, respectively.
A comprehensive device model, which reflects both the static and dynamic characteristics of PEEC, is expected to be proposed from the analysis provided here.

Influence of Hierarchical and Conformal Electrodeposition of $NiCo_2O_4$ Electrocatalyst on Carbon Cloth for Water Oxidation Zahra Albu, Nawal Al Abass and Bandar AlOtaibi; King Abdulaziz City of Science and Technology, Saudi Arabia

To achieve net-zero emissions, consideration of various energy resources is essential for future energy needs. In this regard, green hydrogen production via water electrolysis using renewable energy sources is an attractive route for providing a cleaner energy mix. Water electrolysis has been intensively studied with limited success to produce hydrogen at a very competitive price point. The major bottleneck for widely adopting such a green technology is to find cost-effective electrocatalysts that can efficiently oxidize water and produce hydrogen at practical cost. The best-known oxide electrocatalysts for water evolution reaction (OER) compose of precious metals such as Ru and Ir, which are expensive and impractical for large-scale production. Thus, searching for alternative electrocatalysis based on transition metal oxide is an attractive approach for low-cost electrolysis processes. In this regard, we developed highly efficient hierarchical NiCo2O4 porous electrocatalysts on electrochemically treated carbon cloth (CC) using facile and green electrodeposition method. X-ray diffraction spectra and scanning tunneling microscope images confirm the formation of hierarchical NiCo2O4 porous structure under study. TEM images of peeled off NiCo2O4 particles from CC show that the electrodeposited structure compose of defined nano-sized crystallites of NiCo2O4. Additionally, the developed electrode exhibits improved electrocatalytic performance with low overpotential of ~ 290 mV at J = 10 mA/cm2 and low Tafel slope of 76 mV/dec. Its superior catalytic activities and durability for OER in alkaline media is mainly attributed to the special hierarchically porous nanostructure that led to enhanced charge transport to more accessible active sites.

10:30 AM EN07.08.07
Role of Fe in Enhancement of OER on Fe-Doped NiOOH Catalyst— Insights from Improved Electronic Structure Calculations Zhengda He, Rebekka Tesch, Michael Eikerling and Piotr Kowalski; Forschungszentrum Juelich, Germany

Low cost, high activity and high stability make Fe-doped NiOOH a good electrocatalyst for oxygen evolution reaction (OER) [1]. Although significant efforts have been dedicated to understand the enhanced electrocatalytic activity of this material [2,3,4,5], the complete information on the atomic scale mechanisms leading to the OER process improvement is still lacking. One of the reasons on the computational side is that the widely used density functional theory with Hubbard U correction for strongly correlated d electrons (DFT+U) is unable to predict correctly the electronic structure of NiOOH, especially its wide band gap [7], leading to contradictory results. In order to solve this problem, we use Wannier function to construct a more realistic projector for calculating the occupation of d-orbitals, severely overestimated by standard DFT+U approach [9]. With this approach, we obtained correct occupations of 3d orbitals for Ni and Fe, and the band gaps for $Ni(OH)_2$ and NiOOH that are consistent with experimental findings. With this improvements, we investigated the electronic structure spin of Fe in Fe-doped NiOOH. We show that Fe tends to be in low-spin state, which leads to significant decrease in the thermodynamic overpotential for OER. A spin transition from low-spin to high-spin state is predicted at Fe content of 25%, which contributes to the solubility limit of Fe in NiOOH [1]. We will discuss our computational findings against available experimental data, demonstrating important of joint computational and experimental investigation for understanding of catalytic performance of functional materials.

Ni-Based Composite Electrocatalysts for Urea Oxidation Reaction and Molecular Hydrogen Generation Kangwoo Cho; Pohang University of

Science and Technology, Korea (the Republic of)

Urea oxidation reaction (UOR) has been interrogated as an alternative oxidation to decrease the cell voltage in electrochemical water splitting for industrial-scale hydrogen production. The UOR not only enhances the energy conversion efficiency from renewable energy into molecular hydrogen, but also reduces carbon and nitrogen pollution loadings of urea-rich wastewater. Nickel-based catalysts are up-to-date the most widely investigated materials as the UOR electro-catalyst. This presentation introduces our recent findings on Ni-based UOR electro-catalysts that were prepared by i) galvanostatic electro-deposition of mixed metal (oxy)hydroxide ($NiFeO_x$ or $NiCoO_x$) with variable mixing ratios, ii) potentiostatic dealloying of commercial NiFe alloys under variable pH, and iii) one-pot thermochemical treatment of NiFe alloy foam (NFF), both as substrate and catalyst source to create a self-supporting UOR electro-catalyst. For the anode materials under interrogation, Ni^{3+} in the form of NiOOH served as the active UOR site. The secondary elements (Fe or Co) influenced the $Ni^{2+/3+}$ redox peak potential and current as thoroughly investigated for oxygen evolution reaction (OER) electrocatalysts. This study further revealed that current inflections during potential sweep in the presence of urea could be associated with $Ni^{3+/4+}$ redox peaks. The peak location and intensity continued to change during repetitive scans, due to dynamic dissolution and precipitation of Fe to/from the electrolyte. After the onset of OER, the presence of urea lowered the current responses which should be important consideration for industrial H_2 evolution. On the other hand, oxalic acid treatment of NFF generated prismatic NiFe-oxalate (O-NFF) which marked surprisingly low overpotential and Tafel slope for UOR. The oxalate ligand not only altered the binding site of urea, but also shifted the surface electronic structure of Ni (together with urea), which in-turn affected the rate and potential determining steps. The findings of this study could be further utilized within wastewater electrolysis cell for water-energy nexus.

Doped LaMnO3 for Water Splitting by Density Functional Theory Calculations Ximeng Wang[1], Anuj Goyal[2], Juan C. Nino[1], Jonathan Scheffe[1], Stephan Lany[2] and Simon Phillpot[1]; [1]University of Florida, United States; [2]National Renewable Energy Laboratory, United States

Current solar thermochemical reactors utilize CeO2-x in a two-step redox process. However, the high reaction temperature required for the use of CeO2 and the large temperature difference between the reduction and oxidation steps drives the search for other materials. Perovskite materials are promising candidates for such water splitting applications. The perovskite ABO3 formula yields multiple combinations of potential interest, with various A elements (lanthanides) and B elements (transition metals). In this work, focusing on LaMnO3, we make substitutions of Li, Na, K, Rb, Mg, Ca, Sr, Ba for La-sites and Mg, Zn, Al, Ga, In for Mn-sites. Density functional theory calculations are used to identify candidate materials for water splitting from all these compositions. Thermodynamic stability and oxygen vacancy formation energy (2.5 eV-5.0 eV) are used as criteria to select potential candidates.

This work was supported by the Department of Energy, EERE DE-EE0008840.

Tailoring Binding Abilities by Incorporating Oxophilic Transition Metals on 3D Nanostructured Ni Arrays for Accelerated Alkaline Hydrogen Evolution Reaction Jaerim Kim, Hyeonjung Jung, Jeong Woo Han and Jong kyu Kim; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

Developing efficient and inexpensive electrocatalysts for the hydrogen evolution reaction (HER) in alkaline water electrolysis plays a key role for renewable hydrogen energy technology. The slow reaction kinetics of HER in alkaline solutions, however, has hampered advances in high-performance hydrogen production. Herein, we investigated the trends in HER activity with respect to the binding energies of Ni-based thin film catalysts by incorporating a series of oxophilic transition metal atoms. It was found that the doping of oxophilic atoms enables the modulation of binding abilities of hydrogen and hydroxyl ions on the Ni surfaces, leading to the first establishment of a volcano relation between OH-binding energies and alkaline HER activities. In particular, Cr-incorporated Ni catalyst shows optimized OH-binding as well as H-binding energies for facilitating water dissociation and improving HER activity in alkaline media. Further enhancement of catalytic performance was achieved by introducing an array of three-dimensional (3D) Ni nanohelixes (NHs) that provide abundant surface active sites and effective channels for charge transfer and mass transport. The Cr dopants incorporated into the Ni NHs accelerate the dissociative adsorption process of water, resulting in remarkably enhanced catalytic activities in alkaline medium. Our approach can provide a rational design strategy and experimental methodology toward efficient bimetallic electrocatalysts for alkaline HER using earth-abundant elements.

High-Permeance Hydrogen Selective Membranes Using an Ultrathin Palladium Film Lohyun Kim, Chi Cheng, Aaron Persad, Randall Field and Rohit Karnik; Massachusetts Institute of Technology, United States

Beyond the traditional needs for hydrogen separation in industries, such as H_2/N_2 and H_2/CO_2 in ammonia production, H_2/CH_4 in methane reforming, or H_2/hydrocarbons in petroleum refining, the demand for purified hydrogen has been rising over time and is expected to grow further with transition to a sustainable economy. Emerging applications range from use of hydrogen as an energy carrier, space industry, and nuclear fusion that requires separation and recovery of hydrogen isotopes (deuterium and tritium) from byproduct gases in the rector.

Membrane technology can be a good candidate for hydrogen separations, owing to several advantages, such as the ease of operation, modularity, and low energy consumption compared to other techniques, such as pressure swing adsorption. Especially, metal composite membranes comprising a metal layer such as palladium (Pd) alloy on porous supports have been spotlighted due to their high H_2 selectivity over other gases and good thermal and mechanical stability. This type of membrane, however, generally requires a several micrometers thick metal layer to cover the porous support without defects. Given that the Pd is very expensive, and permeance decreases with increasing thickness necessitating larger membrane area, the overall cost of hydrogen separation scales approximately as the square of the metal layer thickness.

To address this, we developed an ultrathin Pd composite membrane having a thickness in the range of 100 nm. Gas permeation tests of the Pd film

membrane using a customized gas rig showed a remarkable H_2 and D_2 permeance of ~10^{-5} mol/m^2×s×Pa, which is ~1,000x higher than the typical permeance of polymeric membrane and ~10x higher than typical Pd membranes which generally require higher temperature to operate. Single-gas H_2 selectivity against He, CH_4, N_2, and CO_2 was about 20, 40, 50, and 60, respectively. The performance of the membrane was evaluated at different temperatures. Unlike the thick Pd composite membranes, which are typically not compatible with temperatures below 600 K due to the phase change of Pd leading to cracks, our membrane showed stable operation at ambient to moderate temperatures and was able to withstand phase change of palladium due to hydrogen while retaining a good selectivity. The change of phase of Pd between alpha and beta was observed as a sharp change in permeance of the membrane with change in partial pressure of H_2 or D_2 as a function of temperature, consistent with the Pd/H_2 and Pd/D_2 phase diagrams.

To quantitatively understand the membrane behavior under different working conditions, we developed a comprehensive gas transport model of the Pd film membrane based on the flow resistance circuit. The configuration of the circuit was determined by considering the potential pathways of the gas species. Several assumptions were made to simplify the numerical calculation. For example, Knudsen diffusion was used to explain the gas transport through the porous support. For the Pd film, the transport was characterized by a solution-diffusion mechanism, and the major kinetic steps, such as surface reactions and bulk diffusion, were included. There are two notable features of the model: 1) the model accounts for the interactions between hydrogen isotopes in Pd film, and 2) the model can be employed regardless of the Pd phase. Good agreement between the theoretical model and the experimental data was observed, which explained the dominant transport mechanism as diffusion of hydrogen through the Pd layer, as well as the selectivity and its dependence on the membrane structure.

Overall, the very high permeance of the reported membranes cuts down the overall use of precious metal and the membrane cost per unit productivity by orders of magnitude. With reasonably good selectivity and ability to operate at ambient to moderate temperatures, the new membranes show potential for various current and emerging hydrogen separation needs.

1:45 PM EN07.09.02
Current Density Improvement Evaluation of Polymer Electrolyte Electrochemical Cells (PEEC) for Hydrogen Generation Using Electrochemical Impedance Spectroscopy Miyuki Nara[1], Katsushi Fujii[1], Daichi Matsui[2], Takeharu Murakami[1], Atsushi Ogura[2,2] and Satoshi Wada[1]; [1]RIKEN, RAP, Japan; [2]Meiji University, Japan

One of the hydrogen formations from renewable energy is expected to use water electrolysis. Especially, polymer electrolyte electrochemical cell (PEEC) is known as a suitable energy conversion device from renewable electricity to hydrogen because the PEEC is relatively strong for the input energy fluctuation from a reliability point of view.
The energy conversion efficiency improvement of PEEC is an important issue to establish the hydrogen production from renewable energies. The major improvement research for water electrolysis is reducing the operating voltage at the same current density. Therefore, the improvement of the water oxidation catalyst has been discussed because the over voltage of oxygen evolution reaction (OER) is higher than that of hydrogen evolution reaction (HER). However, the device conversion efficiency of PEEC is not defined only by these reaction overpotentials. The series resistance of the PEEC, which is mainly due to the resistance of polymer electrolyte, and ion concentration difference between anode and cathode also affect the device performance. Electrochemical impedance spectroscopy is a powerful tool for the evaluation of these resistances. The spectroscopy can be separated the series resistance, and the resistance due to overpotential at the interface between polymer electrolyte and electrode catalyst interface clearly. Although the reduction of polymer electrolyte resistance has been discussed with the polymer electrolyte thickness, it was found that the reduction with polymer electrolyte treatment also improves the PEEC performance. The overpotential at the interface between polymer electrolyte and electrode catalyst interface was also improved with this treatment. These evaluations clarified that not only the catalytic performance but also the other material properties need to control for the improvement of the PEEC performance.

2:00 PM EN07.09.03
Unveiling the Deceptive Enhancement of Hydrogen Evolution Reaction Overpotential Nageh K. Allam; American University in Cairo, Egypt

Electrochemical hydrogen evolution reaction (HER) is typically studied in a three-electrode system. In this system, several counter electrodes are commonly used to ensure fast kinetics, including Pt, gold, and glassy carbon. However, the extensive application of such electrodes has raised caveats on the contribution of the redox-active species dissolving from such electrodes and redepositing on the surface of the working electrode to the measured overpotential. Consequently, this has been frequently confused with the actual electrochemical signature of the working electrode catalyst, resulting in a deceptive enhancement in the recorded overpotential. This issue becomes more critical when the electrolysis measurements involve an activation step, necessitating the need for alternative counter electrodes that are stable, especially in an acidic medium, which is commonly used as the electrolyte in HER studies. Herein, while we systematically unveil such problems, an alternative counter electrode that overcomes those problems is demonstrated. Specifically, the correlation between the working electrode area to that of the counter electrode, the dissolution rate of the counter electrode, and the potential range used in the activation/cleaning of the surface on accelerating the dissolution rate is explored and discussed in detail. Finally, commercial Ti mesh is demonstrated as an alternative emerging counter electrode, which is proven to be very stable and convenient to study the HER in acidic media.

2:15 PM EN07.09.04
DFT Study of Hydrogen-Evolution Reaction on Mo-Based Alloys Rodion Belosludov, Ruirui Song, Jiuhui Han and Hidemi Kato; Tohoku University, Japan

Electrochemical hydrogen evolution reaction (HER) through water splitting is one of the most effective mechanism among the various hydrogen productions. Although Pt-based catalysts are at present the most active HER catalysts [1], the high cost and scarcity of Pt essentially limit their large-scale practical applications. Therefore, the development of cost-effective and earth-abundant catalysts as alternatives to noble Pt has devoted significant research interest. Among the various materials, intermetallic compounds formed by non-precious transition metals are promising cost-effective and robust catalysts for electrochemical hydrogen production [2]. Using the current theoretical methods it is now possible to study surface chemical reactions in detail and to understand variations in catalytic activity from one catalyst to another as well as compare with available experimental data [3].
Here, we have studied the HER catalytic activity of μ-Co_7Mo_6, μ-Fe_7Mo_6, Mo, $Cr_{50}Mo_{50}$ heterogeneous catalysts and compared with HER catalytic activity of Pt. The geometry optimization of the selected surface structures, the evaluation of the electronic and thermodynamic properties of the selected compounds and the detailed analysis of their catalytic activities toward hydrogen evolution reaction (HER) through water splitting were performed using the density functional theory calculations implemented in the Vienna Ab initio Simulation Package [4]. The activation barriers have been calculated with the nudged elastic band (NEB) method [5].
The most active catalytic sides toward H_2O, OH and H adsorption have been evaluated for the studied catalysts. The values of the adsorption energies have been calculated and the surface effect on these values have been analyzed based on the geometry of top layers and the electronic structures (Partial density

of states) of catalytic surfaces and the charge transfer between surface atoms and adsorbed species. The obtained results showed that the dissociative adsorption of water is demonstrated to be thermodynamically favorable (exothermic) for μ-Co_7Mo_6, μ-Fe_7Mo_6, Mo, $Cr_{50}Mo_{50}$ catalysts and the lowest activation barrier is found in the case of μ-Fe_7Mo_6 one. Based on the calculated DG_{H*} values, the catalytic activity trend of the order of μ-Co_7Mo_6 > Mo > $Cr_{50}Mo_{50}$ > μ-Fe_7Mo_6. In the case of μ-Co_7Mo_6, this value is comparable with the DG_{H*} value calculated for H adsorption on Pt(111) surface. Thus it can be suggested that Mo-based alloys, especially Co_7Mo_6 may be the good candidates for electrolyte fuel cell as substitution of Pt.

Reducing the Noble Metal loading by ALD for Electrocatalysis Sitaramanjaneya M. Thalluri[1,2], Raul Zazpe[1,2], Hanna Sopha[1,2] and Jan Macak[1,2]; [1]Center of Materials and Nanotechnologies, University of Pardubice, Czechia; [2]Central European Institute of Technology, Brno University of Technology, Czechia

Platinum group metals such as Pt, Ru, Pd, Ir, etc., have superior performance for various catalytic applications.[1] Due to their scarcity, efforts were being made to reduce or replace these noble metals. Atomic Layer Deposition (ALD) is one among the best technique to facilitate lowering of loading mass on a support of interest.[2],[3] Our efforts in designing processes for different materials on ALD were successful in developing continuous thin films of thickness down to single atom. Due to the governing surface energy variations between noble metals and support surfaces, the growth initiates as nanoparticles (NP) and with a further increase in ALD cycles the agglomeration among NP's dominates over the individual NP size increase, thus developing thin films of relatively higher thickness.
For electrocatalytic applications, it is important to choose the right substrates. Among available substrates, Carbon papers (CP) and Titania nanotube (TNT) layers are best choices considering their physio-chemical properties, availability, vast literature and low costs incurred using these as support substrates in electrocatalysis and photocatalysis. Several surface modifications for CP's and variations on morphological aspects of TNT layers had received a great attention form applied fields due to their improved surface area, conductivity and stability.[4],[5][6] Uniformly decorating these CP's and TNT layers by nanoparticles or thin films of catalysts proved to be highly efficient with no boundaries on applications.[7]
ALD is the most suitable technology that can decorate high aspect ratio and high surface area nano architectures.[8]
The presentation will introduce and describe the synthesis of different noble metal nanoparticles by our ALD tool (Beneq TFS 200) on various aspect ratio TNT layers and CP substrates. It will also include the corresponding physical and electrochemical characterization and encouraging results obtained in electrocatalysis.

Flash Bottom-Up Arc Synthesis of Single Atom Catalysts for Highly Active Alkaline Fuel Cell Electrodes Jae Young Jung[1], Jeong-Gil Kim[1], Min Ji Kim[1], Min Woo Kim[1], Min Seob Kim[1], Pil Kim[2], Hyung-Kyu Lim[3], Sung Jong Yoo[1] and Nam Dong Kim[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of); [3]Kangwon National University, Korea (the Republic of)

Single atom electrocatalysts (SACs) mark the beginning of a new era in the field of sustainable energy conversion technologies. The atomically dispersed transition metal-nitrogen-carbon (M-N_x-C) materials emerge as a promising SACs due to their cost effectiveness, extraordinary catalytic activity and selectivity. For a decade, a variety of synthesis strategies have been developed to realize highly active M-N_x-C catalysts. However, the most widely applied synthesis methods need general requirements for either a multistep processes or the use of typically selected metals and carbon supports. It is highly desirable to develop more efficient methods for the fabrication of M-N_x-C catalysts, realizing both simple and simultaneously applicable to various metals and supports.
The construction of hierarchical pore structure is equally important in the field of M-N_x-C catalysts for maximizing electrochemical accessibility to internal/external active area. Unfortunately, the recent studies have focused on maximizing the number of active sites to improve catalytic performance. Simply increasing active site density is not enough solution for more practical energy and environmental applications due to the limited access to the active sites. Therefore, developing the hierarchical pore structure and desirable morphology in M-N_x-C catalysts are crucial for effective mass transport in catalyst layer and utilization of active sites.
In this work, we propose a general strategy for fabricating M-N_x-C catalysts using a flash bottom-up arc discharge method. Our strategy is applicable to a broad type of metals and nanocarbons. This study revealed that nitrogen atoms in buffer gases and ligand atoms in precursor molecules played crucial roles in dispersing and stabilizing metal atoms during nanocarbon synthesis. This work provides a new synthesis protocol and novel design for efficient M-N_x-C catalysts, which may have an impact on the industry of fuel cells. Furthermore, we demonstrate an efficient strategy for developing a hierarchical pore structure in arc nanocarbons with Co-N_x-C sites and improving their oxygen reduction activity. Low temperature thermal annealing in air was highly efficient to generate hierarchical pores by opening internal and interstitial nano-channels in carbon nanohorns. Subsequent ammonia annealing modifies coordination environments and relieves local strain around cobalt atom to form more ideal Co-N_4-C sites. The combined computational and experimental studies proved that the improved kinetic activity of arc-derived Co-N_4-C catalyst is attributed to the ligand-push effect of water molecules on the other side of Co-N_4 sites. In a single-cell experiment, a power density of 742 mW cm^{-2} was achieved, which is the remarkably high value among atomic M-N_x-C catalysts using commercialized membrane electrode assemblies (MEAs).

3:30 PM EN07.09.07
3D Geometry-Controlled Superaerophobic Ni Nanoarrays for Efficient Alkaline Hydrogen Evolution Reaction Jaerim Kim, Sang-Mun Jung, Hyeonwoong Hwang, Seokho Moon, Yong-Tae Kim and Jong kyu Kim; Pohang University of Science and Technology (POSTECH), Korea (the Republic

of)

Electrochemical water splitting for producing “green hydrogen” is of central importance in the hydrogen economy to meet the global mission of carbon neutrality. Although the hydrogen evolution reaction (HER) under alkaline conditions has many advantages over acidic HER in cost and stability aspects, it typically shows a high overpotential due to sluggish reaction kinetics.
Besides the reactive activity of the catalysts, the H_2 bubble formation due to the limited solubility of products in the electrolyte becomes one of the major causes of the limited catalytic performance. The adhered H_2 bubbles on the catalyst surface can cause reduced active surface sites, blockage of ion pathways, and destruction of catalyst film by inducing a large stretch force. Given these detrimental impacts of the H_2 bubbles on electrochemical performance, more attention should be paid to the management of H_2 bubbles for meeting the demand for large-scale applications.
Exploiting three-dimensional (3D) nanostructures can be a promising approach to minimize the efficiency loss induced by the adhered gas bubble products. Despite the beneficial effects of 3D nanostructured catalysts, the intricate dependencies between H_2 bubble dynamics and the 3D geometry of electrocatalysts remain elusive.
In this study, we systematically investigated the H_2 bubble release behaviors in alkaline HER by introducing arrays of 3D geometry-controlled Ni electrocatalysts. Through the simple and effective oblique angle deposition (OAD) method, the Ni catalysts with planar film and 3D nanorods (NR)-array architectures were fabricated as the geometry-controlled model catalysts. Based on these model catalysts, the relationship among alkaline HER performance, H_2 bubble release behaviors, and the surface wettability in terms of catalyst’s geometry was investigated. We observed the tailored wetting states of the Ni catalysts with different porosity, showing the superaerophobic properties on the highly porous Ni NR catalyst. As a result, the highly porous Ni NR catalyst with the superaerophobic nature leads to the accelerated H_2 bubble release through the open pore channels, and thus, remarkably enhanced catalytic activities in alkaline media. Our work can help to deduce the fundamental and practical design rules for efficient alkaline HER catalysts including earth-abundant elements.

Modulating the Active Sites of Fe-N-C Catalyst Using Aging Effect for Enhanced Oxygen Reduction Reaction in Alkaline Media Seon Yeong Lee[1], Han Wool Jang[1], Sung Jong Yoo[2], Sungho Lee[2] and Han-Ik Joh[1]; [1]Konkuk University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Fe-N-C catalyst has been regarded as a significant replacement for platinum-group catalyst owing to its outstanding oxygen reduction reaction (ORR) activity in alkaline media. Fe-N_x sites have been recognized as active sites in Fe-N-C catalysts, where a single iron atom is coupled with multiple nitrogen atoms in a carbon matrix. Dual active sites consisting of Fe-N_x sites and iron carbide nanoparticles have recently been proposed as novel active sites for the catalysts, demonstrating improved ORR performance. Both of these types of typical active sites show remarkable activity for ORR, but they are also difficult to synthesize since single atoms should be evenly distributed on the substrate. In this study, we successfully synthesized MOF-derived Fe-N-C catalysts with dense active sites by introducing nano-sized carbon dots (CD) as additional active sites, whose main functional group is pyrrolic N, and controlling the main active sites by simply aging the catalyst for the appropriate duration. Multiple N sites from CD with electronegative force begin electrostatic force with electropositive iron ions throughout the aging process, allowing for a large amount of Fe-N bonding. The ORR activity of the FeNC-24-0.6 and FeNC-48-0.9 catalysts prepared by optimum conditions was superior to that of a commercial Pt/C catalyst. Interestingly, the FeNC-24-0.6 and FeNC-48-0.9 catalysts mainly have dual and single active sites, respectively. However, with accelerated durability cycling, FeNC-24-0.6 exhibited a negative shift in performance, but FeNC-48-0.9 nearly maintained its performance. It was shown that single and dual active sites are both effective for ORR activity, although dual active sites are more susceptible to long-term stability in an alkaline medium. As a result, bringing in extra nitrogen supply and aging at the optimal time is an effective strategy to increase the active site density of Fe-N-C catalysts, and raising the site density of the Fe-N_x structure is more worthwhile than generating secondary active sites to improve ORR performance.

Regulating Impurity in Amorphous TiO_2 for Ultra-Stable Photoanode Protection Yutao Dong[1], Mehrdad Abbasi[2], Lazarus German[1], Jinwoo Hwang[2] and Xudong Wang[1]; [1]Univeristy of Wisconsin-Madison, United States; [2]The Ohio State University, United States

On demand of sustainable fuels under irreversible consumption of fossil fuels crisis, hydrogen production from photoelectrochemical (PEC) water splitting can be promising approach to converting solar light into clean hydrogen energy. Silicon (Si) is a feasible semiconductor with small band gap and high industrial maturity, but bare Si suffers deleterious corrosion during photoelectrochemical reaction which largely limited practical application [1].
Amorphous TiO_2 (a-TiO_2) thin film emerged as an excellent protection layer to avoid Si exposure to corrosive electrolyte directly. However, in comparably thicker a-TiO_2 films, intermediates exhibited conductivity heterogeneity leading to failure in short term [2]. By lowering the deposition temperature, crystallization behavior could be suppressed to form fully amorphous film but impurities from incomplete ligand exchange reaction were also buried into amorphous film to affect film quality.
In this work, we analyzed the low temperature grown ALD a-TiO_2 film failure process and conducted a water annealing treatment to partially remove chlorine (Cl) impurity to achieve ultra-stable Si photoanode protection performance more than 600 hours. In pristine TiO_2 film, Cl impurity was uniformly distributed into whole TiO_2 and could lead to pinhole formation during electrochemical reaction to allow hydroxide groups to attack Si wafer. As a result, photocurrent density exhibited a continuous decay in PEC stability test. With water annealing treatment on pristine TiO_2 films, cross-sectional scanning transmission electron microscopy (STEM) showed it maintained amorphous phase without any crystallization. X-ray photoelectron spectroscopy (XPS) and long-term electron dispersive spectroscopy (EDS) indicated partial Cl impurity was removed at the top of TiO_2 film to form more stoichiometry TiO_2 film as an excellent protection layer. This work provides a promising approach to obtaining high-quality amorphous TiO_2 film at low temperature deposition and points a pathway to achieve maximum protection of ALD a-TiO_2 coating.

Mechanism of Charge Accumulation of Poly(heptazine imide) Seo Goichiro[1], Yuki Saito[2], Miyu Nakamichi[2] and Kaname Kanai[2]; [1]Tokyo University of Science, Japan; [2]Tokyo University of science, Japan

In recent years, carbon nitride polymers have attracted enormous interest studied as inexpensive and easy-to-synthesize photocatalysts. Moreover, carbon

nitride polymers has been actively studied because it can generate hydrogen through photocatalytic activity in visible light region around 450 nm unlike TiO_2, which can be activated in ultraviolet light. Through many pioneering work on carbon nitride polymers, several types of new carbon nitrides have been discovered. In particular, poly(heptazine imide) (PHI) is one of the newly carbon nitride polymers, which structure has two-dimensionally polymerized carbon nitride skeleton. Unlike other carbon nitride polymers, PHI has attracted attention not only as a materials that shows high photocatalytic performance in visible light but also shows dark photocatalytic activity. Dark photocatalysis is a function in which the charges generated by light irradiation are stored inside the material and consumed in the dark state, and Lau *et al.* were firstly reported about dark photocatalytic performance of PHI in 2017. Combining the photocatalytic and dark photocatalytic activities of PHI makes it possible to continue generating hydrogen day and night, which cycle is called day-night photocatalysis. If day-night photocatalysis has realized, it is expected to significantly improve the efficiency of hydrogen collection, which has been an important issue for photocatalysts.
Dark photocatalytic activity has also been reported for materials such as TiO_2+WO_3, and it is generally believed that carriers generated by light irradiation accumulate on the surface and exhibit catalytic activity even in the dark state through a state called charge accumulation. In short, it is important to investigate the charge accumulation in detail in order to improve the function of dark photocatalytic activity. For example, studying the charge accumulation phenomenon and improving the amount of stored charge will lead to increase the evolution of hydrogen by dark photocatalytic activity, and also allow the activity to be maintained for longer periods of time in the dark. However, the dark photocatalytic activity of PHI occurs only in solution, making it difficult to analyze changes in electronic and chemical structure, for this reason the mechanism of charge accumulation in PHI has not been discussed from a microscopic perspective.
In this study, we succeeded in solving such a problem by making it possible to take PHI out of the test tube in the form of a gel. The PHI gel (PHIG) can be obtained by mixing PHI and a substance called an ionic liquid, which has an extremely low vapor pressure and a very high viscosity. PHIG has made it possible to carry out many experiments to explore the properties of PHI, including experiments in vacuum such as X-ray photoelectron spectroscopy (XPS) and scanning electron microscopy/ energy dispersive X-ray spectroscopy (SEM/EDX). In our study, we found two basic features of PHI, photochromism, which is reversibly changes of molecular structure by light irradiation, and light-driven ad/absorption of potassium ions, which is a component of PHI. On the other hand, as mentioned above, the charge accumulation phenomenon of PHI can be observed by photoirradiation in PHI. Therefore, we hypothesized that the charge accumulation may be caused by the two characteristics of PHI, and devised a model to explain the phenomenon. More specifically, we considered that the charge accumulation in PHI is caused by three steps: (1) light irradiation generates photocarriers in PHI, (2) photochromism causes narrowing of the energy gap, and (3) the narrowed energy gap acts as a trap and photocarriers are trapped in it. In this presentation, we will discuss the relationship between photochromism, ab/adsorption of potassium ions, and charge accumulation, both of which originate from photoirradiation in PHI and we propose a new model of charge accumulation in PHI based on the results.

Measurement and Modelling of Potential Profiles in Water Electrolysers to Minimize Titanium Use Gareth Hinds; National Physical Laboratory, United Kingdom

Green hydrogen is an essential component of net zero strategies for ‘difficult to decarbonize’ sectors such as heavy duty transport, domestic heating and industrial processes, but its relatively high price remains a significant challenge. The cost of production using proton exchange membrane water electrolysers (PEMWEs) depends on both CAPEX of the devices and OPEX, which is dominated by the renewable electricity price. The latter is already low and is projected to continue to decrease so reducing CAPEX is the major focus of research efforts.

The assumption of a highly corrosive potential at the anode bipolar plate (BPP) and porous transport layer (PTL) in a PEMWE stack often leads to selection of expensive materials such as platinum-coated titanium. In this talk, a description will be given of a physicochemical model of electrochemical potential distribution in a PTL, validated by *in situ* and *ex situ* electrochemical potential measurement. The model predicts that, under typical PEMWE operating conditions, the corrosive zone associated with the anode polarisation extends only ≈ 200 µm into the PTL from the catalyst layer, removing the need for highly corrosion-resistant materials in the bulk of the PTL and at the BPP.

Guided by the model, single cell PEMWE tests were carried out using anode current collectors fabricated from carbon-coated 316L stainless steel. The material was shown to be tolerant to potentials up to 1.2 V vs RHE and when tested *in situ* for 30 days at 2 A cm^{-2} showed no evidence of degradation. These results strongly suggest that much of the titanium in PEMWEs may be substituted with cheaper, more abundant materials with no loss of electrolyser performance or lifetime, which would significantly reduce the cost of green hydrogen. The combined modelling and experimental approach developed here shows great promise for design optimisation of PEMWEs and other electrochemical energy conversion devices.

Ni-Foam-Graphene-CNTs-SnSeP—An Efficient Electrocatalyst Covering Universal pH Range and Tap Water Splitting for Hydrogen Evolution Reaction Mansi Pahuja, Kehkashan Alam, Kaushik Ghosh and SK Riyajuddin; INST Mohali, India

A day-by-day boost in the hunger of people for renewable energy has to be addressed where green fuel generation via water splitting is a game changer to fossil fuels. The development of rationally designed cost-effective noble-metal free electrocatalyst with high efficiency, and long-term stability has been vigorously pursued. Herein, we report a super- hydrophilic bi-ligand metal phosphide (SnSeP) on the surface of a highly porous Nickel foam-graphene-carbon nanotubes matrix via the facile thermal Chemical Vapour deposition method. The newly developed electrocatalyst renders superior electrocatalytic performance with long-term stability for a minimum of 10 days at a high current density of 250 mA/cm^2 in each acidic, basic and neutral medium, inferring the commercialization of the catalyst toward industrial-grade application. The excellent electrocatalytic performance is analyzed in terms of low overpotential of 45 mV, 85 mV, and 135 mV at 10 mA/cm^2 in acidic, basic, and neutral media respectively. Moreover, the as-designed catalyst has shown a noteworthy performance in the smart utilization of tap water in hydrogen fuel production. This work highlights a new insight in adopting a feasible strategy to develop a cost-effective robust electrocatalyst that is capable enough for the facile usage of tap water that could be an attractive paradigm of green fuel synthesis via renewable electrochemical energy conversion.

Tuning Interfacial Hydrogen Bonding for Enhanced Hydrogen Evolution and Oxygen Reduction Electrocatalysis Yirui Zhang, Tao Wang, Botao

Huang and Yang Shao-Horn; Massachusetts Institute of Technology, United States

Designing electrochemical water splitting and its reverse process is crucial for producing hydrogen and achieving high efficiencies for fuel cells. While conventional design of catalysts has focused on tuning the surface electronic structures of electrodes [1] and binding strength of intermediates [2], recent studies show that changing electrolyte compositions, such as spectator cations and pH [3], can also significantly alter catalytic activity and kinetics by orders of magnitude, highlighting new opportunities in tuning non-covalent interactions in the electrolytes to control catalytic activities. We have recently designed an interfacial layer of protic ionic liquids on platinum and gold to tune the oxygen-reduction reaction (ORR) kinetics, where altering the proton activity of organic ionic liquids increases the intrinsic activity by up to five times [4]. The maximum enhancement of kinetics is achieved when the pK_a of the ionic liquid matches that of the reaction intermediate, which is attributed to the strengthened hydrogen bonding between the ionic liquid and reaction products, supported by density functional theory (DFT) calculations and surface-enhanced infrared absorption spectroscopy (SEIRAS).

To further develop design principles for electrolyte engineering and unravel the role of interfacial hydrogen bonding, we have employed a series of water-in-solvent electrolytes for hydrogen evolution and oxidation reactions (HER/HOR). We systematically confine water in organic matrixes, including acetonitrile (ACN) and dimethyl sulfoxide (DMSO), and tune the hydrogen-bonding networks by changing the water concentration (2% - 100% molar ratio) and altering the donor number of organic solvents. Water molecules become more isolated when decreasing the water-to-organic ratio, and water reduction shifts to a more negative potential. The shifts in onset potentials are solvent-dependent, where DMSO-containing electrolytes suppress HER and lower the onset potential compared to ACN-containing electrolytes. The suppression effect of HER with DMSO is attributed to its stabilization effect of isolated water as a result of the high donor number, while the enhancement effect of HER with ACN is due to the promotion of interfacial hydrogen-bonded water. SEIRAS measurements further support the changes in interfacial hydrogen bonding during the reactions, highlighting the role of interfacial hydrogen bonds between organic solvents and water in controlling HER/HOR kinetics.

These findings open up immense opportunities for using non-covalent hydrogen bonding interactions at the electrified interface to control the kinetics of ORR, HER, and beyond. The understanding would also be impactful across other reactions crucial to improving decarbonizing efforts in energy storage, such as CO_2 reduction and aqueous batteries.

Advanced Water Management in Polymer Electrolyte Fuel Cells at Subzero Temperatures: Gas Diffusion Layer with Patterned Wettability Wenmei Liu[1,2], Jongmin Li[1,1], Yen-Chun Chen[1], Yang Yao[2], Sonja Neuhaus[3], Alok Goel[3], Thomas Justus Schmidt[1,2] and Pierre Boillat[1,1]; [1]Paul Scherrer Institute, Switzerland; [2]ETH Zürich, Switzerland; [3]University of Applied Sciences and Arts Northwestern Switzerland (FHNW), Switzerland

Polymer electrolyte fuel cells (PEFCs) are promising alternatives for automotive and portable applications thanks to zero-emission, low operating temperature, and fast refueling. Water management is a challenge for successful cold-start, as well as stable, long-lasting, and high PEFC performance at subzero temperatures. Sudden freezing of supercooled water leads to rapid voltage degradation, causing cold-start failure[1,2]. In addition, it causes irreversible damage to cell components, including the membrane, catalyst layer, and gas diffusion layer (GDL), so-called freeze-thaw[3,4], which results in a significant reduction of PEFC lifetime.

Our previous work has shown that GDLs with patterned wettability improved water management and cell performance[5,6] in normal operational conditions. In this presentation, we will show the effects of wettability-patterned GDLs on preventing ice propagation with the following parameters being systematically investigated: GDL substrate, water saturation level, hydrophobic polymeric coating, coating loads, and wettability pattern dimensions. Ex-situ differential scanning calorimetry (DSC) and in-situ advanced calorimetry were used as calorimetric techniques to detect the onset of freezing temperatures of water in GDLs. X-ray tomography was used to visualize the water distribution inside GDLs.

The designed pathways allow the effective separation of water and gas. Individual freezing events were found to happen above -15 ºC and below -25 ºC in the patterned Toray (250 µm hydrophilic- 1000 µm hydrophobic), which shows the effective prevention of ice propagation in GDLs. Thanks to the improved water management, the ice-free area can diffuse reactant gaseous to allow continuous operation of the cell, which improves the cold-start capability.

Investigation of Solid-State Metathesis as a Rapid and Convenient Synthetic Method to the Formation of Cobalt-Iron Boride Solid-Solutions and the Effect of Chemical Composition on Electrocatalytic Activity Janaka P. Abeysinghe and Edward Gillan; University of Iowa, United States

Hydrogen has been gaining popularity as a reliable and environmentally friendly energy source for future energy demands. Water is an abundant source of hydrogen and electrochemical water splitting into hydrogen and oxygen gasses is an efficient, effective, and non-greenhouse gas emitting process. The search for cost-effective electrocatalysts for the cathodes and anodes in electrocatalytic hydrogen evolution reaction (HER) and oxygen evolution reaction (OER) that are active at low applied potentials is a subject of great interest. Late transition metal (cobalt, nickel, and iron) compounds have been

extensively studied as electrocatalysts due to their abundance and low cost. Because of their intriguing chemical and physical properties, late transition metal borides are appealing as ideal electrocatalyst with active, long-lasting, and persistent electrocatalytic properties. Borides of cobalt and iron have been investigated and identified as moderate electrocatalysts, both individually and in combination. Some studies have found that a synergistic effect improves electrocatalytic activity of multi-metal combinations as compared to individual metal boride performance. Understanding how synergy works with crystalline cobalt and iron borides and what extent it applies to bulk cobalt iron borides are important research areas. The current study describes cobalt and iron solid-solution formation in crystalline form from rapid and energetic solid-state metathesis reactions using combinations of MCl_2 ($CoCl_2$ and $FeCl_2$) + Mg + B. X-ray diffractograms (XRD) show that solid solutions formed in all cobalt and iron compositions, and chemical compositions of solid-solution samples were confirmed using inductively coupled plasma spectroscopy (ICP) and energy dispersive spectroscopy (EDS). Properties of cobalt-iron solid solutions were characterized using scanning electron microscopy, surface area analyzer, and crystallite sizes (XRD peak width), and the results show that structural properties gradually change from one end of the compositional range to the other. These crystalline borides show no evidence of synergy between cobalt and iron in HER electrocatalysis performed in 1.0 M KOH, instead the relative electrocatalytic activity was highest for cobalt boride (10 mA cm^{-2} at -223 mV), lowest for iron boride (10 mA cm^{-2} at -342 mV), and intermediate for the different solid-solutions compositions. After 24 hours of chronoamperometry, all crystalline cobalt and iron borides showed bulk stability and maintained HER activity. Post-electrochemistry studies confirmed the retention of metal borides after extensive electrochemistry studies.

High-Pressure Hydrogen Production from Formic Acid Catalyzed by Homogeneous Iridium Complexes Yuichiro Himeda; National Institute of Advanced Industrial Science, Japan

Formic acid as a liquid organic hydrogen carrier has been receiving increasing attention, due to low-toxicity, low-flammability, and biodegradability.[1] We have reported a large number of efficient catalysts for dehydrogenation of formic acid (FADH: eq. 1), which were half-sandwich iridium complexes having *N,N*-bidentate ligands, such as bipyridine and imidazoline. Toward practical hydrogen supply, robust, selective, and efficient catalysts are required. Herein, we describe the development of robust and efficient iridium-based catalysts for high pressure hydrogen production by FADH in water without any additives.
$HCO_2H \rightarrow H_2 + CO_2$ (eq. 1)
Recently, we have developed robust catalysts for continuous and constant hydrogen supply toward practical use.[2] The catalyst having pyridylpyrazole ligands remained catalytically active for 35 days in FADH at 70 °C to produce hydrogen gas (1.25 m^3) with a TON of 10 million.
Furthermore, when the reaction was carried out in closed vessel, the pressure of the evolved gases was raised. In initial studies, the catalyst generated more than 100 MPa, which was composed of H_2 and CO_2 (1:1) without CO by GC analysis.[3] Unfortunately, obvious degradation of the catalyst having 4,4'-dihydroxyl-2,2'-bipyridine ligand was observed under these conditions. The catalyst having 4,4'-diamino-2,2'-bipyridine ligand produced 157 MPa of gases from 21 M of FA solution at 80 °C.[4] It was possible to continuously produce high-pressure and CO-free H_2 by addition of concentrated FA.

Enhancing Gravimetric and Volumetric Ammonia Capacities of Metal-Organic Frameworks via Consecutive Post-Synthetic Modification Dae Won Kim and Chang Seop Hong; Korea University, Korea (the Republic of)

Ammonia is a promising energy vector that can store the high energy density of hydrogen. For this reason, numerous adsorbents have been investigated as ammonia storage materials, but ammonia adsorbents with a high gravimetric/volumetric ammonia capacity can be simultaneously regenerated in an energy-efficient manner remain underdeveloped, which hampers their practical implementation. Herein, we reported Ni_acryl_TMA (TMA = thiomallic acid), an acidic group functionalized metal-organic frameworks prepared via double post-synthetic modifications showing top-tier gravimetric ammonia capacity of 23.5 mmol g^{-1} and the unprecedented ammonia storage density of 0.39g cm^{-3} at 1 bar and 298 K with facile regeneration. The ammonia storage properties and adsorption mechanism were characterized by ammonia isotherm, NH_3-temperature-programmed desorption curves, NH_3 breakthrough curves, *in-situ* FT-IR, and DFT-calculation. Detailed synthesis and properties will be presented in the presentation.

9:45 PM EN07.11.03
Relationship Between Anode Deformation and Cell Stress Evolution During Reduction in Solid Oxide Fuel Cells and Electrolysis Cells Junya Tanaka[1,2], Kazuhisa Sato[1] and Toshiyuki Hashida[1]; [1]Tohoku University, Japan; [2]DENSO Corporation, Japan

Solid oxide fuel cells (SOFCs) and solid oxide electrolyte cells (SOECs) are attracting attention as one of next-generation energy devices because of high energy conversion efficiency or non-necessity for expensive catalyst. To commercialize SOFCs/SOECs, it is crucial to ensure their mechanical reliability. Various types of stresses generated in the cells during the lifetime from manufacturing to operation may cause cells failure and system safety degradation. In particular, the anode deformation during reduction is considered to be one of the most important factors causing cell stress changes, but the results reported by previous studies vary, and there are also few reports about the relationship between the anode deformation and cell stress evolution.
In this study, the deformation behavior of anodes with different Ni contents during reduction and the effects of temperature on it were investigated in-situ by a dilatometer and X-ray diffractometry using NiO-YSZ bulk samples which is often used for the anode in SOFCs/SOECs. In addition, the cell stress changes during reduction process are examined by FEM analysis and verified by X-ray diffractometry.
Since YSZ is stable and NiO shrinks under reducing conditions, it was generally assumed that NiO-YSZ shrinks during the reduction process. However, only the sample with the highest Ni content in this measurement was shown to shrank, (specifically, -0.32% strain at 700°C, -0.10% at 800°C and -0.071%

at 900°C), while the other NiO-YSZ samples expanded, (for example, a sample with 27% Ni content showed 0.024% strain at 700°C, 0.013% at 800°C and 0.051% at 900°C). Both the amount of expansion and shrinkage decreased with increasing temperature during reduction. We found that the factor of expansion was the change or release of the residual stress on YSZ side, because the strain change in the NiO-YSZ measured by the dilatometer and that calculated form residual stress change on the YSZ side measured by X-ray diffractometry mached each other in both direction and amount. In addition, it can be explained that the factor of decreasing expansion amount with increasing temperature is also due to the residual stress change on the YSZ side.
In the cell configuration, only the anode is deformed unless the cathode is exposed to a reducing environment. Thus, we hypothesized that the factor for cell stress changes during reduction is the anode deformation, and investigated the cell electrolyte stress change by FEM analysis taking into account the anode deformation, creep behavior and temperature dependence of the relevant physical properties. It was also verified by X-ray diffractometry based on the cosα method. The measured cell was a multilayer structures consisting of an anode, an electrolyte, and an interlayer, which is a structure similar to that of the actual cell. The principal stress on the electrolyte surface was computed form the FEM analysis. Here, the positive side is tensile direction, and the negative side is compressive direction. Specifically, when the anode showed expansion, there were almost no stress changes on the cell electrolyte. However, when the anode showed shrinkage, the residual stress increased by approximately 300MPa on the compressive side during reduction. Then, the residual stresses were relaxed by creep after reduction under both analysis conditions.
The experimental results together with the FEM analysis suggest that the anode deformation may control cell stress change during reduction, and the numerical method developed in this study can offer a useful tool for evaluating the cell stress evolution during the reduction process.

10:00 PM EN07.11.04
Functionalization of Graphene Oxide Membranes by (3-Mercaptopropyl) Trimethoxysilane for PEMFCs Shahjahan K. Chowdury, Young J. Cho, Sung B. Park and Yong-il Park; Kumoh National Institute of Technology, Korea (the Republic of)

Graphene oxide membrane (GOM) has promising electrolyte properties in electrochemical devices, including fuel cells and batteries. However, GOM has a much lower proton conductivity in a through-plane direction (σ_{th}) than that of the most commonly known PEMFC electrolyte of Nafion® membrane. And the lamellar structure of 2-dimensional graphene oxide (GO) nanosheets show a large anisotropic conductivity, fuel crossover, and negative surface functional groups reduced by hydrogen atmosphere while operating in the PEMFC. In this study, rapid proton-conducting GOMs were synthesized by homogeneous mixing of the diluted (3-mercaptopropyl)trimethoxysilane (MPTS, $HS(CH_2)_3Si(OCH_3)_3$) and GO, i.e., M-GOM, and then oxidizes to supply a proton conduction pathways by obtaining a sulfonic acid ligand (-HSO3), where MPTS covalently bonded to the surface of GO through the hydrolysis ($Si\text{-}OCH_3$ to Si-OH) and condensation reaction (Si-OH to Si-O-C), and thiol group (-HS) of MPTS was oxidized to accomplish a $-HSO_3$. Excellent proton conductivity was observed, due to silane-based network formation and a dramatic increase in proton conduction sites. The influence of the fabricated M-GOM on morphology, physicochemical properties, atomic bonding, and crystalline phase are investigated and compared with Nafion®. After depositing a hydrogen-permeable metal thin film (Pd) on M-GOM, it is utilized in a hydrogen membrane fuel cell (HMFC), and its operating characteristics are also reported.

Nanohybrid Graphene Oxide Membranes for PEMFCs Shahjahan K. Chowdury, Young J. Cho, Sung B. Park and Yong-il Park; Kumoh National Institute of Technology, Korea (the Republic of)

Graphene oxide membrane (GOM) is considered a promising alternative electrolyte due to its hydrophilic nature and fascinating proton conductivity in humidified conditions. However, GOM has a lower proton conductivity than high-performance Nafion(R) membrane in the through-plane direction (σ_{th}) and GOM loses its surface functional groups by hydrogen gas in anode when operating in PEMFC, resulting in increased electronic conductivity. Therefore, in this research, a highly proton-conducting composite membrane was synthesized using a silanization process between a highly viscous GO solution (5mg/mL) and a diluted (3-mercaptopropyl) trimethoxysilane (MPTS, $HS(CH_2)_3Si(OCH_3)_3$) (0.790 g/mL). The organofunctional group of the thiol group (-SH) was oxidized by hydrogen peroxide (H2O2) into a sulfonic acid group (-HSO3) on the surface of GOM for providing a high-speed proton conduction path along with the functional group of GOM. Moreover, proton conductivity was raised by adding excess MPTS as a binder in the MPTS-modified GO composites (MGCs). The incorporated MPTS into the GO framework was controlled from 1 to 70 wt%, and a suitable ratio of the high-performance electrolyte properties was reported such as excellent proton conductivity, thermally, mechanically and chemically protected from degradation. In addition, the MPTS-derived siloxane structure further enhances the water uptake with dimensional stability and low fuel crossover without damaging the proton transport path in MGCs. The synthesized composite membrane was investigated not only the morphology by FE-SEM, but also the molecular and microstructure analysis using powder X-ray diffraction, X-ray photoelectron spectroscopy, Raman spectroscopy, Fourier-transform infrared spectroscopy, thermogravimetric analysis/differential scanning calorimetry, and UV-Vis spectroscopy. In addition, hydrogen-permeable 40 nm- thick Pd was deposited on the surface of the MGCs to improve the gas tightness and maintain high mechanical stability to prevent degradation of the membrane by hydrogen reduction during the operation of the fuel cell.

Pt-Free Cathode for Graphene Oxide-Hydrogen Membrane Fuel Cells Shahjahan K. Chowdury, Young J. Cho, Sung B. Park and Yong-il Park; Kumoh National Institute of Technology, Korea (the Republic of)

Electrocatalysts without precious metals are being actively studied in the field of electrochemical devices, including fuel cells due to their low cost and electrocatalytic activity. Graphene, a new 2-dimensional sp^2-hybridized hexagonal (honeycomb lattice) carbon material, provides the noticeable replacing opportunity as an electrocatalyst for oxygen reduction reaction (ORR) because of its excellent chemical, electrical and thermal properties, high catalytic activity, and tolerance against poisoning. In this study, a nitrogen-doped reduced graphene oxide (N-rGO) catalyst for oxygen reduction reaction (ORR) of hydrogen membrane fuel cell was investigated. This process, in this study provides an effective yield and is free of impurities, resulting in the intrinsic catalytic performance. The surface morphology, hydrophobicity and electrical conductivity of the synthesized N-rGO was analyzed by BET and UV-visible spectroscopy. A graphene oxide-hydrogen membrane fuel cells that does not use Pt/C was prepared using the N-rGO electrode and the graphene oxide composite electrolyte membrane modified with 3-mercaptopropyl trimethoxysilane developed in the previous study, and its performance is reported.

10:35 PM EN07.11.08
Power Distribution Control for Improving Lifetime of Proton Exchange Membrane Water Electrolyzers Keiji Watanabe, Daiko Takamatsu, Akio Yoneyama, Futoshi Furuta, Takao Ishikawa and Jun Hayakawa; Hitachi, Ltd., Japan

There is a growing demand for improving lifetime of water electrolyzers in order to reduce the hydrogen production cost. Recently, degradation behaviors of proton exchange membrane (PEM) water electrolyzers operating under fluctuating power such as renewable power sources have been extensively studied. Degradation of electrolyzer appears as increase in the operating voltage (i.e., the overpotential). It was shown that the rate of voltage increase highly depends on the operation parameters such as the current density and the interval of current fluctuation [1,2]. However, it has not been clarified so far what kind of operation control can suppress the degradation of the electrolysis stacks. Here we have developed a novel control technology for improving

lifetime of PEM water electrolyzers.
First, we proposed a control strategy called the Power Distribution Control (PDC) for suppressing the degradation of water electrolyzers. The concept is to decompose a fluctuating power that highly degrades electrolyzers into the power patterns of low-degradation rates. For example, a PEM electrolysis cell operating under the current fluctuation between 2 and 1 A/cm^2 (mode A) degrade rapidly than that between 2 and 0 A/cm^2 (mode B) [1]. When two series of stacks (i.e., two strings) operate in mode A, it is possible to distribute the current by the PDC so that one string operates in mode B and the other at a constant current of 2 A/cm^2 (mode C). It is thus expected that degradation of the stacks can be suppressed by the power distribution. An example of the system architecture to perform the PSC is an array of electrolysis stacks with power converters such as DC/DC converters installed in each string.
In order to experimentally validate the effect of PDC, a series of durability tests for a PEM electrolysis cell were performed. A membrane electrode assembly (MEA) composed of a PEM (Nafion 117), an anode catalyst layer (IrO_2), a cathode catalyst layer (Pt/C) and gas diffusion layers was prepared and used for the tests. The rate of cell voltage increase was 111 and 69 μV/h under the operation in mode A (reference) and in the sequence of mode B and C (simulation of PDC), respectively. This result suggests that the degradation rate was reduced by 38% as a result of PDC. As a result of the analysis of current-voltage characteristics, it was found that PDC is particularly effective in suppressing the increase in the activation overvoltage.
Furthermore, the degradation mechanism has been investigated by analyzing the degraded sample using synchrotron radiation. Scanning X-ray fluorescence microscopy (SXFM) [3] was performed for obtaining elemental maps of the cross section of the catalyst coated membrane (CCM). An X-ray microbeam 1 μm in diameter was formed, and the distribution of Pt and Ir was obtained. While the distribution of Pt showed little change after the durability test, Ir was observed within the PEM and even near the interface between the PEM and the cathode. Then we performed microbeam X-ray absorption fine structure (XAFS) imaging and estimated the Pt and Ir valence state from the white-line height of Pt and Ir L_{III}-edge X-ray absorption near edge structure (XANES), respectively. It was found that Ir within the PEM is in a higher valence state ($Ir^{>4+}$) than Ir at the anode (Ir^{4+}), indicating that highly oxidized IrO_X dissolved and migrated in the PEM. This scenario is consistent with the Pourbaix diagram of Ir [4], where the stable phase changes between IrO_2 (pH = 0) and IrO_4^- (pH = 7) during the operation of PEM electrolyzers.
Our results demonstrate that PDC is a promising technique for improving lifetime of PEM electrolyzers by suppressing degradation such as Ir dissolution.

Selective Oxidation of Aromatic Alcohol and Amine Under Visible-Light Irradiation Using Rh Doped $SrTiO_3$ Photocatalyst Sayuri Okunaka and Kazuhiro Sayama; National Institute of Advanced Industrial Science and Technology (AIST), Japan

Development of selective organic synthesis using environmentally benign, inexpensive and renewable resources has attracted much attention in both fundamental and industrial chemistry. In particular, selective oxidation of alcohol or amine for the synthesis of fine chemicals and pharmaceuticals has received much attention in chemical research. Recently, selective oxidation using a semiconductor photocatalyst is considered to be one of the most sustainable energy conversion processes with significant advantages of operation under room temperature and utilization of clean, renewable solar light as the driving force. However, TiO_2, which is the famous semiconductor photocatalyst, has the following drawbacks; low photoactivity, poor selectivity and lack of utilization of visible light, and therefore hinder its application. Alternatively, the Rh doped $SrTiO_3$ ($SrTiO_3$:Rh) photocatalyst has been known to have a potential that can oxidize organic compounds and produce H_2 from water containing organic media (e.g. methanol) under visible light irradiation. Here, we attempted to use $SrTiO_3$:Rh as a visible light responsible photocatalyst for selective oxidation of benzyl alcohol or benzylamine, which were chosen as one of the model alcohol or amine derivatives, under visible light irradiation.

Tunning the Nanoporous Structure of Cobalt-Iron-Based Nanocomposite via Doping Sulfur and Phosphorus for Charge Storage Application Shiva Bhardwaj[1,2], Mahesh Chaudhari[1,2] and Ram K. Gupta[1,2]; [1]Pittsburg State University, United States; [2]Kansas Polymer Research Center, United States

Running a vehicle needs energy that is derived using fossil fuels mainly (gasoline) leads to the production of greenhouse gases like CO_2, which is the one of the main cause of global warming. So scientists worldwide are looking for clean and sustainable energy for which energy storage devices (ESDs) might be the one solution as they are the past, present, and the future of electric vehicles; without ESDs, these vehicles are not imaginable, providing significant support to the importance of ESDs. Apart from electric vehicles, ESDs have many applications in running electrical and electronic gadgets. The various types of ESDs are batteries, supercapacitor (SC), and fuel cells. Among these fuel cells are the clean and green energy sources, which use hydrogen (H_2) as a fuel. These fuel cells run on the basic principle of water (H_2O) splitting technology. Generally, rare earth metals like Platinum (Pt), Ruthenium (Ru), etc., are used as the electrocatalyst, among which Pt has the lowest possible overpotential ~ 42 mV, but these rare earth metals are expensive. Therefore, researchers worldwide are looking toward the transition metal-based composite. These composites play a vital role in green energy production. This work introduces the use of cobalt-iron (Co-Fe) based composite, which is further followed by the doping sulfur (S) and phosphorus (P) as highly efficient electrocatalyst. The electrocatalyst were synthesized using two facile synthesis routes in which they produce different morphology (nanoflowers and macroparticles). Nanoflowers are produced using the Co and Fe-based precursors via a solvothermal for a week at room temperature. While the macroparticle composite is prepared using a simple co-precipitation method. Their unique structure allows them to have more electroactive sites. Among nanoflowers, the best sample of P-Co-Fe showed an oxygen evolution overpotential of 340 mV at 10 mA/cm^2 with a Tafel slope of 48 mV/dec along with the hydrogen evolution overpotential of 46 mV to deliver 10 mA/cm^2. On the other hand, the macroparticle’s best sample of P-Co-Fe shows the oxygen evolution overpotential of 330 mV at 10 mA/cm^2 with a Tafel slope of 63 mV/dec along with the hydrogen evolution overpotential of 61 mV to reach 10 mA/cm^2. The stability of the prepared electrocatalysts was tested using cyclic linear voltammetry and chronoamperometry. Both the measurements showed high electrocatalytic stability of the prepared samples for over 1,000 cycles of linear voltammetry and 24 hrs of chronoamperometry test. Our research provides a cost-effective and highly efficient electrocatalyst for green energy production.

SESSION EN08.01: Effect of Radiation on Materials
Session Chairs: Tobias Beirau and Mohamed Ruwaid Rafiuddin
Monday Morning, November 28, 2022
Hynes, Level 3, Room 300

11:00 AM EN08.01.02
Radiation damaged zircon and pyrochlore: Mechanical properties and percolation transitions Tobias Beirau[1], Norbert Huber[2,3], Edoardo M. Rossi[4], Marco Sebastiani[4], Michael Carpenter[5], Warren Oliver[6] and Rodney Ewing[7,7]; [1]Martin Luther University of Halle-Wittenberg, Germany; [2]Helmholtz-Zentrum Hereon, Germany; [3]Hamburg University of Technology, Germany; [4]"Roma TRE" University, Italy; [5]University of Cambridge, United Kingdom; [6]KLA-Tencor, United States; [7]Stanford University, United States

Materials with pyrochlore structure ($A_2B_2O_7$), as well as zircon ($ZrSiO_4$) have been proposed as ceramic host phases for the long-term disposal of nuclear waste (especially for actinides, e.g., uranium and plutonium). The decay of incorporated actinides leads to damage in the initially ordered structure. The goal is to better understand the effects of the resulting radiation-damage related structural amorphization and subsequent thermal annealing induced recrystallization on the mechanical properties. The results of modelling [1,2], as well as of experimental work on zircon and pyrochlore, obtained by nanoindentation (CSM and -micro-pillar splitting) and resonant ultrasound spectroscopy [3,4], will be presented to provide a comprehensive picture. Variations in, e.g., elastic modulus (E), hardness (H), and fracture toughness (K_c) have been detected. Percolation theory has found to be appropriate to describe the mainly by alpha-decay induced crystalline-to-amorphous transition. While E and H of pyrochlore and zircon have found to decrease due to radiation-damage, zircon shows an increase in K_c and strong interface effects with increasing amorphous fraction. The recrystallization process in pyrochlore is accompanied by changes in elastic properties and initial heating leads to elastic softening. Zircon and pyrochlore provide useful models for the development of complex ceramics that can be used in high radiation fields.

***In Situ* Ion Irradiation of Rhabdophane- and Churchite-Type Hydrous Rare-Earth Phosphates** Mohamed Ruwaid Rafiuddin; University Of Huddersfield, United Kingdom

Rare-earth phosphates adopting the monazite ($REPO_4$, RE = La to Gd) and xenotime ($REPO_4$, RE = Tb to Lu and Y) structures are proposed as one of the candidate matrices for nuclear waste immobilization applications. Several studies focussing on the effect of radiation and corrosion on the structure of monazite and xenotime materials have been reported in the literature. To the best of our knowledge, the effect of radiation on the structure of metastable polymorphs (rhabdophane – $REPO_4.H_2O$ (RE = La to Dy) and churchite-$REPO_4.2H_2O$ (RE = Gd to Lu and Y)) of the rare-earth phosphate family haven't been reported in the literature. Rhabdophane and churchite phases are proposed as an actinide-solubility controlling phase and is expected to precipitate on the surface of monazite and xenotime materials upon aqueous corrosion of the latter. In the current study, the effect of radiation on rhabdophane ($SmPO_4.H_2O$, $DyPO_4.H_2O$) and churchite ($YPO_4.2H_2O$, $DyPO_4.2H_2O$) materials was studied by irradiating these materials with 650 keV Xe^{2+} ions under in-situ conditions and the structural response were monitored using in-situ TEM (MIAMI facility, University of Huddersfield). Phase-pure rhabdophane and churchite materials were synthesized using wet-chemistry methods at ~25°C - 50°C. Upon irradiation, these materials transform to the amorphous state at much lower ion-fluences in comparison to their anhydrous counterparts. Amorphous rhabdophane and churchite materials were found to be very sensitive to the electron beam and quickly reverts back to their original crystalline state upon electron beam exposure.

11:30 AM EN08.01.04
Effect of Irradiation on the Aging of Hydrated Gels Obtained from Simplified Borosilicate Glasses Amreen Jan and N M Anoop Krishnan; Indian Institute of Technology Delhi, India

Confinement of radionuclides in borosilicate glass matrix is subject to the durability of vitrified nuclear waste glass in the aqueous medium on the geological time scales under repository conditions. It is now well accepted that under the aqueous condition there is a formation of a hydrated gel layer which is expected to play a significant role. However, the properties of this gel layer are not well understood yet. In this work hydrated gels are obtained from a series of pristine and irradiated borosilicate glasses. These gels are then aged at a temperature, of 2000K. It is observed that, indeed, there is a difference in the properties (connectivity, short and medium-range order) of aged gels formed from pristine and irradiated glass. Aging had a significant effect on the irradiated gels as compared to gels obtained from pristine glasses. Further, the role of medium-range order on the mobility of water is studied and it is observed how different ring distributions (pristine and irradiated) upon aging manifest similarly. mean rings size decrease in pristine gel and its

increase in irradiated gel leads to a decrease in mobility of water across the gel upon aging.

11:45 AM EN08.01.05
Radionuclide Distribution in Irradiated BWR Tie Plate Tomofumi Sakuragi[1], Yuki Nakai[2], Syuji Yamamoto[2], Naoto Kume[2], Tsukasa Sugita[2], Yu Yamashita[2] and Hiroyoshi Ueda[1]; [1]Radioactive Waste Management Funding and Research Center, Japan; [2]Toshiba Energy Systems & Solutions Corporation, Japan

After the fuel reprocessing, the metallic components of spent nuclear fuel assembly including hulls and end pieces are projected to be disposed of in deep underground repositories owing to their high activation and strong contamination. Regarding the current post-closure safety case, the corrosion-related congruent release is assumed as a source term for this nuclear waste where the radionuclides are considered to be homogeneously distributed in the metal matrix. Therefore, the radionuclides distribution is a key factor affecting the leaching behavior especially for end pieces because the change in neutron flux is significant at the fuel edges.
This study investigates the radionuclide content and distribution for a lower tie plate (i.e. bottom end piece of BWR fuel) irradiated with burnup of 35.0 GWd/tHM using the imaging plate (IP) method. The detailed burnup conditions were obtained for the activation calculation by Monte Carlo burnup calculation code (MCNP-BURN2). The contents for ^{14}C and ^{60}Co were obtained by liquid scintillation counting and Ge spectrometry, respectively. The experimental conditions of IP measurement (e.g. exposure time) were set based on those radioactivities. The result of IP method showed that the photostimulated luminescence (PSL) intensity decreased as greater the distance away from near fuel to downward. This trend is in good agreement with the MCNP-BURN2 activation analysis.

This study was carried out as a part of R&D supporting program titled “Advanced technology development for geological disposal of TRU waste (2021 FY)” under the contract with Ministry of Economy, Trade and Industry (METI) (Grant Number: JPJ007597).

SESSION EN08.02: Efficient Capture of Radionuclides
Session Chairs: Kyle Brinkman and Amy Welty
Monday Afternoon, November 28, 2022
Hynes, Level 3, Room 300

1:30 PM *EN08.02.01
Sorbents for Capture of Krypton, and Xenon from Used Nuclear Fuel Off-Gas Streams Amy K. Welty, Meghan S. Fujimoto, Mitchell Greenhalgh and Troy Garn; Idaho National Laboaratory, United States

Volatile radionuclides from used nuclear fuel reprocessing (UNF) present significant technical and environmental challenges. Species properties coupled with low concentrations make separation and capture difficult and potentially cost prohibitive. Idaho National Laboratory has spent signifance effort developing materials and strategies for the separation and capture of krypton and xenon from UNF off-gas. Tayloring sorbent materials to the harsh conditions of UNF off-gas stream, coupled with rigorous testing designed to challenge material integrity and capabiltiy is ongoing. The work is focused on bridging the gap between the fundmental material science and the practical applicaltion of those sorbents.

2:00 PM EN08.02.02
Computation-Based Optimization of Functionalized Ni(PyC)2 for Xe and Kr Separation Minbum Kim[1], Alexander Robinson[1], Praveen Thallapally[1], Cory Simon[2] and Sun Hae Ra Shin[1]; [1]PNNL, United States; [2]Oregon State University, United States

Known as a next-generation adsorbent, metal-organic frameworks (MOFs) are a promising material for noble gas separation and capture. The $Ni(PyC)_2$ with a highly Xe/Kr selectivity has optimal pore size and structure for Xe/Kr separation. We synthesized a new $Ni(PyC\text{-}m\text{-}NH_2)_2$ by appending a functional group to the PyC ligand to increase the Xe/Kr separation selectivity. It showed that the Xe adsorption uptakes increased at low pressure due to the high polarizability of amine group, which indicated that $Ni(PyC\text{-}m\text{-}NH_2)_2$ (20) has a higher IAST selectivity for Xe/Kr separation than $Ni(PyC)_2$ (17). The Xe, Kr and Ar adsorption uptakes and selectivities of $Ni(PyC\text{-}m\text{-}NH_2)_2$ were predicted through simulation, and the simulation results were consistent with the trend of single-component isotherms results. The breakthrough experiment results indicated that the $Ni(PyC\text{-}m\text{-}NH_2)_2$ showed a higher Xe/Kr separation performance than pristine $Ni(PyC)_2$ under dynamic flow conditions. These results suggested that $Ni(PyC\text{-}m\text{-}NH_2)_2$ is a promising adsorbent for Xe/Kr adsorptive gas separation process.

2:15 PM *EN08.02.03
Nanostructured Ceramic Membranes for Hydrogen Isotope Processing Kyle S. Brinkman[1], Jun Gao[1], Yuqing Meng[1], Jianhua Tong[1], James Becnel[2] and Jake Amoroso[2]; [1]Clemson University, United States; [2]Savannah River National Laboratory, United States

This work explores the use of interfacial hydrated layers in ionic conducting ceramic materials for tritiated water (HTO) adsorption and recovery. Low-temperature water adsorption properties of nanoscale structured ceramics combined with hydrogen isotope exchange in their hydrated layers may provide a low-cost and transformative avenue to address tritium management challenges. Two categories of materials were explored including i) simple oxides (TiO_2), ii) perovskite phases based on zirconates ($BaZr_{0.8}Y_{0.2}O_{3-\delta}$ (BZY20), $BaCe_{0.7}Zr_{0.1}Y_{0.1}Yb_{0.1}O_{3-\delta}$ (BCZYYb)). Nanostructured membranes were fabricated through multiple sintering methods to investigate the absorption, mobility, and isotope exchange effect. The increased conductivity of nanostructured TiO_2 membrane in the wet atmosphere and its polarization behavior confirm the existence of the proton conductivity in the nanoscale TiO_2membrane at low temperatures (< 250○C). The difference of proton conductivity in H_2O and D_2O reveals the hopping mechanism of the proton conduction. In addition, the thermo-gravimetric analysis reveals strong water uptake below 250○C resulting in high proton conductivity at low temperatures. Control of interfacial proton conductivity was demonstrated by changing the grain size and porosity of the nanostructured membrane. Furthermore, in-situ Raman and electrical conductivity relaxation techniques were used to quantify isotope exchange rates as a function of temperature. Modeling and process level economic analysis was performed using extrapolation of data from H/D systems, and associated separation factors to understand the potential for tritium absorption and recovery.

Adsorption of Uranyl Ions by a Zr-Based Metal-Organic Framework by Density Functional Theory Yuan Liu[1], An Ta[1], Shubham Pandey[1,2], Shenyang Hu[3], Natalia Shustova[4] and Simon Phillpot[1]; [1]University of Florida, United States; [2]Colorado School of Mines, United States; [3]Pacific Northwest National Laboratory, United States; [4]University of South Carolina, United States

Zr-based metal-organic frameworks (Zr-MOFs) have been widely used as ion absorbents for the removal or extraction of toxic and/or radionuclide species from aqueous solutions. However, the mechanisms by which uranyl ions interact with the Zr-MOFs have not been established. Here, the nature of the bonding of a uranyl ion ($UO22+$) with a Zr-MOF was determined using density functional theory for nineteen structurally distinct candidate complexes. The results showed that the uranyl ions bond to Zr-MOF with binding energies of the order of 1.5 eV. In the energetically most favorable structure, this strong adsorption is achieved by the formation of bonds between the uranyl ion with one middle oxygen and one edge oxygen in the Zr-MOF metal node. It was also found that the higher the degree of deprotonation of Zr-MOF, the higher the binding energy between Zr-MOF and uranyl ions.
This work was supported by the Center for Hierarchical Waste Form Materials (CHWM), an Energy Frontier Research Center (EFRC) funded by the United States Department of Energy Office of Basic Energy Sciences through Award DESC0016574.

3:30 PM EN08.02.05
Cesium Capture via Cationic Faujasite Zeolite An Ta[1], Aoub Daouli[2], Vanessa Proust[3], Agnes Grandjean[3], Michael Badawi[2] and Simon R. Phillpot[1]; [1]University of Florida, United States; [2]University de Lorraine, France; [3]The French Alternative Energies and Atomic Energy Commission (CEA), France

Due to its high aqueous mobility and a half-life of thirty years, Cs^{137} is a primary target for ionic capture during long-term storage of used nuclear fuel. Zeolitic faujasite materials have been demonstrated to be promising candidates for the industrial application of Cs^+ capture because of their low cost and relatively high stability under radioactive conditions. However, while faujasites have the capability of possessing various cationic species, their relative Cs^+ ionic exchange performances are yet to be fully established. Here, plane-wave density functional theory calculations are used to thermodynamically survey Cs^+ exchange with several monovalent cations and assess differences between cationic and acidic faujasite zeolites. The effects of differing alkaline metals and selected transition metals on cationic exchange will be discussed while favorable adsorption sites in HY-2.5 faujasite will also be identified. This work was supported by the Center for Hierarchical Waste Form Materials (CHWM), an Energy Frontier Research Center (EFRC) funded by the United States Department of Energy Office of Basic Energy Sciences through Award DESC0016574.

3:45 PM EN08.02.06
***In Situ* Powder X-Ray Diffraction Studies of Cs-Exchange in the Zeolite Chabazite** Dan Parsons[1], Antony Nearchou[2] and Joseph Hriljac[1,2]; [1]Diamond Light Source, United Kingdom; [2]University of Birmingham, United Kingdom

The sequestration of relatively long-lived radionuclides such as ^{137}Cs ($t_{½}$ = 30.2 years) from aqueous nuclear waste streams, or from aqueous environments contaminated with nuclear waste, is significant in nuclear waste management. A favoured option for the removal of radioactive cations are zeolites: porous crystalline aluminosilicates adopting framework structures comprising corner-shared [SiO_4] and [AlO_4] tetrahedra, with exchangeable cations occupying the hydrated pores and cages of the framework. Chabazite is a particular zeolite that is efficacious in the selective removal of aqueous Cs^+ by ion exchange and has been applied in decontamination efforts at Fukushima.[1] The crystallographic positions occupied by extraframework cations, such as Na, K and Cs, within the chabazite crystal structure are well established when the material contains exclusively one type of cation;[2][3] however, the mechanism by which ion exchange occurs in these materials has not been previously probed despite the inherent advantages to enhancing the understanding of this process.

In this study, powder X-ray diffraction (PXRD) patterns have been collected, on beamline I11 at the Diamond Light Source synchrotron, on chabazite samples as ion exchange occurs, facilitated by a liquid flow cell which elutes a dilute Cs-containing solution through the chabazite sample as data is recorded *in situ*. Cs-ion exchange has been studied for two chabazite samples, one containing sodium (Na-CHA) and the other potassium (K-CHA). Through applying Rietveld refinement to the *in-situ* PXRD datasets, time-resolved structural changes are observed as the constitution of extraframework cations changes within the zeolite, providing a mechanistic understanding of how Cs-ion exchange occurs in these materials.

***In Situ* X-Ray Absorption Spectroscopy and Electrochemistry Measurements of Corrosion in Molten Fluoride Salt** Boris Khaykovich[1], Guiqiu Zheng[1], David Sprouster[2], Sean Fayfar[1], Matthew Marshall[3], Eli Stavitski[4] and Denis Leshchev[4]; [1]MIT, United States; [2]Stony Brook University, The State University of New York, United States; [3]RMD, United States; [4]Brookhaven National Laboratory, United States

Molten-salt reactors (MSR) are proposed advanced nuclear reactors that utilize molten salts for cooling and solvents for fissile material. Molten salts with dissolved nuclear fuel and fission and corrosion products present challenges due to their corrosive nature, and as such, interactions between the salts and the materials they interface with need to be understood. We are developing new in-situ analytical techniques for molten-salt characterization and monitoring, especially near the interfaces between alloys and molten salts. Here, we present our examination of the corrosion of NiCr foils in molten LiF-NaF-KF eutectic (FLiNaK) using a combination of x-ray absorption spectroscopy (XAS) and electrochemistry. We distinguished the oxidation state and coordination numbers of dissolved Ni and Cr, as well as the spatial and temporal distribution of the ions in the solution. We also describe reactions at the electrodes.

Structural Characterisation of Advanced Cr & Mn Doped UO_2 Fuels Using X-Ray Absorption Spectroscopy Hannah Smith[1], Luke T. Townsend[1], Ritesh Mohun[1], Theo Cordara[1], Martin Stennett[1], J. Frederick W. Mosselmans[2], Kristina Kvashnina[3,4] and Claire L. Corkhill[1]; [1]University of Sheffield, United States; [2]Diamond Light Source, United Kingdom; [3]Helmholtz-Zentrum Dresden-Rossendorf, Germany; [4]European Synchrotron Radiation Facility, France

Advancements in UO_2 fuel technology are key in the generation of safe and efficient nuclear energy. The doping of UO_2 with transition metals, such as Cr and Mn, provides a method for improving properties, such as increased grain size, improved plasticity, and reduced pellet-cladding interactions. All these enhanced properties result in more accident tolerant and efficient fuels. Despite the implementation of Cr and Mn-doped UO_2 technology within the nuclear industry, there is a lack of fundamental understanding surrounding the local Cr/Mn coordination environment upon incorporation into the UO_2 matrix. Furthermore, the mechanisms by which Cr/Mn are accommodated within the UO_2 lattice are not well established. Here, a variety of spectroscopic techniques, including X-ray absorption spectroscopy (XANES, EXAFS, and HERFD-XANES) and Raman spectroscopy, provide significant insight into mechanisms behind the incorporation of Cr/Mn upon incorporation into the UO_2 structure. In the Mn-doped UO_2 system, Mn^{2+} is substituted onto the U^{4+} site, with vacancies and U^{5+} forming to maintain charge balance. A similar incorporation mechanism is observed in the Cr-doped UO_2 however, the UO_2 matrix accommodates Cr as a Cr^{2+} on the U^{4+} site. Following further heat treatment (to simulate nuclear fuel synthesis), Cr is present as several different species (including, Cr^{2+} and Cr^{3+}) in a variety of locations within the UO_2 fuel. The findings of these studies provide significant new insight into the fundamental chemistry behind doped UO_2 fuels and offer new opportunities for advanced nuclear fuels to be further developed and implemented within the nuclear industry.

4:30 PM EN08.03.02
Single Crystal Spectroscopic Studies of Cr doped UO_2—Resolving the Cr Valence and Chemical State of Cr in Chromia Doped Nuclear Fuels Gabriel Murphy[1], Philip Kegler[1], Kristina Kvashnina[2], Nina Huittinen[3] and Sara Gilson[3]; [1]FZ Juelich, Germany; [2]European Synchrotron Radiation Facility, France; [3]Helmholtz-Zentrum Dresden-Rossendorf, Germany

As a part of modern nuclear fuels, the use of transition metal elements as dopants, such as Cr, has been shown to increase the in-reactor fuel performance over traditional non-doped variants. The small size of the Cr cation relative to the U^{4+} cation results in a low solubility of Cr into UO_2 of approximately 750-1000 ppm depending on the oxygen potential, where higher oxygen potential leads to improved solubility of Cr [1]. Despite this and other advances in the science behind Cr doped UO_2 modern nuclear fuels, significant paucities of information remain such as even the mechanism for incorporation. Pertinently prior to this investigation, there is no definitive conclusion as to the valence state and local environment of Cr within the fuel matrix [2],[3]. Notwithstanding this, we have managed to fabricate Cr single crystals and have studied these using a combination of single crystal X-ray diffraction, electron paramagnetic resonance (EPR) and X-ray absorption spectroscopy (HERFD-XAS/EXAFS). Accordingly, we provide conclusive resolved measurements of the Cr chemical states within the UO_2 matrix, assigning both valence and local structure behaviour. We have further systematically examined the incorporation of Cr doping above and below the solubility limit, providing detailed observation of changes to the lattice parameters and microstructure via synchrotron X-ray powder diffraction measurements and electron microscopy respectively. The results of this investigation will be discussed in detail in linking the local atomic behaviour of Cr in UO_2 to microstructure behaviour in addition to the relevance they have to both modern fuels and spent nuclear fuel disposal.

4:45 PM EN08.03.03
Rheological Behaviour of Bituminized Waste Products Benoit Dussault, Arnaud Leclerc, Charles Brissot, Antoine Marchal, Jean Baptiste Champenois and Arnaud Poulesquen; CEA Marcoule, France

Bitumen is used since the sixties as confinement matrix of radioactive wastes. The behavior of these bituminized waste products (BWPs) under thermal stress, under ionizing radiation or under leaching conditions has to be assessed. Especially, the determination of the rheological behavior is of primary of importance due to its impact on a lot of mechanisms such as the convection, the sedimentation or the migration of gaz bubbles generated under irradiation. BWP are elabrorated by twin screw extrusion and are mainly composed of 40% in weight of various inorganic salts presenting a spread granulometry, and of 60% in weight of 70/100 pur bitumen. BWPs are thus considered as a non brownian dispersion of salts suspended in a viscoelastic matrix highly thermodependant. Pur bitumen and model BWPs, containing various volume fraction of salts, were synthetized and characterized rheologicaly as a function of the temperature by using different rheological sequences (creep, flow curve and shear rate step). The results show that the pure bitumen is a newtonian fluid (in the range of 20-200°C) with a strong dependance with the temperature. On the other hand, the BWPs (with the higher load of salts) behave as a yield stress fluid that could be describe by a Herschel Bulkley model. The yield stress depends not only on the volume fraction of salts but also on the temperature as a power law. We will show that this yield stress is related to the adhesion force between the salts and by normalizing the stress by the yield stress, the relative viscosity can be scaled onto a single master curve. Finally, we will illustrate through some examples, that these rheological properties may induce some particular behavior in the flow of the materials under thermal sollicitation but also on the migration and on the bubble size distribution in the case of irradiated BWPs.

Investigating the Effect of Fe_2O_3 on the Zirconolite Phase Assemblage Merve Kuman, Laura J. Gardner, Lewis Blackburn, Martin Stennett, Russell Hand and Claire L. Corkhill; University of Sheffield, United Kingdom

The UK has one of the world's largest inventory of civil separated plutonium (PuO_2). There are two potential Pu management strategies being investigated in the UK. One option is re-use within mixed oxide fuel (which is the current UK policy) or alternatively, immobilisation in a ceramic or glass host matrix. The latter could be an option for contaminated PuO_2 stocks (e.g. chlorine contamination) that could be unsuitable for MOX fabrication or a larger portion

of the inventory if deemed necessary [1].

In this study, the efficacy of Fe_2O_3 as a cation charge compensator within zirconolite was investigated, with particular focus on the phase assemblage and microstructure (without the presence of Pu or a surrogate in order to isolate the effect of Fe^{3+} on the zirconolite structure). The Fe-doped zirconolite ceramic structures were fabricated via cold press and sintering method. The conceptual ceramic wasteforms were analyzed *via* X-ray diffraction (XRD) and Scanning Electron Microscopy/ Energy Dispersive X-ray Spectroscopy (SEM /EDX) methods. Rietveld refinement was performed to determine the effect of Fe^{3+} incorporation on the unit cell parameters of the zirconolite matrix, whilst Mössbauer spectroscopy and X-ray absorption near edge spectroscopy (XANES) data revealed the coordination environment and oxidation state of Fe substitution in which Ti site into the structure. As a result, XRD revealed the phase transformation from zirconolite-2M to -3T, with the increase of Fe concentration and there was an increase in the occurrence of secondary phases, mainly perovskite. The successful incorporation of the charge compensator cation into the zirconolite structure was proved with the change of unit cell parameters, associating with the reduction in volume, and SEM/ EDX micrograph. XANES analysis showed that Fe was uniformly present in the Fe^{3+} oxidation state in octahedral coordination.

EN08.04.01
Caustic Scrubber Waste Converted to Aluminosilicates—Structures Determined by Nuclear Magnetic Resonance John S. McCloy, Nick Stone-Weiss and David Bollinger; Washington State University, United States

Several options are proposed for reprocessing of used nuclear fuel from power stations. One possibility is aqueous reprocessing of oxide fuel, which will result in some off-gas of fission products including ^{129}I and ^{14}C, which should be captured and immobilized. Of the four volatile radionuclides that are restricted by the release limits governed by the US regulations (^{3}H, ^{14}C, ^{85}Kr, and ^{129}I), ^{129}I will require the greatest degree of abatement, whereas ^{3}H and ^{85}Kr have separate capture and immobilization pathways. Caustic scrubbers (CS) are proposed to be used before sorbent beds to capture radioiodine species. Dissolved anions from the CS are predicted to include I^-, Br^-, Cl^-, OH^-, CO_3^{2-}, NO_3^-, and NO_2^-. One path for immobilization of the high pH CS solutions is to react with kaolinite to form aluminosilicate powders, which can subsequently be consolidated by various means. These aluminosilicates are primarily sodalite phase with amorphous component and minor mixed phases like cancrinite or zeolite Na-P. In the current work, previously reported CS aluminosilicate powders are further characterized by ^{23}Na and ^{27}Al magic angle spinning nuclear magnetic resonance (MAS NMR). These measurements shed light on the structure of crystalline and amorphous species previously identified by X-ray diffraction. The chemical environments probed by NMR are compared to various synthesized and natural standard materials, and ^{23}Na NMR in particular shows that many different chemical environments exist in what appears to be a mixed sodalite assemblage.

EN08.04.02
Simulating Distribution of Carbon in Spent Fuel Cladding of Zirconium Alloys Teppei Otsuka[1] and Tomofumi Sakuragi[2]; [1]Kindai University, Japan; [2]Radioactive Waste Management Funding and Research Center, Japan

Spent fuel cladding made of zirconium (Zr) alloys would be mechanically compressed as cladding hulls in Japan. In view of waste disposal of the hulls, distribution of radioactive carbon-14 (C-14) produced in a Zr matrix is one of important factors to estimate release behavior of C-14 accompanied with oxidation of the Zr matrix [1]. Although C-14 should be distributed in the Zr cladding matrix by diffusion and precipitation under gradients of concentrations and temperatures during operation of nuclear reactors, it would be potentially relocated by isothermal annealing during a mid-term storage becoming longer before processing of the hulls.

In the present study, diffusion, solution and thermo-transport data for carbon (C) as well as hydrogen (H), nitrogen (N) and oxygen (O) in Zr have been revisited and diffusion data of C in oxygen dissolved Zr (Zr(O)) have been experimentally obtained. Using the transport parameters for C in Zr and Zr(O), distributions of C in the Zr matrix have been simulated under various temperature conditions and periods using numerical calculation of the one-dimensional diffusion equation.

To date, no data of heat of transport, Q*, for C both in αZr and βZr have been available whereas those for N and O in βZr were reported as Q*=+0.925 and +1.090, respectively [2]. Assuming Q* for C in Zr is positive, initially uniform concentration of C in a wall thickness (0.5 mm) along a radial direction of the Zr cladding tube and diffusion of C for 3 years under the temperature gradient from 573 K to 773 K, C tends to segregate at the cooler side and deplete at the hotter side by thermo-transport but diffuse to the opposite direction with a driving force to minimize a concentration gradient, resulting in formation of a maximum concentration of C in a middle of the wall thickness at around 0.3 mm from the cooler side. Such the concentration non-uniformity disappears during isothermal annealing at 773 K for more than 10 years. In the presentation, effects of dissolved N and O on distribution of C in the Zr matrix will be discussed.

Densification of Nuclear Waste Incinerator Ashes via Hot Isostatic Pressing Sam Walling[1], Hélène Nonnet[2] and Claire L. Corkhill[1]; [1]University of

Sheffield, United Kingdom; [2]CEA, France

The utilisation of Hot Isostatic Pressing (HIP) for the safe, efficient densification of loose simulant radioactive ashes has been investigated. As part of a multinational project looking at pre-disposal thermal treatment of organic material (PREDIS), the University of Sheffield is collaborating with CEA to determine the wasteform characteristics of specific HIPed ashes.

These ashes arise from processing organic materials surrogates (simulating materials contaminated by α-emitting actinides) within the IRIS process (Installation for Research on Incineration of Solids) in France. It is a multi-step process able to treat high chloride containing wastes via a combined pyrolysis and calcination process. Simulant inactive ashes arising from the IRIS process are comprised of a calcium-zinc aluminosilicate rich material, with a very low level of residual carbon – making these ashes ideal candidates for HIP processing.

HIP trials were undertaken by hydraulically compacting IRIS ashes into stainless steel cans, with no additives or additional components, resulting in a 100 % waste loading. These cans were then processed at 1250 °C with a maximum pressure of 100 MPa. The resultant material was a densified, solidified wasteform, safely contained within the stainless steel canister. Post-processing characterisation revealed the formation of a polycrystalline material consisting of anorthite, diopside, chlorapatite, leucite, and spinel. Wasteform-can interactions were observed as a result of the thermal processing, leading to some internal can corrosion and a chromium rich altered wasteform interface abutting the can wall.

These trials have demonstrated the suitability of HIP towards the processing of such ash materials, resulting in a solidified product with a substantially reduced volume. Though forming a solid product, substantial porosity remains within the final product, creating potential for wasteform improvements. Further wasteform optimisation is ongoing to investigate the impact of inclusion of glass forming additives to lower the wasteform melting temperature and reduce wasteform-can interactions, along with studies into the long-term aqueous durability of these materials.

EN08.04.05
Powder Processing for Hot-Isostatic Pressing of Nuclear Waste Einan B. Solomon[1,2], Ewan Maddrell[2] and Karl R. Whittle[1]; [1]University of Liverpool, United Kingdom; [2]National Nuclear Laboratory, United Kingdom

The UK at present holds a substantial stockpile of civilian-owned plutonium dioxide, which recently has been proposed to be predominantly reused as MOX fuel. However, a significant proportion will not be suitable for this use and will need to be immobilized, with the main focus being on ceramic immobilization, using a zirconolite-based system manufactured using hot isostatic pressing. Key to this work has been the reduction of secondary wastes, such as lubricants, which can have an impact on the final wasteform, whilst at the same time optimize the final product formation. This presentation will examine the options for dry mixing, using lubricants that are both compatible with the process and the final zirconolite wasteform. Results from analysis of the final products using techniques such as X-ray powder diffraction, electron microscopy, and relative density will be shown, indicating the success of the work in being able to use solid lubricants.

EN08.04.06
Excavation of the Prototype KBS-3 Repository to Begin in 2023 Fredrik Vahlund; SKB, Swedish Nuclear Fuel and Waste Management Co., Sweden

The Prototype Repository is a full-scale experiment in 450 meter-deep crystalline rock at Äspö Hard Rock Laboratory (Äspö HRL). The experiment was initiated in 2001 to simulate the KBS-3 concept developed in Sweden for the disposal of spent nuclear fuel. The experiment consists of four deposition holes, each containing a five meter-tall copper canister surrounded by an eight-tonne bentonite buffer. The canisters are equipped with heaters to simulate heat from the decay of spent nuclear fuel. The deposition holes are located within a 64 meter-long backfilled deposition tunnel.
In the experiment, more than 300 sensors have been installed so that i.e. temperature, pressure, humidity can be measured so that re-saturation and related processes like buffer swelling and homogenisation can be analysed under realistic conditions, including the prevalence of coupled processes and boundary effects, at a scale relevant for analysis of post-closure safety of a repository for spent nuclear fuel.
The experiment also demonstrates the installation and handling of equipment at an industrial scale. Experiences from installing this experiment enabled SKB to argue for the feasibility of constructing and operating a KBS-type repository in their license applications.
The Prototype Repository was planned to run for approximately 20 years, long enough for the buffer to resaturate, given the hydrologic conditions at Äspö HRL. The 20-year experiment timeframe also allows for results from the experiment to be considered in the future, operational license application for the KBS-3 repository.
Excavation of the Prototype Repository will start early 2023 and will continue for two years. During this time a large number samples will be taken to study i.e saturation, homogenisation, swelling and mineral transformation of the clay material, status of the canister, incidence of heat-induced spalling in the deposition hole, and other factors of relevance to post-closure safety.

SESSION EN08.05: Nuclear Waste Immobilization

Synroc Technology Options for GEN IV Nuclear Reactor Wastes Daniel Gregg, Rohan Holmes, Lyndon Edwards and Gerry Triani; Australian Nuclear S&T Org, Australia

High feasibility solutions for the safe and responsible management of nuclear wastes generated from the deployment of new nuclear technologies are essential. With regards to public acceptance of new nuclear builds, concerns over the nuclear waste, particularly the intermediate (ILW) and high (HLW) level waste from spent fuel, fall second only to safety. In addition, nuclear regulators now require whole of life strategies which provide an ultimate nuclear waste disposition pathway as part of the approvals process for new nuclear facilities that produce ILW or HLW waste.

The advanced Gen IV reactors currently being commercially developed do not use standard LWR oxide fuel so the currently considered spent fuel storage and disposition options are unsuitable and bespoke waste treatment and disposal solutions are required. Synroc technology is uniquely suited to the treatment of many of these wastes as it employs hot-isostatic processing (HIPing) as a consolidation approach and allows the production of a range of wasteforms (ceramic, glass, and glass-ceramic forms) which can be tailored to the chemical, physical, and radiological properties of the target waste stream

allowing the phases that make up the wasteform to be tailored to appropriately immobilise the different radioactive species.

This presentation will provide an update of the technical maturity of Synroc Technology for the treatment of nuclear wastes. It will also discuss concepts for candidate wasteforms and processing options for the immobilisation of wastes from advanced reactors, including iodine wastes, graphite-based wastes, advanced fuel wastes, and chloride- and fluoride-molten salt wastes.

8:45 AM EN08.05.02
Investigation of Iron Phosphate Glasses for the Immobilisation of Pyroprocessing Wastes Daniel Bailey[1], Laura J. Gardner[1], Martin Stennett[1], Mike Harrison[2], Neil Hyatt[1] and Claire L. Corkhill[1]; [1]University of Sheffield, United Kingdom; [2]National Nuclear Laboratory, United Kingdom

Potential future fuel cycles may produce used nuclear fuels (UNFs) that are incompatible with aqueous reprocessing routes such as PUREX or UREX. Consequently, alternative routes such as pyroprocessing have seen renewed interest. Pyroprocessing is an electrochemical process and uses a LiCl-KCl eutectic (LKE) to dissolve the UNF which is then refined by means of electrochemistry. U and Pu may be recovered but the salt becomes progressively enriched in fission products, reducing efficiency and necessitating regeneration or replacement of the eutectic. Waste streams with high LKE content are highly challenging due to their low solubility in glass and ceramic wasteforms, high temperature volatility and aqueous solubility. Iron phosphate glasses have been reported to have a relatively high tolerance to the incorporation of chloride. As such, this study presents conceptual iron phosphate glass wasteforms for the immobilisation of these high chloride wastes. These materials have been characterised by powder X-ray diffraction, scanning electron microscopy, X-ray absorption spectroscopy, Raman spectroscopy, Mössbauer spectroscopy and aqueous durability testing. Initial results indicate that these wasteforms possess useful properties and could contribute to a toolbox for the immobilisation of challenging pyroprocessing wastes.

9:00 AM EN08.05.03
Iron Phosphate Glass Waste Forms To Immobilize Salt Waste Stream Ming Tang; Clemson University, United States

Glass waste forms are currently used to stabilize legacy high-level waste (HLW) materials, and glass is the baseline technology for treatment of HLW that would result from reprocessing commercial used nuclear fuel (UNF). Electrochemical reprocessing is one option for The United States Department of Energy (DOE) Office of Nuclear Energy (NE) to reprocess used nuclear fuel in advanced nuclear cycles. During electrochemical reprocessing, used nuclear fuel is dissolved in molten salt (e.g., LiCl-KCl eutectic). Due to the low solubilities (< 1.5 mass% for silicate-based glass) of the chloride/fluoride ions and evolution of Cl2/F2 gas from the melt under operation temperature, it is not suitable to employ the borosilicate glasses as the host for the full-salt waste streams. Phosphate glass, especially iron phosphate glass, exhibited promising properties as waste form candidates including good chemical durability; high solubility for many heavy metals (e.g., uranium, cesium, molybdenum), noble metals, and rare earths. However, there are few studies on iron phosphate glass waste forms to immobilize salt waste streams.
In this study, we intend to develop and optimize highly durable and easily processable iron phosphate glass waste form to immobilize the salt streams from advanced nuclear fuel cycle by tailoring the composition of the glasses at intermediate melting temperatures. A simulate salt recipe representing the salt waste stream in our study is 70LiCl-10Li2O-20SrCl2 which is based on previous DOE national laboratory reports. For the compositional variation study, different Fe:P ratio vs waste loading in iron phosphate glass waste forms are fabricated; various glass modifiers are added into iron phosphate glass compositions to improve chemical durability and reduce melting temperature. Further, thermal stability, chemical durability, radiation stability tests are performed on these iron phosphate glass and glass waste form samples. Specifically, DTA/TGA measurements are used to understand thermophysical and structure information of these glass waste forms. Monolithic leaching test is performed to study chemical durability of these glass waste forms. Ion beam radiation is used to simulate self-radiation in nuclear waste storage. Various characterization techniques (including XRD, SEM/EDS, TEM, Raman, X-ray CT) are used to characterize structural and chemical information. The study of composition-property-structure correlations of phosphate glasses is aimed to further optimize the waste forms by pushing the limit of salt loading while targeting high chemical durability and easily processing with present technologies. The preliminary result shows promising for iron phosphate glass waste form being an improvement over other candidate waste forms.

9:15 AM EN08.05.04
Scoping Studies of Wasteform Candidates for Li_2SO_4 Bearing Nuclear Waste Immobilisation Rifat Farzana, Pranesh Dayal, Inna Karatchevtseva, Zaynab Aly, Phillip Sutton and Daniel Gregg; ANSTO, Australia

The secondary waste stream generated during Mo-99 production is challenging to immobilise due to the high concentrations of lithium (Li^+) and sulphate ions (SO_4^{2-}), its acidic nature and its activity content. Glass and glass-ceramic wasteforms were explored in the current work as candidates to maximise SO_4^{2-} incorporation, and to provide sufficiently high waste loadings and chemical durability. The base glass systems considered were barium borosilicate glasses with specific compositions selected for targeted phase formation. The highest sulphate incorporation of 2.78 wt.% SO_3 (from waste loading of 11 wt.% as Li_2SO_4) in the glass wasteform was achieved without crystallisation following melting at 1200 °C. An immiscible sulphate layer rich in $BaSO_4$ and Na_2SO_4 formed on top of the glass at lower temperature (800–1100 °C) and ~65% of the SO_3 was lost during high temperature consolidation. Therefore, tailored glass-ceramic options that can be prepared at lower temperatures with suitably high waste loadings were considered. Single/multi phase ceramics were observed within the glass matrix at 1000 °C with 14-18 wt.% waste loading. Glass and glass-ceramics wasteforms were studied *via* XRD, SEM-EDS, XRF, Raman and thermal analysis. The chemical durability was assessed using the ASTM C1285 Product Consistency Test (PCT) standard protocol and evaluated relative to accepted high-level nuclear waste glasses.

10:00 AM EN08.05.05
Effective Immobilization of Iodine with Ag^0-Aerogel—Different Matrices and Processing Conditions Josef Matyas, Joshua A. Silverstein and Matthew Asmussen; Pacific Northwest National Laboratory, United States

One of the primary challenges for reprocessing of spent nuclear fuel, vitrification of nuclear waste, and development of advanced and innovative reactors and their nuclear fuel cycles is to immobilize iodine into durable and economically viable waste forms. These waste forms must meet criteria of high iodine loading, high chemical durability, and low processing costs. There has been significant progress made over the years with silver-functionalized silica aerogel (Ag^0-aerogel) as a means for efficient removal and sequestration of iodine from various off-gas streams. The number of lab- and bench-scale consolidation tests with hot isostatic pressing and spark plasma sintering were demonstrated. Also included were other potential pathways such as incorporation of Ag^0-aerogel into cement or low-temperature melting matrices. The presentation will focus on summarizing different strategies that have been developed to sequester iodine, discuss results from durability tests and conclude with a summary of highlights and a prognosis for future research.

10:15 AM EN08.05.06
Synthesis and Characterisation of Mixed Actinide Oxide Materials for Radioactive Waste Disposition Claire L. Corkhill, Max Cole, Lewis Blackburn, Latham Haigh, Daniel Bailey, Malin C. Dixon Wilkins, Luke T. Townsend, Ritesh Mohun and Hannah Smith; University of Sheffield, United

Kingdom

In this study, we directly evidence the defect chemistry of mixed actinide oxide materials containing Gd^{3+}, within the context of understanding the basic fundamental chemistry of actinide waste immobilisation matrices. Materials were prepared by two different routes (dry mixing and oxalic wet precipitation) and characterised to quantify the incorporation rate and distribution of Gd within the actinide oxide matrix. The thermal treatment of the oxalic powders was refined to improve the uptake of Gd by the final material. Besides measuring the general characteristics of the final sintered materials, such as grain size, density and crystallographic parameters, the defect chemistry was determined using Raman spectroscopy and through analysis of U M_4-edge X-ray absorption near edge spectra, collected in high energy resolved fluorescence detection mode (HERFD-XANES). These data revealed that, despite containing the same amount of Gd, the incorporation method between the two synthesis routes differed. Materials prepared *via* the wet co-precipitation route had defect bands typically associated with the formation of oxygen vacancies, and the HERFD-XANES data evidenced the presence of U^{5+}. Both observations are consistent with the charge-balance mechanism required when Gd^{3+} is incorporated on the actinide oxide lattice sites. Conversely, the materials prepared by the dry mixing route did not evidence the presence of U^{5+}, and the defect bands attributed to oxygen vacancies were significantly reduced.

10:30 AM EN08.05.07
Engineering Dual-Phase Zeolite Composites for Cs-137 and Sr-90 Immobilization James Reed[1], Phoebe Allan[1], Joseph Hriljac[2,1] and Thomas Carey[3]; [1]University of Birmingham, United Kingdom; [2]Diamond Light Source, United Kingdom; [3]National Nuclear Laboratory, United Kingdom

The control over zeolite selectivity is crucial for numerous industrial applications, including catalysis, gas separation and ion-exchange. In the nuclear industry, natural zeolites are employed for the removal of caesium-137 and strontium-90 from aqueous nuclear decommissioning waste, via an ion-exchange process. However, sourcing a material capable of simultaneous dual-cesium and -strontium removal, such as Mud Hills clinoptilolite, which is currently employed at Sellafield, UK, is challenging. One documented method to improve the strontium affinity of natural mordenites (MOR) and clinoptilolites (HEU) is a structural transformation to a more aluminous Na-P (GIS) structure, achieved by means of a hydrothermal NaOH treatment. However, studies have generally used concentrated NaOH solutions (>2M), ensuring complete transformation into the GIS-type structure, with composite materials seen as undesirable. This work reports the generation of composite zeolites through the partial transformation of polycrystalline mordenite and clinoptilolite aggregates into Na-P, with high levels of chemical control. Subsequently, the ion-exchange performance for cesium and strontium uptake are assessed, granular materials developed and trialed in a rapid, flow system using active nucleotides. The mechanism of transformation and nature of granular composites are also investigated through use of state-of-the-art quasi-simultaneous imaging and diffraction techniques performed at the recently commissioned DIAD beamline, Diamond Light Source.

Four series of composite zeolites were generated through partial transformation of four naturally sourced zeolites, three clinoptilolites and a mordenite. This was achieved through a partial structure transformation into Na-P, where a high level of control is exhibited and a desired blend of zeolite phases can be obtained. Batch ion-exchange experiments highlighted an increase in strontium affinity as the transformation proceeds, at the expense of cesium selectivity. Composites with around an equal blend in phases showed a significant improvement in dual-uptake behavior. Granular composites, suitable for use in ion-exchange beds, were also developed by pre-sieving of the natural zeolite prior to treatment with NaOH. SEM images suggest particle size is retained in this process through crystallization of the new phase on the surface of existing particles. X-ray computed tomography and image-guided micro-diffraction show an ‘outer shell’ comprised of Na-P, with an intact mordenite interior. This is further confirmed by diffraction tomography data. Similar analysis suggests that fully converted Na-P granules consist of large, spherical sub-particles on the exterior and similar, smaller sub-particles on the interior. These findings suggest the macroscale mechanism to be one of surface dissolution-recrystallisation, resulting in an ‘outer shell’ encapsulating a partially dissolved interior. The base then penetrates the outer shell, dissolving the interior, which then recrystallizes into Na-P. Containment by the outer shell possibly aids this process by restricting diffusion of aluminosilicate nano-parts into the bulk solution and retaining the original granule morphology.

Rapid ion-exchange data of composites of around a 50:50 mixture of phases shows a remarkable improvement in Sr-90 uptake compared to the parent materials. The enhancement was to such an extent that composite materials exhibited superior Sr-90 affinity when compared to industry standard, Mud Hills clinoptilolite. Critically, this was not at the expense of Cs-137 uptake, which remained high. This work creates scope for a novel route to a host of potential resins from low-cost natural mineral sources, with the added opportunity to tune material compositions for a particular waste stream. Additionally, the potential of the newly commissioned DIAD beamline for advanced materials analysis is showcased.

Hot Isostatic Pressing—A Potential Thermal Treatment Process for Pu Immobilisation Laura J. Gardner, Merve Kuman, Malin C. Dixon Wilkins, Lewis Blackburn, Amber R. Mason, Martin Stennett, Sarah Pepper and Claire L. Corkhill; University of Sheffield, United Kingdom

Hot Isostatic Pressing (HIPing) is a batch thermal treatment process where wastes are heated and compressed within a sealed container under controlled conditions. This results in consolidated high density wasteforms with minimal loss of volatile elements and easy accountability of active inventory [1]. In the UK, HIPing was highlighted as one of the credible options for plutonium immobilisation in the event that disposal is chosen as a management strategy [2]. To help inform the science underpinning larger-scale industrial applications of this technology, the University of Sheffield have a small-scale HIP facility capable of processing radiological simulant wasteforms using an active furnace isolation chamber (AFIC) [3]. The AFIC is designed to function within a conventional HIP set up and provides a novel opportunity in the UK to fabricate and characterise conceptual radioactive wasteforms and gain experience with radiological HIPing. It was under this remit that HIP wasteforms were fabricated as part of a broad research portfolio targeting zirconolite ($CaZrTi_2O_7$) as a single host ceramic wasteform. These trials investigated the bulk phase assemblage and HIP canister-ceramic interactions with a range of potential charge compensation cations (Al^{3+}, Fe^{3+}, Mg^{2+}). Comparison was made with wasteforms produced using typical sintering methods, for which, semi-dynamic static dissolution was performed to understand zirconolite durability. Overall, both HIPing and conventional sintering were determined to yield robust and durable zirconolite ceramic wasteforms across a range of compositions.

11:00 AM EN08.05.09
Solid Solubility in the $CeTi_2O_6$ – $CeTiNbO_6$ System—A Multi-Element Laboratory X-Ray Spectroscopic Study Malin C. Dixon Wilkins[1,2], Lucy M. Mottram[1], Martin Stennett[1], John S. McCloy[2] and Claire L. Corkhill[1]; [1]The University of Sheffield, United Kingdom; [2]Washington State University, United States

Following separation of Pu and/or the minor actinides from spent nuclear fuel, there are currently three possible routes of management: storage above ground (temporarily or indefinitely), reuse within nuclear reactors for further power generation (*e.g.* as MOX fuels or within inert matrix fuels), or disposal in a tailored wasteform material. Many studies have examined materials for the effective immobilisation of Pu, but the minor actinides have received comparatively little attention. Mineralogical brannerites and aeschynites have both been observed to have become metamict over time, yet samples still retain a significant fraction of their U/Th inventory, suggesting that both phases are significantly durable with respect to aqueous attack, even after partial or full amorphisation. The titanate family of synthetic brannerites includes the prototypical end-members $CeTi_2O_6$, UTi_2O_6, $ThTi_2O_6$ and $PuTi_2O_6$, with only Ce-brannerite being non-radioactive. In this work the Ce-brannerite – Ce-aeschynite system has been examined (following an expected substitution of $Ce^{4+}_{1-x}Ce^{3+}_{x}Ti_{2-x}Nb_xO_6$, with x = 0, 0.2, ... , 0.8, 1.0), with Ce acting as a surrogate for both Pu^{3+}/Pu^{4+} and the trivalent minor actinides.

Materials were produced following a solid state route (starting from CeO_2, TiO_2, and Nb_2O_5), and reacted at 1350 °C for 48 hrs in an air atmosphere. Materials were analysed using XRD, SEM-EDX, and Raman spectroscopy. Ce L_3-edge and Nb K-edge XANES were collected using a laboratory X-ray spectrometer, and utilised to examine the Ce and Nb oxidation states, with further measurements planned at the Ti K-edge to examine the Ti coordination environment in these materials.

The system exhibits significant solid solubility towards the Ce-brannerite endmember, with no aeschynite observed until the target stoichiometry reached $CeTi_{1.4}Nb_{0.6}O_6$ (x = 0.6), where it was observed as a minor phase (approx. 7.5 wgt.%). Preliminary XANES measurement at the Ce L_3-edge and Nb K-edge show that Nb is likely incorporated into the brannerite structure as Nb^{5+}, with an equivalent fraction of Ce^{4+} reduced to Ce^{3+} to retain charge balance. Rietveld refinements show that the Ce-brannerite structure expands significantly to accomodate the larger cations (Ce^{3+}, 1.15 Å; Ce^{4+}, 1.01 Å; Nb^{5+}, 0.78 Å; Ti^{4+} 0.745 Å), with changes in the unit cell volume of up to approx. 5.5% with increasing Nb substitution. This work further expands the crystal chemistry of the brannerite structure, with significant structural flexibility displayed by the inforporation of up to 0.4 f.u. Nb^{5+}/Ce^{3+} (*i.e.* $Ce^{3.6+}Ti_{1.6}Nb_{0.4}O_6$).

SESSION EN08.06: Safeguards
Session Chairs: Nicolas Clavier and Josef Matyas

11:15 AM *EN08.06.01
Particulate Reference Materials for Nuclear Safeguards—from Hydrothermal Synthesis to Shelf-Life Study Pierre Asplanato[1,2], Wassima Zannouh[2], Anne-Laure Faure[1], Nicolas Dacheux[2], Fabien Pointurier[1] and Nicolas Clavier[2]; [1]Commissariat à l'énergie atomique et aux énergies alternatives, France; [2]ICSM, France

Particle analyses are a key tool for safeguards verification by the International Atomic Energy Agency (IAEA). They mainly consists in measuring the isotopic composition of individual sub-micrometric particles of nuclear materials. Indeed, despite confinement precautions, nuclear processes may release nanometer to micrometer-sized particles inside the facility. Detection and measurement of the isotopic composition of these particles provide precious information on the activities implemented in the facility, for example by assessing the enrichment rate of a fuel through the $^{235}U/^{238}U$ ratio, or the date of the last chemical purification thanks to the $^{230}Th/^{234}U$ radio-chronometer. For this purpose, analytical methods based on mass spectrometry techniques, such as Thermo-Ionization Mass Spectrometry (TIMS) and Large Geometry Secondary Ions Mass Spectrometry (LG-SIMS) have been developed and are nowadays applied by a few specialized laboratories in support of the IAEA's nuclear safeguards program. However, because of the low number and extremely small size of the particles of interest, such measurements are always an analytical challenge. Hence, laboratories need reference materials representative of the samples analyzed, i.e. actinide oxide particles with well-known sizes, densities and isotopic compositions, for optimization and qualification of analytical methods and instruments.
Therefore, the synthesis of actinide oxide particles is a field of growing interest. Several production methods based on physical processes were developed, but frequently required specific equipment and cannot be easily implemented in standard nuclear chemistry labs. In this frame, we developed since several years original wet chemistry routes, which aim at precipitating directly morphology-controlled actinide oxides from mixtures of solutions. Such methods are mostly based on the hydrothermal decomposition of An(IV) carboxylate, followed by the hydrolysis of the cations which leads to the formation of amorphous $An(OH)_4$ samples, finally aging to $AnO_2.nH_2O$.
The first part of this presentation will cover the multi-parametric studies undertaken to monitor the morphology and the size of UOx and mixed (U,Th)Ox particles. Particularly, the impact of pH, aspartic acid concentration, or mechanical stirring was evaluated, leading to prepare monodisperse microspheres in the 400 nm – 2.5 µm diameter range. In both cases, particles were fired in controlled atmosphere to monitor the final O/M stoichiometry of the samples, then extensively characterized, especially to point out any chemical heterogeneity, or residual porosity.
In a second part, alteration tests of the produced particles will be discussed. These latter were undertaken in various media, with the aim to store these samples as suspensions before use. Preliminary results revealed that only a negligible weight loss occurred after several months in ethanol, while significant modification of the general morphology was observed in presence of water. In addition, first measurements of the isotopic composition of uranium by LG-SIMS led to comparable results between raw and leached samples, the behavior of the particles under the SIMS beam being comparable to typical field sample particles. This set of results then demonstrates the feasibility of producing reference actinide oxides particles through hydrothermal wet chemistry methods, with a large range of chemical compositions and sizes, thus offering various possible applications in the field of nuclear safeguards.

11:45 AM EN08.06.02
Investigation on the Structural Incorporation of Various Dopants into Uranium Oxides in Consideration of Application Requirements as Reference Materials Shannon K. Potts[1], Philip Kegler[1], Giuseppe Modolo[1], Simon Hammerich[2], Irmgard Niemeyer[1], Dirk Bosbach[1] and Stefan Neumeier[1]; [1]Forschungszentrum Jülich GmbH, Institute of Energy and Climate Research – Nuclear Waste Management (IEK-6), Germany; [2]Heidelberg University, Institute of Earth Sciences, Germany

In the last few years, an aerosol-based process has been implemented and established in the laboratories of Forschungszentrum Jülich to produce microparticulate uranium oxide reference materials. These microparticulate reference materials with well-defined properties are needed to consolidate the quality controls of the analytical methods used in particle analysis in nuclear safeguards. As a result, these reference materials must fulfill certain requirements. These requirements are specified by the International Atomic Energy Agency (IAEA) to be similar to the U-containing microparticles collected by an IAEA safeguards inspector during in-field verification activities. These so-called environmental samples are analyzed for their isotopic composition by the IAEA's Office of Safeguards Analytical Services and their dedicated Network of Analytical Laboratories (NWAL). In order to further develop analytical methods and quality control of the analytical results from particle analysis to even detect small quantities of fission products, the microparticulate reference materials must be refined. For this purpose, first attempts were made to synthesize Nd-mixed uranium oxide microparticles.

However, due to yield limitations in the µg range, no state-of-the-art analytical methods can be used for the characterization of these materials and the corresponding chemical stability of the mixed microparticles. Therefore, a co-precipitation method was adapted to synthesize bulk-scale comparison materials with various lanthanides and thorium in order to unravel the incorporation mechanism of those dopants into the uranium oxide structure in depth. Through TG-DSC studies on the mixed bulk-scale materials, the temperature range of phase transitions from UO_3 to U_3O_8 were identified and analyzed in dependence on the used dopant. By additional systematic structural investigations of the long-and short-range order phenomena with XRD and Raman, IR, and XAS, respectively the obtained doped UO_3 and U_3O_8 materials could be characterized in more detail. This presentation will show results regarding the incorporation of lanthanides and thorium into the uranium oxide structures and the corresponding phase transformation of the orthorhombic U_3O_8 to the hexagonal U_3O_8 crystal structure. These results will be integrated into the particle production process to design well-defined microparticulate mixed oxide reference materials.

SESSION EN08.07: Containment of Isotopes in Disposal Environments

What Long-Term Diffusion Experiments in Compacted Bentonite Reveal Kazuya Idemitsu, Yaohiro Inagaki and Tatsumi Arima; Kyushu University, Japan

Methods for determining diffusion coefficients include the flow-through method and the profile one. If the diffusion coefficient is small, only the profile method is applicable. In the profile method, the apparent diffusion coefficient can be obtained by setting an appropriate diffusion period. However, if an experiment is conducted with a longer diffusion period, the apparent diffusion coefficient may appear small. This phenomenon is observed in the diffusion of neptunium in compacted bentonite in an atmosphere with high carbonate ion concentrations. One interpretation is that the neptunyl carbonate complex can only pass through a limited size of pores in the compacted bentonite because the complex is so large and negatively charged. In fact, long term diffusion experiment as long as 3 years, the diffusion profile of neptunium in compacted bentonite was exponential, as filtered, and did not change over time. Such exponential profiles have also been observed for relatively large oxo-anions, e.g., molybdate ions. An exponential diffusion profile has also been observed for plutonium in a 20-year iron corrosion environment. With additional information, little plutonium was observed in the iron corrosion products.

2:00 PM EN08.07.02
Functionalized Organoclays for Increased Tc and I Sequestration Elizabeth Gager, Emily Maulden, Nathalie Wall and Juan C. Nino; University of Florida, United States

Nuclear energy production is a promising process for sustainable energy due to its relatively small carbon footprint and low carbon emission. However, the containment of highly mobile isotopes in nuclear waste such as technetium and iodine presents environmental challenges. Therefore, it is imperative to design new buffer materials to immobilize radionuclides to prevent waste from entering water streams. Organoclays, organically modified clays, are promising material systems for sequestration of radionuclides. Focusing on alkyl amine-based modifications, we have recently examined the role of carbon chain length and number of chains on the structure and Tc removal performance for montmorillonite. We will show that Tc removal performance and affinity are increased for longer chains and a greater number of chains. Functionalization with an 8-carbon chain length amine with 2 long chains shows a Tc removal > 90% and K_d of 4700 ± 300 mL/g while a single 8-carbon chain length amine shows < 10% removal and K_d of 10 ± 3 mL/g. Additionally, we will show that the performance of amine functionalized clays can be increased by additional functionalization with a cation such as Fe. For example, montmorillonite modified with a single 16-carbon chain length amine shows a Tc removal of just ~ 40% while the addition of Fe increases the removal to ~ 75%. We will demonstrate that these performance increases correlate with structural changes in the functionalized clays captured via Fourier-transform infrared spectroscopy (FTIR) and x-ray diffraction (XRD). Specifically, as the clay's basal plane spacing is increased, the Tc removal performance is also increased and there are associated changes in the orientation and structure within the interlayer of the clay. To better understand the separate effect of the organic and cation modifications on sequestration performance, we will also show the performance in zirconium and amine functionalized clays focusing on the basal plane spacing and CH_2 vibrational bands as a function of concentration.

2:15 PM EN08.07.03
Effects of Hydration on the Stability of Smectite Edge Surface Formation An Ta, Seaton Ullberg and Simon R. Phillpot; University of Florida, United States

Iodine and technetium-99 radionuclides are among those of concern for safe deep geological storage of used nuclear fuel (UNF) due to their high environmental mobility. Smectite clay materials have been considered as an additional protection feature against these isotopes due to their capabilities to capture ions (via adsorption) and to sufficiently swell in the region between vitrified UNF and surrounding rock. Even so, the adsorption behaviors of smectite edge surfaces are yet to be fully understood. Here, plane-wave density functional theory calculations are used to characterize the formation of (010), (100), (110) and (130) of isolated and hydrated edge surfaces of pyrophyllite and montmorillonite. Pyrophyllite is considered as a model for all smectites given its simple form and the consideration of isolated/hydrated surfaces provided the ability to quantifiably survey the impact of hydration on surfaces during termination processes while montmorillonite is a candidate clay material. Specifically, edge distortion will be discussed from a thermodynamic perspective throughout this presentation. This work was supported by funding received from the U.S. DOE Office of Nuclear Energy's Nuclear Energy University Program under Project 20–19198.

2:30 PM EN08.07.04
Sorption Behavior of Cesium and Strontium During the Formation Process of Calcium Silicate Hydrate as a Secondary Mineral Under the Condition Saturated with Groundwater Tsugumi Seki, Reo Tamura, Taiji Chida and Yuichi Niibori; Tohoku University, Japan

Calcium silicate hydrate (C-S-H) is formed also as a secondary mineral in the vicinity of the radioactive waste disposal site by the reaction between calcium (Ca) ions leached from the cement and silicic acid dissolved from the host rock. It is well known that C-S-H significantly absorbs cationic radionuclides as reported by many previous studies. In such researches, C-S-H samples have been once dried after 7 days or more of the curing period from their synthesis. In an actual disposal environment, however, the C-S-H of secondary mineral would be formed under the condition saturated with groundwater. Additionally, C-S-H under a transient condition may also react with nuclides because C-S-H continuously forms and alters by supplying Ca

ions and silicic acid. Therefore, this study examined the sorption behavior of cesium (Cs) and strontium (Sr) during the CSH formation under the condition saturated with groundwater by the sorption experiments without any drying process.
The sorption experiments were conducted with the C-S-H samples adjusted Ca/Si molar ratios to 0.4, 0.8, 1.2, and 1.6. C-S-H was synthesized by mixing calcium oxide, fumed silica, and pure water. The total weight of the solid phase was set to 1.5 g, and the total volume of the liquid phase was 30 mL. The concentrations of Cs or Sr in the samples were set to 1.0 mM with stable isotopes. The sorption conditions were prepared in two types: adding Cs or Sr simultaneously with the C-S-H synthesis (hereinafter referred to as "co-precipitation condition"), and adding Cs or Sr after 30 days of C-S-H curing (hereinafter referred to as "hydration condition"). The reaction periods were selected to 1, 3, 7, and 14 days for co-precipitation conditions and 1, 3, and 7 days for hydration conditions. After the reaction period, the solid and liquid phases were separated by centrifuging and filtering with a 0.20-µm membrane filter. The concentrations of Ca, Si, and Sr were measured by ICP-AES, and that of Cs was measured by AAS. The solid phase was analyzed by Raman spectroscopy and XRD.
In the analysis results of dissolved ions, the concentrations of Ca and Si were negligibly small in the comparison to the amount of Ca and Si used for the C-S-H synthesis, more specifically, the Ca/Si molar ratios of the solid phase were kept almost constant through the experimental period including just after the synthesis. This means that the soluble components quickly reach apparent solid-liquid equilibrium. On the other hand, the Raman spectra of the solid phase showed that the polymerization of the silicate chain in C-S-H progressed with time, and the lower Ca/Si molar ratio increased the degree of polymerization. In addition, the coexistence of amorphous parts and crystalline tobermorite structure was observed in the solid phase just after the C-S-H synthesis by XRD. These suggest that C-S-H continuously alters from its formation even after reaching apparent solid-liquid equilibrium. Besides, as for the sorption of Cs and Sr onto C-S-H, their sorption rates decreased with increasing the Ca/Si molar ratios because the surface charge of C-S-H was negative for the lower Ca/Si molar ratios and positive for the higher ones. Furthermore, these sorption rates were almost constant regardless of the reaction period, the curing period of C-S-H, and the conditions adding Cs or Sr to the C-S-H samples. These suggest that the sorption sites for cations such as silanol groups and interlayers of C-S-H are formed just after the C-S-H synthesis, and hardly change over 30 days or more even if C-S-H gradually alters as mentioned above. The distribution coefficients were estimated to be approximately 1 - 15 mL/g for Cs and 2 - 35 mL/g for Sr under these experimental conditions. As a result, C-S-H which continuously forms as a secondary mineral around the repository is also expected to retard the migration of Cs and Sr because of its sorption property occurring immediately after its formation.

2:45 PM EN08.07.05
Radionuclide Sequestration in Functionalized Montmorillonite Clay from Molecular Dynamics Simulations Seaton Ullberg[1], Emily Maulden[1], Elizabeth Gager[1], Juan C. Nino[1], Nathalie Wall[1], James Szecsody[2], Carolyn Pearce[2] and Simon Phillpot[1]; [1]University of Florida, United States; [2]Pacific Northwest National Laboratory, United States

Safe and reliable storage of radioactive waste (vitrified high-level waste (HLW) and spent nuclear fuel (SNF)) is a necessity for effective nuclear power infrastructure. Proper disposal requires buffer materials which can sequester radionuclides such as iodine and technetium for durations of up to 10^6 years. In this work, the performance of functionalized montmorillonite as a buffer material is evaluated via molecular dynamics (MD) simulations. Functionalizing agents such as alkylammonium, thiol groups, and metallic species react via interlayer exchange to capture the anionic radionuclides which would otherwise be electrostatically repulsed by montmorillonite's net negative charge. The simulations utilize a combination of ClayFF, SPC/e, and OPLSAA potentials to parameterize interactions between the clay sheet, water, and organic functionalizing agents respectively. Differences in performance between a neutral charge pyrophyllite clay, unfunctionalized montmorillonite, and montmorillonite with various functionalizing agents are evaluated to inform an optimal choice for future buffer material applications.

This work was supported by the US Department of Energy Office of Nuclear Energy NEUP Project Number 20-19198.

Inhibiting Airborne and Groundwater-Borne Transport of Radionuclides During Decommissioning Operations with Colloidal Silica Grout Rebecca Lunn[1], Arianna G. Pagano[1], Grainne El Mountassir[1], Claire L. Corkhill[2] and Joshua Radford[2]; [1]University of Strathclyde, United Kingdom; [2]The University of Sheffield, United Kingdom

Nuclear site decommissioning involves the retrieval and handling of radioactive waste. Waste removal from nuclear reactors and/or storage facilities, such as spent fuel pools and storage silos, represents a potential hazard in terms of radiation exposure for the workforce and the surrounding environment. This may be due to the accidental release of airborne radioactive particulates during waste recovery and transport, or to the loss of radioactive debris upon retrieval due to waste corrosion and degradation. The development of innovative techniques to reduce hazard in decommissioning operations is a critical aspect of site decommissioning.

This study explores the suitability of colloidal silica grouting around radioactive waste, prior to its removal, to reduce radiation exposure during nuclear waste retrieval operations. Colloidal silica is an aqueous suspension of silica (SiO2) nanoparticles, with average particle size <100 nm. The creation of siloxane bonds (Si – O – Si), typically triggered by the addition of an electrolyte accelerator, leads to the formation of a solid-like network of silica nanoparticles in the form of a hydrogel. Previous work on colloidal silica gel has proved its potential to form low-permeability hydraulic barriers against fluid migration, and to inhibit the diffusion of radionuclides through the gel, making it a promising material for use in retrieval operations.

Here we present research to determine the potential for colloidal silica to be used in a range of decommissioning operations. For example, spent fuel removal requires evidence that colloidal silica hydrogel can maintain its integrity upon exposure to temperatures higher than ambient, typical of the nuclear waste stored within pools and silos. These might be in the range 40-60 °C in standard conditions, but could exceed 100 °C during loss of cooling/loss of coolant accidents. We also consider grouting of particulate wastes prior to their retrieval, during which the grout must prevent particle release, and must not compromise formation of a suitable final wasteform.

Experiments were carried out to simulate colloidal silica grouting operations around objects and particles at temperatures higher than ambient, up to a maximum of 120 °C and to determine their suitability for subsequent vitrification. The effect of the temperature of the grouted object, and of the silica grout properties, on the performance of the gel was explored by a) microstructural analyses using x-ray imaging, to detect the presence and spatial distribution of temperature-induced cracks within the gel, and b) mechanical tensile and shear strength tests at different temperatures and silica concentrations. Experiments were then conducted within a furnace, using contaminated soil samples grouted with colloidal silica, to investigate the additives and processes required to produce a uniform glass and to determine its radionuclide retention. Our results confirm the strong potential of colloidal silica grout to reduce hazard during spent fuel and radioactive waste retrieval operations.

4:00 PM EN08.07.07
The PLEIADES Facility for Long-Term Experimental Investigations of Disposal Environments and Storage—Part of the UK National Nuclear

User Facility Sarah Pepper, Martin Stennett, Clare L. Thorpe, Russell Hand and Claire L. Corkhill; University of Sheffield, United Kingdom

As part of the UK Government's commitment to managing its historical radioactive waste inventory, in addition to any future generated waste, disposal of higher activity waste in a geological disposal facility is considered the safest option. Understanding how radioactive waste and different waste forms respond to storage conditions over extended periods of time is key in developing a robust safety case for disposal in a GDF.
To support this, the PLEIADES (Platform for Long-term Experimental Investigation of Alteration Disposal Environments and Storage) Facility is being established to allow the determination of radio-material corrosion and long-term degradation relevant to radioactive waste storage, disposal and decommissioning associated with legacy, new-build and future fuel cycles.
The facility comprises a suite of laboratories capable of allowing research into radio-material alteration in realistic environments and over extended timescales. Here we will describe the facilities and present some of the research being performed in the facility.

4:15 PM EN08.07.08
Evaluation of the Leaching Behavior of Heavy Metal Including Cement Solidified Waste in Simulated Radioactive Waste Disposal Facility Environment Yulim Lee, Jaeyeong Park and Hyeongjin Byeon; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Radioactive waste containing hazardous substances (mixed waste) frequently occurs around the world for reasons such as radiochemistry, nuclear species analysis, and nuclear decommissioning. These mixed wastes are thoroughly classified and disposed of in the United States, but not dealt with in other countries. Most countries distinct radioactive waste and hazardous waste separately, and there is no clear treatment standard for mixed waste with both properties. Inadequately treated mixed waste could cause crucial issues with both radiation and non-radiation hazard (chemical and biological).
For proper disposal of mixed wastes, specific technical standards and regulatory guidelines are required. In order to set these standards, it is possible to consider the application of environmental regulations on hazardous substances. However, there are many differences between non-radioactive waste disposal facilities and radioactive waste depository such as the facility design, post-closure operating standards, and leachate creation. Therefore, rather than simply applying environmental regulations for disposal of mixed waste, appropriate regulations should be established in consideration of the radioactive waste disposal environment.
In this study, the leaching behavior of hazardous substances which is frequently generated from the nuclear industry was tested in the simulated disposal condition. The target harmful substances were selected as lead, cadmium, and antimony focusing on heavy metals, and sample waste was produced by cement solidification method, which is commonly used for the disposal of hazardous and radioactive wastes. The leaching properties of these wastes were tested using TCLP, a leaching test method of hazardous waste, and ANS 16.1, a leaching test method of radioactive waste. Test conditions of leachate pH, leachate composition, and exposure dose were modified and applied to simulate the leachate environment. As a result, it was found that the leachability of the simulated waste increased significantly within the environment of the radioactive waste disposal facility compared to standard leaching test condition. In addition, as a result of the irradiation-leaching test, it was observed that the non-leached heavy metal(Cd) showed leaching though a small amount. Consequently, it was confirmed that Pb and Sb had increased leaching rate in the radioactive waste disposal environment. In the case of lead, it is expected that cement solidification is an inappropriate treatment method due to high leaching amount in cement solidification. Cd was not detected at all in the non-irradiation-leaching experiment, but it was observed that radiation could affect the leaching properties of heavy metals of detection in the irradiation-leaching experiment. Using this approach, it is possible to establish specific regulations for the disposal of mixed waste. It is suggested that wastes containing Pb should be treated with other method than cement solidification. Cd has a highly insoluble property in cement solidification, so cement solidification is considered an appropriate disposal method. In addition, both lead and cadmium show changes in leaching properties as a result of irradiation-leaching experiments, raising the necessity to establish proper leaching criteria in consideration of the expected dose exposure in the disposal facility.

4:30 PM EN08.07.09
The Methodologies to Reduce the Thermal Impact of Vitrified Waste from Spent MOX Fuel on Geological Repository Ryo Hamada[1], Tomofumi Sakuragi[1], Hidekazu Asano[1], Toshiro Oniki[2] and Midori Uchiyama[2]; [1]Radioactive Waste Management Funding and Research Center, Japan; [2]IHI Corporation, Japan

In Japan, the storage of spent MOX fuels discharged from some commercial nuclear power plants has started. In the future, reprocessing, vitrification and final disposal of the spent MOX fuel will be needed in order to reduction of waste volume and radiotoxicity in a potential repository.
Compared to the vitrified waste from spent UO_2 fuels (UO_2-HLW glass), the MOX-HLW glass has high heat generation for a long period, and thus it takes about 300 years to cool down to the same heat generation. So, it is essential to decrease heat generation in order to prevent the bentonite buffer alteration, otherwise the waste volume and repository footprint will be huge.

In this study, 5 options are considered to decrease the bentonite buffer temperature in geological repository for the MOX-HLW glass. One option is minor actinides (MA) separation from high-level liquid waste (HLLW). MA separation is greatly effective to decrease thermal impact because main nuclide of heat generation of MOX-HLW glass is Am-241. MA separation ratio from HLLW requires 80% to lower the bentonite buffer temperature limit of 100 ° C. So, the development of MA separation technology is important.

The other options such as long-term storage or low waste loading of MOX-HLW glass, expansion of repository footprint, and mixing with UO_2 and MOX reprocessing liquid waste will be discussed in detail.

This work was carried out as a part of the basic research programs of vitrification technology for waste volume reduction supported (JPJ010599) by the Ministry of Economy, Trade and Industry, Japan.

4:45 PM EN08.07.10
Nuclear Waste from Small Modular Reactors Lindsay Krall[1,2], Allison Macfarlane[3] and Rodney Ewing[4]; [1]Stanford University (former), United States; [2]Swedish Nuclear Fuel and Waste Management Company (current), Sweden; [3]The University of British Columbia, Canada; [4]Stanford University, United States

Small modular reactors (SMRs, *i.e.,* nuclear reactors that produce <300 MW_{elec}, each) have attracted considerable attention because of inherent safety features and reduced cost, but there are remarkably few studies that analyze the impact of SMRs on the back-end of the nuclear fuel cycle, specifically with respect to changes in waste stream management and disposal. Here, we characterize the notional high-, intermediate-, and low-level waste streams for

three, distinct SMR designs in terms of volume, (radio)chemistry, decay heat power, and fissile isotope composition[1]. Results reveal that the analyzed water-, molten salt-, and sodium-cooled SMR designs will increase the energy-equivalent volume of nuclear waste in need of management and disposal by two- to thirty-fold relative to an 1100 MW_{elec} pressurized-water reactor. Much of the excess waste volume is attributed to the use of neutron reflectors and/or of chemically reactive fuels and coolants in SMR designs. That said, volume is not the most important parameter for assessing the implications for storage and disposal of a nuclear waste stream; rather the critical issues in the performance of a geologic repository are driven by the decay heat power and the (radio)chemistry of the spent nuclear fuel. SMRs provide no benefit for these two important parameters. For instance, SMRs will not reduce the energy-equivalent generation of geochemically mobile ^{129}I, ^{99}Tc, and ^{79}Se fission products—important dose contributors for various repository designs—relative to a full-scale commercial reactor. Instead, SMR spent fuel will contain relatively high concentrations of fissile nuclides and, therefore, will demand the development of novel approaches to criticality safety during storage and disposal, including increased handling, treatment, and conditioning operations. Since the properties of the waste streams are influenced by neutron leakage, a basic physical process that is enhanced in small reactor cores, SMRs will exacerbate the challenges of nuclear waste management and disposal.

Stage III Glass Corrosion Behavior for Different Glass Compositions at Multiple Temperatures Jarrod Crum, Benjamin Parruzot, Sebastien Kerisit, Richard Daniel, Joelle Reiser, Richard Reyes, Neeway James, Joseph Ryan, Gary Smith and Matthew Asmussen; PNNL, United States

The corrosion of borosilicate waste glass has been studied by groups around the world to understand and estimate the long-term performance of the waste form in the disposal environment. In static conditions, glass first briefly corrodes at the forward rate (Stage I), but the corrosion rate then progressively slows by orders of magnitude to a residual rate (Stage II) due to a combination of solution feedback effects and formation of a stable protective gel layer. However, the corrosion rate can later accelerate above the sustained Stage II corrosion rate, referred to as the resumption (or Stage III) rate. This behavior may be induced by the precipitation of a sink phase, which perturbs the leachate chemistry and stability of the protective gel layer. The sink phases commonly observed during Stage III are zeolite phases, such as analcime, P1, P2, and chabazite. These sink phases act as sources that consume major glass and gel components (alkali, alkaline earth, Al_2O_3, and SiO_2) resulting in accelerated glass corrosion rates. While Stage III behavior has been observed at 70 °C and 90 °C in long-term static testing of crushed glass (e.g., Product Consistency Test), its stochastic nature and long onset times make Stage III corrosion rate measurements extremely challenging. In this work, zeolite seeds (zeolite P1, P2, analcime, and clinoptilolite) were used to induce Stage III behavior at 22 °C, 40 °C, 70 °C, and 90 °C to measure Stage III corrosion rates of low-activity waste glasses and examine resulting alteration products. Results showed that zeolite P2 consistently triggered a Stage III response, the magnitude and persistence of which were correlated to glass composition, solution pH, and temperature. The response to zeolitic seeds varied from transitory acceleration (short events) to sustained linear acceleration to progressively faster acceleration. In many cases, additional zeolite types formed in addition to the original zeolite seeds, which was generally accompanied by a second faster acceleration than the initial response to seeds. Apparent activation energy measurements between 22 °C to 90 °C showed that lower temperature resulted in smaller differences between Stage II and Stage III corrosion rates, along with decreased persistence of Stage III behavior.

8:45 AM EN08.08.02
Predicting the Long-Term Durability of Nuclear Waste Immobilization Glasses Using Machine Learning Yu Song and Mathieu Bauchy; University of California, Los Angeles, United States

The long-term durability of a glass is a key performance metric for nuclear waste immobilization application. Although some models have been proposed to predict the short-term forward dissolution kinetics of glasses, long-term dissolution is a more complex behavior that is influenced by the glass structure, the feedback from the solution, and the precipitation of secondary phases. This complexity has limited our ability to robustly predict the long-term dissolution rate of nuclear waste immobilization glasses. Here, based on the analysis of a large dataset of vapor hydration tests (VHT), we develop using machine learning a Gaussian Process Regression (GPR) model to predict the long-term durability of glasses. Importantly, GPR models are non-parametric and intrinsically capture the uncertainty of the prediction. We demonstrate that our GPR model features an excellent accuracy. This model allows us to decipher the propensity for each oxide to accelerate or slow down the dissolution kinetics of glasses.

9:00 AM EN08.08.03
The Synthesis and Durability of Cs-Bearing Analogue Glasses Relevant to the Meltdown of the Fukushima Dai-ichi Nuclear Power Plant Luke T. Townsend, Joshua Radford, Sam Walling, Sarah Pepper and Claire L. Corkhill; University of Sheffield, United States

In 2011, the Fukushima Dai-ichi nuclear power plant was hit by a 14 m high tsunami which resulted in one of the worst nuclear disasters in history. As a consequence of the meltdown of reactor units 1-3, radiation was spread widely across Japan (up ~280 km) with radioactivity entering the environment in a variety of forms. A key form of radioactivity was the Cs-bearing microparticle, or CsMP, which consists of glassy silica microparticles embedded with a variety of debris and radionuclides, most prominently ^{137}Cs. Due to the small size (~20 µm) of the particles and their distribution throughout the environment in Japan, studying the materials properties of CsMPs is challenging. To this end, analogue glasses have been synthesised with the aim of studying the durability and environmental behaviour of CsMPs, whilst determining the potential for ^{137}Cs leaching. Three analogue glasses have been produced based upon compositions of CsMPs scavenged from the environment, with one candidate glass chosen for dissolution testing by the ASTM PCT-B protocol. Over 112 days, the Cs-bearing analogue glass showed dissolution behaviour similar to that reported for soda lime silica glass and was comparable with the limited studies performed on environmentally-sourced single $^{137}CsMPs$. The results of this study validate the use of analogue glasses in the study of the materials properties of Cs-bearing silica glasses, laying the foundation for further investigation into the durability of CsMPs and informing any environmental remediation or mitigation that may be required.

9:15 AM EN08.08.04
Quantification of the Kinetics and Mechanisms of Dissolution of Full-Scale Simulant UK HLW Glasses Incorporating Post Operational Clean Out (POCO) Waste Jenny Ayling[1], Adam Fisher[1], Mike Harrison[2], Clare L. Thorpe[1] and Claire L. Corkhill[1]; [1]The University of Sheffield, United Kingdom;

[2]National Nuclear Laboratory, United Kingdom

As the UK's spent nuclear fuel reprocessing capability draws to a close, a period of Post Operational Clean Out (POCO) of the highly active liquor storage tanks (HASTs) will begin, with the resulting waste vitrified to form a stable disposal product. Since the waste removed from the HASTs is expected to be compositionally different from the HA liquor generated in the last several decades of reprocessing, most notably enriched in molybdenum, an alternative glass composition, containing Ca to promote formation of insoluble $CaMoO_4$ (powellite) and Zn to improve viscosity, has been developed.

This work focuses on quantifying the dissolution behaviour of full-scale simulant UK HLW CaZn glass, produced at the Waste Vitrification plant, as a function of waste type and waste loading. Glasses containing different waste loadings of Magnox and Thorp calcine blend are compared with glasses containing a blend of simulant calcine derived from high active liquor, HAST and HAST heel waste. Two additional glasses, the International Simple Glass (ISG) and SON68, were also included for comparison.

Dissolution tests were performed for 730 days at 40°C in highly alkaline solution (saturated $Ca(OH)_2$) on glass monoliths using the ASTM MCC-1 methodology and the release of elements was followed using aqueous analytical techniques. Surface analysis was used to determine the thickness of gel layer formation and to identify secondary phases.

The CaZn glasses displayed similar chemical durability despite differences in composition, microstructure and waste-type, and the dissolution rates consistently lay below SON68, and above the International Simple Glass. The CaZn-Magnox glasses, which were contained a greater proportion of Mg, displayed a higher dissolution rate compared to the CaZn-POCO glasses. These CaZn-POCO glasses showed the lowest rates of Mo dissolution despite having the highest proportion of Mo. This is credited to the durability of the $CaMoO_4$ crystalline phase even under hyper-alkaline conditions.

9:30 AM EN08.08.06
The Stabilization of Particulate Solid Wastes in Ambient Temperature Waste Forms Alessandra Lie Fujii Yamagata, Matthew Asmussen, Sarah Saslow and Gary Smith; Pacific Northwest National Laboratory, United States

During the processing of nuclear wastes, different particulate solid secondary wastes (SSW) can contain radionuclides and other contaminants. In many cases, these spent particulate materials will require stabilization/blending for disposal. Ambient temperature waste forms, such as cementitious waste forms, are common candidates for the stabilization of SSW due to their low cost, receptiveness to a variety of material types, tailorable properties and ability to meet various waste acceptance criteria. A variety of solid secondary wastes (SSW) have been investigated for stabilization in ambient temperature waste forms, including silver mordenite (AgZ), granular activated carbon (GAC), high efficiency particulate air (HEPA) filters, and organic-based ion exchange resins. This presentation will cover the development and characterization of candidate ambient temperature waste form formulations for the stabilization of these SSW with a focus on overlapping behaviors and unique challenges to specific SSW types.

9:45 AM EN08.08.07
Studies on Properties and Aging Behaviour of Corium Generated Under Severe Accident Conditions Daniel Serrano Purroy, Vincenzo Rondinella and Jakub Kokinda; European Commission, Joint Research Centre Karlsruhe, Germany

During a severe accident, large amounts of volatile fission products, such as caesium and iodine, are released during the core degradation. A significant fraction of the non-volatile ones, including actinides, lanthanides and some of the so-called semi-volatile ones (e.g. barium, strontium), remains trapped in the corium debris. The trapping of low- to non-volatile fission products in corium phases limits the short-term airborne source term during and after the accident. The long term decommissioning and remediation perspectives of the Fukushima Daiichi more than a decade after the accident highlight the importance of adequately assessing the ageing and corrosion behaviour of corium debris and their impact on the "delayed" aqueous source term. In this context, water/corium interaction has to be assessed to be able to estimate the amount and chemical form of fission product that can be released.

In this work, results of ongoing leaching tests on real corium samples from the FPT2 test of the Phébus FP Program are reported. The objective of the FPT2 test was to study the degradation of an irradiated UO_2 fuel bundle and the fission product behaviour under conditions of low steam flow that created reducing conditions. One of the main objectives of the present experiments was to compare to previous tests on TMI-2 corium samples. Indeed considering the "reducing" conditions imposed during the Phébus FPT2 test, a different behaviour of the corium compared to that of TMI-2 could be expected since much more oxidising conditions prevailed during the TMI-2 accident.

Sequential batch leaching experiments at room temperature under ambient atmosphere in static conditions were performed. The composition of the leaching solution was based on the boric acid containing water from the storage tanks (2-2.5g/L). The used vessels were rinsed with 1 M HNO_3 at room temperature. Subsequently, the leachates and the rinse solutions were analysed using ICP-MS to quantify the release kinetics of the fission products and the actinides. Results are discussed in terms of Fraction of Inventory in the Aqueous Phase (FIAP) and dissolution rates, and compared to similar experiments carried out on TMI-2 corium and on LWR UO_2 and MOX spent nuclear fuels. In addition, preliminary surface area characterisation by Raman spectroscopy was carried out.

The present experimental results are part of a programme dedicated to the analysis and the management of LWR after severe accidents. In particular, they will be used to support decommissioning and remediation strategies for the Fukushima Daiichi nuclear power plants.

Chemistry of Fission Products in Molten Salt Reactors and Uptake into Waste Forms Joanna McFarlane[1] and Brian Riley[2]; [1]Oak Ridge National Laboratory, United States; [2]Pacific Northwest National Laboratory, United States

Waste from molten salt reactors is more varied and will need to be handled differently than waste from water-cooled reactors. As the fuel is transported by a carrier salt through the primary heat transfer system, radionuclides generated by fission and transmutation have exposure to several different materials and
environments. In addition, the headspace of the fluidic loop, or cover gas system, will also be loaded with radionuclides depending on partitioning between the liquid and vapor phase. The cover gas system is designed to delay radionuclide transport for several months to allow most of the fission products to decay
to stable forms. In some designs, the headspace is sealed. In others, the filtered gas is recirculated through the cover gas system.

Hence, certain questions need to be addressed when considering how to manage waste from molten salt reactors. The most important relates to mass accountancy for the fission products and actinides and their collection during fuel preparation, reactor operation, maintenance, online processing if used, and post-processing. Each step in the lifecycle of the reactor will generate different waste materials with varying levels of hazard. Waste materials will include the fuel salt itself, structural metals, graphite in some cases, and off-gas filters. In most cases, these materials will need to be processed to form chemically and radiolytically more stable waste forms, to reduce volume, to dissipate decay heat and reduce radiolysis while in storage or in a permanent repository.

Aspects of molten salt waste handling have been reviewed as have chemical hazards associated with pre- and post-processing of reactor materials. There has also been an effort to identify routes to convert chloride and fluoride salts to stable waste forms. This talk will review some of these efforts and identify needs for bridging the gap that exists between designing an operating MSR and developing pathways for safe and secure waste handling.

11:00 AM *EN08.09.02
Analysis of Aerosols and Gases Relevant to Molten Salt Reactor Off-Gas Monitoring Using Laser-Induced Breakdown Spectroscopy Hunter Andrews, Kristian Myhre and Joanna McFarlane; Oak Ridge National Laboratory, United States

Molten Salt Reactors (MSRs) are one category of advanced nuclear reactors receiving increased attention in recent years, as evidenced by significant investments from both government and private industry into MSR technology development. The attractiveness of MSR technology predominately stems from inherent safety features including low pressure operation, passive decay heat cooling, and large negative temperature coefficient of reactivity. A key component of any nuclear reactor is the off-gas system. MSR designs present a unique set of off-gas related challenges due to the fuel being in liquid form. In general, MSR designs will involve an inert cover-gas, such as argon or helium, that is over the liquid fuel. Both stationary and flowing conditions are possible. Volatile species, such as noble gas fission products, and salt aerosols may be partitioned into the cover-gas under both normal and off-normal operating conditions. An off-gas treatment system is therefore required to ensure that radioactive species are not released under any condition. It is expected that although several off-gas treatment systems for MSRs may look similar to those currently in operating reactor designs, there will be differences. A key aspect of developing and deploying these off-gas treatment technologies is instrumentation for monitoring the concentrations of species in the off-gas before and after treatment. Laser-induced breakdown spectroscopy (LIBS) is one of several promising analytical techniques for MSR off-gas monitoring. This contribution will give an overview of MSR off-gas monitoring requirements as well as recent progress on the use of LIBS off-gas monitoring system for MSRs. This will include results from real-time monitoring of various surrogate aerosol streams relevant to MSRs.

SESSION EN08.10: Spent Nuclear Fuel
Session Chairs: Laurent Claparede and Lena Evins
Wednesday Afternoon, November 30, 2022
Hynes, Level 3, Room 300

1:30 PM *EN08.10.01
Spent Fuel Dissolution in Repository Environments Lena Z. Evins; SKB, Sweden

When considering spent nuclear fuel (SNF) for direct disposal, it is necessary to estimate the rate of radionuclide release from this waste form in the repository environment. Since the majority of the radionuclides are contained within the UO2-matrix of the spent nuclear fuel pellets, the matrix dissolution rate strongly impacts the rate of radionuclide release from the SNF and therefore also the safety assessment. Radionuclides are also located in and on the SNF cladding and other metallic parts of the fuel, and in the gap between the SNF pellets and the cladding. These radionuclides are released more rapidly than those found in the SNF matrix. It is important to quantify these fractions, especially the so-called Instant Release Fraction (IRF), to estimate the effect of this on the safety assessment. Therefore, efforts are made to fully understand the matrix dissolution as well as the fast release of radionuclides observed in SNF leaching experiments [1,2,3]. As soon as it was clear that direct disposal of SNF was likely to be the preferred strategy in some countries, experiments were started to gather radionuclide release data [4]. These first experiments were mainly performed in aerated conditions. Later, there was a focus on reducing conditions, as these are more relevant to the expected repository environment. Many studies in published in the last decade have shown that hydrogen in the gas phase can strongly reduce the oxidative dissolution rate [1, 5]. However, some questions still remain regarding the mechanisms and conditions for which the hydrogen is most efficient in this respect. The effects of iron in the system is another important issue [6]. In this contribution, experiments performed under hydrogen and/or corroding iron are reviewed and discussed. Recent advances concerning oxidative and non-oxidative dissolution, gap and grain boundary inventories, as well as fuel microstructure are also presented. As an outlook, some aspects concerning the ongoing and future fuel development, such as fuel with various additives, are also discussed.

Accelerated Dissolution of Doped UO_2-Based Model Systems as Analogues for Modern Spent Nuclear Fuel Under Repository Conditions Philip Kegler, Martina Klinkenberg, Andrey Bukaemskiy, Robert H. Thümmler, Guido Deissmann, Felix Brandt and Dirk Bosbach; Forschungszentrum Juelich, Germany

Decades of research have demonstrated that spent nuclear fuel is a good waste form supporting its direct disposal in a deep geological repository. Due to the use of doped nuclear fuels (doped with Gd, Al, Cr, etc.) in recent years, a verification of the favourable behaviour of these modern fuels was needed. Here we have studied tailor-made UO_2 model materials that can provide additional insights into the influence of doping on the dissolution behaviour of spent nuclear fuels. Thus, within this work single-effect dissolution studies were carried out using systematically produced and carefully characterised UO_2-based model materials, to provide additional insights into the dissolution behaviour of spent modern LWR-fuels under the post-closure conditions expected in a DGR.
The first step in this study was the development of an optimised synthesis route for the production of UO_2 reference materials, Cr-doped UO_2 as well as Nd- and Gd-doped UO_2 based materials. A special focus was set on a high density of the sintered pellets, control of grain growth and homogeneous distribution of the dopants in the UO_2 matrix.
Here, we present recent results on the dissolution behaviour of these tailor made UO_2 model materials in accelerated static batch experiments using H_2O_2 as simulant for radiolytic oxidants, present in long-term disposal scenarios for SNF in failed container conditions due to the alpha-irradiation of water. In these dissolution experiments, pure UO_2 reference pellets exhibiting different densities and grain sizes, as well as Cr-, Nd-, and Gd-doped UO_2 pellets with varying doping levels, produced using different doping methods and having different grain sizes, were used. In addition, industrially produced Cr- and Cr/Nd-doped UO_2 pellets were used. The dissolution experiments were performed under strictly controlled conditions with respect to exclusion of oxygen, temperature control, and exclusion of light.
This bottom-up approach was followed to understand how the addition of the different dopants into the fuel matrix affects SNF dissolution behaviour. The results of the dissolution experiments indicate that the addition of Cr and the consequential modification of the fuel matrix does not lead to a significant change of the dissolution behaviour of these model materials compared to pure UO_2 reference materials (i.e., dissolution rates agree within an order of magnitude). This is in strong contrast to the dissolution rates of Ln^{3+}-doped pellets, which are significantly lower than those of pure and Cr-doped pellets.

2:15 PM EN08.10.03
Hydrogen Inhibition Effect on Spent Nuclear Fuel Matrix Dissolution Under Anoxic/Reducing Atmosphere and Alkaline pH Luis Iglesias Pérez[1], Roberto Gaggiano[2], Xavier Gaona[1], Michel Herm[1], Tobias Koenig[1], Katrien Meert[2], Tomas Vandoorne[2] and Volker Metz[1]; [1]Karlsruhe Institute of Technology-Institute for Nuclear Waste Disposal, Germany; [2]National Agency for Radioactive Waste and Enriched Fissile Materials (ONDRAF/NIRAS), Belgium

In many countries (United States, Germany, China, etc.), final disposal of spent nuclear fuel (SNF) in deep geological repositories is the preferential option to permanently and safely isolate the radionuclide inventory from the biosphere. In post-closure safety assessments of such facilities, access of water to the emplaced SNF and the consecutive release of radionuclides from the waste is considered. The UO_2 matrix of the SNF retains many radionuclides, which can be released upon its dissolution. Therefore, an improved understanding on the interaction of SNF with pore water solutions under repository conditions is required in safety analyses of deep geological repositories.
In this study, the release of radionuclides from spent UO_2 fuel under relevant geochemical conditions, representative of the Belgian “Supercontainer concept” were investigated. Three leaching experiments with SNF cladded pellets were performed in highly alkaline (cementitious) solution and anoxic/reducing atmosphere using autoclaves to analyse the impact of the presence of hydrogen and how influences the hydrogen partial pressure on the release of relevant fission products and actinides.
The SNF specimens, comprising one full and two half pellets in each experiment, were sampled from a fuel rod with an average burn-up of 50.4 MWd/kg_{HM}. The fuel rod was irradiated in the Gösgen pressurised water reactor in Switzerland. Each experiment was divided in two stages, replacing the previous titanium liners and using fresh solution when starting the new stage. The experiments were conducted under different gas atmospheres and total pressures. All other experimental conditions were the same.
- 40 bar of an Ar/H_2 gas mixture with a H_2 partial pressure of 3.2 bar in experiment 40/3.2H.
- 3.75 bar of an Ar/H_2 gas mixture with a H_2 partial pressure of 0.3 bar in experiment 3.75/0.3H.
- 1.0 bar Ar atmosphere (in absence of H_2) during the first stage of experiment 1-40/0; in this experiment the Ar pressure was raised to 8 bars after 497 days until termination of the first stage, 288 days later. Then, the experiment was conducted for another 603 days during the second stage at 40 bar Ar atmosphere.
The findings demonstrate a hydrogen inhibition effect on the dissolution of the fuel matrix (as displayed by an inhibited release of U-238) and on the release of mainly matrix bound radionuclides e.g., Sr-90. Measured uranium and strontium concentrations are lower in the two experiments with hydrogen overpressure compared to respective results of the experiment under solely anoxic conditions. A comparison of the measured U-238 concentrations in the current experiments with calculated solubility limits of respective U(IV) and U(VI) solids indicate that U-238 concentrations approach towards the solubility limit of UO_2(am, hyd) in presence of hydrogen. The observed concentration levels and kinetic data show that the presence of hydrogen inhibits the dissolution kinetics of SNF and favours the formation of a U(IV) solid phase. At the end of the experiments, the Cumulative Fraction of Inventory in Aqueous Phase (CumFIAP) values of Sr-90 are similar to the CumFIAP of U-238. It is concluded that the strontium release behaviour is coupled to the dissolution of the UO_2 matrix.
In the three experiments the CumFIAP values of Cs-137 are several orders of magnitude higher than the respective values of U-238. During the experiments, there was no pronounced effect of the redox conditions on the Cs-137 concentrations or release rates observed.
The fission gases Kr and Xe are continuously released throughout the experiments, too. An effect of the redox conditions on the fission gas release was not detected.

2:30 PM BREAK

3:30 PM EN08.10.04
***In Situ* Raman Oxidation of Undoped and Zr-Doped UO_2** Sam Karcher and John S. McCloy; Washington State University, United States

Uranium dioxide is used as an analogue for used nuclear fuel (UNF) doped with small amounts of lanthanide and rare-earth elements to simulate fission

products. Structural and thermodynamic data from these materials can be used to help predict the long-term behavior of UNF stored in geological repositories where elevated temperatures, oxidizing environments and eventual groundwater contact may accelerate UNF degradation.
Raman spectroscopy is a particularly useful tool for studying the structures of uranium oxides and defects induced by processes like doping, irradiation, and oxidation.
In this work, the Raman spectra of undoped UO_2 and Zr-doped UO_2 are presented from in-situ heating experiments performed in air at 250°C. After 1 hour, the undoped sample begins to show spectral features indicative of U_4O_9, whereas immediately after heating the Zr:UO_2 sample shows features of U_4O_9 and U_3O_8. U_3O_8 features were not observed in the undoped sample even after >10 hours of heating. Accelerated oxidation of Zr:UO_2 compared to undoped UO_2 is consistent with previous work. Optical images of the Zr:UO_2 captured during ramping from 250°C to 400°C show accelerated oxidation along grain boundaries leading to cracking along grain boundaries and eventually intergranular cracking. Raman mapping and principal component analysis together indicate U_3O_8 forms along grain boundaries while grain interiors remain primarily U_4O_9. Additionally, using 455 nm Raman excitation proved most useful for in-situ experiments; 532 nm gave poor spectra from U_4O_9 and 785 nm gave poor spectra from U_3O_8.

3:45 PM EN08.10.05
Impact of Lanthanide and PGM Elements on the Chemical Durability and Surface Modifications During Leaching Tests of UO_2 Pellets Mimicking Interim Repository Laurent Claparede, Paul-Henri Imbert, Nicolas Clavier, Stephanie Szenknect and Nicolas Dacheux; ICSM, University Montpellier, CNRS, CEA, France

Managed by ANDRA, the European collaborative research program EURAD aims to federate research efforts and to share scientific and technical knowledge of some 100 European players in the field on the long-term management of radioactive waste. In this context, ICSM/LIME is interested in the chemical durability of spent nuclear fuels under interim storage conditions (i.e. in conditions mimicking their stay in cooling pool).
Due to the complex structure and microstructure of spent nuclear fuels (SNF), the global understanding of their behavior when leaching is very difficult to analyze, although it appears as a very important task. In this study, the role of two families of fission products (FP, i.e. lanthanide and PGM elements) was thus specifically examined. Indeed, in SNF, lanthanide elements are incorporated in the UO_2 structure, inducing redox constraints or formation of oxygen vacancies while PGM elements (Ru, Rh, Pd) are forming metallic inclusions in contact with UO_2 grains.
In order to discriminate the structural, microstructural and chemical impacts of these elements on the chemical durability, a series of simplified model samples has been prepared by direct precipitation of hydroxide-based precursors. A calcination step (800°C, reducing atmosphere) led to fluorine type oxides. After shaping by uniaxial pressing, a sintering step (1600°C, 8 hours, reducing atmosphere) led to dense pellets (up to 90 % and 96 % for PGM and lanthanide doped samples, respectively, considering geometrical measurements and He pycnometry). In addition, the pellets were characterized in terms of microstructure and cationic homogeneity by SEM and X-EDS.
At the macroscopic scale, leaching tests were performed on all the model compounds in conditions mimicking an interim storage, i.e. at pH = 5 and 7, at 50 and 70°C and in the presence (or not) of boron ($5.0.10^{-2}$ M). Simultaneously, the monitoring of the solid/liquid interface was performed by ESEM. The normalized dissolution rate of UO_2 during leaching test in $5.0.10^{-2}$ M boric acid, at pH = 7 and 50°C reached about $(5.5 \pm 0.1) \times 10^{-4}$ $g.m^2.d^{-1}$ (i.e. 0.04% of dissolved material after 300 days of alteration). The presence of PGM elements induced the significant increase of the alteration rate $(2.0 \pm 0.1) \times 10^{-4}$ $g.m^2.d^{-1}$ (i.e. 0.2% of dissolved material after 300 days of alteration). Moreover, this dissolution rate reaches 3.3% in the medium at pH = 5. On the other hand, lanthanide elements induced a particular behavior. Indeed, after 80 days of leaching, the uranium concentration was found to be constant in the leachate, suggesting the precipitation of a secondary U-based phase onto the surface of the pellets. This phase is now under characterization.

4:00 PM EN08.10.06
Detailed Investigation of the Microstructure of UO_2 Based Model Systems for Spent Nuclear Fuel Robert H. Thümmler[1], Juri Barthel[1], Martina Klinkenberg[1], Matthew Wolf[2], Philip Kegler[1], Roger De Souza[2], Joachim Mayer[1], Dirk Bosbach[1] and Felix Brandt[1]; [1]Forschungszentrum Jülich GmbH, Germany; [2]RWTH Aachen University, Germany

In safety assessments for the deep geological disposal of high-level nuclear waste, the possibility and results of direct contact between spent nuclear fuel (SNF) and water are considered. In contact with SNF, oxidative species are continuously produced due to the radiation induced hydrolysis of water, which then corrode the SNF, releasing radionuclides [1]. Radiation induced hydrolysis and oxidative dissolution are relevant for early conditions of deep geological waste disposal - depending on the burn up, for the first 6000 to 8000 years. Oxidative corrosion is typical for metals and unusual for oxide ceramics like UO_2. For many ceramics, grain boundary (GB) dissolution is the dominant dissolution mechanism. However, a detailed mechanistic understanding of the role of microstructure in SNF corrosion is still largely absent. The details of the grain boundary structure have to this day been the subject of just a handful of studies [2]. In a previous work, the microstructure of high burnup SNF was studied, documenting the change in microstructure across the fuel pellet with distinct microstructural regions [3]. To gain a deeper understanding of the effects of individual components on the dissolution kinetics of the complex SNF, a study on UO_2 model systems is used, with a focus on the microstructure and grain boundaries.
In this project, polycrystalline UO_2 samples are synthesised using a co-precipitation method. Besides pure UO_2, also samples doped with rare earth elements up to a few mass percent are prepared mimicking fission products in SNF [4]. The success of the synthesis is verified by sample density, XRD and SEM. Further extensive microstructure characterization is performed on polished surfaces using EDX, SEM and EBSD. Statistic on grain size, pore size, grain orientation are presented. In the course of the project corrosion experiments will be performed on these samples.
For the purpose of a more detailed analysis of GB structure and their reactivity under oxidizing conditions, the focus is placed on coincidence site lattice (CSL) GBs. CSL boundaries have a comparatively simple structure, which is feasible for modeling. However, this choice requires in experiment to first identify specific GBs and second to extract thin samples suitable for the subsequent transmission electron microscopy (TEM) investigation. The first problem is solved by an efficient EBSD scanning approach, where measurements are only taken near grain boundaries. A pole-figure analysis is performed to determine the crystallographic orientation of the grains and the boundary in order to solve the second problem by extracting a cross-section thin foil using focused ion beam milling. Target of the TEM measurements is to determine the atomic structure including oxygen lattice positions, which play a role in the reactivity of the grain boundaries. The results of these experiments are used as input and crosscheck in molecular dynamic simulations. The simulations are performed to understand the driving forces responsible for the stability of specific GBs and the influence of dopants.

Drying of Spent Advanced Gas Reactor Fuel for Storage and Disposal Thomas O. Bainbridge[1], Nicole Hondow[1], Carlos de la Fontaine[2] and Bruce

Hanson[1]; [1]University of Leeds, United Kingdom; [2]TUV Sud, United Kingdom

In 2012 the Nuclear Decommissioning Authority took the decision to cease reprocessing spent Advanced Gas-cooled Reactor fuel, with any fuel arisings beyond the contracted amount to be stored pending a decision on whether to classify the fuel as waste for disposal. If the fuel is deemed waste then it will be sent to the high heat generating part of the UK's Geological Disposal Facility (GDF), expected to be in 2075. The current strategy till then is to use extended wet storage while work is being conducted to support dry storage as an alternative and as a pre-treatment for final disposal. The aim of the drying process is to prevent radiolysis of any water left in or on the fuel pin which could lead to both hydrogen and hydrogen peroxide in either the dry store or the GDF. With hydrogen and hydrogen being of particular concern due to hydrogen being explosive and hydrogen peroxide being corrosive. Regarding wet storage the primary concern is that water may seep through the cladding of any failed fuel with stress corrosion cracking the likely cause of this failure. This mechanism causes highly tortuous and branched cracks making characterisation difficult. This work aims to produce a process model to be used to inform the conditions for a future drying procedure. To achieve this two work streams have been set up. The first beign the computational side where the flow through the cracks in the cladding is being modelled and the second, the experimental side, aiming to produce representative crack to aid in validating the process model. Current progress and results will be presented here.

Microstructural Characterization of the Critical Regions of Copper Coatings for Canada's Used Nuclear Fuel Containers Liyang Zheng[1], Jason Tam[1], Alex Zhang[1], Jason Giallonardo[2], Jane Howe[1], Roger Newman[1] and Uwe Erb[1]; [1]University of Toronto, Canada; [2]Nuclear Waste Management Organization, Canada

For many decades, nuclear energy has been utilized worldwide as an efficient, stable, and sustainable source of electricity with low carbon footprint; however, with increasing amounts of used nuclear fuel, their proper management and disposal has become a challenging issue. In Canada, the Nuclear Waste Management Organization (NWMO) is responsible for the long-term management of Canada's used nuclear fuel. NWMO is developing a deep geological repository (DGR) that consists of multiple engineered barriers to safely isolate the nuclear waste from the environment. In this design, used Canada Deuterium Uranium (CANDU) fuel bundles will be stored in used fuel containers (UFC), which will then be placed underground at a reference depth of approximately 500 m in a suitable rock formation and sealed with bentonite clay.
The UFC is a core component of the multiple-barrier system. In the current design, the inner vessel of the UFC is fabricated from low carbon steel, which comprises a cylindrical shell welded to two hemispherical heads. A minimum 3-mm thick copper layer is applied to the exterior surface of the steel vessel as a corrosion barrier. Two coating techniques are jointly used to coat the entire UFC: the copper coatings on the cylindrical shell and hemispherical heads are applied via electrodeposition (ED), while after loading the fuel bundles into the container, the head is welded to the shell, and the closure-weld zone is copper-coated by the cold spray (CS) process followed by local annealing to impart ductility.
The expected long service life of the UFCs (~one million years) placed high demands on the structural integrity and corrosion resistance of the copper coating. As two deposition techniques are used, it is essential to develop a deeper understanding of how the processing history affects the microstructure, and in turn, the macroscopic properties of the copper coatings. Specifically, the interfaces where ED-Cu and CS-Cu converge might perform differently from the rest of the coatings due to the inherent structural heterogeneity in these regions. In the current study, detailed characterizations including scanning electron microscopy (SEM), electron backscattered diffraction (EBSD) and transmission electron microscopy (TEM) were conducted on the interfacial regions to reveal the microstructural characteristics of different copper coatings (ED, CS, different annealing temperatures), complemented with hardness measurements.

Shelf-Life of Uranium Oxide Microparticle Reference Materials and Possible Implications for the Identification of Optimal Storage Conditions Simon Hammerich[1], Shannon K. Potts[2], Philip Kegler[2], Stefan Neumeier[2], Axel K. Schmitt[1] and Mario Trieloff[1]; [1]Heidelberg University, Germany; [2]Forschungszentrum Jülich GmbH, Germany

Among other tasks, the International Atomic Energy Agency (IAEA) is responsible to verify the peaceful use of nuclear material and technologies concerning the Non-Proliferation Treaty (NPT). Therefore, the IAEA Safeguards were introduced as technical measures to assure the compliance with the NPT by its member states. To secure this, IAEA officials conduct inspections of nuclear facilities all around the world and – among other measures – take swipe samples of surfaces in said facilities. Cotton swipes with collected particles are then sent to the IAEA Safeguards Analytical Service Environmental Sample Laboratory (IAEA SGAS-ESL) and its dedicated Network of Analytical Laboratories (NWAL) to analyze particle elemental and isotopic composition. The quality of these measurements is dependent on the abundance of suitable reference materials. To qualify as potential reference materials, uranium microparticles must be of a size and shape as well as an isotopic and elemental composition similar to the environmental samples. In the Forschungszentrum Jülich (FZJ), uranium microparticles are produced using a Vibrating Orifice Aerosol Generator (VOAG).

A core requirement for distribution of a potential reference material is to guarantee a practical shelf-life. Previous studies of structure and shape of uranium oxide microparticles demonstrated alteration process leading to the formation of uranium hydroxide like schoepite. To further investigate this alteration process, a systematic shelf-life study of VOAG-produced uranium microparticles has been launched in late 2021. In a first part of this study, the influence of different atmospheric conditions was evaluated. Uranium microparticles from the same production batch were deposited on Glass-like Carbon Disks (GCDs) and stored under different atmospheric conditions. The second part of the shelf-life study is related to the long-term stability in different solvent media. The uranium particles used in both approaches were periodically measured using Scanning Electron Microscopy (SEM) and μ-Raman Spectroscopy for structural as well as Large Geometry-Secondary Ion Mass Spectrometry (LG-SIMS) for isotopic investigation. The combination of these aforementioned methods allows to check the long-term stability of uranium microparticles in suspension and under different atmospheric conditions and therefore identify optimal storage conditions for potential reference materials. In this presentation recent results of atmospheric and suspension shelf-life studies will be discussed.

Study on Borehole Sealing Corresponding to Hydrogeological Structures by Groundwater Flow Analysis Takuma Sawaguchi, Shizuka Takai, Tsuyoshi Sasagawa, Emiko Uchikoshi, Yusuke Shima and Seiji Takeda; Japan Atomic Energy Agency, Japan

The leakage of radioactive material shall be monitored for the intermediate depth disposal (e.g., 70−100 m from the surface) of relatively high-level, Category 2, radioactive waste in Japan. At the end of the monitoring period, several hundred years later, the monitoring borehole is backfilled and sealed to prevent potential migration pathways for radioactive materials. However, the diameter of borehole is small (e.g., 20 cm) and the depth is several hundred meters, and thus there is a possibility of insufficient backfilling in the borehole. Therefore, a method to confirm whether the borehole is properly sealed should be developed in advance. In this method, it is important to understand the effect of backfill design condition (material selection, layout, permeability, etc.) corresponding to the surrounding hydrogeological structure on the borehole sealing. In this study, groundwater flow analyses were performed for the hydrogeological structures with backfilled boreholes, assuming sedimentary rock area in Japan, to understand what backfill design conditions could prevent significant or early water pathways in the borehole, and to identify the confirmation points of borehole sealing. The analysis area was around and upstream of the borehole; therefore, groundwater flow to the surface was not evaluated. In these analyses, some kinds of backfill design condition proposals, combining bentonite, sand and cementitious materials based on previous studies [e.g., 1-3], were set for each hydrogeologic structure characterized in predominant water-bearing fractures, in aquifers isolated by clay layer and in faults. Whether or not significant water pathways would be formed in the backfilled borehole was considered using flow rate in the borehole and flow path-lines obtained from the analysis. In these analyses, the effect of grouting BDZ (Borehole Disturbed Zone) on borehole sealing were also considered. It was assumed that the grouting BDZ would restore the permeability around borehole increased by boring to that of host rock.
These results indicated the backfill design conditions to prevent water pathways in the borehole and BDZ, such as designing the permeability of bentonite material less than or equal to that of the host rock, and grouting BDZ. In the case considering clay layers and faults, it was also found that if the borehole in the intact rock immediately above these characteristic structures was not backfilled with bentonite material, significant water pathways would be formed.
Acknowledgments: This research was funded by the Secretariat of Nuclear Regulation Authority, Nuclear Regulation Authority, Japan.

Corrosion of Nuclear Waste Glass in Complex Natural Environments—A Natural Analogue Approach Clare L. Thorpe[1], Garry Manifold[1], Rachel Crawford[1], Christopher Boothman[2], Katherine Morris[2], Jonathan Lloyd[2], Russell Hand[1] and Claire L. Corkhill[1]; [1]University of Sheffield, United Kingdom; [2]The University of Manchester, United Kingdom

Borosilicate glass is commonly used to immobilise high activity waste liquors and is increasingly considered for low and intermediate activity waste streams[1]. Radioactive elements, chemically incorporated in the glass structure, will be released at the same rate as the glass itself dissolves. Understanding the long-term behaviour of glass is therefore important in constructing the safety case for its storage and eventual subsurface disposal. The majority of studies aimed at understanding glass dissolution rates and mechanisms have been conducted at elevated temperatures and under, static, sterile conditions, taking no account of changing geochemistry, adjacent mineralogy or geomicrobiology[2]. Here, a combination of field and laboratory tests are used to explore the behaviour of glasses in complex natural environments.

Alteration observed on glasses from long-term studies, in neutral - high pH, iron rich environments relevant to the subsurface disposal of radioactive waste, is compared to alteration observed in short-term laboratory based tests. In addition to observing the mineralogy of the glass alteration layers, field experiments also aim to identify and characterise the unique microbial communities that colonise the interface between nuclear waste type glasses and their environment. Under laboratory conditions, inactive surrogate nuclear waste glasses, containing the essential nutrients, had a controlling effect on the microbial community that were able to utilized nutrients dissolved from the glass where they were absent in solution. The influence of microbial respiration on the dissolution rate of the glass was found to be complex with some conditions inducing a pacifying effect due to biomineral precipitation whilst other conditions appeared to enhance glass corrosion.

The Importance of Secondary Phase Formation in Natural Aqueous Systems M Nieves Rodríguez-Villagra, L.J. Bonales, Abel Milena-Pérez and Hitos Galán; CIEMAT, Spain

Irradiated fuel based on UO_2 is expected to be disposed of in an underground repository according to a “once-through” fuel cycle policy. In addition, those countries that have chosen reprocessing their irradiated fuel will also need this kind of repository, as there is international consensus on this option as the best to properly dispose high-level waste. In any case, after storage times of several thousand years, it is foreseen and accepted that groundwater will penetrate and infiltrate in the emplacement, and will eventually interact with the spent fuel.
As a consequence of water radiolysis, uranium is oxidized from its tetravalent state to the hexavalent uranyl ion, being known to be far more soluble in water than uranium (IV). Then, during the oxidative dissolution and depending of the surface/volume ratio, secondary phases containing uranyl cationic UO_2^{2+} will precipitate at the whole pH range. These secondary phases play an essential role on the radionuclide release in the final disposal environment due to its capacity to seize trace radioelements, and then, to reduce radionuclides mobility. In fact, some important radionuclides can precipitate into its inner solid structure (*e.g.* Schoepite UO_3x2H_2O, Becquerelite $Ca(UO_2)_6O_4(OH)_6x8H_2O$, Soddyite $(UO_2)_2SiO_4x2H_2O$, Uranophane $(H_3O)_2Ca(UO_2)_2(SiO_4)_2x3H_2O$, Studtite UO_4x4H_2O).
The objective of this work is to provide an overview of current knowledge on precipitation and dissolution of potential radionuclide-bearing phases under repository relevant conditions. Different approaches carried out are presented, *i.e.* long-term behavior of natural analogs such as uraninite [1, 2], short-term laboratory coprecipitation experiments [3] and theoretical studies [4,5]. A review of the analysis methods is also presented.

Durability of Iodine Waste Forms Bill Ebert; Argonne National Laboratory, United States

Radioiodine can be captured from off-gas and other waste streams by reaction with metallic silver to generate AgI, which can then be immobilized by microencapsulation in a durable matrix material. Waste forms can be generated by densifying the material used to support the silver or by vitrification in a low-temperature glass. Both the intrinsic durability of AgI and the durability of the encapsulating matrix will contribute to degradation resistance of iodine waste forms in a high-level waste disposal facility and should be taken into account in degradation models. Although AgI is only sparingly soluble under oxidizing conditions, reduction of ionic silver to metallic silver under even moderately reducing conditions will increase the solubility of iodide. The degradation model that is used to represent iodine waste form behavior in simulations used for repository assessments should include a redox-dependence term. Argonne is using a combination of electrochemical and immersion test methods to quantify the dissolution behavior of AgI alone, in galvanic couples, and encapsulated in inert matrix materials. The conceptual basis, testing methods and results, and mechanistically-based model being developed for iodide waste forms will be presented.

9:30 AM EN08.11.05
Application of the ASTM C1308 Semi-Dynamic Dissolution Methodology to Ceramic Materials for Radioactive Waste Immobilisation Amber R. Mason, Lewis Blackburn, Laura J. Gardner, Ismail Aldean, Sarah Pepper and Claire L. Corkhill; University of Sheffield, United Kingdom

Semi-dynamic dissolution experiments were performed using the ASTM C1308 methodology, where the dissolution media is renewed periodically, to understand more about the fundamental chemistry of the corrosion behaviour of ceramic wasteforms [1]. Zirconolite ($CaZrTi_2O_7$) and pyrochlore (Gd_2Ti_2O7) have frequently been proposed as ceramic wasteform compositions, due to their passive safety, and are known to be chemically flexible and radiation tolerant with excellent overall aqueous durability [2]. However, a recent literature review highlighted a gap in the understanding of the dissolution mechanism of these wasteforms, which the semi-dynamic nature of the C1308 test could elucidate. In this study, the dissolution of a zirconolite and a pyrochlore composition was investigated using the ASTM C1308 test, with an extensive test matrix, where the temperature (40, 60, 90 °C) and dissolution media (0.01M HNO_3, FIN groundwater and 0.01M LiCL / 0.011M LiOH) were varied. The results have contributed to the understanding of the application of the ASTM C1308 methodology to ceramic materials dissolution, highlighting the merits of this test procedure compared to other commonly used dissolution protocols. This research also supported the development of a standard operating procedure for a series of round robin experiments with partners worldwide to further verify the efficacy and reproducibility of this methodology (allowing direct comparison between different formulations and wasteforms).

9:45 AM EN08.11.06
Exploring a Surrogate of Pellet-Cladding Interaction—Characterization and Oxidation Behavior M Nieves Rodríguez-Villagra, L.J. Bonales, Sergio Fernández-Carretero, Abel Milena-Pérez, Luis Gutierrez and Hitos Galán; CIEMAT, Spain

The thermal gradient at which the nuclear fuel is subjected during operation is one of the reasons of the deformation caused in the pellet, which could affect to its interaction with the cladding. Thus, a potential pellet-cladding contact could take place because of a decrease in the cladding diameter (creep-down due to pressure from the coolant) and an increase in the pellet diameter (thermal expansion, swelling due to the inclusion of solid fission products in the matrix and inter- and intra-granular accumulation of fission gases in pores). Contact between the pellet and the cladding, through a bonding layer called Fuel Cladding Chemical Interaction (FCCI) layer, first occurs at the inter-pellet spaces while a continuing pellet fragmentation (radial and axial cracks) takes place simultaneously. Previous studies conducted on fuel with burnups higher than 55 $MWdxkgU^{-1}$ showed the formation of a restructured region, named as “rim” structure or High Burn-up Structure (HBS) at the periphery of UO_2 pellets [1]. The risk of enhanced Pellet-Cladding Interaction (PCI) grows with burnup. As the burnup increases, some effects turn out to appear in this new region, such as smaller grains (0.1 μm vs initial grains of ~10 μm diameter), lattice contraction controlled by recrystallization, higher porosity, hardness decrease and the closure of pellet-cladding gap in fuel rods [2]. The FCCI layer consists in principle of two regions, one closer to the cladding (cubic polycrystalline ZrO_2) and a second nearer to the fuel pellet, characterized by an interphase formed by cubic solid solutions of $(U,Zr)O_2$ and an amorphous phase, with variable relative concentrations of U and Zr.
PCI is considered as a mid-priority process in the investigation of the safety approach for LWR reactor fuel due to the possibility of cladding failure during a power transient. In addition, it could be one of the causes identified as leading to potential fuel failure. Understanding the potential chemical oxidation resistance of UO_2 (matrix fuel) to U_3O_8 as a consequence of ZrO_2/Zr system in case of undetected damaged cladding (zirconium alloy), a potential air intrusion is relevant in terms of assessing fuel cladding integrity.
To gain insight into the PCI response to oxidation, in the present work, a collection of Zr-doped UO_2 (0, 20, 40, 80 and 100 %) pellets were prepared via solid-state synthesis by mimicking the chemical bonding between ZrO_2 and UO_2. After sintering, the Zr-doped UO_2 monoliths were characterized by (i) surface morphology and average grain size calculation by SEM; (ii) BET Specific Surface Area (SSA) with N_2; (iii) evaluation of the purity and the crystalline structure by both XRD and Rietveld Quantitative Phase Analysis (RQPA); (iv) Raman spectroscopy; and (v) geometrical and experimental density obtained by Archimedean immersion.
Theinterpretation of these characterizations shows non-uniform distribution of Zr in the UO_2 matrix and ZrO_2 segregation in grain boundaries, presumably because the solubility limit has been reached in the fabrication procedure. Controlled air oxidation of Zr-doped UO_2 samples has been monitored by thermogravimetric analysis (TGA). Based on those results, we observe a profound effect of delayed oxidation with the addition of Zr to UO_2, and then, an increased resistance of UO_2 to oxidation to U_3O_8 when compared to pure UO_2 pellet.

9:50 AM EN08.11.07
Measurements of Thermodynamic Data of Water in Na-Bentonite in the Standard Condition by Relative Humidity Method Haruo Sato; Okayama University, Japan

Buffer material (compacted bentonite) composing engineered barrier in the geological disposal of a high-level radioactive waste develops swelling stress (pressure) by penetration of groundwater from the surrounding rock mass after disclosure. In the past studies, we measured the activity of water and the Gibbs free energy (relative partial molar Gibbs free energy) of water in Na-montmorillonite which is the major component of Na-bentonite by vapor pressure method, and reported a model to analyze the swelling stress of bentonite based on thermodynamic theory. On the other hand, data for the vapor pressure of water in bentonite are limited. In this study, we determined vapor pressure by measuring relative humidity (RH) and temperature for water in Na-bentonite and Na-montmorillonite, and calculated the activity of water and the Gibbs free energy. In addition, we analyzed the swelling stress of bentonite based on the thermodynamic model and discussed by comparing to data reported so far.

Kunigel-V1® and Kunipia-F® (provided from Kunimine Industries Co. Ltd.) were used as a Na-bentonite. The montmorillonite contents of both bentonites are approximately 51 % and 99 %, respectively. Bentonite powder which was dried at 105-110 °C for at least 24 hours in an oven was placed in a polyethylene bottle in an amount of 3.00 g each (repeatability n=3), and slowly adsorbed water vapor in a closed container (vacuum chamber) with 100 % RH for about 9 months. The water content of the bentonite was checked by weighing periodically. Next, RH and temperature sensors and moisturized bentonite powder were placed in the vacuum chamber, and the chamber of which inside pressure was reduced to -95 kPa (6.3 kPa with absolute pressure) or less was submerged in a constant temperature water bath at 25 °C. The RH and temperature in the chamber were measured after 24 hours and the weight of the bentonite was measured. The bentonite sample was returned to the chamber again and the water content of the bentonite was reduced by evacuating for a while, and then the chamber was submerged in a constant temperature water bath again. This operation was carried out every about 24 hours. Thus, RH and temperature were measured as a function of water content (ca. 10-100 %), and the activity of water and the Gibbs free energy as a function of water content were determined.
The activities of water and the Gibbs free energies for both bentonites decreased with decreasing water content in water contents lower than approximately 40 %. This trend is the same as the trend obtained in the past studies. On the other hand, the data (both activities of water and the Gibbs free energies) obtained in this study were slightly higher than conventional data. This indicates that the swelling stress of bentonite slightly decreases than conventional analysis results. This is considered to be due to that conventional data were obtained for purified Na-montmorillonite (no impurities). Although the swelling stresses of bentonite calculated using thermodynamic data obtained in this study were slightly lower than conventional analysis results, those were closer to the measured values than the conventional analysis results.

Molten Salt Fast Reactor with End of Live Waste Disposal or Recycling? Claude A. Degueldre, Joshua Findlay and David Cheneler; Lancaster University, United Kingdom

The Molten Salt Fast Reactor **(**MSFR) liquid fuel is made of uranium chloride dissolved in sodium or rubidium chloride. ^{235}U enrichment goes from 0.3% (depleted) for power plant to 20% enriched for research reactor. At End of Live (EoL) the fuel cycle strategies go from the once through then out i.e. full geological disposal (spent fuel, core vessel and structurals' of primary) to spent fuel and primary loop material reprocessing and recycling. The late case is emphasized when the chloride of the fuel and from the reflector are made of ^{37}Cl enriched chloride and has to be reprocessed and recycled for economical reason in new fuel and reflector.
The first option would require addition of neutron absorber prior to final geological disposal in a water free environment e.g. in salt dome. The option of Molten Salt drainage in specific tank designed for radwaste disposal would be associated with intelligent barrier to minimise first nuclide release such as ^{36}Cl and ^{126}I. Among them Ag or Cu barriers could be envisaged.
The second option deals with the $Na/Rb^{37}Cl$ - $^{dep}U^{37}Cl_4$ spent fuel in which case ^{37}Cl has to be, for economic reason, reprocessed for recycling.
In memory of Lou Vance, Ansto

Harnessing the Power of Natural Products Towards the Synthesis of High Performance Materials Samantha L. Kristufek; Texas Tech University, United States

Society is highly dependent upon plastics to add value to everyday life, however, the end-of-life products are highly problematic, especially when they enter into our waterways, crowd our waste streams, and produce nanoplastics that get into the environment. Sustainable polymers have the potential to overcome many of these challenges. Particularly, polymers derived from sugars or polyphenolic compounds that contain degradable moieties in the backbone are of great promise. Through the synthetic manipulations of these natural products, we aim to produce and characterize high performance materials.

11:00 AM EN09.01.02
Manufacture of PHB-Based Biodegradable Composite Film and Evaluation of Mechanical Properties Kwan-Soo Lee, Jihyeon Kim, Nevin Gupta and Jacqueline A. Linn; Los Alamos National Laboratory, United States

Biodegradable plastics can be decomposed into water, carbon dioxide, and biomass by the action of living organisms, typically micro-organisms. Biodegradable plastics are commonly produced with renewable raw materials, micro-organisms, petrochemicals, or combinations of all three. These plastics have been considered as a promising solution to troubleshoot the plastic pollution problem bedeviling the world. Currently, most of biodegradable plastics such as PLA, PBS, PBAT, and PBSA, are degraded in well-managed industrial composting systems providing the specific environments. If products made from these plastics are discarded into conventional waste streams such as landfills, or find their way into the open environment such as rivers and oceans, the potential environmental benefits of the biodegradable plastics are not exploited and can actually exacerbate plastic pollution problems.
Polyhydroxyalkanoates (PHAs) are a class of biodegradable polymers that produced from various micro-organisms. Specific types of PHAs include poly-3-hydroxybutyrate (PHB)s. PHBs have been shown to be biodegradable in less than about one year in various natural and biologically active environments even without the industrial composting systems. Furthermore, PHB's properties are similar to those of conventional petroleum-based polymers (e.g. melting temperature, young's modulus) such as polypropylene (PP), polyethylene (PE), and polyethylene terephthalate (PET). On the other hand, the use of pure PHB has been restricted due mainly to its inherent brittleness, which renders it too frangible for most practical applications. In this study, we have developed a new component of PHB-based polymer composite films using various green additives to overcome the mechanical instability of PHB and optimize the film condition. As a result, the bioplastics films prepared show huge potential, offering 30 times increase of the elongation property with decreasing the melting temperature and the degree of crystallinity. In this presentation, some prototypes of PHB-based packaging (e.g. disposable label, bag) which LANL has developed, will be presented.

11:15 AM EN09.01.03
Intercepting Intermediates in the Depolymerization of Poly(ethylene terephthalate) Shelby Watson-Sanders, Joshua Moncada and Mark Dadmun; University of Tennessee, United States

There is a need to develop new processes for end-of-life plastics to limit waste accumulating and contaminating our environment. One possibility is the chemical recycling of polymer, such as the depolymerization of polyethylene terephthalate (PET). PET is one of the most widely used commercial plastics, which can be depolymerized via glycolysis. In order to broaden the available products from the depolymerization process, we are interested in understanding the evolution of chain structure during chemical recycling. This study therefore monitors the evolution of chain structure in the depolymerization of PET in a heterogeneous reaction as a function of catalyst and reaction temperature. PET, sourced from Coke bottles, is depolymerized by glycolysis catalyzed with the salt of Triazabicyclodecene (TBD) and methanesulfonic acid (MSA) (1:1) or Zinc Acetate (ZnAc) in heterogenous reactions with ethylene glycol (EG). PET was depolymerized with TBD:MSA at 180 C, and with ZnAc at 165 C, 175 C and 185 C. Products of each depolymerization reaction were taken at predetermined intervals to monitor the evolution of chain structure. The chain size as a function of reaction time was determined by NMR (M_n) and intrinsic viscosity (M_v), offering a measure of chain length and dispersity of the chain length (i.e. M_v/M_n) with reaction time.
The depolymerization process entails the interfacial reaction of the EG and insoluble PET, where progress of the reaction forms smaller PET chains that become soluble in EG. This analysis follows the decrease in chain length, and solubility of depolymerized PET in ethylene glycol. Comparison of the two catalysts shows that the decrease in chain length occurs more quickly in the ZnAc catalyzed reaction than the TBD:MSA, where increasing temperature increases the rate of depolymerization. Correlation of reaction rate to change in solubility is underway. Monitoring the dispersity of the PET in the reaction vessel shows that the polymer chain size distribution becomes narrower with depolymerization. These results will therefore provide insight into the mechanism that controls the chain depolymerization and available products from the depolymerization reaction over the course of the reaction.

Informatics Pipeline to Identify Polymers Capable of Controllable Depolymerization Aubrey R. Toland, Huan Tran, Lihua Chen, Yinghao Li, McKinley Paul, Kellie Stellmach, Chao Zhang, Will R. Gutekunst and Rampi Ramprasad; Georgia Institute of Technology, United States

Enthalpy of polymerization is a key thermodynamic property to determine if a polymer can be controllably degraded to monomer feedstock at the end-of-use, a capability essential to mitigating the global polymeric waste problem. Due to the favorable thermodynamics of ring opening polymerizations (ROP) in creating depolymerizable polymers, the enthalpy of ROP (ΔH^{ROP}) is the focus of this study. Thanks to a recently developed first-principles computational scheme, a high-quality database for computed ΔH^{ROP} has been developed in order to help overcome the issue of data scarcity present in the current literature. Using this computational database, along with the limited experimental data present in literature, a data-fusion approach has been adopted to create a machine learning (ML) model capable of predicting experimental ΔH^{ROP} near chemical accuracy, ~5 kJ/mol. This ML model is then used in conjunction with the first-principles computational method to create a pipeline where the ML method screens the massive chemical space that makes up ROP chemistries, and the most promising candidates are then passed to the first-principles calculations for validation. This iterative process exploits the ML model uncertainty as well as discrepancies between ML predictions and first-principles calculations to create active learning cycles used to optimize the generalizability of the ML model. This informatics pipeline provides an important step towards creating an automated process for the discovery and design of depolymerizable polymers, meant specifically to create plastics that can truly be sustainable.

Data-Driven Property Prediction for Accelerated Discovery of Molecular Additives in Robust yet Chemically Deconstructable Thermoset Plastics Yasmeen S. AlFaraj[1], Somesh Mohapatra[1], Peyton Shieh[1], Keith Husted[1], Douglas Ivanoff[2], Evan Michael Lloyd[2], Jeffrey Moore[2], Nancy Sottos[2], Rafael Gomez-Bombarelli[1] and Jeremiah Johnson[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Illinois at Urbana-Champaign, United States

Novel materials discovery approaches are imperative to address time-critical challenges in materials design. Considering that discovery typically precedes and inspires applications, traditional screening methods often rely on arduous and inefficient experimental processes requiring the identification of novel molecules prior to application determination. Recent breakthroughs in data-science approaches have shown great promise for accelerating materials design cycles by leveraging pre-existing data to learn composition-processing-performance models which feed into active learning cycles in experimental lab spaces. However, non-standardized experimental acquisition strategies and sparsity in dataset size variability limits the ability to utilize data-driven

methods for advances in the low-data regime. One such application with limited available data and which poses a time-critical environmental challenge includes the development of thermoset plastics with accessible pathways to deconstructability for improved end-of-life practices and possible reprocessing. More notably, the retention of desirable thermomechanical properties whilst introducing viable pathways to deconstructability remains a challenge. In this work, we propose the use of an ensemble of machine learning models with variable architectures, each trained on distinct parts of a training dataset consisting of data on deconstrucable polydicyclopentadiene (pDCPD) thermosets, to overcome the limitations of said low-data regime. We report a closed-loop discovery approach rooted in experimental synthesis, machine learning, and virtual screening to discover potential cleavable comonomer additives (CCAs) which, when introduced in low quantities in accordance with the reverse-gel-point model, enable the degradation of thermosets without compromising desirable thermomechanical properties. Moreover, our approach allows for concurrent prediction of resultant bulk materials properties, introducing tunability into the design process. In this work, we show it is possible to train accurate models on reconstructible pDCPD systems with as few as 101 data points to screen new chemistries and synthetic conditions, whilst predicting and experimentally validating glass transition temperatures within reasonable accuracy. This work lays a ripe foundation for the translation of closed-loop data-driven design cycles for the development of other reprocessable thermoset plastics with tailored thermomechanical properties.

Sustainable and Degradable Epoxy Resins Containing Multifunctional Lignin-Based Components Megan Robertson, Minjie Shen, Rosalie Berg and Venkatesh Balan; University of Houston, United States

Lignin was investigated as a sustainable source to produce epoxy resins with desirable physical behavior. Epoxy resins are thermoset polymers widely used in composites, coatings and adhesives, with applications spanning automotive and aerospace industries, structural components, and wind turbine blades, among others. Vanillic acid, a product of lignin depolymerization, was investigated as a replacement for conventional diglycidyl ether of bisphenol A (DGEBA) in anhydride-cured epoxy resins. The resulting vanillic acid-based epoxy resins exhibited high glass transition temperatures and similar elongation at tensile behavior as compared to DGEBA-based epoxy resins. The ester groups in the cured network were also leveraged to enhance the end-of-life options for the epoxy resins. The accelerated hydrolytic degradation behavior of the epoxy resins was explored, through monitoring the mass loss after exposure to basic or acidic solutions at moderate temperatures. The vanillic acid-based epoxy resins exhibited rapid degradation, in contrast to the slow degradation rate of the DGEBA-based epoxy resin. The mass loss behavior showed good agreement with predictions with a solid-state kinetic model and chemical analyses confirmed the degradation mechanisms were surface and bulk erosion in basic and acidic solutions, respectively, through ester hydrolysis.

2:30 PM *EN09.02.02
Facile Chemical Modification of Lignin for Synthesis of Lignin-Based Sustainable Polymers Hoyong Chung and Sundol Kim; FAMU-FSU College of Engineering, United States

Lignin is abundant and low-cost biomass polymer that has high concentration of aromaticity. Therefore, the lignin may provide high mechanical and thermal properties which are not easily available from other bioplastics. In addition, because lignin is not a human food, the supply and cost are very stable. However, a natural lignin cannot be used as an original form because of its poor processibility and compatibility with other materials. This presentation will discuss 1) chemical modification of lignin for further material applications and 2) synthesis of well-defined degradable lignin-based polymers. Commonly available kraft lignin, byproduct of paper industry, is not readily processible to produce commodity polymers due to its poor compatibility to other polymers. Thus, a new technology is developed to modify the lignin that possess carboxylic acids in the presence of capping agents. Herein the addition of capping agent is croitically important because the capping agent deactivates excessive number of active functional groups on lignin. The remaining a few selected functional groups of lignin works for the next reaction. Without the capping agent, the lignin-based polymer proceeds to unwanted reactions through the excessive functional groups. The unwanted reactions led solubility change and brittleness of the yielding polymers. The modified lignin was then used for a new polyester synthesis. The new lignin-based polyester is a graft copolymer (lignin-graft-poly(ethylene brassylate)) that has strong and stable covalent bonds between lignin and poly(ethylene brassylate) rather than blending of two polymers. The new polymer’s main linkage, ester, is scientifically proven biodegradable functional group in natural conditions. The new lignin modification and polymer synthesis method will enable to produce 100% biomass-based and completely biodegradable commodity polymers.

Biogenic and Bioinspired Functional Materials for Sustainability Ulrike G. Wegst; Northeastern University, United States

The creation, use and disposal of any engineering product carry with it an environmental burden. On the one hand, materials contribute much to the environmental impact of a product over its lifetime, on the other, materials offer considerable potential to minimize a product's environmental burden. The sustainable and circular economy, which we increasingly desire, requires the development, informed selection and application of new materials that—without compromising product quality—are lighter and less energy intensive, create less toxic by-products, enable a longer product life, are more easily recycled, and whenever possible, use non-critical, renewable or biogenic resources. Presented will be examples for the design and manufacture of biogenic and bioinspired functional materials and how these can be integrated into teaching strategies and tools in support of eco-design and eco-audits, which introduce students to a holistic approach to environmentally-conscious materials selection and its importance at the early stages of the design process. Illustrated will be, how through case studies on the environmentally-conscious redesign of an existing product, students learn to identify and focus on the life phase with the greatest environmental impact, how a trade-off analysis of energy cost of function versus pecuniary cost of function can guide decision making for a given set of design constraints, and whether, in fact, offering a service that would provide the same service unit of the existing product, but at a reduced footprint over the entire life cycle, might be the better solution. Finally, introduced will be the 'Discover Materials!' a “please touch” materials library and exhibition, which links physical materials and product examples, sustainable or not, with software- and web-based selection and information tools and the processes available to students in workshops on campus, in which students can turn materials into technical solutions to engineering problems, or art, or both.

4:00 PM *EN09.02.06
Educating about Critical Raw Materials and Life Cycle Sustainablity Assessment Vakhitova Tatiana Vadimovna; Ansys Ltd., United Kingdom

Materials Criticality is not a new topic, but it is taking a stronger place in sustainability discourse now due to various factors, such as an increased complexity and globalisation of supply chains, proliferation of frameworks for Environmental Social and Governance performance (ESGs) disclosure for companies to name just a few. Social risk, related to materials, is getting more and more recognised, similar to environmental impact or a price volatility risk. More research and teaching on the topic of critical raw materials is taking place. An example is a Massive Open Online Course SusCritMOOC, developed by consortium of academics and industry representatives, initiated and funded by the European Institute of Innovation and Technology (EIT RawMaterials). This MOOC has now run on EdEx several times with satellite online and onsite events. In this talk we discuss the topics, surrounding critical materials and how they could be integrated in teaching, provide example of a tool to introduce Social Life Cycle Assessment – Social Impact Audit Tool, developed in-house at Ansys, and, taking a step further, showcase an approach to Life Cycle Sustainability Assessment (LCSA), as a framework for integrating social, economic and environmental impact of a product, based on Mike Ashby's latest LCSA methodology (Ashby, 2022). This is an approach to be used in education and for decision-making.

EN09.03.01
Bioinspired Amphoteric Sorbent for Water Remediation Kelvin Adrah, Hemali Rathnayake, Sheeba Dawood and Sujoy Saha; University of North Carolina Greensboro, United States

According to UN estimates, 4 billion people will lack access to safe drinking water by the year 2025. This projection can be attributed to rising population and industrialization, resulting in an insurgence of pollutant deposition in water bodies. Heavy metals have been identified as common inorganic contaminants produced in significant amounts by battery manufacturing, metal plating, and mining industries, among other industries. Consumption of these dissolved species in ultra-trace amounts is hazardous to human health. Current water treatment methods such as ion exchange and reverse osmosis are time consuming, generate waste, and costly. Presently, adsorption technology has been adopted in water purification systems to remove heavy metals from water resources due to its effectiveness and low cost, but lacking the high adsorption, environmental sustainability, and versatility. This project aims at overcoming these technical barriers by developing a novel sorbent from biomass by products with high porosity, and high surface area with amphoteric surface properties for selective cleansing of heavy metals in surface water. The sorbent of hierarchical microstructures with a robust metal-organic framework was synthesized by catenating the naturally occurring tannic acid with iron (II) acetate in an aqueous media. The synthesis method follows the green chemistry principles, offering an energy-efficient versatile synthesis method. The chemical composition, shape, physicochemical properties, and colloidal stability of microstructures were investigated using a wide range of characterization techniques. Supporting their amphoteric sorption, Fe (III)-TA microstructures efficiently removed Ag^{+} and Cd^{+2} from a highly alkaline synthetic water, with > 96% removal efficiency. Experimental data fitted into Langmuir, Freundlich, and Temkin adsorption isotherms and Pseudo first and second order kinetic models suggests a monolayer adsorption of Ag^{+} and Cd^{+2} onto the surface of the microstructures. The effective adsorption of metal ions onto the microstructures is attributed to the highly branched and hydroxyl dense polytopic tannic acid ligand, which provides multiple bonding sites through diverse chemical interactions. These highly porous, amphoteric polyphenol-based metal organic coordination polymers synthesized under environmentally benign conditions are cost-effective and easy to scale-up for pilot or industrial applications. Thus, they offer a great potential for use in tertiary treatment of water remediation.

EN09.03.02
Turning Waste Into Wealth—From Fly Ash to Highly Functionalized Graphitic Anodes by Laser Irradiation for Advanced Sodium-Ion Batteries Eman Alhajji and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

The urgency to develop sodium-ion batteries (NIB) as an eco-friendly alternative to lithium-ion batteries and the issue of massive waste generated by the linear carbon economy are at their peaks. However, the limited sodium-ion intercalation capacity of graphitic anodes hinders the utilization of NIBs, while the costly treatment processes of waste make recycling unfeasible. Laser irradiation of fly ash is an effective approach to enhance Na-ion storage and energy density while simultaneously upcycle waste into a high-value functional material (LFAC). This approach yields three synergistic benefits (1) structurally transforming a soft carbon material into a highly ordinated graphitic nanomaterial, (2) increasing carbonylic functional groups on the surface of the electrode, and (3) efficiently producing an additive and binder-free electrode. LFAC anodes exhibit a high first discharge specific capacity of 450 mAh g^{-1} at 0.1 A g^{-1} whereas FAC anodes exhibit 285 mAh g^{-1}. LFAC anodes deliver three times higher capacity than the untreated material, an enhanced reversible capacity of 250 mAh g^{-1} at the current density of 0.1 A g^{-1} after 100 cycles, indicating a slow capacity degradation of 0.2% decay per cycle. In contrast, FAC electrodes demonstrate a low reversible capacity of 80 mAh g^{-1} at a current density of 0.1 A g^{-1} and capacity degradation of 0.3% decay per cycle after 100 cycles. The high intensity of carboxylic functional groups on the surface of LFAC breaks the barriers of Na ion intercalation by increasing the adsorption energy of sodium and enhancing its ion diffusion.

EN09.03.04
Tacky-Free Polyurethanes Pressure-Sensitive Adhesives by Bio-Based Thermoplastic Polyurethane Design from Eco-Friendly Isosorbide Ji-Hong Bae, Won Bin Lim, Jin-Gyu Min, Ju-Hong Lee, Si-Woo Kim and PilHo Huh; Pusan National University, Korea (the Republic of)

A series of Isosorbide-based thermoplastic polyurethanes (ISB-TPUs) were newly developed through the synthetic process by reacting methylene diisocyanate, poly(ethylene glycol) (PEG), and bio-based material isosorbide (ISB) for chain extender based on the different HDI/HDI trimer ratios. The structures of ISB-TPU series were analyzed by Fourier transform infrared spectroscopy and gel permeation chromatography. The changes in the thermal and physical properties due to the hard segment crystallinity were also measured by thermogravimetric analysis, differential scanning calorimetry and universal test machine. The sticking properties of polyurethane pressure-sensitive adhesives (PU-PSAs) depended on both the HDI/HDI trimer ratio and crosslinking-agent composition in the formulation. The differences in the crosslinking-density significantly affected the cohesion, adhesion, and tack in PU-PSA. The formulation of 50 wt% 600PEG and 50 wt% crosslinking-agent and an HDI/HDI trimer ratio of 1.0 led to the optimal balance between the

adhesion and cohesion properties owing to the sufficient tack, high 180-peel strength, and good cohesion. The results showed that biopolyol used in polyurethane can be applied according to the characteristics required in eco-friendly products fields.

EN09.03.05
Reliability and Lifetime of Chemically Sintered Printed Zinc for Highly-Conductive Biodegradable Antennas Carol Baumbauer[1], Anupam Gopalakrishnan[2], Alyssa Umino[1], Gregory L. Whiting[2] and Ana C. Arias[1]; [1]University of California Berkeley, United States; [2]University of Colorado Boulder, United States

Biodegradable or transient electronics are a class of electronics that break down under physiological or environmental conditions into harmless components, offering a solution to the problem of electronic waste generation. Biodegradable electronic devices need conductors to serve as interconnects as well as antennas or inductive loops for wireless power transfer and data communication. In these antennas, conductivity is crucial for functionality, but the majority of biodegradable conductors are significantly less conductive (on the order of 10^3 S/m or less) than their non-degradable counterparts like evaporated copper or printed silver. Additionally, many existing printed biodegradable conductors have functional lifetimes measured in minutes or days, which can be useful in some applications, but is insufficient for applications in which weeks' or months' of data is desired. Higher conductivity, longer-lasting biodegradable conductors are needed.
In recent years, printed zinc treated with acetic acid solution has emerged as a promising biodegradable, highly conductive material, with conductivity greater than 10^5 S/m possible. The low-temperature nature of this process makes it compatible with many biodegradable substrates, which cannot withstand thermal sintering processes. The acid treatment conditions—concentration, exposure time, drying temperature, and drying time—needed to achieve high conductivity are very precise. Small deviations from optimal conditions can cause conductivity to fall by more than four orders of magnitude, rendering devices unusable. These optimal acid treatment conditions also depend on which polymer is used as the ink's binder and on the substrate. Here, we present the optimization of chemically sintered zinc traces, taking binder and substrate material into account. The resulting traces maintain their conductivity for a few weeks.

EN09.03.08
Degradable Silyl Ether-Based Thermoset Under Acidic Condition Boyun Choi and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)

Recently, as plastic usage increases, the environmental pollution due to plastic waste is becoming severe. Incomplete degradation of waste plastics produces microplastics, which are difficult to remove by their small sizes. Microplastics, harmful to human health, flow into the marine ecosystem and accumulate in the human body. Many researches are being conducted to develop degradable polymers. However, thermosetting plastics such as epoxy resin used in various industrial fields are still challenging to degrade. In this study, we developed a degradable epoxy thermoset using silyl ether derivative as a curing agent that easily hydrolyzed under acidic or basic conditions. The synthesized silyl ether derivatives were mixed with bisphenol A and formed network structures through thermal curing. To compare the effects of degraded behaviors on the chemical structures of curing agents, we used several types of silyl ether derivatives having different functional groups. The weight loss of the cross-linked epoxy network immersed in HCl solution for a certain time was observed the degradable behavior. As a result, it was confirmed that the crosslinked epoxy network was completely degraded. In addition, curing agents having more sterically hindered functional groups exhibit a slow degraded rate. The results suggest that curing agents containing silyl ether bonds can form the degradable epoxy network, and the rate of degradation can control by chemical structure.

EN09.03.09
Isosorbide-Based Organic-Inorganic Hybrid Materials for Green Chemistry Gwang-Mun Choi, Ki-Seok Jang, Jin-Hyuk Oh, Jiho Joo, Chanmi Lee, Ho-Gyeong Yun, Seok Hwan Moon, In-Seok Kye, Yoon-Hwan Moon, Kwang-Seong Choi and Yong-Sung Eom; Electronics and Telecommunications Research Institute, Korea (the Republic of)

Bio-based plastics using an isosorbide, a 100% biomass obtained from corn starch, have received much attention in last decade due to the demand for low carbon, sustainable growth. In particular, researches on synthesis of isosorbide-based curable resins have been extensively conducted to replace petrochemical-based ones. For example, there are two well-known synthetic methods: an isosorbide-based epoxy resin via etherification reaction of isosorbide with epichlorohydrin[1]; an isosorbide-based (meth)acrylic resin via esterification reaction of isosorbide with (meth)acryloyl chloride[2]. However, these methods do not satisfy the green requirements because epichlorohydrin and (meth)acryloyl chloride are severe toxic chemicals for which special precautions is required. Besides, to the best of our knowledge, the isosorbide-based curable resin, which shows superior properties compared with the petrochemical-based one, has not been reported yet. In this study, we demonstrate novel bio-based organic-inorganic hybrid curable resins synthesized by reaction of isosorbide with organofunctional alkoxysilanes. The molecular structure was investigated based on comprehensive understanding by FT-IR, GPC, and NMR analysis, which revealed that isosorbide and alkoxysilane were chemically linked by silyl ether and siloxane bonds. In addition, the thermomechanical properties of cured materials using the isosorbide-based organic-inorganic hybrid curable resins were characterized using DSC, TGA, and rheometer, which showed outstanding properties compared with the petrochemical-based one. For green and sustainable chemistry, we think our material solution can replace petrochemical-based ones and be applicable to advanced semiconductor and display fields.

EN09.03.10
A Highly Self-Healable Elastomer Based on Urea Oligomeric Blocks for the Enhanced Mechanical Properties and Long-Term Storage Stability Kiwon Choi[1], Yong Ju Kim[1], Ahyeon Noh[1], Sung Woo Hong[2] and Min Jae Ko[1]; [1]Hanyang University, Korea (the Republic of); [2]Korea Institute of Industrial Technology, Korea (the Republic of)

Flexible electronics are enjoying a renaissance with the 4th industrial revolution. However, the change of form factor toward flexibility requires replacing the hard glass with the flexible elastomer as a protective coating layer. The softened surface suffers from repeated cracks and scratches. To address these issues, two kinds of elastomers are developed to strengthen surface hardness and to give self-healing properties. Herein, a highly self-healable elastomer with superior optical and mechanical properties is synthesized based on the urea oligomer in this study. Acrylate-based polyol, linear urea oligomer with isocyanate group at both ends, and cross-linker containing multiple isocyanate groups are blended and the resulting blended precursor is reacted to generate the self-healable elastomer (EUo). The process of oligomer synthesis of urea can successfully ensure processability, thus avoiding potential reactor fouling during commercialization. EUo exhibits a high transmittance (~92%) and low yellow index (~1.5), which makes it applicable to optical-electronic devices as a protective film. The elastomer based on urea oligomer shows remarkable self-healing efficiency (94%), which is extremely enhanced compared to

conventional elastomer without urea oligomer (47%) and the elastomer based on urea diol (62%). This result is due to the strong hydrogen bonding interaction between urethane and urea groups, and we thoroughly analyze this result through a modeling system of FT-IR spectroscopy. Moreover, the strong hydrogen bonding produces a secondary cross-linking network, resulting in enhanced tensile strength (43 MPa) and surface hardness (0.177 GPa). This study suggests a facile strategy that can overcome the conventional trade-off between self-healing property and mechanical robustness that limit the application of self-healing polymers.

EN09.03.12
Green Synthesis of Amino Acid-Based Poly(Ester Urea)s Katharina Fransen and Bradley Olsen; Massachusetts Institute of Technology, United States

Industrial biotechnology has provided the polymer chemistry community with access to a wide variety of monomers that have traditionally been difficult to synthesize via fossil-fuel based chemistry, leading to new replacements for many of our unsustainable chemistries with both biomass-based and biodegradable polymers. While polyesters based on molecules like furan-dicarboxylic acid (FDCA), ethylene glycol, lactic acid, and 1,3-propanediol have attracted the most attention, these represent a small fraction of all possible polymers and are suitable replacements for only a fraction of synthetic polymers in use today. A complementary set of materials that may be useful for replacing many polyurethanes and polyamides is poly(ester urea)s (PEUs), a known class of biodegradable polymers that can be synthesized from a wide range of amino acids and diols that are easily produced via fermentation in high yield. The monomer chemistry of PEUs consists of both a diol and amino acid, presenting broad opportunities for structural manipulation and tunability to specific applications. However, existing synthetic routes for PEUs are time-consuming, carbon inefficient, and utilize toxic materials necessitating the development of a green chemistry route to produce these promising materials sustainably. We have developed a greener approach to the synthesis of these polymers, making them a truly sustainable biomass-derived and biodegradable chemistry.

EN09.03.14
Closed Loop Recycling of High T_c Biodegradable Polymers by Reactive Distillation Connor Gallin, Won-Woo Lee, Jiangwei Liu and Jeffery Byers; Boston College, United States

A closed loop cycle for polymer production and disposal is needed to handle the estimated half a billion metric tons a year of polymer that will be used by 2050. Current methods for polymer recycling are insufficient to meet this need. Herein, we disclose a simple and inexpensive catalyst system that can readily and selectively depolymerize polyesters and polycarbonates with high ceiling temperatures (T_c > 200 °C) back to their constituent monomers. Quantitative recovery of the depolymerized monomer was demonstrated for a variety of aliphatic polyesters and polycarbonates, including the stereo-retentive depolymerization of poly(lactic acid) and the depolymerization of polyethylene-like poly(pentadecalactone). The catalyst was readily recyclable for multiple depolymerization batches using the same distillation apparatus, making the method readily adaptable to continuous feed distillations. The catalyst is also capable of carrying out selective depolymerization from a mixture of post-consumer polymers. Finally, monomer recovered from the reactive distillation reactions can be used without further purification to reform the polymer, closing the loop for polymer recycling.

EN09.03.16
Silica Aerogel Preparation and Characterization from Rice Husk by Ambient Pressure Drying Yang m. Gu[1,2] and Jin Hyung Lee[1]; [1]Korea Institute of Ceramic Engineering & Technology, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Rice husk is a promising abundant bioresource for the production of high value added silica materials because it has the highest SiO_2 content among all plant based resources. In this study, silica aerogel are synthesized from rice husk by combining alkali extraction, acid leaching, solvent exchange and ambient pressure drying. Especially, the effect of Trimethylchlorosilane (TMCS)/n-hexane volumetric ratio on the synthesis of silica aerogel was investigated. They were characterized by their properties such as Brunauer-Emmett-Teller theory (BET), X-ray diffraction (XRD), Scanning electron microscope (SEM), Transmission electron microscope (TEM), Thermogravimetric analyzer (TGA), and Fourier transform infrared spectroscopy (FTIR). The synthesis of high value-added silica aerogel from an abundant bioresource can open up new avenues for sustainable and environment-friendly industrial development.

EN09.03.17
Fluoropolymer Based Radiative Cooler Having High Durability for External Environment Jisung Ha, Soomin Son, Dongwoo Chae, Hangyu Lim, Sucheol Ju and Heon Lee; Korea University, Korea (the Republic of)

Global warming is accelerating as fossil fuel consumption increases. The global temperature is rising every year due to global warming. According to this environmental issue, exposure of heat stress can reduce people's satisfaction with life in outdoor activities especially in hot summer. Also, it can decrease the efficiency of machine ability. Therefore, a lot of electricity is used for cooling purpose to relieve the heat in the city. In Korea, household electricity consumption is concentrated in August. Also, according to the current trend, the number of days with heat waves is expected to increase further. The increase in electricity consumption leads to an increase in the use of fossil fuels, which is a vicious cycle that causes global warming worse. Passive daytime Radiative cooling (PDRC) can lower the temperature without consuming energy. By reflecting sunlight (0.3-2.5μm) and radiating the heat to the space (0K) through the atmosphere's window (8-13μm), it can cool the ambient temperature below the radiative cooler. When it is set on rooftop, the building inside temperature goes down. PDRC is new-coming energy saving technology. In this study, we fabricated radiative cooling material in the form of solution and we can obtain white film caused by diffused reflection of nanoparticles. It shows white surface without metal layer so it doesn't cause glare. Fluoropolymer is fluorocarbon-based polymer and it has a high resistance to solvents. Especially, Ethylene Tetra fluoro Ethylene(ETFE) has good chemical resistance among various fluoropolymers. Also, ETFE material has high thermal resistance and its operating temperature is around 520K. In other words, this material can remain at extreme environment. Due to the nature of PDRC installed outside, exposure to weather conditions is inevitable. When acid rain falls in hot summer, normal radiative cooling material which is made of ceramic particle and polymer binder can be degraded by acid and high-temperature, thereafter its cooling performance decrease and durability also downgraded. In this work, ETFE particle is used to make white monolayer with PUA (polyurethane acrylate) for radiative cooling and inside can be cooled easily by coating it thinly on substrate like building outside. ETFE radiative cooler coated on glass substrate shows solar reflectivity of 92.5% and emissivity of 91.7% across atmosphere's window and its calculated cooling power is 95.6W/m2. Because ETFE material which is one of fluoropolymer has good high-temperature resistance and high-chemical resistance, we propose PDRC which can operate at high-temperature and chemical environment. ETFE particle cannot solve with organic solvent and also cannot melt at room temperature. Soomin Son et al. fabricated PVDF film using PUA with UV hardening. We dissolved PUA to ethanol and combined white ETFE particle into solution with film forming agent. We fabricated heating chamber which continues to radiate heat by halogen lamp. With 20W lamp, the temperature inside heating chamber can increase up to maximum 400K. By putting ETFE radiative cooling material coated on aluminum on heating chamber, it decreases 24K contrast to ambient temperature when outdoor measurement with heating chamber. By chemical resistance test, we dipped ETFE radiative cooler into sulfuric acid which is same PH range of acid rain during one day with white commercial paint sample (e.g., titanium dioxide-based paint) and zirconia based radiative cooler. Commercial paint sample was yellowed, and also zirconia based radiative cooler was cracked and its film came off. But the film of ETFE radiative cooler was remained and its optical properties was also remained within a small range of error. In this way, ETFE radiative cooling coating hosts promising future in building cooling and it might be also found wide applications in outdoor or devices which of efficiency is sensitive to its

temperature.

EN09.03.18
Easily Recyclable White Polymer Films as Replacement for TiO_2 Pigments Luisa Borgmann, Siegbert Johnsen, Gabriele Wiegand and Hendrik Hoelscher; Karlsruhe Institute of Technology, Germany

Titanium dioxide (TiO_2) has developed in recent decades as a standard white pigment for paints, coatings, films, cosmetics, and foods. But it has repeatedly come under criticism for its potential hazard for the environment and health. Therefore, its use as a food additive has been banned in Europe and further restrictions are expected worldwide. Consequently, replacements are being intensively sought. We, therefore, present a bio-inspired polymer structure that is fabricated via foaming polymers with supercritical CO_2. In that way, tiny nanobubbles are formed inside the polymer, turning the originally transparent material perfectly white. This is a purely structural effect; all other material properties of the respective polymer stay unchanged. Therefore, the respective polymer remains a mono-fraction simplifying recycling dramatically. The process is environmental-friendly and can be utilized with bio-based polymers such as PLA (polylactide) or cellulose acetate and is highly scalable. The foamed films can be used directly and also tolerate further process steps, such as thermoforming.

EN09.03.19
Readily Degradable Thermoset Network Derived from Biomass Resource Ji Won Joo, Ka Hyun Lim and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)

Indiscriminate use of non-degradable petroleum-based thermosetting polymers has caused many environmental problems. In particular, plastic waste and microplastics are emerging as major causes of environmental pollution. Therefore, there is growing interest in materials derived from renewable resources such as biomass. These biomass-based polymers offer the benefits of environmentally friendly materials and solve the problem of waste plastic accumulation. In this study, we suggest isosorbide diglycidyl ether (ISEPO) as a sustainable alternative to diglycidyl ether bisphenol A (DGEBA) as an epoxy monomer. The bio-based thermosets with high degradability were cured via a simple cationic polymerization of ISEPO and ester linkages. We discussed the hydrolysis mechanisms according to the contents of ester bonds and examined various factors affecting the degradation of the thermoset. We also identified potential applications for the use of ISEPO as degradable prepregs for the printed circuit boards. It is expected to be a solution to solve the plastic disposal and microplastic problems caused by non-degradable epoxy composites. The presence of degradable connections in the entire thermoset network structure can contribute to solving fundamental environmental problems and even provide a valuable route to recycling.

EN09.03.20
Triboelectric Energy Harvesting System Based on Recyclable Polymers and Electrodes Junseong Ahn[1,2], Jiseok Kim[1], Il-Kwon Oh[1], Jun-Ho Jeong[2] and Inkyu Park[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Machinery and Materials (KIMM), Korea (the Republic of)

As the problem of environmental pollution due to the use of fossil fuels has emerged, interest in eco-friendly and renewable energy has rapidly increased. Especially, triboelectric nanogenerators (TENGs) has a great interest in because they can efficiently harvest wasted mechanical energy at low frequencies. From the first invention of TENG by Prof. Wang's group, TENGs with various advantages such as large effective surface area, operating mode, and efficient energy harvesting system have been actively studied for about 10 years. However, an eco-friendliness and recyclability of TENG itself was rarely considered, and only water-degradable and disposable materials as triboelectric surfaces were selected for eco-friendly and recyclable TENG, which hinders a broad application of TENG in water energy harvesting such as rain, ocean, river, and humid environment. Herein, we propose an all-recyclable TENG (AR-TENG) which consists of thermoplastic polymer, poly(methyl methacrylate) (PMMA) with a nanohole pattern and an electrodeposited ultrathin Pd film for ocean energy harvesting. We chose a PMMA film as a dielectric material because it can be easily dissolved in acetone, nanopatterns can be introduced by thermal nanoimprinting lithography method, and it has a great mechanochemical stability by maintaining its performance after immersion into water and seawater or even 1,000,000 cyclic tests. The proposed AR-TENG has a superior energy harvesting performance with an advantage of large effective contact area by nanopatterns. The practical application of AR-TENG was demonstrated by charging Li-ion batteries using a rectifier, a capacitor, and an ultralow-power step-down regulator with input voltage monitoring and regulation functions. The harvested electrical energy can be stored in Li-ion batteries and it can power the ocean monitoring system which consists of a micro-controller, wireless communication node, various sensors such as salinity sensor, pH sensor, temperature sensor, and oil leakage sensor. We expect that the proposed AR-TENG can provide eco-friendly and effective triboelectric energy harvesting technology considering the mechnochemical stability, recyclability, and eco-friendliness.

EN09.03.21
The Effect of Different Types of Starch on Silicon Anode Binder for High-Performance in Lithium-Ion Batteries Ohhyun Kwon, Seohyeon Jang, Jihyeon Kang, Hojong Eom, Seyoung Choi, Junhyeop Shin, Jongkwon Park and Inho Nam; Chung-Ang University, Korea (the Republic of)

Starch is the most abundant polysaccharide in plants. Starch exists in its native form as semi-crystalline granules that are essentially composed of two main components: linear amylose and highly branched amylopectin. Various type of starch has a different ratio between amylose and amylopectin with different crystallinity. Starch crystallinity is ensured by packing of amylopectin double helices in a unit cell. Several polymorphs characterized by different crystalline structure are differentiated: A, B, and C-type starches which is combination of A-type and B-type starch.
Due to its low cost, abundance, renewability, and continuous structure, starch is considered as one of the polysaccharides with the most potential. Several researchers have vouched to utilize the starch from many sources for the development of solid-state electrolytes, carbon materials, and li ion battery binders. Despite its benefits, not enough attention is being put towards exploring the applications of starch as a silicon anode binder.
Silicon (Si) is a promising high-capacity anode material for high-energy-density lithium-ion batteries. However, the massive volume change of Si during repeated charge-discharge cycles has been identified as the main origin of insufficient cycle lives of Si anodes. It has been found that binders can contribute substantially to improving their cycle lives. To find a better high performance Si anode binder, we attempted to use a unique starch binder. The presence of several hydroxyl groups in starch can enhance its interaction with the Si particles using the formation of multifaceted hydrogen bonds. Unlike normal polymer binders using silicon anode, starch possesses an intrinsic free volume and periodic crystalline frameworks, which is favorable for a fast Li^+ transfer.
In this study, the relationships between the structure and properties of the novel starch binder are systematically investigated with the objective of improving electrochemical performance of Li-ion batteries. Corn starch, potato starch and waxy maize only consisting of amylopectin were selected to find out the effect of crystallin differences on li ion conductivity and the effect of amylose and amylopectin on silicon binders. We reveal that the structure of the crystalline of the starch affects the li-ion conductivity of the binder. Also, the one-step chemical synthesis was applied in this work to fabricate the binder more efficiently. A-type has a packed structure which restrains the lithium ions' movement. However, B-type has well-defined directional channels that plays a key role in the conduction of ithium ions. During the process of lithiation and delithiation, the structural properties of amylose and amylopectin lead to the formation of SEI layer. Highly branched amylopectin promotes the development of a thick SEI layer at the initial stage, which resulted in a decrease in performance. Due to the potato starch's aforementioned advantages, its electrode displayed a significantly improved cyclic and rate

performance for lithium half battery. The Si anode with the potato starch which has B-type crystallinity could enhance the li ion conductivity of the binder which in turn, delivers a good electrochemical performance, especially at a high C rate. As expected, the prepared potato starch binder demonstrated a good reversible capacity of 2500mAh/g after 100cycles at 1C for Li half battery. This systematic study is helpful towards understanding the structural difference starch has on the cycling performance of Si anodes and thus further provides insights for the rational design of novel polymeric binders.

EN09.03.22
Synthesis of Biocompatible Rice Husk-Derived Silica Nanoparticles Jin Hyung Lee[1,2], Ji Yeon Park[1], Wonsik Mun[3], Jinyoung Chun[1], Yang m. Gu[1], Eun Sung Kan[2] and Robert J. Mitchell[3]; [1]Korea Institute of Ceramic Eng. Tech, Korea (the Republic of); [2]Texas A&M University, United States; [3]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Although silica nanoparticles (SiNPs) can be artificially synthesized, they are also produced naturally within rice plants, but the biocompatibility of these natural SiNPs has thus far remained unknown. Within this study, several different methods (combustion, acid leaching or alkali extraction) to purify SiNPs from rice husks were explored, with an emphasis on their inherent toxicity towards human cell cultures. Whereas acid leaching and alkali extraction both generated highly pure SiNPs (>99.1% SiO_2 vs. 93.1% with combustion), toxicity tests performed with human and mouse cell lines found the alkali-extracted SiNPs to be much less harmful and, consequently, more biocompatible. We explored the toxicity further by incorporating polyethylene glycol (PEG) in the alkali-extracted SiNPs prior to the calcination step to mimic the presence of organic carbon during this step. Not only did the inclusion of PEG render the alkali-extracted SiNPs highly toxic, we found that this depended on the calcination conditions employed.

EN09.03.23
Fully-Recyclable All-Hydrocarbon Multifunctional Yarns for Circular Sustainable Fashion and Aerospace Applications Volodymyr Korolovych, Duo Xu, Rachel Bellisle, Cody A. Paige, Dava Newman and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

Development of multifunctional, lightweight, durable, and circular materials is critical for high-performance athletic apparel as well as for aerospace and military applications. Most conventional high-performance textiles are blends of multiple polymers, made by combining high-tenacity and elastomer fibers into e.g., polyester-spandex or nylon-spandex yarns. Typically, the elastomer content in such yarns is low, but it renders the textiles non-recyclable, resulting in majority of them ending up in landfills or incinerated. To address this problem, we engineer new high-performance core-sheath elastic yarns that are composed exclusively from all-hydrocarbon polyethylene (PE)-based fibers and exhibit high tensile strength, excellent elastic recovery, resistance to environmental degradation, and full mechanical or chemical recyclability.

The new yarns are fabricated by scalable melt-spinning techniques from PE-based polymer resins derived from either fossil fuels or sugar cane biomass [1]. We demonstrate that these fibers can be engineered through control of their polymer chain structure, crystallinity, and alignment to exhibit mechanical properties spanning the range from single-network elastomers (such as e.g. spandex) to high-performance fibers (such as polyester and nylon). We further engineer multifunctional core-sheath yarns made from a combination of high-performance and elastic PE-based fibers and show that they exhibit reversible elongation between 40% and 100% and breaking force above 9 N [2]. These new yarns are 100% mechanically recyclable at the end of their lifecycle without the loss of performance and enable 75% to 89% reduction in the cradle-to-grave carbon footprint of the textile products composed from either recycled or bio-derived PE resins, respectively.

Other applications that can benefit from a combination of elasticity and high tensile strength of the all-PE yarns as well as their degradation resistance, tunable thermoregulation [3], and radiation shielding capability [3] include medical garments, pilot uniforms, artificial muscles for soft robotics, and skin-tight mechanical counter-pressure (MPC) space suits. In particular, MCP suits offer advantages over conventional gas-pressurized spacesuits, by reducing volume, improving mobility, and enabling natural thermoregulation [4,5]. These suits rely on conventional elastic fibers (elastane and rubber cord) to maintain the necessary pressure and offer little protection from ionizing radiation. The all-hydrocarbon lightweight PE-based flexible yarns offer stretch, moisture wicking, thermal and ionizing radiation control for revolutionizing advanced MPC spacesuits as well as advanced garments for zero-gravity space adventure flights [6]. These materials may help to improve human capability to live and perform in extreme environments, while maintaining material circularity and reducing the environmental footprint needed for their fabrication, maintenance, and disposal.

This work was supported by the DEVCOM Soldier Center through the US Army Research Office (W911NF-13-D-0001), the MIT Deshpande Center, and the United States Navy and NERAMCO LTD (N6833521C0489). We thank the Dow Chemical Company and Braskem for providing polymer resins.

EN09.03.24
Biodegradation of PHB-Based Bioplastic Films in Soil Jihyeon Kim, Jacqueline A. Linn and Kwan-Soo Lee; Los Alamos National Laboratory, United States

Plastic materials produced from fossil fuel derivatives cause serious environmental problems due to their non-degradable nature. In general, such synthetic polymers are inexpensive, but their abundance has a significant negative environmental impact. Even most of the bioplastic materials produced currently are non-biodegradable, including Bio-PP, Bio-PET, and Bio-PA. Accordingly, recent research has focused on developing biodegradable polymers such as polymers produced by microorganisms, which have lower carbon footprints and greater ability to be recycled. Recently, Polyhydroxyalkanoates (PHAs) have attracted considerable attention as a biodegradable thermoplastic resin. In particular, polyhydroxybutyrate (PHB), which is the most well-known among PHAs, has been shown to rapidly degrade within 6 months under various natural active environments. The biodegradation of PHB takes place either under anaerobic or aerobic conditions. Implementation of the anaerobic condition will lead PHB to produce H_2O, CO_2, and methane. Under aerobic conditions PHB will produce CO_2 and H_2O. In anaerobic conditions a sludge containing several microorganisms is produced and can degrade PHB in different environments such as soil, salt water, and fresh water. However, soil was found to be the most natural environment for PHB degradation.
In this study, we propose a new type of biodegradable bioplastic composite film made of PHB bearing green additives. The green additives implemented to overcome the mechanical instability of PHB and to substantially increase the elongation property of the film. In addition, we have investigated the degradation of two different types of PHB-based biodegradable composite films over a 6 week period in compostable soil. The degradation was evaluated by measuring polymeric material molecular weight loss, crystallinity, mechanical properties, and physical changes within the surface of polymeric films.

EN09.03.25
Wafer-Scale Heterostructured Piezoelectric Bio-Organic Thin Films Jun Li; University of Wisconsin--Madison, United States

Piezoelectric biomaterials are intrinsically suitable for coupling mechanical and electrical energy in biological systems to achieve in vivo real-time sensing, actuation, and electricity generation. However, the inability to synthesize and align the piezoelectric phase at a large scale remains a roadblock toward practical applications. We present a wafer-scale approach to creating piezoelectric biomaterial thin films based on γ-glycine crystals. The thin film has a sandwich structure, where a crystalline glycine layer self-assembles and automatically aligns between two polyvinyl alcohol (PVA) thin films. The heterostructured glycine-PVA films exhibit piezoelectric coefficients of 5.3 picocoulombs per newton or 157.5×10^{-3} volt meters per newton and nearly an order of magnitude enhancement of the mechanical flexibility compared with pure glycine crystals. With its natural compatibility and degradability in physiological environments, glycine-PVA films may enable the development of transient implantable electromechanical devices.

EN09.03.27
Engineering Proton Exchange Membranes for Hydrogen Fuel Cells from Low Cost Micro Cellulose Filters Yuhao (Ben) Pan[1], Thomas Luong[2], Sean Fang[3], Aniket M. Raut[4], Haoyan Fang[4], Md Farabi Rahman[4], Konnie Duan[5], Helee Shukla[6], Quinton Geller[7], David Sprouster[4], Rebecca Isseroff[4] and Miriam Rafailovich[4]; [1]Stuyvesant High School, United States; [2]Plano West Senior High School, United States; [3]Maggie L. Walker Governor's School, United States; [4]Stony Brook University, The State University of New York, United States; [5]Harvard-Westlake High School, United States; [6]New Hyde Park Memorial High School, United States; [7]Los Alamos High School, United States

Hydrogen fuel cells are an emerging form of green energy that can produce electricity from hydrogen and oxygen gas with the only by-product being water. However, the fuel cell component materials themselves may not be environmentally sustainable. Currently the material most commonly used for the electrolyte membrane is Nafion, which is a perfluorosulfonic acid polymer created by free radical copolymerization of a perfluorinated vinyl ether sulfonyl fluoride co-monomer with tetrafluoroethylene. This has multiple toxic components and hence is not environmentally sustainable. Cellulose has been proposed as an inexpensive renewable alternative material where both microcellulose [1] and nanocellulose [2] have demonstrated the ability to generate power when used as an electrolyte membrane on the fuel cell. However, nanocellulose requires a complex synthesis process where functionalization with strong acids is performed [2]. This research presents a more natural membrane by taking low-cost, bulk-produced commercial cellulose filter papers and treating them with weak acids and a few drops of Resorcinol bis(diphenyl phosphate) (RDP). A power output of approximately 12mW/cm2 was obtained from membrane electrode assemblies (MEAs) constructed from filter paper membranes soaked in solutions consisting of a single weak acid with added RDP drops, and operated in air at 60oC with 0.1mg /cm2 of Pt at the cathode and anode. This value compared favorably with that of an MEA constructed from nanocellulose produced via the nitro oxidation method and operated under similar conditions which generated 11mW/cm2. Treatment of the filter paper membrane to a combination of acids and RDP and incorporation into a similarly constructed MEA yielded a power output of 16mW/cm2 when operated under the same conditions. However, operation under O2 produced a power output of 35mW/cm2 which was significantly larger than the 19.1Mw/cm2 output reported for a nanocellulose membrane operated in O2. SEM/EDX analysis of the cellulose filter paper membranes shows a phosphate-rich membrane forming between the fibers which possibly explains the lack of hydrogen gas crossover, despite the porosity expected from filter paper construction. Micro-CT analysis of the filter paper membranes further confirms the absence of porosity throughout the entire membrane. Further solid state NMR, as well as XPS is in progress in order to understand the chemical synergy enabled by the combination of acids and RDP.

The authors would like to thank the Morin Charitable Trust and the Office of Naval Research for funding.

EN09.03.28
Opportunities for Cellulose-Based Materials in Sustainable Manufacturing—On Earth and Beyond Shiwei Ng and Javier Gomez Fernandez; SUTD, Singapore

In nature, cellulose is the most abundant structural polysaccharides available from different sources and in different forms. Without extensive modification, it can be used to form composites that mimic natural material synergies and are perfectly integrated within nature's ecology. In circular, closed loop economies where functional objects are manufactured within a geographical region; its diverse utility coupled with material ubiquity and biodegradability drives continuous composite material innovations. More than ever, accentuated supply chain vulnerabilities and resource scarcity accelerates the transition toward circular systems. As materials enabling a sustainable manufacturing strategy within closed loop systems, cellulose-based materials could be a solution for regionalized manufacturing anywhere on Earth; and even ventures beyond Earth where forementioned constraints are further stressed.

Here, to highlight these opportunities where bio-based materials such as cellulose can meet resource constraints challenges for sustainable development on Earth while drawing parallels to similar challenges when establishing sustained human presence beyond Earth, this article presents both preliminary findings of a cellulose-based material solution on Earth as a concrete example and discusses the path for a cellulose-based material solutions to bridge the gap for extra-terrestrial applications.

As a natural source of pure cellulose without requiring intensive chemical post-treatment for contaminant removals like its lignocellulosic counterparts, bacteria cellulose was used to form composites with inorganic elements such as zinc metals, whose use has largely been defined by high energy processes. Due to the high-water holding capacity of bacterial cellulose, the evaporation water drastically reduced volume of composite from wet to dry state, agglomerating zinc particles into a basic functional anode. As a fully water based cellulosic composite, an assembled zinc ion battery sustained a steady columbic efficiency for nearly 50 cycles. While not ideal without further optimization at this stage, it points the way forward to a more sustainable battery anode. In addition, for applications in other types of battery such as lithium-ion battery, metallic oxides such as zinc-oxide can be precipitated and calcinated within bacterial cellulose pellicle. The presence of zinc-oxide was observed through Scanning Electron Microscopy and verified by X-ray Diffraction to be dispersed within the mesh composite.
From the standpoint of sustainable, alternative cellulose material production without reliance on lignocellulosic resources, regionalized production of pure cellulose could be obtained for land scarce nations without dedicated forestry. Furthermore, as a product of microbial fermentation, industrial waste sugar could be used in its culturing; diversifying feed stock components for production and closing the loop for organic industrial waste. Beyond Earth, any

artificial ecosystem enabling sustained human presence requires organic food resources and produces organic waste. This allows for cellulose and chitin to be extracted from bio converters, heterotrophs and microbial fermentation; laying down the basic materials needed for composites made with in-situ materials.

EN09.03.29
Decarbonization of Chemical Manufacturing Using a Membrane Reactor Mia Stankovic and Curtis Berlinguette; The University of British Columbia, Canada

Membrane reactors use electricity and water to drive hydrogenation reactions without H_2 gas. In these reactors, a palladium membrane physically separates the site of electrochemical hydrogen formation from the site of chemical hydrogenation. This separation broadens the scope of reaction conditions (e.g., solvents) that can be studied and simplifies reagent handling and purification compared to existing electrochemical hydrogenation methods. We leveraged this feature of the membrane reactor to demonstrate the industrially-relevant hydrogenation of furfural (an important biomass derivative) into furfuryl alcohol (84% selectivity) and tetrahydrofurfuryl alcohol (98% selectivity). To achieve these selectivities, we designed and built a novel membrane reactor design that enabled high-throughput testing of combinations of solvents, catalysts (identities and thicknesses), and applied currents. One key finding was that employing bulky solvents with weak nucleophilicity suppressed side product formation to enable these high selectivities. These solvents are not compatible with conventional electrochemical hydrogenation, but they are compatible with the membrane reactor. This work highlights the utility of the membrane reactor for selective furfural hydrogenation without H2 gas, and presents the opportunity to decarbonize a >350,000 ton/year hydrogenation industry.

EN09.03.30
Wood Template-Supported Phase Change Materials Composites for Durable and Form-Stable Thermal Energy Storage Shuang Cui[1,2]; [1]The University of Texas at Dallas, United States; [2]National Renewable Energy Laboratory, United States

To reduce building energy consumption, phase change materials (PCMs) with high transition enthalpies and transition temperatures close to the thermal comfort of humans are desirable for thermal energy storage (TES) in building envelope applications. But traditional high-enthalpy solid-to-liquid PCMs suffer from leakage issues during thermal cycling and thus require encapsulation to be form-stable, which reduces the effective transition enthalpy. Polyethylene glycol (PEG) is a compatible PCM with wood templates (WT). Still, we show that with just PEG infiltrated into the wood, 30 wt% of PEG is stored within wood before detectable phase changes occur, indicating inefficiency of PCM usage. We developed a method to (1) improve the leakage stability of balsa and pine composites (BWT+PCMs and PWT+PCMs) under isothermal conditioning for one month at 50 °C and (2) reduce the inefficiency of the unused PCM within the composites to 10 wt% by incorporating a cross-linkable polymer (<10 wt%). These composites exhibit transition properties as high as 114.2 J/g at 25.4 °C, exhibit no shift in properties after 1000 thermal cycles and retain flexural strengths comparable to the raw balsa and pine wood. Our shape-stabilized WT+PCM composites enrich the functionality of wood materials as both ideal TES material candidates and building construction materials.

EN09.03.31
High-Throughput Coating with Biodegradable Anti-Microbial Pullulan Fibres Extends Shelf-Life and Reduces Weight Loss in an Avocado Model Huibin Chang[1], Jie Xu[1], Luke Macqueen[1], Zeynep Aytac[1], Michael Peters[1], John Zimmerman[1], Tao Xu[1], Philip Demokritou[1,2] and Kevin K. Parker[1]; [1]Harvard University, United States; [2]Rutgers, The State University of New Jersey, United States

Food waste and food safety motivate the need for improved food packaging solutions. However, current films/coatings addressing these issues are often limited by inefficient release dynamics that require large quantities of active ingredients. Here we developed antimicrobial pullulan fiber (APF)-based packaging that is biodegradable and capable of wrapping food substrates, increasing their longevity and enhancing their safety. APFs were spun using a high-throughput system, termed focused rotary jet spinning (FRJS), with water as the only solvent, allowing the incorporation of naturally derived antimicrobial agents. Using avocados as a representative example, we demonstrate that APF-coated samples had their shelf life extended by inhibited proliferation of natural microflora and lost less weight than uncoated control samples. This work shows that FRJS is a promising technique to produce scalable, low-cost, and environmentally friendly biodegradable antimicrobial packaging systems.

EN09.03.32
Life Cycle Assessment of Metal Recovery from Perovskite Solar Cells Emma L. McCalmont, Jon Kellar, Brett Carlson, Tanner Y. O'Hara, Achyuth Ravilla, Gonzalo Rodriguez Garcia and Ilke Celik; South Dakota School of Mines, United States

Perovskite photovoltaic (PVs) cells have created a significant interest over the last few years due to their low-cost and high-power conversion efficiencies. However, the environmental performance of perovskite PV technology can be improved if its material components can be reused. In this study, we focused on the environmental life cycle assessment of recovering metals such as lead, copper, gold, nickel, and silver from the end-of-life perovskite PVs. We assessed the recovered metal efficiencies in the reusing process, determining if recovering and recycling the metals is more sustainable than extracting raw materials. We also focused on the life cycle costing to find ways we can optimize the recovery of these materials and determine the most economically feasible way to separate the cell layer-by-layer. For extracting the back contact material two methods were assessed, physical and chemical. The physical extraction method uses an adhesive to recover the back contact layer while the chemical extraction method uses chlorobenzene, the cost of these processes is no more than \$64.00 per 1 m^2 of perovskite PV module.

EN09.03.34
Fracture And Fatigue Behavior of Self-Organized Mycelium Nanocomposites— Structure and Mechanical Properties Precious O. Etinosa and Wole Soboyejo; Worcester Polytechnic Institute, United States

The flexural strength, fracture toughness, fatigue behavior, and resistance-curve behavior of bioprocessed mycelium nanocomposites reinforced with self-organized cellulosic fibers were examined in a combined experimental and analytical study. The bioprocessed mycelium nanocomposite blocks were composed of cellulose/hemicellulose hemp-duct with optimized laterite percentage compositions. The compositional dependence of the flexural strength, fracture toughness, and fatigue on different volume fractions of the composite constituents was explored using crack-tip shielding models; small- and large-scale bridging models. The underlying crack-microstructure interactions with the resistance-curve behavior experiments were examined through *in-situ/ex-situ* optical microscopy. The microscopy studies revealed clear evidence of crack bridging by the hemp fibers transverse to the crack propagation. Simulation results from the crack bridging models were shown to be consistent with the experimental data of the resistance-curve behavior. The structural implications of the results are then discussed to provide valuable insights into the design of mycelium biocomposites for potential applications in eco-friendly and sustainable buildings.

EN09.03.35

Active, Selective, and Stable COPROX Catalysts Based on Ceria Aerogel–Supported Cu Nanoparticles Debra R. Rolison, Travis G. Novak, Paul DeSario, Todd H. Brintlinger, Ryan H. DeBlock and Jeffrey W. Long; U.S. Naval Research Laboratory, United States

The size comparability of the networked, covalently bonded nanoparticles (NPs) that define aerogel architectures and the catalytic NPs supported thereon permits a degree of interfacial intimacy uncommon in heterogeneous catalysis. We find that reducing oxide aerogels such as titania and ceria control the catalytically active chemical state of Ni and Cu catalysts at low weight loadings (<5 wt.%) to thermally oxidize CO with high activity and on-stream durability. This morphologically and chemically resilient arrangement of reducing oxide NPs and metal NP yields high activity (mol of product per second per mol of catalyst), low values of T_{50} (temperature of 50% CO conversion), and persistent activity in the presence of gas-phase water. We now show that Cu NPs photodeposited on ceria or gadolinium-substituted ceria aerogels preferentially oxidize CO in H_2-rich feedstreams, a critical reaction to purify H_2 for use in proton-exchange membrane fuel cells. The catalysts convert >95% of CO with >95% selectivity vs. H_2 and maintain this unprecedented activity for >16 h at 100°C in dry or humidified feedstreams.

EN09.03.36
Developing Fire-Retardant Green Materials For Sustainable Housing Michael Difrieri, Joseph Avalos, Jeanette Cobian-Iñiguez and Lilian P. Davila; University of California, Merced, United States

As human civilization continues to expand, numerous unsustainable resources are exceedingly consumed to satisfy the population's growth needs. To counteract some of the undesirable effects on the environment, researchers are using different approaches to address the challenges related to the fabrication of sustainable housing materials (e.g., reproducibility, reliability, and use of renewable materials) while reducing the carbon footprint arising from the housing industry. Despite current efforts, there are still fundamental limitations in the current fabrication methods of housing materials. To solve those challenges, we have produced a novel waste-derived material (e.g., wood-based insulating material, in combination with ceramic binding agents) to create green materials of varied dimensions for housing applications. This new green material can lead to high-strength load-bearing house components (e.g., walls) and robust weather- and fire-resistant components (e.g., sidings, fences), where burning is not required in the molding process during sample preparation. In this study, we are investigating the fire-retardant properties and structural characteristics of our green material with a biogel coating additive. We have investigated the effect of the biogel coating on our samples using materials characterization techniques (e.g., scanning electron microscopy, SEM) and fire experiments. We have previously evaluated ecological traits (e.g., energy, CO_2 footprint) of the new green material using life-cycle assessment (LCA). Here, we also investigate the effect of biogel coated green samples on the environment via LCA. The hypothesis is that by modifying the biogel coating composition, the impact on the environment could be further decreased. Overall results from this study are in good agreement with recent experiments reported elsewhere independently, and mechanical verification (e.g., fire tests) together with LCA data of the new green material are significant in determining sustainable alternatives compared to other counterparts. This research contributes to improving material discovery by the combination of recyclable sustainable materials, design, low-energy processing methods, fire testing, and LCA evaluation, which allows to define the technical and commercial feasibility of low-cost and sustainable house components.

SESSION EN09.04/SB02.04: Joint Session I: Nanocellulose-Based Materials

Mechanisms Underpinning the Mechanical Properties of Lignocellulose-Based Materials Teng Li; University of Maryland, United States

The natural abundance and exceptional intrinsic mechanical properties of cellulose have motivated surging interests in developing lignocellulose-based materials of high performance. Enthusiastic aside, there exist large variations of the mechanical properties of lignocellulose-based materials, far from exhausting the intrinsic potential of cellulose, which essentially result from the lack of mechanistic understanding of the property-governing parameters. This talk discusses the key mechanisms that underpin the mechanical properties of lignocellulose-based materials, with particular focus on those that govern the strength, toughness, as well as flaw sensitivity of lignocellulose-based materials. Such mechanistic understandings shed light on designing lignocellulose-based materials with desirable mechanical properties.

9:00 AM *EN09.04/SB02.04.02
Bioinspired Anisotropic and Multifunctional Nanocellulose Gels Gustav Nyström[1,2]; [1]Empa, Switzerland; [2]ETH Zürich, Switzerland

Nanocellulose represents an important class of sustainable biocolloids that has shown great potential for use in e.g. high strength, optically responsive and thermal insulating materials. To maximize the inherent potential of these colloids in materials requires however a well-controlled organization of the nanocellulose particles across the length scales. In the first part of this talk I will discuss anisotropic structuring of nanocellulose in gels and show examples of how this can be used to control actuation and shape morphing in hydrogels and optimize directional thermal properties including superinsulation in aerogels. In addition to structuring and controlled nanocellulose assembly, the formation of biological, chemical and physical cellulose biohybrid materials has the potential to significantly expand the functionality and application space of these materials. In the second part of this talk I will focus on cellulose biohybrids where at least one other conductive nanomaterial component (e.g. MXenes or carbon nanotubes) has been added to the system and show how this can render multifunctional materials including mechanical sensing hydrogels with dual optical and resistive readout, aerogels with optical birefringence and hydrogels with bioinspired structural colors.

Structure-Properties Relations in Reinforced Fibrous Materials—Strength, Toughness and Non-Linear Deformation Catalin R. Picu, Mithun Dey and Shengguang Jin; Rensselaer Polytechnic Institute, United States

Most cellulose products are network materials, that is their mechanical function is provided by a network of fibers. The strength, toughness and mechanical behavior of these materials are of obvious importance during processing and in service. Therefore, it is of interest to establish design methodologies that ensure enhanced properties, based on a fundamental understanding of how the material structure controls mechanical properties in stochastic networks. Establishing such relations is the overarching goal of this work. We focus on reinforced networks, i.e. networks embedded in soft matrix and networks with

particulate or reinforcing fiber additives. We explore by computational means the relation between various structural parameters (network density, fiber orientation, fiber properties and their distribution, flocculation), reinforcement characteristics (reinforcement density and distribution) and the strength, toughness and non-linear deformation of such materials. The talk will outline ways to obtain exceptional properties with minimal amount of reinforcement. These relations can be used in design to develop network materials and, in particular, cellulose-based materials, with exceptional combinations of properties .

Hairy Cellulose Nanocrystals—Fundamentals and Emerging Applications Amir Sheikhi; The Pennsylvania State University, United States

For decades, cellulose nanocrystals (CNCs) have been produced by hydrolyzing the disordered (amorphous) regions of cellulose fibrils. These colloidal particles comprise highly ordered arrays of cellulose chains, impeding the physicochemical modifications of inner crystalline layers, which in turn results in limited/compromised dispersion stability, functionalizability and charge, response to external fields, and transport. Nanoengineering cellulose fibrils via controlled oxidation reactions can partially disintegrate the disordered cellulose chains attached to the crystalline body, which yields patchy nanoparticles with a needle-shaped crystalline body (similar to CNCs) attached to two highly functionalized disordered cellulose regions (hairs). This newly emerged class of nanocelluloses are called hairy cellulose nanocrystals (HCNC). The protruding soft brushes from HCNC poles impart significant modifications to the colloidal properties of HCNCs, enhancing their functionality, charge density, stability, and self-assembly. In this presentation, we will discuss our recent progress in understanding the fundamental properties of HCNCs produced from a range of lignocellulosic sources and engineering them for advanced applications, such as rare-earth element recovery, biodetoxification, and functional hydrogels. We will show how HCNCs enable several technologies that would otherwise be non-trivial to develop using conventional CNCs. The outcome of our research may leverage universal biomass-based sustainable solutions for several long-lasting industrial challenges in water and healthcare sectors.

10:45 AM EN09.04/SB02.04.05
Advancing Renewable Barrier Packaging with Lignocellulosic and Chitinous Biomaterials Yue Ji[1], Yang Lu[1], Greg Schueneman[2], Meisha Shofner[1] and Carson Meredith[1,1]; [1]Georgia Institute of Technology, United States; [2]US Forest Products Laboratory, United States

There is strong interest in the introduction of renewable sources of packaging into global society. In particular, flexible barrier packaging and coatings are of interest due to their prevalence in the supply chain, e.g., at least 40% of all packaging is nonrenewable/nonrecycled flexible plastic. Forest-derived cellulose nanocrystals (CNCs) are a promising renewable source, and have been shown to be coatable as films with high oxygen barrier properties. Generally, CNCs are derived by acid hydrolysis processing that leaves pendant sulfate groups, imparting negative charge in aqueous media. Recent work in our group has shown that combining anionic CNCs with renewably sourced cationic nanofibers is a promising approach to developing manufacturable barrier films. Notably, chitin nanofibers (ChNFs) and nanowhiskers (ChNWs), which can be derived from renewable sources including crustacean food waste and fungi, are cationic and form complexes with CNCs that lead to dense barrier films. This talk describes recent innovations in optimizing the synergy between ChNWs and CNCs through careful tuning of the ChNW density and length. We find that optimal deacetylation of the ChNWs leads to formation of layered ChNW/CNC structures with oxygen permeability lower than poly(ethylene terephthalate) (PET), and blended ChNW/CNC structures that have permeability near poly(ethylene-co-vinyl alcohol) (EVOH). We also explore the use of thermal treatment and deposition temperature to further improve the film structures. These bilayers and blends have been applied to a variety of renewable and biodegradable substrates, such as poly(lactic acid) (PLA) and cellulose acetate (CA), as well as recyclable films like poly(ethylene terephthalate) (PET). We will discuss methods to improve the water vapor transport rates of these materials that include thermal and chemical treatments, as well as substrate pairing. Finally, we will discuss data that illustrate the biodegradability of these structures and the potential for recycling and upcycling.

11:00 AM EN09.04/SB02.04.06
Solid-State Adsorption as a Means to Modify Lignocellulosic Surfaces Eero Kontturi[1], Wenyang Xu[2], Ruige Qi[1] and Panagiotis Spiliopoulos[3]; [1]Aalto University, Finland; [2]Abo Akademi University, Finland; [3]Chalmers University of Technology, Sweden

Modifying lignocellulosic surfaces can often be difficult. The modification routes may require special synthetic skills and/or environmentally hazardous chemicals, and their scalability can be questionable. Furthermore, particularly the covalent modification of nanocellulose particles can impair hydrogen bonding in the eventual nanocellulose networks. Here, we demonstrate a conceptually new method for modifying lignocellulosic surfaces by solid-state adsorption of thermoplastic polymers. A thin, so-called Guiselin layer forms on a substrate when a thicker polymer layer is heated above its glass transition temperature or melting point. When the excess polymer is removed by rinsing with a good solvent, the Guiselin layer (usually of 1-10 nm thickness) stays on the surface. This layer has a substantially higher coverage and it is attached more firmly than an adsorbed polymer layer that has been cast by conventional adsorption from a solution. We demonstrate how Guiselin layers of polystyrene and poly(lactic acid) can be applied to simple hydrophobation of a number of different lignocellulosic surfaces: ultrathin cellulose films, cellulose nanopaper, ordinary paper, and wood chips. However, this approach is not limited to mere hydrophobation as virtually any soluble thermoplastic polymer can be applied to Guiselin layer deposition, given that its glass transition temperature or melting point is below the thermal decomposition temperature of cellulose. This includes, for example, certain semi-conducting or responsive polymers that can be combined especially with the recently emerged nanocellulosic substrates by a unique technology.

11:15 AM EN09.04/SB02.04.07
High-Performance Biobased Nanocellulose and Chitin-Based 3D Printing Materials and Smart Coatings Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Biobased and renewable feedstocks or derived natural materials for direct utilization (little conversion or synthetic procedures) have been of high interest in materials chemistry. This can be derived from agro-waste or harvested high fiber content grass (Miscanthus) or from shrimp-shell waste polysaccharides. Moreover, the use of 3D printing and additive manufacturing has opened up a host of possibilities for bio-inspired materials development. In this regard, the preparation of cellulose nanocrystals (CNC) and cellulose nanofibers (CNF) for polymer nanocomposites is useful as an additive for improving thermo-mechanical properties and improved processability. In this talk, we will focus on the use of polysaccharides and CNC derived from two classes of sources: 1) high fiber and alpha-structure miscanthus grass, Abaca, and coconut fibers. 2) chitosan-derived polysaccharide complexes and CNC. The mode of raw materials can be from processed pulp or directly from coconut coir or agro-waste. These nanofiller materials have been utilized in two types of applications: nanofiller materials for 3D printed parts via stereolithographic apparatus (SLA) and the preparation of smart aerogels and coatings. Chitosan nanomaterials derived from chitin have advantages in terms of functional group interaction with electrostatic charge pairing to form soluble complexes. LIkewise in SLA 3D Printing, enable improved biocompatibility and complex materials-design development for biomedical applications. The talk will focus on materials development for 3D printing and coatings and discuss the methods of synthesis, fabrication, and characterization for their specific intended applications.

11:30 AM EN09.04/SB02.04.08
Plant-Derived Nanocellulose as Structural and Mechanical Reinforcement of Freeze-Cast Chitosan Scaffolds for Biomedical Applications Kaiyang Yin[1,2,3], Prajan Divakar[3] and Ulrike G. Wegst[2,3]; [1]University of Freiburg, Germany; [2]Northeastern University, United States; [3]Dartmouth College, United States

Despite considerable recent interest in micro- and nanofibrillated cellulose as constituents of lightweight structures and scaffolds for applications that range from thermal insulation to filtration, few systematic studies have been reported to date on structure–property-processing correlations in freeze-cast chitosan–nanocellulose composite scaffolds, in general, and their application in tissue regeneration, in particular. Reported in this study are the effects of the addition of plant-derived nanocellulose fibrils (CNF), crystals (CNCs), or a blend of the two (CNB) to the biopolymer chitosan on the structure and properties of the resulting composites. Chitosan–nanocellulose composite scaffolds were freeze-cast at 10 and 1 °C/min, and their microstructures were quantified in both the dry and fully hydrated states using scanning electron and confocal microscopy, respectively. The modulus, yield strength, and toughness (work to 60% strain) were determined in compression parallel and the modulus also perpendicular to the freezing direction to quantify anisotropy. Observed were the preferential alignments of CNCs and/or fibrils parallel to the freezing direction. Additionally, observed was the self-assembly of the nanocellulose into microstruts and microbridges between adjacent cell walls (lamellae), features that affected the mechanical properties of the scaffolds. When freeze-cast at 1 °C/min, chitosan–CNF scaffolds had the highest modulus, yield strength, toughness, and smallest anisotropy ratio, followed by chitosan and the composites made with the nanocellulose blend, and that with crystalline cellulose. These results illustrate that the nanocellulose additions homogenize the mechanical properties of the scaffold through cell-wall material self-assembly, on the one hand, and add architectural features such as bridges and pillars, on the other. The latter transfer loads and enable the scaffolds to resist deformation also perpendicular to the freezing direction. The observed property profile and the materials' proven biocompatibility highlight the promise of chitosan–nanocellulose composites for a large range of applications, including those for biomedical implants and devices, as is briefly illustrated with examples and outcomes of first in vivo studies.

Design of Advanced Filaments from Cellulose Nanofibrils Using a Coaxial Spinning Strategy Lars Wagberg and Michael Reid; KTH, Sweden

The use of flow-focusing for the preparation of filaments from Cellulose I fibrils has allowed for the preparation of ultrastrong, continuous fibres with excellent wet-strength (1). By applying careful hydrodynamic alignment of the fibrils in combination with a colloidal control and locking of the oriented state it is possible to, almost, fully utilize the excellent inherent properties of the CNFs (Cellulose Nano Fibrils). It has also been shown that it is possible to use a simpler, coaxial set-up to prepare oriented filaments where the coaxial alignment also allows for the preparation of interactive filaments using a combination of CNFs and for example Carbon Nano Tubes (CNTs) (2). In this work (2) a core-shell structure was produced where the active components were assembled in a thin layer outside a core of CNFs. In the present work the coaxial spinning strategy has been further expanded by using a coaxial spinning equipment with three channels allowing for the preparation of even more advanced structures. With this set-up it has been possible to prepare filaments containing an external thin layer of high-quality CNFs encapsulating core materials with dimensions from the nano-scale to the macroscale. In this way is has been possible to form filaments containing gases, conductive polymers, nanoparticles and macroscopic fibres modified to meet certain end-use properties. The details behind the preparation of the filaments and the final filaments properties will be discussed.

2:15 PM EN09.05/SB02.05.02
Charge Control on the Surface of Ionic Cellulose Nanocrystal for the Stable Pickering Encapsulation Jonghyun Shin and Jinho Hyun; Seoul national university, Korea (the Republic of)

The charge of surface-active particles is one of the critical factors in Pickering emulsion. It is difficult for charged surfactant particles to form emulsion droplets due to the repulsive force of Coulomb's law against oils with high polarity. In order to form stable emulsion droplets and introduce thermodynamically stable colloidal dispersion between droplets, it is necessary to control the charge of the surface-active materials. Here, we present the CNC surface modification method for controlling charge density from high to low and its effect on the stabilization of Pickering emulsion. The sulfated cellulose nanocrystal (S-CNC) was hydrolyzed with sulfuric acid, and the S-CNC was desulfated with hydrochloric acid at different reaction times to observe the surface charge effect of CNCs on the Pickering encapsulation. In desulfation, we used a low concentration of hydrochloric acid, which does not affect the morphologies of CNCs. Then, the morphologies and surface properties of CNCs were analyzed by TEM, AFM, conductometric assay, zeta potential, FT-IR, and XRD. As a result, the ionic groups on the S-CNCs were successfully substituted for the non-ionic groups without changing CNCs' length and crystal size. After preparing CNCs, to understand the surface effect of CNCs on Pickering encapsulation, we chose n-decane, n-dodecane, n-tetradecane, and n-hexadecane as non-polar oils and chloroform and 1-octanol as polar oils. The stability of Pickering emulsion was evaluated by emulsion phase stability, surface tension, emulsion droplet size, and zeta potential. The dS-CNCs desulfated for 30 h formed small emulsion droplets with high stability for long-term storage. CNCs are potential emulsifiers based on particles. It is critical to control the surface chemistry of CNCs to form a stable Pickering emulsion of oils. These results will find potential utility in pharmaceutical, cosmetic, agriculture, food chemistry, and other related fields.

2:30 PM EN09.05/SB02.05.04
Lignocellulosic Materials in 3D Printing—From Biomedical Applications to Metal Parts Fabrication Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Lignocellulosic-based feedstocks are renewable natural materials that are of high interest in materials chemistry for manufacturing. As polysaccharides, their ability to complex with surfactants or metal ions are derived from some of their ligand function and the presence of hydroxyl and carboxylic groups.

Thir use of 3D printing has gained ground as both additive and host matrix and gel materials. In this talk, we will focus on the use of lignocellulosic-based polysaccharides isolated from pulp or directly from the raw fiber: 1) polysaccharide complexes and nano cellulose in SLA 3D printing, and 2) Host hydrogels for metal 3D printing. SEM, X-ray, and tensile-compression properties as 3D printed parts were investigated. Their advantages for improved thermo-mechanical properties and biomedical applications will be evident.

2:45 PM DISCUSSION TIME

3:00 PM BREAK

3:30 PM *EN09.05/SB02.05.05
Comparative Study of Lignocellulosic Nanomaterials Production from Different Heterogeneous Waste Feedstocks Renata Bura, Danielle U. Pascoli, Anthony Dichiara, Richard Gustafson and Eleftheria Roumeli; University of Washington, United States

Nanocellulose products may be produced from various heterogeneous waste feedstocks such as agricultural residues, invasive plant species, and other low-cost lignocellulosic biomass, providing economic and sustainability advantages related to the conventional bleached wood pulp feedstock. However, for this to become a reality on a large scale, robust conversion processes that accommodates such heterogeneous feedstocks must be developed. In this study, four different heterogeneous waste feedstocks were utilized (wheat straw, corn stover, reed canary grass, and industrial hemp) to assess the robustness of a novel conversion process previously developed by our group to make lignocellulosic nanomaterials. In our process we utilize inexpensive lignocellulosic feedstock and mild peracetic acid (PAA) pretreatment to produce lignocellulosic nanomaterials (nano and microfibrils) with potential bioplastics applications. PAA was chosen due to its biodegradability, non-toxicity, and high reaction selectivity.

Lignocellulosic nanofibrils (LCNF) and microfibrils (LCMF) were successfully produced from all biomass feedstocks tested, but the original biomass's chemical and physical characteristics influenced the final nanomaterials' properties. The chemical composition and nature of the initial feedstock showed a direct effect on the total mass yields during the process as well as on the surface charge of the final nanomaterials. In addition, the physical characteristics of the feedstock affected the degree of delignification during the reactions, producing materials with different residual lignin contents. This work has demonstrated the successful production of nanomaterials from various low-cost waste feedstocks, advocating for the large-scale production of nanocellulose products in the United States.

4:00 PM DISCUSSION TIME

4:30 PM EN09.05/SB02.05.07
Using Light Scattering to Measure Aggregation of Cellulose Nanomaterials Nayomi Z. Plaza and Carl Houtman; USDA-FS Forest Products Laboratory, United States

As cellulose nanocrystals (CNC) and cellulose nanofibrils (CNF) move to commercial products, simple methods for doing quality control to assess their size, stability and/or dispersion are required. Irreversible aggregation during drying continues to limit the wider commercialization potential of these nanomaterials. If one desires fully dispersed materials, one typically ships slurries, which are 10% solids for CNCs and 1% solids for CNFs. Understanding what governs aggregation and developing simple methods to assess the aggregation state of CNCs and CNFs is essential. We are using a combination of dynamic light scattering (DLS), multiangle static light scattering (MASLS), and small angle light scattering (SALS) to characterize the size (from 5 nm to over 300 nm) and solution behavior of CNC and CNF solutions. SALS is proving to be ideal for identifying aggregates in solution. Moreover, SALS is also being used to measure film products containing cellulose nanomaterials. The scattering of light is proving to be a convenient way to determine the size of the embedded nanomaterials as well as their alignment and dispersion.

4:45 PM EN09.05/SB02.05.08
High Performance Wood Scroll Evaporator for All-Day Evaporation in Saline Water Bokyeong Sohn, Hyunsoo Han, Sangmin Jeon and Minjae Song; Pohang University of Science and Technology, Korea (the Republic of)

A novel all-day evaporator in the form of a scroll is developed by rolling a thin layer of wood. Two different wood layers are used to fabricate a wood scroll with diagonal natural water channels (d-WS) and a wood scroll with parallel natural water channels (p-WS). Vertical water transport through gap channels (i.e., spaces between the overlapping wood layers) is >10 times higher than that through natural water channels. Because only diagonal channels allow water transport across the wood layer, d-WS exhibits good lateral water transport whereas p-WS exhibits poor lateral water transport. The synergistic effect of the gap channels and diagonal channels in d-WS increases evaporation performance. The total evaporation rate of water of d-WS is 9.08 kg m^{-2} h^{-1} in the absence of wind, which increases to 37.95 kg m^{-2} h^{-1} in the presence of 2 m/s wind. These evaporation rates are among the highest values ever reported under similar conditions. Furthermore, the difference between the evaporation rates of p-WS and d-WS increases with height. The higher evaporation rate of d-WS is attributed to the presence of diagonal channels, which enhances lateral water transport to the outermost surface, where dark evaporation occurs. The difference in lateral water transport affects not only the dark evaporation rate but also salt resistance. The evaporation experiments are conducted in a 3.5 wt% NaCl solution under 1 sun illumination. No salt is observed on the top surface of p-WS, but a significant amount of salt is accumulated on the side surface, indicating that the gap channels facilitate sufficient water supply to the top surface, but the microchannels alone fail to supply sufficient water to the side surface. Interestingly, no salt accumulation is observed on both the top and side surfaces of d-WS. The excellent salt resistance of d-WS is attributed to the synergy between its gap channels and diagonal channels, which enables sufficient water supply to the top and side surfaces. The evaporation rate of d-WS does not deteriorate even after 5 days, demonstrating the possibility of long-term operation.

Sustainable Synthesis of Spider Silk and Other Biopolymers via Photosynthesis Keiji Numata[1,2]; [1]RIKEN Institute, Japan; [2]Kyoto University, Japan

In nature, high-performance biological polymers and composites consist of various organisms and their tissues. Those high-performance biopolymers are

mainly protein/polypeptide, and have therefore been recognized as bioactive and functional material. My research group also reported new findings in spider silk spinning, which is important to design tough structural polymers. However, use of those biopolymers as structural materials is still challenging due to several technical issues. One of the major drawbacks of polypeptide-based materials is their limited synthesis method. To clear the potential issue, my research group is interested in marine purple photosynthetic bacteria as ideal organisms and platforms for production of useful materials to reduce production costs and to contribute sustainable society, because they can utilize sun energy, seawater and carbon dioxide and nitrogen gas in the air for their growth. My research group studies on the photosynthetic bacteria to produce spider silk-like polymers. *Rhodovulum sulfidophilum*, a marine purple non-sulfur photosynthetic bacterium as well as a good polyhydroxyalkanoate (PHA) producer, was genetically engineered for the production of synthetic spider dragline silk protein. The successful construction of photosynthetic microbial host for silk production could reduce the production cost, especially the marine photosynthetic bacteria can fix CO2 and N2 with using seawater as a cheap culture medium. To establish the fundamental platforms for photosynthetic bacterial technology, we are currently developing peptide-mediated transformation and protein introduction methods for alga and photosynthetic bacteria. These new methodologies will be able to support the high-throughput characterizations for biopolymer productions.

9:00 AM *EN09.06.02
Modulating the Properties of Functional Biocomposites with Engineered Bacterial Protein Fibers Noemie-Manuelle Dorval Courchesne; McGill University, Canada

Protein-based materials can be genetically customized for a range of applications. In addition to displaying biocompatibility, tunable bioactivity and responsiveness, they represent sustainable alternatives to conventional synthetic polymers. In particular, proteins that self-assemble into higher order structures and can be produced at large scale are of interest for deployment into wearable devices and alternatives for commodity materials like plastics, textiles and electronics. Curli fibers produced as part of the extracellular matrix of *Escherichia coli* bacteria represent a promising protein scaffold, due to their unique physicochemical properties, including their ability to self-repair and their resistance to harsh conditions. Once secreted by bacterial cells, CsgA subunits, the self-assembling repeats of curli fibers, form fibrous structures that can further aggregate, entangle, and gel into macroscopic materials. Among other functionalities, we have genetically encoded in CsgA the ability to fluoresce, to conduct charges, and to respond to stimuli.

Here, I will present an overview of advances that we have made to engineer biocomposite materials containing functional curli fibers. The fibers allow to modulate the mechanical, electrical, self-healing and sensing properties of the composites. First, I will highlight the scalable and simple bioprocesses that we have developed to express, extracellularly secrete, and isolate genetically engineered curli fibers. Then, I will present two main applications of biofunctionalized composites: 1) a curli fiber – conductive polymer composite that exhibits self-healing properties and tunable electrical conductivity dependent on the protein content, and 2) a “living” self-repairing biofilm-based textile in which the curli fibers part of the biofilm’s extracellular matrix act as glue to repair the textile via a water-induced healing mechanism. So far, we have applied curli-functionalized textiles to the fabrication of sweat pH sensors and we foresee several applications of curli-based composites for wearable devices and biocompatible electrodes. These devices enable novel functions that can only be achieved by biological materials, and bring us closer to a bio-based economy.

9:30 AM DISCUSSION TIME

9:45 AM EN09.06.04
Amyloid-Nanocellulose Interactions and Self-Assembly Nico Kummer[1,2], Caroline E. Giacomin[2], Peter Fischer[2], Silvia Campioni[1] and Gustav Nyström[1,2]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland

Amyloid fibrils from abundant and inexpensive food proteins and nanocellulose in the form of cellulose nanocrystals (CNCs) and nanofibrils (CNFs) are renewable and biodegradable materials with broad ranging applications in water purification, for biomedical engineering and as bioplastics. To increase the mechanical and functional properties of hybrid amyloid-nanocellulose materials, the fundamental understanding of the interactions between the two colloids needs to be improved. Using zeta potential measurements, rheology and atomic force microscopy all experimental evidence point to the importance of electrostatic interactions. We found that entropy-driven polyelectrolyte complexation occurred under pH conditions where the amyloids and nanocellulose particles are oppositely charged, whereas stable co-dispersions are possible above the isoelectric point of the amyloid fibrils, when both amyloids and nanocellulose are negatively charged.
During the polyelectrolyte complexation, the addition of CNCs proportionally increased the elasticity by crosslinking individual fibrils of the hen egg white lysozyme (HEWL) amyloid network. The scaling of the elasticity with amyloid concentration cross-linked with a fixed concentration of CNCs is in agreement with theory (affine thermal model). Finally, strong, transparent hybrid amyloid-nanocellulose hydrogels were fabricated using amyloids from HEWL and beta-lactoglobulin (BLG). The self-assembly was started from stable amyloid-nanocellulose co-dispersions above the isoelectric point of the amyloids and followed by dialysis to decrease the pH and induce amyloid-nanocellulose attraction and cross-linking. In summary, the gained knowledge on colloidal interactions provides an important basis for the design of functional biohybrid materials based on amyloid fibrils and nanocellulose.

10:00 AM BREAK

10:30 AM *EN09.06.05
Green Products for the Red Planet—Sustainable Materials for Human Exploration Lynn J. Rothschild[1,2], Ivan Paulino-Lima[3], Simon Vecchioni[4] and Christopher Maurer[5]; [1]NASA, United States; [2]Brown University, United States; [3]Blue Marble Space Institute Science, United States; [4]New York University, United States; [5]Redhouse Studios, United States

Synthetic biology – creating new capabilities with life – promises to create a greener future for planet Earth, from fields as diverse as pharmaceuticals to manufacturing, agriculture and nanotechnology. Progress can be stymied by such considerations as economics, politics, legal and philosophical issues surrounding GMOs. Often solutions to these problems already exist, so it is difficult for a new, superior method to displace the old. As we move humans beyond Earth, to long duration stays in the International Space Station, and then onward to the Moon and Mars, the challenges of supporting human life will need radical new solutions. For example, while life on Earth uses an enzymatic machinery which evolved over 3.5 billion years ago, synthetic biology promises to be able to engineer the systems to adapt to current natural or industrial environments. A focus on solutions off planet require a focus on a circular economy. While there are new constraints, such as worrying about the mass of a solution, constraints offer opportunities for game-changing solutions that will then allow revolutions back on our home planet. Example projects include biomining and fungal-based habitats off planet.

11:00 AM *EN09.06.06
The Power of Biology to Build-Up and Break-Down Polymeric Materials Hal Alper; The University of Texas at Austin, United States

Biology has an exquisite potential to transform the chemical industry. Advances in strain engineering, synthetic biology, and machine learning are leading to a rapid transformation in the reach and potential of bio-based solutions. Within this scope, biotechnology can enable the production of a diverse suite of customized monomers and polymers. On the other side, biotechnology can enable the depolymerization of used polymers. This talk will highlight the

potential for sustainable materials production and reuse through both cell and enzyme processes. Examples include rewired cells for producing polymer precursors, enzymatic plastic waste depolymerization, and conversion of biologically-derived lipids into thermoset plastics. Throughout the talk, there will be a focus on sustainability and the fundamental principles necessary to rewire metabolism and expedite the design-build-test-learn-deploy cycle of engineering for these applications.

11:30 AM *EN09.06.07
Protein-Based Elastomers as Replacements for Polyurethanes Bradley Olsen, Yiping Cao, Wui Yarn Chan, Emil Andersen and Sarah Av-Ron; Massachusetts Institute of Technology, United States

Proteins are biopolymers widely studied for materials applications due to their abundance as waste feedstock and their structural role in producing high performance materials in biological systems. While greater utilization of proteins in materials can provide a sustainable alternative to petroleum-derived polymers, proteins are generally brittle and have high softening temperatures in the absence of plasticizer, making them unsuitable for many applications. Inspired by the chemical and structural similarity between the hard blocks of polyurethanes and the b-strands of proteins, we hypothesized that natural protein materials could be utilized in polyurethane like hard-soft copolymers in order to overcome these limitations and produce sustainable commodity materials.

Simple bioconjugation strategies allow the preparation of polyfunctional proteins that can be co-polymerized with a wide variety of different monomers to produce thermoset plastics. These materials have variable modulus, toughness, and extensibility depending upon the protein content, degree of protein functionalization, and monomer choice. While hydrophilic monomers were first used to enable facile copolymerization with the protein, this leads to strong humidity-sensitivity. To reduce this effect, we developed formulations based on oleophilic monomers using surfactants to compatibilize the protein and monomer before polymerization. This leads to a two-fold reduction in water uptake while preserving the favorable mechanical performance of the materials. Tuning the surface charge of the protein biomass via chemical reaction was further explored in order to control the humidity sensitivity, leading to further stabilization of mechanical properties across a broad range of environmental conditions. Recently, we have also demonstrated that thermal treatment to induce changes in protein conformation can lead to substantial strengthening of the materials, and that this approach generalizes across a wide range of different protein feedstocks and purities. Overall, this work demonstrates the ability to produce biomass-based materials that can mimic the mechanical response of polyurethanes while simultaneously managing moisture uptake, demonstrating promising steps towards a new sustainable material platform.

Cement Decarbonization Using Photosynthesis Sarah Williams, Danielle Beatty and Wil V. Srubar III; University of Colorado Boulder, United States

The production of portland cement is responsible for 7% of global carbon dioxide (CO_2) emissions. Multiple strategies, including portland cement clinker substitution with supplementary cementitious materials (SCMs) and carbon capture, utilization, and storage (CCUS), are being explored to decarbonize the cement production process. This presentation will highlight recent research that leverages the carbon capture and storage mechanisms of microalgae to decarbonize cement production. In one study, the pozzolanic reactivity of biosilica extracted from photosynthetic diatoms was investigated as an alternative SCM. In a second study, raw algal biomass was investigated as a carbon-storing set-retarding admixture for portland cement. Finally, biogenic calcium carbonate from microalgae was investigated as a potential carbon-storing mineral replacement for ground limestone in portland limestone cement. In addition to these studies, other opportunities for cement decarbonization that leverage the carbon capture and storage mechanisms of microalgae will be highlighted and discussed.

Regenerated Cellulose Structured Materials for Coral Reef Restoration Guillermo A. Reyes[1], Colleen Flanigan[2] and Orlando J. Rojas[1]; [1]Aalto University, Finland; [2]Zoe – A Living Sea Sculpture in Cozumel, Mexico

Regenerated cellulose materials using the ionic liquid, 1-ethyl-3-methylimidazolium acetate ([emim][OAc]), were used to produce filaments and 3D-printed meshes *via* wet spinning and Direct-Ink-Writing (DIW); these structures with highly aligned nanofibrils (wide-angle X-ray scattering) simultaneously displayed extensibility (wet strain as high as 39 %), and tenacities (up to 2.3 cN/dtex). DIW of the respective gels led to meshes with up to 60 % wet stretchability. The IL regenerated structures were demonstrated for reliable performance in marine environments, with prospects of replacing plastic cords and other materials used to restore coral reefs on the coast of Mexico.
Additionally, considering the unique ability of alkali dissolved cellulose to absorb CO_2 at room temperature in a non-catalytic, highly reactive media, here a mineralization process is proposed to produce artificial coral-like supports. The resulting Mineralized Cellulose Material (MCM) exhibits tunable flow properties and a wide range of mechanical properties. The synergistic combination of dissolved cellulose and in-situ mineralized CO_2 into calcium carbonate at different Cellulose: Carbonate ratios allows the production of heterogeneous fluid streams with shear-thinning behavior (viscosities from 10^2 to 10^7 mPa.s; and storage modulus G' ranging from 10 to 10^5 Pa). The CO_2 absorption capacity tracks inversely with cellulose concentration. Two types of MCMs are obtained, the first with low cellulose content, namely MCMl is a dry powder with applications as a flux material for ceramic glazes or cement with porous structures. In contrast, the material with an increased cellulose content, namely MCMh, is a moldable/printable paste that transforms into a tough (stone-like) material after drying. MCMh was tested as an artificial substitute for coral stones in the Gulf of Mexico. LCA results suggest that these technologies bring new opportunities to cellulose and construction industries by removing and utilizing CO_2 emissions for different materials, including the imperative coral reef restoration in the oceans.

Use of Waste Bioproducts as a CO_2 Sink in Sustainable Structural Composites Marcos M. Hernandez, Adalee R. Witt, Yuliia Trujillo, Raul C. Gonzalez Esquer, Babetta L. Marrone and Joseph H. Dumont; Los Alamos National Laboratory, United States

The establishment of a bio-based economy that can compensate for the hundreds of megatons of waste generated annually is vital to the successful utilization of waste as a resource. [1] Upon identifying useful waste streams, bio-manufacturing technologies such as sustainable composite materials can

be developed to offset CO_2 emissions. Biomass offers many advantages such as biosequestration, biomineralization, and improved material properties when integrated into such materials. [2, 3, 4] In this study, we incorporate waste from various biological waste streams into cementitious, pressed, and hydrogel materials to develop sustainable composites for applications as structural materials, 3D printing, and fuel pellets. Samples were prepared and characterized using a wide range of chemical, mechanical, and spectroscopic techniques. From this study, we evaluated the effects of waste biomass in sustainable composites for CO_2 mitigation, reduced construction cost, and waste utilization potential.

High pH and Temperature Tolerant Molecular Mimic of Carbonic Anhydrase for Self-Healing Cementitious Material Rebecca J. Gilchrist, Shuai Wang, Nima Rabhar, Suzanne F. Scarlata and Ronald L. Grimm; Worcester Polytechnic Institute, United States

Carbon storage in concrete was recently reinvigorated by the use of carbonic anhydrase to yield an enzymatic self-healing cementitious material. While this material demonstrates high strength and self-healing properties, the reliance on enzymatic catalysis limits the performance based on the two-week lifetime of carbonic anhydrase, and motivates the exploration of non-biological alternatives. We have explored organometallic carbonic anhydrase mimetic materials with a view towards longevity and performance in the highly alkaline environments of cement as well as the high temperatures to which concrete may be subjected. Inspired by bio-relevant carbonic anhydrase mimetics, results with zinc cyclen (cyclen = 1,4,7,10-tetraazacyclododecane) demonstrate high stability at pH above 13 and temperatures above 50 °C with good conversion of gas-phase carbon dioxide to carbonate. We discuss these results in the context of molecular alternatives for self-healing cementitious material and carbon storage in concrete.

The Influence of Biomineralized Contaminated Waste Plastics in Reinforced Cement Mortar Kylee Rux, Seth Kane, Michael Espinal, Cecily Ryan, Adrienne Phillips and Chelsea Heveran; Montana State University, United States

The demand for cement infrastructure and plastic products are continuously increasing, and the production of these materials generate greenhouse gas emissions. An additional problem is the low recycling rate of plastics — with only 9% of plastics ever produced being recycled. Instead, these waste plastics are accumulating in landfills and the environment. One contributing factor to low plastic recycling rates is that contamination from food waste and oil necessitates treatment steps that may increase the cost and reduce the quality of recycled plastic. Researchers have made headway against these challenges by using waste plastic as reinforcement in cementitious materials. However, increasing the amount of plastic reinforcement leads to a decrease in composite compressive strength. To combat the loss in compressive strength, it may be possible to use microbially induced calcium carbonate precipitation (MICP) to coat waste plastic in calcium carbonate and improve the strength of plastic-reinforced cementitious materials. The objective of our research was to optimize the amount of clean and contaminated waste plastic that can be added to plastic-reinforced mortar and whether MICP coating of waste plastic enhances the strength. The performance of plastic-reinforced mortar cylinders was investigated using compressive strength tests at a 5%, 10%, and 20% volume replacement for cement. Results indicate that even at a 20% replacement with untreated, clean post-use plastics (HDPE, PVC, LDPE1 (larger chips), and LDPE2 (smaller granules)) produced compressive strengths acceptable for several applications such as foundation walls, garages, and sidewalks. A coating of MICP on clean waste plastic did not significantly improve the compressive strength of the specimens. MICP treatment of oil-coated waste plastics (HDPE, LDPE1, and LDPE2) recovered the strength by 28.28% relative to cylinders containing untreated oil-coated plastics, on average. However, washing the same oil-coated plastics with only water resulted in compressive strengths similar to that of MICP-treated, contaminated plastics. Our results demonstrate that incorporating greater volumes of waste plastics into mortar at optimized replacement ratios could improve the sustainability of cementitious composites by the dual mechanisms of reduced cement production and repurposing plastic waste.

4:00 PM EN09.07.08
Fungal Mycelium as a Scaffold for Biomineralized Building Materials Ethan T. Viles[1], Erika Espinosa-Ortiz[2], Arda Akyel[2], Robin Gerlach[2], Adrienne Phillips[2] and Chelsea Heveran[1]; [1]Montana State Univerity, United States; [2]Montana State University, United States

Concrete manufacturing contributes 5-8% of anthropogenic CO_2 emissions. Biomineralization is a less energy intensive process that could improve the sustainability of building material manufacturing. Microbial biomineralization can occur when ureolytic microbes are cultured in media with urea and calcium (Ca). Ureolysis by microbes increases carbonate alkalinity and pH of the environment—inducing calcium carbonate ($CaCO_3$) precipitation. Bacterially induced $CaCO_3$ precipitation (BICP) is used to seal cracks, stabilize soils, and manufacture low weight building materials. Typically, BICP-structures require substantial urea, Ca, and microbial inputs. Biomineralizing a scaffold may increase the effiency of manufacturing biomineralized materials by templating mineral nucleation for more precise mineralization. Here we draw inspiration from biomineralized tissues, such as bone, which mineralize a compliant scaffold. Fungal mycelium may serve as an environmentally robust scaffold for biomineralization. *Neurospora crassa* is a ureolytic microbe that has the potential for either self-mineralization or exogenous mineralization. The goal of this study was to determine how biomineralization efficiency and biomineral characteristics differ between self-mineralized, abiotically mineralized, and bacterially mineralized fungal scaffolds. *N.crassa* was mineralized using 4 conditions: fungally induced $CaCO_3$ precipitation (FICP) with malt media (FICP-malt), FICP where urea is the only nitrogen source (FICP-urea), abiotically induced $CaCO_3$ precipitation (AICP), and BICP where ureolytic bacteria, *Sporosarcina pasteurii*, mineralize the fungal scaffold.

Electron microscopy (EM) and X-ray diffraction (XRD) were used to determine the morphology and elemental composition of scaffolds. For FICP scaffolds, *N. crassa* was cultured for 10 days in media with Ca and urea. For AICP and BICP scaffolds, *N. crassa* was cultured for 5 days in Ca-free medium and then autoclaved. AICP scaffolds were mineralized in a Ca-bicarbonate solution via a pH increase. *S. pasteurii* was first cultured onto BICP scaffolds in Ca free medium, then placed in medium with urea and Ca. Dissolved Ca and urea concentrations, during mineralization, were measured using colorimetric Ca and urea assays. The Ca content of mineralized scaffolds was determined by measuring the mass before and after an acid Ca digest

EM showed different morphologies and mineral attachment locations for all 4 conditions. FICP-malt scaffolds had small Ca minerals coating the top of a mycelium mat. FICP-urea scaffolds did not have a mat of mycelium, but had individual hyphae coated with small Ca minerals. AICP produced Ca minerals

that also coated the outside of the mycelium, but these were much larger than both FICP scaffolds. BICP produced the largest minerals of the 4 conditions, which were incorporated within the mycelium. XRD shows that each condition produced calcite and a minority phase of vaterite. Ca digests showed the FICP-urea scaffolds had the most Ca per weight of scaffold. FICP-malt and AICP both had the least amount of Ca deposited. BICP scaffolds had the second most Ca deposited. FICP-urea samples had lower ureolysis, but a faster decrease of dissolved Ca than FICP-malt samples. BICP showed the most ureolysis and had a faster decrease in dissolved Ca than FICP conditions. AICP scaffolds showed an instantaneous drop of dissolved Ca with the pH increase.

Our results suggests BICP is the most promising technique to mineralize fungal scaffolds as it showed the most ureolysis and the most dissolved Ca loss. The integration of $CaCO_3$ within the mycelium itself found for BICP scaffolds is promising for conferring strength to biomineralized scaffolds. Future work will include nanoindentation to analyze the material properties of biomineralized fungal scaffolds. Biomineralizing fungal scaffolds with bacteria may lead to new approaches for engineering sustainable building materials.

A Chemically Recyclable Thermoplastic Elastomer Synthesized with Redox Switchable Polymerization Jiangwei Liu[1], Sarah Blosch[2], Jeffery Byers[1] and John Matson[2]; [1]Boston College, United States; [2]Virginia Tech, United States

Poly(lactic acid) (PLA) as a biodegradable and bio-derived polyester has limited application due to its brittleness. In an effort to increase the flexibility, a redox-switchable catalytic system was developed to make A-B-A' triblock copolymers containing stiff PLA end blocks and a flexible poly(tetrahydrofuran-*co*-epoxide) midblock. The tensile test demonstrated high flexibility of the triblock (strain at break ε_b up to 200%) compared with PLLA (ε_b < 10%). The mechanical properties were dependent on the amount of tetrahydrofuran (THF) repeating units in the mid-block: low THF incorporation led to more thermoplastic features while higher THF incorporation resulted in more rubbery materials. In addition to being derived from commodity monomers like lactide and THF, the triblock copolymer can be depolymerized to their constituent monomers. A reactive distillation system with a dual catalyst system was designed that allowed us to recover THF and lactide monomers from the thermoplastic elastomer.

EN09.08.04
Development of Continuous Extraction of Bio-Silica from Rice Husk in Pilot Scale Ji Yeon Park[1,2], Jinyoung Chun[1], Yang m. Gu[1,2], Byoungseung Jeon[1] and Jin Hyung Lee[1]; [1]Korea Institute of Ceramic Engineering & Technology, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

The use of renewable biomass, instead of petroleum, could be effective strategy to reach to carbon neutral society. Rice husks can be an alternative to silica raw material because it contains 15~20% of silica. Annually, 194 million tons of rice husk was produced worldwide in 2020. The initial step to use silica in rice husks is extracting silica from rice husk. Generally, alkaline extraction was performed at high temperature and pressure condition to extract silica from rice husks. In this study, the continuous extraction of silica from rice husk has developed at 80°C and atmospheric pressure. First, the optimal conditions of NaOH concentration, reaction temperature and time, and solid/liquid ratio were investigated at a lab-scale. The optimal conditions found in the lab-scale were 80°C reaction temperature, 2.5hr reaction time, 10 wt% solid/liquid ration and 0.5M NaOH. Based on the optimal conditions found in the lab-scale, continuous extraction process was operated in the pilot-scale having 20.2kg/d processing capacity. The stability of the continuous process was proved by operating for 190 hr. The process showed stable during the operation and extraction efficiency was maintained about 82%.

EN09.08.05
Autonomously Self-Healing Effect of Thermoplastic Polyurethane Containing Multiple Self-Healing Moieties Yoojin Rho, Hyojin Kim and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)

Inspired by self-healing phenomena in nature such as repairing of plant tissues or the healing of animal skins, there have been many studies about self-healing materials. Normally, materials lose most of their mechanical properties when facing external damage. However, self-healing materials can heal the wound spontaneously or by external stimuli such as light and heat. This self-healing property can extend the life of the material and maintain durability through recovery from damage. Research on self-healable polymers have been shifted from extrinsic to intrinsic self-healing. In extrinsic self-healing, if the healing agents in polymer matrix are not sufficient, repeated healing is limited. In comparison, the surface can be repeatedly cured by intrinsic self-healing methods due to reactions between chains or interactions between supramolecules. In this study, we have developed a thermoplastic polyurethane that is intrinsically healed under the moderate condition due to multiple hydrogen bonding and a disulfide metathesis. The synthesized thermoplastic polyurethane contains ureido-pyrimidinone type supramolecular interactions and aromatic disulfide type dynamic covalent bonds. The results demonstrated that the thermoplastic polyurethane was healed at room temperature in an hour. The mechanical properties of polymers were improved by multiple hydrogen bonding monomers. Also, we extruded these self-healing polymers as fibers via wet spinning technique. Using these fibers, we observed the fibers spooled and packed within silicone droplet. These fibers could be applied to artificial muscles because they stretch or release through the spooling phenomenon like real muscles. Also, it is expected that the mechanical properties of fibers are improved than non self-healable polyurethane fibers due to multiple self-healing moieties on polymers' main chain.

EN09.08.06
Capturing of Inorganic and Organic Pollutants Simultaneously from Complex Wastewater Using Recyclable Magnetically Chitosan Functionalized with EDTA Adsorbent Monu Verma and Hyunook Kim; University of Seoul, Seoul, Korea (the Republic of)

Herein, we synthesized new and versatile magnetite-doped chitosan-ethylenediaminetetraacetic acid (Fe_3O_4@CS-EDTA) composite for simultaneous capturing of multiple heavy metal ions: Hg^{2+}, Cd^{2+}, and Ni^{2+}, and methyl orange (MO) dye from complex wastewater through the adsorption process. We believe that EDTA in the synthesized adsorbent work as a cross-linker as well as a chelating agent for the capturing of heavy metal ions, while the protonated amino groups of CS adsorb MO through electrostatic interaction. In the monocomponent system, the adsorption followed to Langmuir model and gave the maximum adsorption capacities of 232.70±14.30, 121.40±7.0, 56.50±2.20, and 732.10±72.40 mg g^{-1} for Hg^{2+}, Cd^{2+}, Ni^{2+}, and MO, respectively. Kinetics data well fitted to the pseudo-second-order (PSO) models, confirmed the chemisorption process. Interestingly, in the case of the

binary component system containing both metals and MO, the adsorption capacity of the adsorbent for the dye was not affected by the metal presence, while the adsorption of metal ions was enhanced with increasing MO concentration. The adsorption mechanism was confirmed by elemental mapping, XPS, and FTIR. Moreover, no significant loss in the adsorption efficiency even after the six continuous adsorption-desorption cycles confirms the great stability and potential of the adsorbent in treating the complex wastewater.

EN09.08.08
Living and Adaptive Microstructures by Combining Laser Printing and Dynamic Covalent Exchange of Alkoxyamines Manuel Tsotsalas; Karlsruhe Institute of Technology, Germany

Two-photon lithography, also known as direct laser writing or 3D laser printing, allows to structure polymer networks in unprecedented definition and can generate interesting optical, mechanical and biomedical properties in the micro and nanoscale. The polymer networks applied usually relies on covalent bonds, lacking dynamic or living characteristics. Inclusion of dynamic and living characteristics to 3D laser printing microstructured polymer networks provides new and exciting possibilities to dynamically modify the molecular structure of the networks, such as crosslinking density or mesh sizes.[1] Such modifications at the molecular level strongly influence important characteristics, such as swelling degree or mechanical properties. For creating polymer network structures containing dynamic and living bonds, it is important to adopt the dynamic covalent chemistry to the radical chemistry applied in the laser printing process.
Here, we include dynamic covalent bonds, based on nitroxide radicals, into the 3D laser printing microstructures. In our approach, dynamic alkoxyamine bonds form during the printing process via trapping of radical species by functionalized nitroxide radicals. The alkoxyamine bonds within the final microstructured polymer networks can afterwards be activated for nitroxide exchange reactions or nitroxide mediated polymerization, providing dynamic, adaptive and “living” properties to the microstructured networks. In addition, the alkoxyamine functionalities provide the networks with self-healing and recyclable properties. [2] [3] [4] [5] [6]

EN09.08.10
Chlorella-Laden Cements for Green Construction Materials—Effects of Algae Incorporation on the Structure and Mechanical Properties of Cement Meng-Yen Lin, Paul Grandgeorge, Andrew M. Jimenez and Eleftheria Roumeli; University of Washington, United States

Concrete industry, which accounts for 5-8% of global CO2 emissions, raises increasing concerns regarding its environmental impacts. To improve the environmental footprint of cementitious materials, a wide variety of biobased fillers across macro-to-nano scales, including hemp fibers, nanocellulose, and cellulose microfibrils, has been studied. Promising findings on the effects of incorporating such biobased fillers to cementitious materials include improvements on the mechanical properties of the produced composites, as well as enhancement of thermal and acoustic insulation properties. However, limitations involving the use of costly food crops as a source for biobased materials, and the energy-intense processing methods to extract and pretreat such materials prior to introducing them to concrete, have impeded their further applications. Algae-based materials, owing to their high capacity of carbon fixation, rapid growth rate, and capability of growing on non-arable spaces, represent a promising biomass resource for construction materials.

In this work, we investigated the effects of adding a photosynthetic algae, Chlorella, in forms of dry powder into Type I/II ordinary Portland cement (OPC) at concentrations ranging from 0.5-15 wt.%. We find that the mixing process, which is crucial to disperse chlorella powder in cement mixture, together with the water absorption capacity and particle sizes of chlorella increase the viscosity and affect the workability of the fresh paste. The compressive strength evolution across 3-91 days is studied and associated with the development of microstructure by scanning electron microscopy. We observed a drastic decrease in strength throughout the entire curing duration with only 5 wt.% addition of chlorella, which suggests a hindrance of the conventional hydration reactions. We further examine the interactions between chlorella and OPC at different concentrations by thermogravimetric analysis (TGA), X-ray diffraction (XRD), Fourier-transform infrared spectroscopy (FTIR), and energy-dispersive X-ray spectroscopy (EDS). Our results show that the presence of chlorella significantly alters the hydration reactions of OPC with the formation of different compounds, which subsequently leads to micro morphological changes and notable difference in macroscopic mechanical properties.

EN09.08.11
Volatile Organic Compound-Free, Eco-Friendly, Colored Lacquer Pallets Derived from Catechol Lipid-Based Bio-Resin Ju Young Shin and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)

We report the method for producing volatile organic compound (VOC)-free, eco-friendly, colored lacquer pallets characterized by excellent adhesion strength and strong durability from catechol lipid-based bio-resin extracted from lacquer trees. It is challenging to develop the desired color or predict the color of the lacquer-coated surface as oriental lacquer reflects a shade of dark brown. We focused on the saturation behavior of the color of the coated surface based on the amount of the added pigments. The optical properties of the pigment-containing lacquer were studied using the Kuballka–Munk theory by measuring the degree of absorbance and reflectance. The colors were also observed using the CIE L*a*b color space. Color saturation for the colored lacquer-coated surfaces was achieved at the pigment content of 50 wt.% for red and blue. When the pigment content was 40 wt.%, color saturation was achieved for green and yellow. The results indicated that clear colors that could be observed with the naked eye could be generated without using an excess of pigments. The materials exhibited excellent adhesive properties (5B), and the hardness was 2–3H. In addition, it was observed that with the

progress of the aging time over two years, the color of the lacquer-coated surfaces changed, and a bright and intense surface was formed. The color change could be attributed to the bleaching effect of the oriental lacquer binder. The results reported herein can potentially help in obtaining a green solution for preparing VOC-free colored lacquer pallets and predicting the color development observed for highly decorative and protective coatings.

EN09.08.12
Low-Cost and Efficient Biobased Material for Removal of Noble Metals in Gold Tailing Dam Ruben D. Sinisterra, Vanessa Alves de Paula Soares and Roberto Galery; University Federal-Minas Gerais, Brazil

The technological advance of the industry is an important factor in the increase of environmental pollution by industrial effluents, since high amounts of chemical load, metals, toxic and highly dangerous elements are produced. In Brazil, the mining activity is responsible for providing mineral resources for technological development and source of economic resources, however generates numerous tailings dams. In addition, when the mine is closed, there is a high cost for disposing of wastewater to achieve metals standards established by legislation.
Thus, the treatment of these effluents must be efficient and continuous, and the treatment methods are commonly divided into "active", which requires the addition of alkaline chemicals to neutralize acidity, or "passive". The term "passive treatment" corresponds to biological, geochemical and gravitational processes. Currently, in the short term, most mines use “active treatment” methods such as: neutralization treatment, purification, and recovery of heavy metals, with conventional machines, spent with a large number of chemical products and electric energy.
Among the technologies for the removal of pollutants from industrial and mines effluents, adsorption using biosorbent material has been classified as a low-cost, efficient, and easy-to-implement methodology since they can adsorb metals with high efficiency and being a biodegradable option.
The present technology refers to a method of recovering noble metals, Au (III), Ag (I), Pt (IV) and Pd (II), in wastewater from a gold tailings dam, using seeds from Bixa Orellana L and biodegradable nanofibers with Bixin. The recoveries of these noble metals in aqueous solutions containing these metallic ions and in real samples from a gold tailings dam were evaluated.
The noble metals Au (III), Ag (I), Pt (IV) and Pd (II) recovery from aqueous solutions with Bixa Orellana L and biodegradable nanofibers with Bixin were carried out at different contact times, pH and amounts. The quantification of metals was carried out using atomic absorption spectroscopy; characterization of seeds and biodegradable nanofibers by TGA, MEV-EDS and Zeta potential. A prove of concept of metal removal using the biosorbent was made with wastewater from a gold tailings dam. The optimal adsorption of Au (III), Ag (I), Pt (IV) and Pd (II) ions were recorded at pH 2, with the addition of a 0.2 mol/L Na_2HPO_4 buffer solution and an acid solution citric acid 0.1 mol/L, the adsorbent concentration between 5 and 200mg/L, at room temperature around 25 °C, under agitation at 50 rpm, after 48h of contact. Solid/liquid separation was performed by centrifugation and metal recovery rates was calculate. The seeds of Bixa Orellana L. showed a high degree of selectivity for adsorption of Au (III), where a removal percentage of approximately 84.35% was identified from a gold tailings dam. This technological process, with high efficiency, low cost and commercial value could be serve as alternative to treat industrial effluents, such as the mining industry.
Acknowledgments: The authors would like to thank to the Network for the study, development and application of technologies based on sustainable nanomaterials for the recovery of water from the Doce River basin (N°06/2016), sponsored by the entities: FAPEMIG, CNPQ, CAPES, ANA, FAPES and development in Chemistry Department of UFMG.

EN09.08.13
Modifying Gas Diffusion Electrode with Food Waste-Derived Materials for Enhancing Electrochemical Conversion of CO_2 Ying Chuan Tan[1] and Dan Kai[2]; [1]Institute of Sustainability for Chemicals, Energy and Environment, Singapore; [2]Institute of Materials Research and Engineering, Singapore

The disposal of organic wastes from food sources contributes to undesirable environment impact and the loss of valuable resources. These food wastes usually end up in incineration plants or landfills, which could result in the unintended release of greenhouse gases. Considering that the global population is expected to reach over 9 billion in 2050, the demand of food resources, and thus the production of food waste will increase. Therefore, there is a need to develop strategies to upcycle food wastes toward valuable materials to maximize the utilization of resources while minimizing the environmental impact. In this study, we demonstrated the fabrication of gas diffusion electrodes integrated with food waste-derived materials for the electrochemical conversion of CO_2 to CO. By using commercial Ag nanoparticles as electrocatalysts, the incorporation of the as-prepared food waste-derived materials enhanced the maximum production rate of CO by 48%. At the same time, the faradaic efficiency of CO was improved by 28% at an applied potential of −1.1 V vs RHE. The materials derived from food wastes were shown to improve the conductivity of the gas diffusion electrode, which facilitated the charge transfer between the electrocatalysts to the reactants. This work thus represents an approach to avoid greenhouse gas emissions by valorizing food waste into functional materials, which further enable a more efficient conversion of CO_2 to useful chemicals.

EN09.08.14
Rubber Adhesives and Mixed Mode Recycling to Achieve Over 80% Recycled Content in Rubber Composites Clara Troyano-Valls[1], Sarah Av-Ron[1], Michelle Calabrese[2], Wui Yarn Chan[2] and Bradley Olsen[1]; [1]MIT, United States; [2]University of Minnesota, United States

Diene-based rubbers vulcanized with sulfur are one of the most widely used polymer networks today. Nowhere is their impact more visible than in tires, which form the foundation of our transportation infrastructure. However, the same crosslinking process that imparts desired mechanical properties and chemical resistance makes these thermosets difficult to recycle, frustrating the development of wide-scale and effective methods of rubber waste management. Current rubber mechanical recycling efforts focus on incorporating ground tire rubber (GTR) into other materials as filler. This process yields products with degraded mechanical properties and, as a result, downcycled materials of limited applicability. Chemical recycling via devulcanization, a process in which sulfur crosslinks are cleaved, is similarly unsuccessful: it is energy intensive and cleaves both backbone and crosslink bonds, leading to a partially degraded product [1].

To improve upon existing methods of rubber recycling, our group has developed a GTR coating inspired by tire retreading—an application that requires a strong adhesive to patch two pieces of vulcanized rubber together. We have developed a process and an adhesive formula that increases the performance of GTR and virgin rubber composites by up to 45% as compared to uncoated GTR composites [2]. Here, we present the work further modifying this formula and combining this approach with GTR chemical devulcanization that has enabled us to produce composites containing over 80% post-consumer rubber waste. This optimized composite formulation at this recyclate level exhibits superior performance to that of earlier composites containing only 15% post-consumer waste. Structure-property relationships in the material are explored through coating reinforcement, changes in coating to GTR ratios, and matrix material. The goal is to create a coating capable of handling a wide variety of chemically variable post-consumer GTR, incorporating it into high-performing recycled rubber composites.

EN09.08.15
Bio-Trapping of Ureolytic Microorganisms on Sand Surfaces to Enhance Microbially Induced Calcium Carbonate Precipitation Elif Ugur, Recep Avci, Adrienne Phillips and Chelsea Heveran; Montana State University, United States

Microbially induced calcium carbonate precipitation (MICP) has been widely studied for its potential to improve sustainability in the construction industry and geotechnical applications. The presence of urease-producing bacteria is essential for catalyzing the conversion of urea into ammonium and carbonate ions to promote $CaCO_3$ precipitation. The effectiveness of the MICP process highly depends on the spatial uniformity of the bacterial concentration and $CaCO_3$ precipitation. In this study, we functionalized sand surfaces with amine groups to trap urease-producing bacteria from the planktonic phase to enhance MICP. The purpose of this study was to investigate the impact of 3-Aminopropylmethyldiethoxysilane (AMDES) treatment on microbial viability, attachment, and urea hydrolysis. Bioactive sand surfaces were prepared using 1% AMDES to create positively charged surfaces to promote the adhesion of urease-producing bacteria *Sporosarcina pasteurii via* electrostatic interaction. This approach enables the concentration of urease-producing bacteria on the sand surface, which can then precipitate a full monolayer of $CaCO_3$ acting as an initial binder to adjacent sand particles. X-Ray Photo Electron Spectroscopy (XPS) was used to confirm the amine groups on the functionalized surface. Zeta Potential measurement was used to understand the changes in surface charges, which proved the negatively charged sand surface becomes positively charged after AMDES treatment. Microbial growth and viability after on AMDES-treated sand were measured using Optical Density(OD_{600}), and Confocal laser scanning microscopy (CLSM) of live dead stained cells, respectively, and compared to untreated sand. The results demonstrated that the bio-trapping of microorganisms on AMDES-treated sand surfaces reduced the growth rate of microorganisms and potentially compromised microbial viability. CLSM images of live dead stained cells at 0h showed more bacteria with compromised cell walls attached to AMDES-treated sand. Untreated sand particles did not show any bacterial attachment at 0h. After 24 hours of growth, CLSM images showed no bacterial growth on AMDES-treated sand and untreated sand particles showed densely packed live bacteria. Ureolytic activity was measured using a colorimetric Jung assay. Although the growth of the microorganisms was slowed with the AMDES treatment, ureolytic activity was maintained, and urea was completely hydrolyzed although at a slower rate. The resulting biocemented structures show excellent density and edge definition, which exceed those of conventional MICP. Our results show that bio-trapping of urease-producing bacteria on sand particles may promote uniform and effective biocementation of sand.

Porous Scaffolds as Catalysts for New Waste-Reduction Solutions Miriana Vadala, Eva Kroell, Marco Kueppers, Ruth Brunstermann and Doru C. Lupascu; University of Duisburg-Essen, Germany

With the word “scaffolds” a variety of research fields is addressed, ranging from chemistry to medicine, from biology to civil engineering. Scaffolds can be found at different length scales, from supporting structures in construction sites to tissue engineering and bone regeneration. Scaffolds are open porous structures that can be made active by applying a magnetic or electric field or be used as backbone structures for biological and medical purposes. They can be used also as filters, for instance for wastewaters treatment, where hydrogen is produced. Hydrogen production from wastewaters can achieve the dual environmental benefits of waste reduction along with production of high value energy fuel. Moreover, wastewaters can be considered as ideal substrates for biohydrogen production since they are rich in carbon and nitrogen. The addition of nanoparticles (NPs) can improve the biohydrogen production, can promote the bioactivity of hydrogen-producing species and increase the bacterial growth. Micro- or nanosized porous materials possess large surface areas and large pores, which are beneficial for the diffusion, adsorption, and activation of reactants, especially if pores are interconnected.
Materials containing porous silicones with excellent mechanical performance, e.g., high compressibility and stretchability, and thermal stability, are in high demand in many practical applications. Recently, porous polydimethylsiloxane (PDMS) materials have been successfully synthesized for selective oil absorption from water. For example, Choi et al. fabricated PDMS sponges with fast oil absorption and excellent recyclability using sugar particles as templates [1]. Zhang et al. prepared PDMS sponges with high oil absorbency by using *p*-xylene as solvent and sugar particles as templates [2].
In this contribution we show our first attempts to fabricate porous scaffolds which can host bacteria colonies and can serve as catalysts for wastewaters treatment. The samples were produced via sugar cube template and consist of PDMS and Fe_2O_3 or TiO_2 nanoparticles. The samples went through several water treatment cycles and maintained their structure without deterioration, creating a suitable environment for bacteria colonies, with consequential hydrogen production.

Pattern-Integrated Paper Li-Ion Microbatteries Through Large-Scale Roll-to-Roll Flexographic Printing Ying Wang, Daxian Cao, Xiao Sun, Haoze Ren, Tongtai Ji and Hongli Zhu; Northeastern University, United States

The large-scale manufacturing of architecture designable lithium-ion (Li-ion) batteries poses a significant challenge but raises an emerging need for enhancing battery performances and enlarging application scenarios. However, traditional methods of manufacturing Li-ion batteries (LiBs) rely on roll-to-roll (R2R) bar coating, which cannot render the customized pattern or structure for fabricated electrodes and limited electrodes’ application. To get around this bottleneck, we innovatively introduced the well-developed R2R flexographic printing technology to manufacture pattern-integrated Li-ion electrodes. Compared to alternative electronic printing substrates such as metal, plastic, and glass, the inexpensive and biodegradable cellulosic paper with high printability was selected as a printing substrate to improve printing resolution, reduce cost, and protect the environment. Furthermore, the special pores between the cellulosic fibers in the paper were utilized for transferring ions. Therefore, paper can be used both for a separator in LiBs.
In this study, as a novel approach, we integrated large-scale R2R flexographic printing and LiB production to manufacture LiBs with unique patterns, in which flexible and high printable paper was used as both the printing substrate and separator in LiBs. Accordingly, we developed a series of LiFePO4 (LFP) flexographic printable inks and successfully printed them on thin (25 μm) and lightweight (23.4 g/m^2) paper with a large-scale R2R flexographic printer. A high-quality and high-resolution flexographic printed pattern was achieved with 35% solid-content LFP at 80 in/min. Moreover, a thin layer of Al_2O_3 was coated to modify the separator. The flexographically printed paper battery exhibited a high-rate performance (97.2% discharge capacity retention at 2 C of that at 0.1 C) and outstanding capacity stability (~100% discharge capacity retention after 1000 cycles at 3 C). The results highlighted the immense potential of integrating flexographic printing with R2R manufacturing architecture for designable LiBs and using flexible, inexpensive, sustainable, and high printable paper as a printing substrate and separator in printed LiBs for the scalable fabrication of flexible batteries with high-resolution patterns to obtain microbatteries for applications in wearable electronics and bioengineering.

EN09.08.18
Excellent Mechanical and Electrical Properties of Anisotropic Freeze-Cast Native and Carbonized Bacterial Cellulose-Alginate Foams Kaiyan Qiu[1,2] and Ulrike G. Wegst[3,2]; [1]Washington State University, United States; [2]Dartmouth College, United States; [3]Northeastern University, United States

Native and carbonized freeze-cast bacterial cellulose-alginate (BC-ALG) foams possess an ice-templated honeycomb-like architecture with remarkable properties. Their unique pore morphology consists of two levels of porosity: 20–50 μm diameter pores between, and 0.01–10 μm diameter pores within the

cell-walls. The mechanical properties of the BC-ALG foams, a Young's modulus of up to 646.2 ± 90.4 kPa and a compressive yield strength of up to 37.1 ± 7.9 kPa, are high for their density and scale as predicted by the Gibson–Ashby model for cellular materials. Carbonizing the BC-ALG foams in an inert atmosphere at 1000–1200 °C in a second processing step, both pore mor-phology and mechanical properties of the BC-ALG remain well preserved with specific mechanical properties that are higher than those reported in the liter-ature for similar foams. Also the electrical conductivity of the BC-ALG foams is high at 1.68 ± 0.04 S cm−1 at a density of only 0.055 g cm−3, and is found to increase with density as predicted, and as a function of the degree of carbonization determined by both carbonization temperature and atmosphere. The property profile makes freeze-cast BC-ALG foams and their carbonized foams attractive for energy applications and as a sorbent.

EN09.08.19
Fully Fashioned and Curbside Recyclable Mono-Material 3D Textiles Leslie Yan, Volodymyr Korolovych and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

3D printing polymer structures onto fabric substrates can be used to develop fully-fashioned, three-dimensional textiles that unlock new functionalities and aesthetics for a wide range of textile-based applications. Moreover, the accessibility of fused-deposition modeling (FDM) 3D printing can streamline the material design and fabrication process, while presenting sustainability advantages with regards to low-waste and localized manufacturing. However, developing these hybrid textiles with traditional filament and fabric types can render high-level material recovery infeasible and present adhesion challenges.

Our work addresses these gaps with a mono-material approach to 3D printing on fabric realized through the lens of polyethylene, producing a textile that is fully curbside recyclable without disassembly. Polyethylene (PE) is among the most popular commodity plastics due to its versatility, affordability, and excellent engineering characteristics. PE offers significant potential as a performance fabric due to its washability and lightweightness, as well as moisture-wicking properties introduced through the standard yarn production process [1-4].

Woven polyethylene fabric was produced from HDPE resin using scalable techniques, then developed into a three-dimensional mono-PE textile through an integrated process utilizing an unmodified FDM 3D printer and commercially-available HDPE printing filament. The digital design workflow for the three-dimensional structures, as well as possible variation in the woven pattern of the textile substrate, enables significant diversity and customizability in the design of the 3D textiles. Moreover, utilization of different densities of PE for either filament of fabric presents an opportunity for optimizing the mechanical performance of the recyclate following material recovery. The advantages of the sustainable, three-dimensional PE textile can be leveraged for uses ranging from athletic footwear to space applications.

EN09.08.20
Electrochemical Properties of Carbon Monolith from Kenaf Fibers Han-Yul Park[1], Minhu Huang[2], Kyung-Hun Song[1], Jae-Suk Lee[2] and Tae-Ho Yoon[2]; [1]Pai Chai University, Korea (the Republic of); [2]Gwangju Institute of Science & Technology, Korea (the Republic of)

Carbon monoliths (CM) were prepared from kenaf fibers via moulding column-shape samples and then pyrolysis at 500, 600, 700 or 800 ºC, followed by activation with KOH at 700 °C. Then, the samples were characterized by thermogravimetric analyser (TGA), field-emission scanning electron microscopy (FE-SEM), field-emission transmission electron microscopy (FE-TEM), x-ray photoelectron spectroscopy (XPS), Raman spectroscopy, x-ray diffraction (XRD) and N_2 sorption instrument. The prepared CM was subjected to electrochemical property evaluation via cyclic voltammetry (CV), galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS). The GCD study using a three-electrode system showed that the specific capacitance decreased with higher pyrolysis temperature (PYT), exhibiting the highest specific capacitance of 217 F/g with that from 500 °C pyrolysis. A two-electrode system provided 95.9 % retention upon the 5,000 cycling test as well as the specific capacitance of 212 F/g, being converted to the energy density of 6 Wh/kg at the power density of 215 W/kg.

EN09.08.21
Toxicity of Tin-Based Catalysts on Polymer-Degrading Bacteria Alex Zappi, Katharina Fransen, Sarah Av-Ron, Kristala L. Prather and Bradley Olsen; Massachusetts Institute of Technology, United States

Biodegradable polymers are synthesized using a wide range of transition metal catalysts to control the molecular properties of the final polymer. While catalysts are traditionally chosen only for their efficacy in polymerization, they may also be toxic to microorganisms, impacting the measured biodegradation rate of the final polymer. In particular, catalyst toxicity could cause otherwise biodegradable materials to fail biodegradation testing, undervaluing the actual degradability of the polymer. Tin-based catalysts are widely used to synthesize biodegradable polymers through ring-opening polymerization of lactones due to their availability, cost, and effectiveness; however, their toxicity in environments relative to biodegradation is not well understood. Existing studies suggest toxic effects of tin in aquatic microorganisms with little focus towards the effect on bacteria important for biodegradation. In this study, we first quantify the toxicity of widely used tin-based catalysts in culture media on common soil bacteria with key roles in biodegradation. Using this information to assess the relevant concentration range, we then use clear-zone assays to measure the direct effects of these catalysts on biodegradation of solid state plastics and exemplify the extent of these effects using realistic concentrations of a variety of catalysts doped into commercial polymers. Combined, these results indicate the role that residual catalyst plays in affecting biodegradation results, and the high-throughput methods applied here provide a basis for catalyst screening to identify catalysts that best promote polymer biodegradation.

EN09.08.23
Solar Harvesting Biodegradable Photonic Smart Labels for Mobile Sensing and the Internet of Things (IoT) Maria Rute Ferreira Andre[1], Gabriela Kovaleski[1], Lilia Dias[1], Lianshe Fu[1], Sonia P. Ventura[1] and Paulo Andre[2]; [1]University of Aveiro, Portugal; [2]Instituto de Telecomunicaçoes, Portugal

Sensors play a key role in the Internet of Things (IoT) providing monitoring inside and outside the communication networks in a multitude of parameters[1]. The coupling of optical sensors to smartphones appears as an exciting and affordable strategy to sustainably convert a signal from an optical sensor network into a digital data sequence for the new generation of mobile optical (mOptical) sensing[1,2]. The opportunity of using luminescent natural renewable materials for smart labels will be addressed, in line with the increasing demand for natural products and underpinned by the recent policies to reduce the environmental impact of industrial processes and products when integrated into a smart and low-waste chain of different products or within a

circular economy approach. Using the concept of colored multiplexed QR codes, bio-based inks will be used to design smart IoT devices to track and sense in real-time[2] and to address temperature monitoring in buildings[3], in which photonic sensors under the configuration of luminescent solar concentrators appear as a solution to integrate energy-generating devices in windows or façades.

EN09.08.24
Sugar Derived Nanoporous Carbon Material for CO_2 Direct Air Capture Amanda Sanchez, Guangping Xu, Yongliang Xiong, Yifeng Wang, Sean Dwyer and Hongyou Fan; Sandia National Laboratories, United States

The mitigation of the impact of anthropogenic carbon dioxide is important to the reversal of the trend of the climate change that has been already observed in the world. One of the key approaches for solving this problem is to capture carbon dioxide (CO_2) from the atmosphere in advance of fixation, conversion, or injection into the aquifers for long-term storage. Successful CO_2 capture is further complicated by the fact that nitrogen (N_2) is the dominant gas in the Earth's atmosphere. Thus the separation of carbon dioxide from the mixture of carbon dioxide and nitrogen gases requires economic and environmentally friendly technologies is vital to enable anthropogenic intervention to the reverse of the current trend of climate change.

Current state-of-the-art CO_2 capture technologies involve amine-based chemical sorption in corrosive KOH solution. It is an energy intensive process to regenerate the absorbent. In this work, we synthesized nanoporous carbon material using sugar as precursor to adsorb CO_2 via a physical sorption process to achieve the separation of CO_2 from N_2. We have successfully synthesized both mesoporous and microporous carbon materials utilizing the common table sugar sucrose ($C_{12}H_{22}O_{11}$) as the carbon precursor material. Addition of polystyrene-block-poly(4-vinylpyridine) (PS-P4VP) or n-Dodecyl beta-D-maltoside (DDM) ($C_{24}H_{46}O_{11}$) serve as the sugar surfactant and also enhance product porosity. The mesopores synthesized using PS-P4VP are mostly between ~10 nm and ~40 nm. The micropores synthesized using DDM are between 1 – 2 nm. Ongoing work includes characterization of the separation of CO_2 from the mixture of CO_2 + N_2 with the newly synthesized nanoporous carbon materials using mass spectrometry to investigate the relationship between CO_2 separation efficiency and pore size.

The synthesis technology developed will have an important impact in mitigating the negative effect of anthropogenic CO_2 on the climate change. Since the precursor materials for producing the nanoporous materials are cost-effective, abundant, and widely available, and the methods developed in this work for generating the nanoporous materials are environmentally friendly and are sustainable.

SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Nano-/Bio- Is Not an Either/Or Choice for Composites Jeffrey P. Youngblood; Purdue University, United States

Cellulose Nanomaterials (CN) are attractive materials for possible applications in nanocomposites reinforcement, nanomaterials and biomedicine as they are high strength and stiffness, yet are renewable, biodegradable, non-toxic, cheap, and optically transparent. Here, an overview will be presented on renewable/sustainable nanocomposites based on CN. Specifically, extraction, functionalization and nanocomposite preparation will be covered. We will detail our efforts to characterize CN and CN composite mechanical and thermal properties and understand what factors dictate behavior as well as our efforts at utilizing CN in a variety of application spaces such as for structural composites, infrastructure materials, and food packaging.

9:00 AM EN09.09.02
A Recyclable, Re-Processable Stretchable Conductive Polymer Complex Exhibiting Repeatable Autonomous Self-Healing Colton Duprey[1], Hadi Rouhi[1], Yang Lu[2] and Evan K. Wujcik[1]; [1]The University of Alabama, United States; [2]Georgia Institute of Technology, United States

E-skins and wearable strain sensors are essential for the realization of applications in the broad fields of sensing, soft robotics, and immersive gaming, among many others. These flexible materials can be safely and comfortably adhered to the skin and capable of monitoring human motions with high accuracy, as well as exhibiting excellent durability. However, it is challenging to develop electronic materials that possess the properties of skin. compliant, elastic, stretchable, and self-healable. This work demonstrates a low-energy processing method of producing a polymer complex composed of poly(2-acrylamido-2-methyl-1-propanesulfonic acid), polyaniline, and phytic acid (a transient, plant-based small molecule dopant) for electronic polymer materials. It exhibits ultrahigh stretchability (1935%), repeatable autonomous self-healing ability and linear response to flexion bending, outperforming many current reported wearable strain sensors. Most importantly, the material is recyclable and re-processable, allowing one synthesis to produce a long-lasting lifetime of the sensor material.

9:15 AM EN09.09.03
Strong Backyard-Compostable Bioplastics from Algal and Plant Renewable Resources Ian Campbell, Paul Grandgeorge, Andrew M. Jimenez and Eleftheria Roumeli; University of Washington, United States

Research in sustainable materials continues to produce alternatives to the unsustainable sourcing, manufacturing, and disposal of synthetic plastics. Innovative bioplastics developed during the past decade have properties comparable to commodity plastics. However, seldom are novel bioplastics both bioderived and biodegradable and only rarely are they truly backyard-compostable. The majority of biodegradable plastics are engineered to degrade only in given controlled, aerobic environments and not in landfills or the biosphere, where they regularly wind up. In this work, we demonstrate the production of plant and algal biocomposites, both from whole-cells and from isolated cellular components. We also introduce varying concentrations of natural plasticizers and adapt processing conditions to tune the bioplastic mechanical and thermal behavior. Processing conditions are controlled via mixing in a twin-screw extruder and during hydraulic pressing of biological matter into bulk materials. By changing the time, temperature, shear rate, and plasticizer content, we develop diverse micro-morphologies and properties. The effects of varying processing conditions and plasticizer concentration on microstructure and mechanical and thermal behavior in the resulting bioplastics are characterized. The micro-morphology of plant and algal bioplastics are evaluated using scanning electron microscopy (SEM). The mechanical properties of the bioplastics are measured (flexural modulus and strength, modulus of resilience) and the thermal stability is assessed by thermogravimetric analysis (TGA). We identify the relationship between the bioplastic composition and processing parameters and the microstructure and mechanical performance. Finally, we measure the mass-loss profiles of the bioplastics during soil burial to assess their compostability.

9:30 AM EN09.09.04
Biopolymer Composites with Tunable Biodegradation Rates Nicolas A. Lee, Hannah Gazdus and Markus J. Buehler; Massachusetts Institute of Technology, United States

The growing environmental impacts of solid waste accumulation have driven an increased demand for biodegradable alternatives to conventional plastics. While several products have begun to gain popularity as biodegradable or compostable plastics, such products still pollute terrestrial and aquatic environments, as they frequently require precise conditions in order to fully decompose. Furthermore, there often exist tradeoffs between a product's shelf stability, mechanical properties, and biodegradability. Here, we characterize biodegradation rates in a series of biopolymer composites, which can be tuned according to their composition. The raw materials in these composites are abundant, organic polymers known to be digestible by common soil organisms. We report relationships between composition and the biodegradation rates of these composites in live-soil environments as well as their degradation rates in aqueous environments. The described biocomposites are solidified from hydrogels containing apple pectin, chitosan (deacetylated chitin), and fibrous delignated cellulose and contain no synthetic binding agents. We demonstrate the suitability of these composites for casting, injection molding, and 3D printing using pneumatic extrusion. This study demonstrates the potential for tunable biopolymer composites to replace bioplastics as a superior alternative to conventional plastic.

9:45 AM EN09.09.05
Degradation of Regenerated Silk Fibroin in Soil, Fresh Water and Marine Environments Augustine Zvinavashe, Zeina Barghouti, Yunteng Cao, Hui Sun, Doyoon Kim, Muchun Liu, Eugene Lim and Benedetto Marelli; Massachusetts Institute of Technology, United States

There is a compelling need to find new materials that meet stringent performance requirements for application in food, water and agriculture industries while addressing biodegradability, circular life cycle, and sustainable sourcing at scale. Regenerated silk fibroin (RSF) is a structural biopolymer with applications in biomedicine, optoelectronics, food, water, and agriculture. Extracted from largely available *Bombyx mori* cocoons through a water-based process, RSF is fabricated into advanced materials that have competitive performance and merits of natural origin and non-toxicity. As a protein, RSF is considered slowly degradable in the human body but as a material it is known to be environmentally stable, and its biodegradation is mostly unknown. In this work, we report for the first time the degradation of silk fibroin films in the soil and water environment as a function of abiotic and biotic factors such as sodium chloride concentration, presence of microorganisms, and bacteriostasis.

Microbial activity was determined to be a key driver for silk film degradation in different environmental conditions. Exogenous bacterial colonization from soil resulted in an accelerated surface degradation, while the encapsulation of a soil-dwelling α-Proteobacteria, *Rhizobium tropici* CIAT 899, in RSF materials at the point of material assembly further accelerated the material degradation, promoting a bulk degradation. It is speculated that the production of proteases by the bacteria, or biofertilizer, contributes to the accelerated biodegradation, and results in the complete degradation of the silk materials considered in soil in 8 weeks.

Studies of biodegradation in freshwater and seawater environments indicated slower biodegradation profiles when compared to the measurements obtained in soil, even when bacteriostats were added. Exposure to seawater resulted in <10% of weight loss in 8 weeks. SF mass loss measurements over time showed that *R. tropici* induced silk fibroin biodegradation in water and the degradation rate was higher at sodium chloride concentrations that allow for the biofertilizers survival (NaCl 50-200mM). A statistically significant decrease ($p<0.05$) in the mechanical properties (i.e. Young's modulus and hardness) of the SF films exposed to seawater was measured with nanoindentation, when compared to SF films after 8 weeks of exposure to 0, 50, and 100 mM of NaCl solution. These results may suggest that degradation of SF films in seawater and freshwater requires the presence of active heterotrophic bacteria that possess the capability of digesting the silk material.

The effects of silk fibroin polymorphism on degradation in soil was also investigated by modulating beta sheet content with post-processing water annealing and a statistically significant difference of film films degradation occurred across time ($p<0.05$) and across different beta sheets content ($p<0.05$).

Together, this study shows that RSF biodegradation can be controlled by material design and by regulating the interaction with microorganisms present in the environment. Given the rising need to predict materials' biodegradation in the environment and to embed circular life principles in the design of technical innovations, it will also provide the basis to engineer silk fibroin materials for applications in food, energy, water, and agriculture.

Techno-Economic and Life Cycle Analyses of Lignocellulosic Nano-Microfibrils (LCNMF) Production from Wheat Straw Danielle U. Pascoli, Gabriel V. Seufitelli, Anthony Dichiara, Renata Bura and Richard Gustafson; University of Washington, United States

Lignocellulosic nano- and microfibrils (LCNMF) are sustainable biomass-derived materials with multiple potential applications due to their high surface areas, excellent mechanical properties, and biodegradability. Cellulose nano-microfibrils have has not become a commercial product because of high production costs. This work presents techno-economic (TEA) and life cycle analyses (LCA) of lignocellulosic nano-microfibril production from agricultural residues via a newly developed, low cost environmentally friendly process. . The standalone process presented is comprehensive, including the areas: 1) Feedstock handling, 2) Pulping and refining, 3) Peracetic acid pretreatment, 4) Mechanical fibrillation, and 5) Wastewater treatment. A facility using 100-tonne wheat straw feedstock per day was modeled with process simulation software with a production capacity of 18,400 tonnes of LCNF per

year. In the economic analysis we break down the capital and operating costs and establish a LCNMF selling price to achieve a 15% return on investment. In addition, we present the impact of facility size and co-location with an existing biorefinery on the process economics.

Finally, results from LCNMF life cycle analyses, including life cycle global warming potential (100 year) and fossil usage, are presented. This work demonstrates the outstanding economic potential and environmental performance of a standalone process to produce cost-competitive nanocellulose products of small widths (2-17 nm), promoting the commercialization of such products for many applications.

11:00 AM *EN09.09.07
Industrial Decarbonization—Gap and Opportunity for Ammonia, Bioproducts and Cement Carlos Quiroz-Arita; Sandia National Laboratories, California, United States

This research seeks to identify carbon-neutral and carbon-negative processes to decarbonize the U.S. economy within the opportunity space of i) hydrogen and ammonia production, ii) bioresources to bioproducts, and iii) cement and steel. To understand the drivers of sustainability metrics in these decarbonization exemplars, we have developed new models for industrial-scale systems, techno-economics analysis, and life cycle assessment. Our research results show decarbonization opportunities that can significantly decrease Nationwide CO2 emissions. Sandia's ammonia production process shows promising results that can dramatically reduce energy requirements, resulting in 95% of scenarios at or below -0.017 ton CO2eq ton NH_3^{-1}. Probabilistic results of algae-derived animal feed and bioplastics show that more than 50% of scenarios can result in negative-net life cycle CO2eq emissions, which can be improved using more sustainable production of nutrients, i.e., ammonia. Lastly, the resulting probability distribution of emissions from cement varies from 638 to 1,075 $kgCO_2eq\ ton^{-1}$ of cement, consistent with the literature, demonstrating that decarbonization strategies that displace direct and indirect emissions in the kiln are priorities to improve the carbon footprint in these systems.

11:30 AM EN09.09.08
Sustainability-by-Design—Achieving State-of-the-Art Performance with Reduced Environmental Impact Anna-Marie Gorman, Amy Clayton and David Johnson; CPI, United Kingdom

Electronic waste generation is predicted to double by 2050 to reach approximately 111 million tonnes per year.[1] Currently only around 20% of this waste is recollected and recycled[1], leaving a significant amount of plastic and heavy metal waste to be released into the environment. The use of printed electronics has grown significantly over the last decade[2], offering flexible, light, freeform circuits that can be more easily incorporated into products. This however only compounds the problem of increasing waste by adding functionality to everyday objects with a short lifespan. Material selection is a crucial consideration to ensure that e-waste that is not or cannot be recycled will not introduce damaging and long-lasting species into the environment. In this presentation we propose several methodologies that could be used to maximise the potential of printed electronics by reducing health and environmental impacts of associated material sets and processes.

Bio-based binders have long been used in the printed ink industry, with ethyl cellulose and cellulose acetate butyrate being two of the most common. However, these are often paired with harmful and environmentally damaging solvents. By combining the use of Hansen solubility parameters with a safety-by-design approach we have been able to select an array of sustainable solvents with reduced health and environmental impact that can be employed for a range of printing methods. For example, we have demonstrated the use of a renewable and safe solvent benzyl acetate to achieve high conductivity in the range of 10^{-5} Ohm-cm, which is comparable to commercial equivalents and doesn't require extraction or special handling conditions.

Other areas that have been explored include selection of bio-derived substrates, assessment of alternative conductive fillers and use of low energy and fast light-based curing and sintering methods.

Finally, we will show how these approaches can lead to developing new materials and processes to enable better recycling, to re-claim high value materials and components that would otherwise be lost to landfill.

Cannabinoid-Based Bioplastic Conductive Composites for Circular-Lifecycle Medical Electrodes Michael Sotzing[1], John M. Toribio[2], Amy Pollock[2], Gregory A. Sotzing[2] and Alex Chortos[1]; [1]Purdue University, United States; [2]University of Connecticut, United States

Establishing bioplastics derived from renewable resources as an alternative to petrochemical-derived plastics is an emergent strategy for combating the effects of plastics on the environment. Current bioplastics exhibit uncertain biocompatibility and limited mechanical and processing characteristics. We prepare poly(cannabinoid)s by step growth polymerization of bifunctional carboxylic acids with hemp-derived cannabinoids containing two hydroxyl groups. The resulting thermoplastic poly(cannabinoid)s are the first of their kind to include cannabinoids directly in their polymeric backbone. Homopolymer and copolymer synthesis utilizing a wide variety of available cannabinoids and dicarboxylic acids enables a large range of mechanical properties, in turn promoting development of application-specific materials. Melt and solution processibility of poly(cannabinoid)s broadens fabrication capabilities. The observed natural anti-inflammatory and anti-oxidative behavior of poly(cannabinoid)s provides improved biocompatibility. Furthermore, the capability of poly(cannabinoid)s to degrade through base-catalyzed hydrolysis facilitates repolymerization and reprocessing of polymer composites. The healthcare industry, the second largest producer of waste globally, is a suitable gateway for this nascent materials platform. Medical waste is increasing due to the proliferation of single-use devices such as electrocardiogram (ECG) electrodes that are commonly employed for patient monitoring. We fabricate electrodes composed of tungsten particles, a biodegradable and biocompatible metal, dispersed in a homopolymer of poly(cannabinoid)s. Adhesives are prepared from poly(cannabinoid) copolymers with low glass transition temperature. Fabrication is performed using direct-ink-write printing. Ink rheology

is optimized using solvents such as di(propylene glycol) methyl ether that have minimal impact on the biosphere compared to other organic solvents. Electrodes exhibiting a volume resistivity of 0.2 ohm-meters are demonstrated functionally using ECG acquisition techniques.
Poly(cannabinoid)s enable chemical recycling of the electrodes after use. Ester linkages in poly(cannabinoid)s provide a path for facile depolymerization via base-catalyzed hydrolysis. Exposure of electrodes to dilute ammonium hydroxide at 80 degrees Celsius yields cannabinoid monomers, dicarboxylic acids, and tungsten. Concurrently, exposure of tungsten to ammonium hydroxide results in selective etching of surface oxide layers, increasing interparticle electrical conductivity resulting in low volume resistivity of new composites. After hydrolysis, components can be easily separated because the high density of tungsten facilitates centrifugation, whereas the hydrophobicity of the cannabinoids and hydrophilicity of the diacids facilitate chemical separation. To assess the lifecycle of materials post-recycling, we repolymerize poly(cannabinoid)s using reclaimed cannabinoids and carboxylic acids and form composites with recycled tungsten particles to show that functional medical electrodes can be reformed. This chemically-driven circular process ensures the preparation of electrodes that meet the required properties for medical devices, including high reproducibility and high materials purity.

1:45 PM EN09.10.03
Biodegradable Polymers for Reducing Electronic Waste Kaitlyn E. Crawford; University of Central Florida, United States

Plastics enable our modern standard of life from safety and shelter to advanced technologies in electronics and aerospace applications. Thus, we must accelerate fundamental research to innovate advanced polymer materials with new properties. Our modern lifestyle is coming at a severe cost, however, with serious and legitimate economic, energy, and environmental concerns in using plastic. For example, electronic devices, while primarily thought of as agglomeration of metals and semiconductors, are often comprised largely of plastic—up to 90% plastic in some cases. Unfortunately, however, ~50 million tons of electronic waste (e-waste) is generated annually with up to 80% of that waste expected to reach landfills. With the emergence of new electronic technologies, including flexible electronics for human health monitoring, identification of more bio-friendly materials is critical to offset their environmental impact. To this end, the development and integration of degradable materials for wearables can facilitate the decomposition of electronic devices when they are no longer needed. This talk focuses on the development of biodegradable polyesters using step-growth polymerization and incorporation of naturally occurring materials such as polysaccharides. The purpose is to move toward identification of new materials to replace non-degradable plastics in flexible electronics. Included in this talk is a discussion of the synthetic pathways for formation of high glass transition temperature (≥ 80 °C) polyfluorene derivatives and use of polysaccharides with respect to their corresponding structure-property relationships. A demonstration of their use in flexible electronics as either an active component or encapsulating layer, followed by a study of their degradation pathways will also be covered.

2:00 PM EN09.10.04
Biomass-Derived Super Hygroscopic Polymer Films for Sustainable Moisture Harvesting Youhong Guo[1,2], Weixin Guan[2] and Guihua Yu[2]; [1]Massachusetts Institute of Technology, United States; [2]The University of Texas at Austin, United States

Extracting ubiquitous atmospheric water is a sustainable strategy to enable decentralized access to safely managed water. Early efforts on fog capture and dewing enabled the gathering of small water droplets from air, which is only applicable to regions with high relative humidity (RH). The state-of-the-art sorbent-assisted atmospheric water harvesting presents a promising and universal approach for a wide humidity range but remains challenging due to its limited daily water output at low relative humidity (≤ 30% RH). Here, we will present our newly developed super hygroscopic polymer films (SHPFs) made from renewable biomasses consisting of konjac glucomannan (KGM) and hydroxypropyl cellulose (HPC), exhibiting excellent water uptake of 0.64 g g^{-1} at 15% RH and 0.96 g g^{-1} at 30% RH. KGM facilitates the highly porous structures with enlarged air-polymer interfaces for active moisture capture and water vapor transport. Thermoresponsive HPC enables phase transition of SHPFs at a low temperature to assist the release of collected water via hydrophobic interactions. With rapid sorption-desorption kinetics, SHPFs are capable of operating 14-24 cycles per day in arid environments, equivalent to a water yield of 5.8-13.3 L kg^{-1}. Synthesized via a simple casting method using sustainable raw materials, SHPFs highlight the potential for low-cost and scalable atmospheric water harvesting technology to mitigate the global water crisis.

2:15 PM EN09.10.05
Nanocellulose Aerogels as a Solid Template to Induce Protein Aggregation and Amyloid Formation Ashutosh Sinha[1,2], Nico Kummer[1,2], Tingting Wu[1], Kevin J. De France[1], Silvia Campioni[1], Peter Fischer[2] and Gustav Nyström[1,2]; [1]Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland

For decades, amyloid proteins were mostly studied in the context of their roles as contributors to disease. However, the increasing interest in the development of sustainable materials led to researchers exploiting and engineering amyloids for a myriad of functions. These include filtering heavy metals [1], antimicrobial activity [2], and enhancing biocompatibility [3] to name a few.
The formation of amyloids (ordered aggregates) as opposed to disordered aggregates upon protein unfolding is influenced by various factors such as temperature, pH and interfaces. In this research, we focus on the role of interfaces, particularly we are investigating how solid surfaces influence protein aggregation and amyloid formation. Previously, inorganic solid nanoparticles such as silica nanoribbons, carbon nanotubes, quantum dots, and cerium oxide nanoparticles were shown to induce amyloid formation in proteins such as human β2-microglobulin and Islet Amyloid Polypeptides [4, 5]. However, inorganic and synthetic solid templates are often not sustainable or biocompatible, limiting their utility and acceptability. Therefore, we instead used cellulose, the most abundant biopolymer on earth. Cellulose, obtained from plants, can be converted into cellulose nanofibers with a high surface to volume ratio and cross-linked to form CNF aerogels [6]. In order to induce amyloid formation on their surface, these CNF aerogels were exposed to a solution of hen egg white lysozymes at varying pH. The surface aggregation was studied via various microscopic and spectroscopic methods including FTIR, TIRF, and SEM. Previous reports indicated the adsorption of lysozymes onto the surface of aerogels via electrostatic complexation [7]. Our results indicate not only adsorption of lysozymes, but also the induction of protein aggregation and amyloid formation on the aerogel surface. Additionally, bulk aggregation (or a lack thereof) was investigated using DLS and AFM. By tuning the experimental conditions, amyloid formation was found to either take place exclusively at the aerogel surface or alternatively the presence of aerogels could accelerate bulk aggregation under conditions where little or no lysozyme aggregation was previously reported [2].
Our research provides a new, sustainable method for amyloid aggregation on solid templates. Additionally, the structural integrity of CNF aerogels along with the abundant availability of cellulose provides fascinating new opportunities to create amyloid-cellulose biohybrids.

2:30 PM EN09.10.06
Three-Dimensional Printing of Mycelium Hydrogels into Complex Living Materials Kunal Masania; ASM Aerospace Engineering TU Delft, Netherlands

Biological materials constantly adapt to their environment, display low embodied energy, and possess remarkable mechanical properties granted by their hierarchical structures. Adapting these principles to human-made objects promises to disrupt the way we engineer our high-performance critical structures. However, today's engineering materials remain lifeless, and show only limited abilities to adapt and reinforce under load, or to heal and repair in response to damage. Here we harness the livingness of fungal mycelium to reach emerging properties of complex adaptive systems in an engineering context. The potential of the resulting complex material is illustrated by 3D printing living functional skins. We show that fully biobased material is able to autonomously self-heal, self-regenerate and adapt its growth depending on the availability of nutrients in the environment. The adaptive nature of the living mycelium imbues the functional skin thus far inexistent in conventional synthetic materials. To create the animate complex material, we 3D print grid-like structures that provide a mechanically robust architecture combining open airways and a nutrient-rich environment for mycelial growth. The grid is printed using a granulated hydrogel ink that consist of a gelled culture medium inoculated with the fungus. The shaping freedom of the 3D printing process allows us to generate geometries that fulfill specific engineering requirements, such as the encapsulation of robotic parts with a living protective skin. The nutrient concentration in the grid is tuned such that the living mycelium features a balanced growth strategy that combines exploration and exploitation of its surrounding environment. In addition to this decision-making feature, the resulting living material presents several of the hallmarks of complex adaptive systems, such as the emergent behavior of decentralized cells, the efficient processing of information via a scale-free network, the dissipative self-organization processes that promote growth and the organization of building blocks over multiple length scales. This ultimately leads to self-healing, self-regeneration and adaptive properties that are chemically fueled by nutrients in the absence of human intervention.

3:15 PM EN09.10.07
Technological Prospecting, Assessment and Scale-Up of Macauba (Acrocomia aculeata)-Based Biosorption of Metal Ions from Water Alfonso Martinez Andrade[1,2], Julio C. Vargas Sáenz[2], Ângelo M. Denadai[3], Ricardo Orlando[1], Leticia Costa[1], Fernanda Costa Pinheiro[1] and Ruben D. Sinisterra[1]; [1]Universidade Federal de Minas Gerais, Brazil; [2]Universidad Nacional de Colombia, Colombia; [3]Universidade Federal de Juiz de Fora, Brazil

Superficial water contamination by anthropomorphic activities and environmental disasters has reached dangerous levels for the water security of humanity, turning this situation in a global concern, which is why the United Nations (UN), in the sixth Objective of Sustainable Development, proposes sanitation and access to clean water for all. Thus, alternative strategies using innovation for metal ions for removal from water is an urgent necessity, where environmental disasters such as those that occurred in Brazil (MG), Mariana (2015) and Brumadinho (2019), have polluted the water to levels that make their consumption unviable. These emerging technologies must ensure synergy with conventional technologies and guarantee economic and environmental viability.
Among the alternatives one could find the bio-based materials, as agricultural waste, for biosorption is a green strategy which helps to the solution of two problems and same time, recovery of polluted water and reuse of biomass materials. The main objective of the present work is the assessment and scale-up of bio-based residual materials for biosorption of metal ions in polluted superficial waters using the residual biomass Macauba (Acrocomia Aculeata) from the vegetable oil extraction process and its use in the design of adsorption systems with a high fluid dynamic regime.
Chemical treatments of the macauba endocarp with NaOH, H_2SO_4, H_2O_2 and NaClO were evaluated, as well as physical treatment with ultrasound waves, to improve the biosorption capacity. The materials obtained were characterized by TGA, MEV-EDS, X-Ray Fluorescence, metal quantification and Zeta potential. Adsorption tests were carried out, on a laboratory scale, with the metals Al^{3+}, Mn^{2+}, Pb^{2+} and Fe^{3+} at different conditions of pH, temperature and contact time, and a comparison was made with the use of natural material. Metals quantification was made by atomic absorption. The best results were obtained with the material treated with NaOH, achieving removals above 34% for Fe^{3+}, 28% for Mn^{2+}, 51% for Pb^{2+} and 46% for Al^{3+}, using 100 grams of macauba biomass and 234L/h of flow in a high-rate system.
Considering these results, the potential of this material for scale-up into a continuous separation operation is concluded, for which different strategies, as combination with minerals materials, are being tested to obtain a prototype of a high fluid dynamic regime adsorption system as an innovative strategy. In addition, technology prospection and bibliometric studies were carried out using public and private database, such as Scopus and Questel-Orbit.
Acknowledgments: The authors would like to thank to the Network for the study, development and application of technologies based on sustainable nanomaterials for the recovery of water from the Doce River basin (N°06/2016), sponsored by the entities: FAPEMIG, CNPQ, CAPES, ANA, FAPES and development in Chemistry Department of UFMG.

3:30 PM *EN09.10.09
Overcoming Challenges to Identifying Safer Materials/Products to Per- and Polyfluoroalkyl Substances (PFAS) Mark Rossi; Clean Production Action, United States

In the search to replace per- and polyfluoroalkyl substances (PFAS) in materials and products, how can concerned/relevant parties such as researchers, companies, non-governmental organizations (NGOs), and governments have greater certainty that the alternatives to PFAS are safer and not regrettable substitutes? Regrettable substitutes are alternatives that themselves become problematic; for example, replacing polystyrene foam clamshells with compostable fiber-based (e.g., bagasse) containers made with PFAS.

The entire class of PFAS is now a focus for elimination or restriction in many jurisdictions including state governments and the European Union. This is because over the past few decades PFAS contamination has grown into a serious global health threat due to the ability of these chemicals to persist in the environment for hundreds of years; their presence in almost all human populations; and increasing evidence of their health impacts. PFAS use in all industry sectors is under scrutiny, including food packaging, furniture, apparel/fabrics, firefighting foam, oil and gas, carpets and rugs, and cosmetics.

The journey to safer chemicals in materials and products includes the following stages: a) identify all intentionally added chemicals in the material/product as well as residual chemicals of high concern; b) assess the toxicity of those chemicals; c) avoid known chemicals of high concern; and d) select materials/products with safer chemicals. This journey to safer solutions, for example, to products free of per- and polyfluoroalkyl substances (PFAS) is fraught with many challenges.

Significant challenges to identifying safer alternatives to PFAS and other chemicals of high concern include: 1) confidential business information -- very few materials/products have complete disclosure of all the chemicals intentionally added to the product as well as residual chemicals of high concern to human health or the environment; 2) toxicological capacity -- very few organizations possess the technical capacity to assess the toxicity of the chemicals

in materials/products and to understand how to interpret that data; and 3) availability of materials/products that do not contain chemicals of high concern.

Product certifications provide a unique framework for overcoming these challenges because they create incentives for manufacturers to disclose chemical constituents to a trusted third party with the goal of receiving a product certification that can be used to promote a product for being "PFAS-free" and using preferred chemicals. "PFAS-free" is in quotes because it must be defined, for example as encompassing, no intentionally added PFAS and no residuals above a specified threshold such as 100 parts per million (ppm) per homogeneous material.

To identify PFAS-free and preferred products Clean Production Action developed a certification program called GreenScreen Certified. The methodological requirements for identifying preferred products include: a) chemical ingredient disclosure; b) all chemicals assessed for hazards; c) avoidance of known chemicals or classes (e.g., PFAS) of chemicals of high concern, including carcinogens, mutagens, reproductive or developmental toxicants, endocrine disruptors, persistent/bioaccumulative/toxic chemicals (PBTs), or other similarly toxic chemicals; d) meets analytical testing requirements – for example, for PFAS residuals in the products.

Overall, PFAS-free and preferred products have been identified for significant uses of PFAS, including in firefighting foam, food service ware, furniture and fabrics, textile chemicals, and cleaners and degreasers used in manufacturing.

4:00 PM *EN09.10.10
Sustainable Chemicals and Materials—An Update on Policy Drivers Molly Jacobs; University of Massachusetts Lowell, United States

Our materials economy is extremely reliant on a small number of feedstock chemicals, massive economies of scale and limited innovation – all of which is not sustainable. This dependency on fossil fuel derived chemicals and materials is at the epicenter of the dual crises of climate change and toxic pollution. However, global action on climate change, a growing focus on material circularity and increased attention on a transition towards safer and more sustainable chemistry are generating significant opportunities to rethink and recreate how materials are designed for the future.

Policy is in important driver supporting these changes. Advancing sustainable and renewable polymers and bio-based materials is dependent in part on government policies that help to counter-act the tremendous barrier that unsustainable incumbent materials have on the marketplace. This presentation will provide an update on policy developments, primarily those in the United States (US) and the European Union (EU), that are underpinning progress related to safer and sustainable chemicals, materials and products. Policies to be discussed include the US Sustainable Chemistry R&D Act, policy actions by US States including the California Safer Consumer Products regulation, and a range of policy developments in the EU tied to the Green Deal and the Chemical Strategy for Sustainability.

SESSION EN09.11: Virtual Session
Session Chair: Bichlien Nguyen
Tuesday Morning, December 6, 2022
EN09-virtual

10:45 AM EN09.11.02
Tuning the Mechanical and Dynamic Healing Properties of Bio-Degradable Supramolecular Polylactone Copolymers by Controlling the Arm-Chain Crystallinity Woojin Lee[1], Jae Woo Chung[2] and Seung-Yeop Kwak[1,3,4]; [1]Seoul National University, Korea (the Republic of); [2]Soongsil University, Korea (the Republic of); [3]Research Institute of Advanced Materials, Korea (the Republic of); [4]Institute of Engineering Research, Korea (the Republic of)

Recently, supramolecular polymeric networks have attracted great scientific interests due to their healing ability of damaged fractures, which can significantly enhance the reliability and sustainability of materials. In particular, the multiple healing capability of supramolecular polymers can be imposed by the dynamic dissociation/re-association of various supramolecular interactions such as hydrogen bonding, ionic bonds, metal-ligand coordination, and π-π interaction etc. In general, most supramolecular polymer networks are consist of low T_g amorphous polymeric chains with more dynamic supramolecular bonds for faster healing performances. Although the more dynamic supramolecular polymeric networks, which is composed of flexible chain and rather weaker supramolecular bonds, exhibit an improved healing ability, the mechanically robust supramolecular network structure may not be facilitated. Thus, to resolve these challenges, most research has been focused on developing the alternative supramolecular polymeric network structures with mechanically robustness and excellent healing performances, simultaneously.
In this study, a quadruple hydrogen-bonded supramolecular polylactone copolymer (QSCP) was successfully synthesized using an alkyl-branched ε-decalactone (ε-DL), which is renewable and bio-degradable ring-shaped lactone derivative, and ε-caprolactone (ε-CL), via ring-opening copolymerization. The effects of P(ε-DL) on structural, mechanical, and dynamic healing properties of QSCP were comprehensively characterized. The degree of polymerization (DP) and segment compositions of QSCP arm-chain are precisely adjusted by controlling the feed monomers-to-core ratio and monomeric fractions. As the composition of ε-DL increased for QSCPs, the maximum melting temperature (T_m) and enthalpy (DH_m) values gradually decreased. These indicates that the alkyl-branched P(ε-DL) disrupted the formation of hard P(ε-CL) crystalline phases. Especially, the prepared QSCP s with ~ 10 mol% of P(ε-DL) (i.e., QSCP90) displayed a significantly improved elongation at break (~ 700%) with a highly enhanced tensile strength (~ 6 MPa). In addition, the optically- and mechanically-measured self-healing of QSCP90 were found that the mechanically-damaged QSCP90 was sufficiently recovered after ambient self-healing conditions (50 °C). These results clearly suggested that an optimum composition of arm-chain enabled QSCPs to form the complementary hard/soft multi-phase system, i.e., a hard phase bearing crystalline PCL and a soft phase containing P(ε-DL) with quadruple hydrogen bonding moieties, eventually resulting in highly improved tensile properties with a facile healing behavior.

10:50 AM EN09.11.03
Advances in Self-Healing Concrete Lauren Marshall; The American School in London, United Kingdom

With three tonnes utilized per person, concrete is one of the most common building elements in our society. However, cracks in concrete pose dangers to the concrete's strength and structures built with concrete. For decades, the most common method of maintaining safe structures after cracks have developed in concrete has been through replacement with new concrete. This production of concrete leads to approximately eight percent of the world's carbon dioxide emissions.

Identification of methods to significantly reduce the negative impacts associated with cracked concrete as well as newer ideas to minimize the waste associated with cracked concrete will be explored. This presentation will include an examination of the effectiveness and sustainability of various

approaches to self-healing concrete and whether safety concerns associated with repairing concrete through these methods can be adequately addressed.

10:55 AM EN09.11.04
Surface Enhancement of Coir Fibers for Better Bacterial Accumulation Keshani R. Perera and Madhubhashini Maddumaarachchi; Faculty of Applied Sciences, University of Sri Jayewardenepura, Sri Lanka

Nowadays, contamination of water via pathogenic bacteria, viruses, and parasites is one of the major health problems facing by the society. Therefore, an effective method is essential to rapidly capture the bacteria from water to minimize water contamination by pathogens. The usage of chemical disinfectants in conventional water purification processes has become a challenge due to the formation of carcinogenic by-products and antibiotic-resistant bacterial pathogens. As a solution to that, this study introduces an eco-friendly bacteria capturing strategy using natural coconut fibers as a substrate, which is modified by a novel polymeric coating. This polymer coating consists of an amine functionalized diatomaceous earth/poly(vinyl acetate) composite. Diatomaceous earth (DE) is an inexpensive, environmentally benign, highly porous amorphous silica structure and DE has been treated with a (3-Aminopropyl)triethoxysilane coupling agent to enhance bio-affinity toward bacteria. A poly(vinyl acetate) (PVAc) binder is used to disperse treated DE. PVAc is a nontoxic, eco-friendly thermoplastic adhesive used as a binder to prepare coatings. Alkaline treated coconut fibers were dipped in the treated DE/PVAc composite coating to prepare the modified fibers. The positive charges of the surface amine functionality of the treated DE can promote strong electrostatic interaction with the negatively charged bacterial cell membrane. Further, the pendent propyl group of amine functionality can also play a supplementary role in attracting bacterial pathogens by forming hydrophobic interactions. Fourier transform infrared (FTIR) spectroscopic analysis was conducted to confirm the presence of silane coupling agents on the DE and to characterize the chemical components of (3-Aminopropyl)triethoxysilane treated DE/PVAc coated coconut fiber and raw coconut fiber. The bio-affinity of raw coconut fiber and modified coconut fiber was compared in terms of bacteria capturing ability. Bacterial capturing ability was investigated based on UV spectrophotometer absorbance measurements using *E. coli* bacteria as a model bacteria type. The UV absorbance measurements of the *E.coli* cell suspensions containing modified coconut fibers were gradually decreased over time. Further, the *E.coli* solution containing raw coconut fibers showed an approximately similar absorbance variation to the control sample containing the *E.coli* cells only. The obtained results indicated that the (3-Aminopropyl)triethoxysilane treated DE/PVAc composite coating could be considered as a favorable surface treatment for the coconut fibers for better bacterial accumulation from the aqueous medium.

11:00 AM EN09.11.05
Ureolytically Induced Calcium Carbonate Composites as Bioadhesives Sobia Anjum, Kaylin Clark, Kendall Parks, Chelsea Heveran, Albert Parker and Robin Gerlach; Montana State University, United States

Synthetic adhesives, which currently dominate the adhesives market, are generally petroleum-based and commonly release volatile organic compounds (VOCs) during production or use. Indoor accumulation of VOCs can have detrimental human health effects, and outdoor release of VOCs can have adverse environmental effects (*e.g.,* photochemical smog). Therefore, there is a need for alternative, more sustainable, natural, and natural-synthetic hybrid materials as adhesives. Ureolytically induced calcium carbonate composites (UICCs) are a new design space for sustainable, and low VOC natural adhesives. UICCs are currently used for a broad array of applications, including soil stabilization, concrete remediation, creating subsurface barriers, etc. The aim of this work is to investigate UICC adhesive shear strength and environmental durability.
UICCs are produced by a reaction driven by ureolytic bacteria (*e.g., Sporosarcina pasteurii*) or by crude urease enzyme preparations (*e.g.*, from Jack bean meal). Urea hydrolysis generates carbonate ions, which can form calcium carbonate in the presence of dissolved calcium. The composite adhesive is formed by aggregation of the urease source (bacteria or extracted enzyme), organics, and calcium carbonate precipitates. To test the adhesivity of the UICC adhesives, a modified ASTM D1002.10 method was used. The adhesive was applied to glass and stainless-steel coupons in single lap joint mode, cured, and then tested in tensile extension to measure its shear strength. The shear strength of the adhesives was optimized for glass and stainless-steel surfaces by varying the type of additive (guar gum and soy protein isolate), the concentration of the urease source, and the concentration of calcium ions. UICC shear strength was also evaluated after exposure to various temperatures (-20°C, 25°, 100°C, and 300°C) and relative humidities (50%, 80%, and immersed in deionized water).
The highest shear strength achieved for the UICCs was 2MPa, as compared to the UICC free formulation at 0.2MPa. Image-based surface coverage analysis indicated that the majority of the samples exhibited a mixed failure (both adhesive failure at the composite-surface interface as well as cohesive failure within the composite). Temperature and humidity testing showed that the shear strength of the UICC composite increased by 41% at -20°C, and by 16% at 50% RH. Up to 75% of the initial shear strength was retained at 100°C. This data demonstrates the potential of UICCs for applications as bioadhesives on a range of surfaces and for common environmental conditions.

11:05 AM EN09.11.07
Bio-Inspired Polymer Matrix Based on the Chicken Waste to Novel Polyurethanes A.A.P.R. Perera, K.A.U. Madhushani, Felipe M. de Souza, Tim Dawsey and Ram K. Gupta; Pittsburg State University, United States

Although researchers are focusing on the production of bio-based polyurethane using plant sources, only a few studies have reported the use of animal waste, such as fish oil, in the production of polyurethanes. The amount of chicken waste produced in the United States is staggering, and chicken fat is a valuable by-product of chicken waste and is currently used for a variety of useful purposes. The high unsaturated fatty acids contents in chicken fat make it a prospective alternative source for greener polyurethane formation. This study was conducted to propose a feasible pathway to formulate new low-cost rigid polyurethane foams (RPUFs) with variable mechanical and thermal properties from the chicken fat. The hydroxyl groups were introduced along the fatty acids' chains through simple wet chemical methods. These CF-derived polyols had 96 mg KOH/g hydroxyl group content. The combination of 25−75 wt. % of chicken fat-based polyols with isocyanates formed the semi-rigid, rigid foams with a maximum of 142 kPa compressive strengths that can be further modified for various commercial applications. The characteristics of RPUFs were studied using density, closed-cell content, and scanning electron microscope. As the chicken fat-derived polyol replacement increased to 75 wt.%, the closed-cell content decreased significantly. The thermal behaviors of RPUFs were studied by gradually increasing the percentage of phosphorous-based flame retardant. More importantly, the burning time and thermal stability results revealed that the flame retardant mechanism depends on the matrix of the polyurethane foam. In summary, this work provides an innovative strategy for creating a new alternative source for the polyurethane industry.

11:10 AM EN09.11.08
Green Synthesis of Metal Oxide Nanoparticles Using Mandarin Orange Peels (Citrus reticulata) for Phase and Electrochemical Study of Supercapacitor. Rishabh Srivastava, Shiva Bhardwaj and Ram K. Gupta; Pittsburg State University, United States

Nanoparticle-based materials are the class of significantly emerging materials in all aspects of the field for research in biomedical, pharmaceutical, sensors, and electrical applications which incorporate various branches of science. These nanoparticles can be synthesized using a variety of methods like laser ablation, spark discharge, sputtering, sol-gel, and many more but the products obtained using these methods cause an adverse effect on the environment due to the presence of hazardous, non-biodegradable, and toxic products in nanoparticles. However, green synthesis is one of the solutions to the above-mentioned issues. Therefore, many researchers are pursuing green synthesis methods nowadays where plant parts such as leaves, stems, roots, flowers, and

fruit peels are currently utilized for the fabrication of nanoparticles (NPs) by their extracts. Hence it is considered an inexpensive and eco-friendly method of synthesis where bio-based NPs shows versatile characteristics. These bio-based NPs are widely used in energy storage applications. There are various devices that can store energy like fuel cells, batteries, and supercapacitors (SCs). Among all the energy storage devices (ESDs) SCs show extremely vibrant properties such as fast charge-discharge, high specific capacitance, and cyclic stability. This work includes a facile synthesis route of Cobalt Oxide nanoparticles (CONPs) using Mandarin orange peels. An aqueous extract of orange peel was considered as a precursor which performs a biological reduction mechanism for the synthesis of CONPs from Cobalt nitrate hexahydrate $Co(NO_3)_2.6H_2O$. Additionally, CONPs are also synthesized by using sodium hydroxide (NaOH) as a precursor for the comparative phase study which has been characterized by X-ray diffraction (XRD) and Fourier Transform infrared spectroscopy (FTIR). Furthermore, the obtained NPs are sulfurized and phosphorized to study the effect of morphology and crystalline structure on electrochemical activity. The pseudo-capacitor traits were analyzed by cyclic voltammetry (CV), galvanostatic charge-discharge (GCD), electrochemical impedance spectroscopy(EIS) in 3M KOH, and cyclic stability for over 5000 cycles. The noticeable specific capacitance showed by phosphorized cobalt oxide (P-Co_3O_4) is 244 F/g at a discharge current density of 1 A/g. Furthermore, the prepared CONPs retain a capacity of more than 82% after 5000 cycles.

11:15 AM EN09.11.09
Molecular Level Studies of Acetic Acid Adsorption and Reactions on Platinum and Nickel Lotanna Ezeonu, Simon Podkolzin, Ziyu Tang, Yue Qi and Fangliang Huo; Stevens Institute of Technology, United States

Pt and Ni-based catalysts are actively studied in the development of imporoved technologies for the conversion of biomass-derived feedstocks into fuels and chemical feedstocks, specifically for hydrodeoxygenation and steam reforming of bio-oils. Since acetic acid is a component of bio-oils as well as a widely used model compound, it is important to better understand its reactivity on Pt and Ni catalytic surfaces at the molecular level. In this study, acetic acid adsorption and reactions on Pt(111) were studied with infrared reflection absorption spectroscopy (IRAS), temperature-programmed desorption (TPD) and density functional theory (DFT) calculations. The results were compared to Ni(111) and Ni(110) surfaces.
At the dosing temperature of 90 K, acetic acid forms a physisorbed layer on Pt(111). At 140 K, acetic acid predominantly chemisorbs molecularly through its carbonyl oxygen atom. In addition, some dissociative adsorption is observed with the formation of acetate and hydrogen. Annealing to 193 K leads to a mostly complete conversion of molecularly adsorbed acetic acid to acetate species. At 440 K, acetate species decompose, evidenced by desorption of H_2, CO and CO_2. In contrast, due to differences in the adsorbed structures, acetate species decompose on Ni(110) at a lower temperature of 425 K. Above 425 K, only residual carbon remains on the Ni surface.

Rice Husk Based Biodegradable Cardboards for Packaging Applications Steven Delbove, Deepa Kodali, Siripong Malasri, Louie Lin and Ali Pourhashemi; Christian Brothers University, United States

Rice husk, also known as rice hull, is a byproduct created in the production of rice. With over 500 million tons of rice produced yearly in the world, the supply of rice husk is very high while the usage of it is low. Although United States accounts for only 2% of global rice production, it has become the World's fifth largest exporter with more than 6% of global exports. In 2019 alone, the state of Arkansas has harvested rice in 1,126,000 with an average yield of 7480 pounds per acre. Dried paddy yields around 20% of hull, 15% of stalk and 10% of bran. Taking advantage of this huge sustainable yield, this study focuses on developing the biodegradable cardboard utilizing the discarded rice husk that can be used for packaging applications while lowering the amounts of conventional pulping material. Rice husk contains about 15-25% lignin and 35-40% cellulose and is coarse and abrasive in nature. Hence, the rice husk is softened initially to make it into pulp. This study is aimed to determine the tensile and compressive strength of the paper. Hence, pretreatment of rice husk is performed by using various concentrations of NaOH and the effective pretreatment was observed at 2g of NaOH with 1000 ml of water for 100gms of ricehusk. The mixture thus obtained is blended into pulp and is placed in the trays to dry. When blended and softened, the husk alone was not able to hold any shape when tested in paper making molds. Hence, binding agent was added to the pretreated rice husk to hold the rice husk together and to improve the strength of the specimen. Four specimens were prepared by adding 5g of starch reagent, 5g of tapioca starch, 5g of clear elmers glue and 5g of starch reagent and 5g of elmers glue together. The specimen with tapioca starch was the weakest whereas the specimen with elmers glue and starch reagent was the strongest. The optimization tests with varying amounts of glue and starch reagent were in progress and the tensile and compressive strengths of the cardboards are yet to be determined. However, the studies showed favorable results suggesting that the rice husk together with biodegradable additives can be used to make cardboards for packaging applications.

11:25 AM EN09.11.11
A Flame Retardant Poly(lactic acid) Blend with Modified Cellulose and Ammonium Polyphosphate Minsik Shin[1], Christian Apostol[2], Allen Bethancourt[2], Yiwei Fang[2] and Miriam Rafailovich[2]; [1]Seoul International School, Korea (the Republic of); [2]Stony Brook University, United States

Poly(lactic acid)(PLA), a sustainable and biodegradable polymer, has the potential to be the next generation of eco-friendly materials to replace petroleum based thermoplastic. To further develop PLA applications in a wide range of areas such as tissue engineering, 3D printing, and food packaging, enhancing its flammability and mechanical strength remains challenging as most reinforcing fillers are non recyclable or environmentally destructive. Therefore, it is urgent to design a PLA composite with enhanced flame retardancy and balanced mechanical properties by only using green additives.
Cellulose is a renewable source that received lots of studies when combined with solid phase phosphate flame retardant, namely ammonium polyphosphate (APP), since cellulose generates char under combustion which acts as a physical barrier to stop the flame. APP is reported to effectively increase PLA flame retardancy but deteriorate ductility. While, as other scientific studies show, cellulose incorporated in polymer blend actually strengthens the overall tensile strength and maintains polymer toughness. In a polymer/solid phase flame retardant system, the interfacial energy between the polymer matrix and flame additives is essential to flame resistance performance. Contact angle measurement revealed that the high surface tension of PLA/cellulose and PLA/APP limits the efficiency of flame additives when burnt. Resorcinol bis(diphenyl phosphate) (RDP) can be easily coated with cellulose fibers under mild condition due to strong H-bonding interactions which is elucidated by Fourier Transform Infrared Spectroscopy (FTIR). Based on Young's equation and Owen-Wendt method, RDP lowers the surface tension between each component. Therefore, RDP coated cellulose fibers also act as a compatibilizer in PLA/APP blend, which is correlated with lower Tg analyzed by DMA. So that PLA melt blended with 5%RDP-Cellulose and 5% APP easily passes UL-94 V-0 criteria. The flame retardancy was also confirmed with limiting oxygen index and cone calorimetry. Thermogravimetric analysis (TGA) indicates that PLA/RDP-cellulose/APP has a different thermal decomposition history and higher residue~10% after 800 celsius compared with PLA/untreated cellulose/APP blend. Moreover, the addition of RDP coated cellulose fiber minimizes the negative effect of APP on mechanical properties. Izod Impact and tensile testing showed that the PLA/RDP-cellulose/APP composite has impact strength and tensile strength comparable to those of neat PLA.

Nanocellulose and Carboxymethyl Cellulose Beads as a Protective Matrix for Microbial Inoculants Mariana G. Brondi[1,2], Camila Florencio[2], Luiz Mattoso[2], Caue Ribeiro[2] and Cristiane Farinas[1,2]; [1]Federal University of Sao Carlos, Brazil; [2]Embrapa Instrumentation, Brazil

The application of microbial inoculants in agriculture is a sustainable alternative to increase crops productivity and reduce the environmental problems

related to the exacerbated use of agrochemicals. For a successful product, its formulation must provide protection to microorganism from its production to its final application on crops. The use of natural polysaccharides as encapsulation matrices has shown interesting results in the maintenance of cell viability. Matrices of cellulose and its derivatives (nanocellulose, carboxymethyl cellulose, among others) can be interesting to be used in this type of application, since these materials are abundant, renewable and biodegradable. Therefore, this study evaluated the encapsulation of spores of the biocontrol fungus *Trichoderma harzianum* in a green matrix of nanocellulose (CNC) and carboxymethyl cellulose (CMC), through a simple process of ionic cross-linking in a $CaCl_2$ solution. For beads production, two different polymeric dispersions with the spores (10^9 spores/g polymer) were evaluated: a 5% (w/v) CNC and a mixture of CNC (5%) with CMC (1.5% w/v) in a volume ratio of 3:1. These dispersions were dripped into the salt solution for beads formation. After the coagulation process, the beads were stored wet and under refrigeration. X-Ray microtomography and SEM micrograph showed the uniform distribution of the materials and highlighted the spore's presence within the matrices, respectively. Shelf-life tests showed that the free microorganism presented a much higher viability loss over time than the ones encapsulated. Antagonistic tests showed that the *T. harzianum* spores, encapsulated in both matrices and stored for 1 year, were able to suppress the growth of the phytopathogenic fungus *Fusarium solani*, maintaining its effect as a biocontrol agent. Therefore, our results indicated that both CNC and the composite CNC:CMC are interesting sustainable matrices for improving microbial inoculants protection and shelf-life.

Thermoelectric and Thermionic Transport in MoSe2 Mona Zebarjadi and Md. Golam Rosul; University of Virginia, United States

We study the thermoelectric properties of bulk $MoSe_2$ within relaxation time approximation including electron-phonon and ionized impurity interactions using first-principles calculations. The anisotropy of this 2D layered metal dichalcogenide is studied by calculations of electron mobility in the cross-plane and the in-plane directions. We show that the cross-plane mobility is two orders of magnitude smaller than the in-plane one. The inclusion of van der Waals interactions further lowers the carrier mobility in the cross-plane direction but minimally affects the in-plane one. The results for in-plane electrical mobility and conductivity are in close agreement with experimentally reported values indicating the accuracy of the calculations. In addition to thermoelectric transport, 2D layered heterostructures are appropriate for solid-state thermionic applications. We study electron transport across metal-$MoSe_2$-metal structures using first-principles calculations combined with Green's function method. We study the effect of the number of layers, the energy barrier, and the asymmetry of the contacts on the performance of MoSe2-based thermionic converters and show that the key to high-performance thermionic diodes is to make a low-energy barrier, low-resistance metallic contacts and we identify copper as the optimum metallic contact to $MoSe_2$ based devices.

Symmetry-Guided Design of Thermoelectric Materials Rinkle Juneja[1], Tribhuwan Pandey[2], Duncan H. Moseley[1], Raphael P. Hermann[1] and Lucas Lindsay[1]; [1]Oak Ridge National Laboratory, United States; [2]University of Antwerp, Belgium

Structural symmetries of crystals put strong constraints on the dynamics of quasiparticles and their associated transport behaviors. Here, I will discuss the role of twist symmetries in a variety of one-dimensional and bulk materials' classes, using first-principles calculations. The symmetry-driven behaviors will be discussed in the context of enforced degeneracies, chirality-induced topological crossings, and quasiparticle interactions governing transport behaviors of thermoelectric materials.The deeper insights into the selection rules for thermal transport and unique scattering observables validated by inelastic

neutron scattering measurements, provide new avenues in designing efficient thermoelectric materials.

The authors acknowledge support from the U. S. Department of Energy, Office of Science, Basic Energy Sciences, Materials Sciences and Engineering Division.

11:15 AM EQ01.01.03
Material Descriptors to Search for Low-Temperature Thermoelectric Materials Michael Toriyama[1], Adam N. Carranco[2], G. J. Snyder[1] and Prashun Gorai[2]; [1]Northwestern University, United States; [2]Colorado School of Mines, United States

Thermoelectric (TE) cooling offers an environmentally-friendly and reliable alternative to modern vapor compression cycles that utilize harmful refrigerants. One of the major bottlenecks in adopting TE cooling is the lack of low-temperature TE materials. In this study, we derive computationally-accessible material descriptors from a two-band Boltzmann transport model and predict the TE performance of narrow-gap semiconductors and semimetals. Through analytical modeling, we find that materials exhibiting high asymmetry between the transport distribution functions of electrons and holes yield high TE performance in narrow-gap semiconductors and semimetals. The high asymmetry manifests in the suppression of bipolar conduction. Inspired by the high TE performance of semimetallic Mg_3Bi_2-based materials near room temperature, we apply the material descriptors to search for Zintl phases with narrow and negative band gaps for low-temperature applications. By applying the material descriptors developed in this work, we screened 667 Zintl phases from the Inorganic Crystal Structure Database (ICSD) and identified few phases as promising low-temperature TE candidates. The material descriptors can be generally applied to search for other low-temperature TE materials with narrow and negative band gaps, beyond the Zintl phases considered in this study.

11:30 AM EQ01.01.04
When Power Factor Supersedes zT to Determine Power in a Thermocouple Duncan Zavanelli[1], Alex Pröschel[1], Joshua Winograd[1], Radion Cherkez[2] and G. J. Snyder[1]; [1]Northwestern University, United States; [2]Yuriy Fedkovych Chernivtsi National University, Ukraine

The primary material parameter determining power in a thermoelectric is the figure of merit zT. This figure of merit comes from the requirement for thermal impedance matching between the thermoelectric legs and heat exchangers in an optimally designed thermoelectric module. However, in a thermocouple temperature sensor, the geometry is constrained for temperature sensing. If the geometry is constrained so that the length of the thermoelectric elements is greater than a characteristic length, then the material thermal conductivity becomes less relevant. This makes the power factor the determining material metric for power output in such a device designed for temperature sensing.

11:45 AM EQ01.01.05
Using High-Throughput Calculations and Machine Learning to Understand Electronic Transport in Thermoelectrics Alex M. Ganose[1], Junsoo Park[2] and Anubhav Jain[3]; [1]Imperial College London, United Kingdom; [2]NASA Ames Research Center, United States; [3]Lawrence Berkeley National Laboratory, United States

The temperature dependence of experimental mobility is commonly used as a predictor of the dominant scattering mechanism in thermoelectric materials. However, if the scattering mechanism is determined incorrectly, this can lead to wildly inaccurate predictions of materials properties, frustrating efforts to optimise devices. In this work, I use a combination of high-throughput workflows and machine learned materials properties to generate a dataset of 24,000 mobility calculations. Based on this dataset, I demonstrate that the temperature-dependence of mobility is not a reliable indicator of the dominant scattering mechanism and instead reveal that many materials long considered to be dominated by deformation-potential scattering are instead controlled by polar optical phonons. This work highlights the potential for data driven approaches to provide insights for materials discovery and optimisation.

SESSION EQ01.02: Magneto-Thermoelectric Transport and Materials

Giant Nernst and Thermal Hall Effects in the Weyl Phase of $Bi_{1-x}Sb_x$ Topological Insulators Joseph P. Heremans[1] and Dung Vu[2]; [1]The Ohio State University, United States; [2]Yale, United States

Single-crystal $Bi_{1-x}Sb_x$ alloys with x>8 at.% are topological insulators (TI's) that become Weyl semimetals in a magnetic field applied along the trigonal axis. When a heat flux is applied parallel to the field, they display the thermal chiral anomaly, also known as the gravitational anomaly [1]. In this talk we present the thermal Hall effect and Nernst effect obtained on samples with x=11 and 15%. The data cross the TI-to-Weyl phase transition with the field along the trigonal direction but the measurement here are carried out with the heat flux perpendicular to the field. The thermal Hall effect is the second largest of any material (only the semimetal Bi has a larger effect, due to the simultaneous presence of electrons and holes). Above 100 K, it is of classical origin. Below 90K, it saturates in field, which cannot be classically explained. The Nernst effect is almost an order of magnitude larger than the Seebeck effect. It is classical above 100 K. However, the Nernst conductivity saturates at a non-zero value below 90K, another non-classical effect and possibly a signature of topological semimetals [2].

2:00 PM EQ01.02.02
Magnetic Fluctuation Enhancement of the Thermoelectric Energy Conversion at a Critical Doping in Magnetic Semimetal $Cr_{1+\delta}Te_2$ Mohamed M. Atwa[1], Yuita Fujisawa[1], Takatsugu Onishi[1], Markel Pardo-Almanza[1], Mathieu Couillard[1], Keita Harada[1], Tsunehiro Takeuchi[2,3] and Yoshinori Okada[1,3]; [1]Okinawa Institute of Science and Technology, Japan; [2]Toyota Technological Institute, Japan; [3]Japan Science and Technology Agency, Japan

$Cr_{1+\delta}Te_2$ is a self-intercalated transition metal dichalcogenide that hosts tunable electronic filling and magnetism in its semimetallic band structure. Recent angle-resolved photoemission spectroscopy (ARPES) studies have unveiled a systematic shift in this semimetallic band structure relative to the chemical

potential with increased Cr doping. This presentation reports on the temperature and magnetic field dependence of the longitudinal thermopower S_{xx} for different $Cr_{1+\delta}Te_2$ compositions. We show that as doping increases, the sign of S_{xx} changes from positive to negative at the critical doping level of $\delta \sim 0.5$. This observed doping-dependent trend in the thermopower is consistent with the evolution of the semimetallic band structure from ARPES. An anomalous enhancement of the thermoelectric response is also observed around $\delta \sim 0.5$, where the formation of a pseudogap and competing magnetic interactions are expected to become prominent. Our findings collectively point to the critical nature of the doping level δ_c (~0.5) in magnetic semimetal $Cr_{1+\delta}Te_2$. Around δ_c, near-Fermi-energy pseudogap formation and magnetic fluctuations play a vital role in enhancing thermoelectric energy conversion.

2:15 PM EQ01.02.03
Doping as a Tuning Mechanism for Magneto-Thermoelectric Effects to Improve zT in Polycrystalline NbP Eleanor Scott[1], Katherine Schlaak[1], Poulomi Chakraborty[2], Chenguang Fu[3,4], Satya Guin[4,5], Safa Khodabakhsh[1], Ashley Paz y Puente[1], Claudia Felser[4], Brian Skinner[2] and Sarah J. Watzman[1]; [1]University of Cincinnati, United States; [2]The Ohio State University, United States; [3]Zhejiang University, China; [4]Max Planck Institute for Chemical Physics of Solids, Germany; [5]Birla Institute of Technology and Science Pilani, India

Weyl semimetals combine topological and semimetallic effects, making them candidates for interesting and effective thermoelectric transport properties. Here, we present experimental results on polycrystalline NbP, which demonstrates a simultaneous existence of a large Nernst effect and a large magneto-Seebeck effect, typically not observed in a single material at the same temperature. We compare transport results from two polycrystalline samples of NbP with previously published work, observing a shift in the temperature at which the maximum Nernst and magneto-Seebeck thermopowers occur, while still maintaining thermopowers of similar magnitude. Theoretical modeling shows how doping strongly alters both the magneto-Seebeck and Nernst thermopowers by shifting the temperature-dependent chemical potential, and the corresponding calculations provide a consistent interpretation of our results. Thus, we offer doping as a tuning mechanism for shifting magneto-thermoelectric effects to temperatures appropriate for device applications, improving zT at desirable operating temperature. Additionally, the simultaneous presence of both a large Nernst and magneto-Seebeck thermopower is uncommon and offers unique device advantages if the thermopowers are used additively. Here, we also propose a unique thermoelectric device which would collectively harness the large Nernst and magneto-Seebeck thermopowers to greatly enhance the output and zT of conventional thermoelectric devices.

2:30 PM EQ01.02.04
Enhanced Thermoelectric Properties Through Carrier Scattering by Localized Nano-Magnetism Junphil Hwang[1], Jae Hyun Yun[2], Jong-Soo Rhyee[2], Jungwon Kim[3], Sujin Kim[1] and Sung-Jin Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Kyung Hee University, Korea (the Republic of); [3]Institute of Advanced Composite Materials, Korea Institute of Science and Technology(KIST), Korea (the Republic of)

Thermoelectric energy conversion has a lot of attention because of its simple and convenient energy conversion of heat to electricity. In this work, the thermoelectric energy conversion efficiency was enhanced in huge amount by introducing nano-magnetic impurity. The localized spin moment of nano-magnetic impurity interacts with conduction electron spin, resulting scattering of conduction electron. The scattering changes the energy dependence of electron scattering time, inducing decoupling of Seebeck coefficient(S) and electrical conductivity(σ). In general, the S and σ are coupled and limit the enhancement of thermoelectric conversion efficiency. The powerfactor($S^2\sigma$) was enhanced in whole temperature range, thus the thermoelectric figure of merit, zT was enhanced up to 1.8 at 923 K in Mn doped SnTe nanocomposite. The sophisticated theoretical analysis about electron scattering was conducted using Boltzmann transport equation.

2:45 PM EQ01.02.05
Thermal Hall and Nernst Effects in the Direction of sPin Canting in Antiferromagnet $YbMnBi_2$ Jiamin Wen[1], Dung Vu[1], Sarah J. Watzman[2], Claudia Felser[3] and Joseph P. Heremans[1]; [1]The Ohio State University, United States; [2]University of Cincinnati, United States; [3]Max Planck Institute for Chemical Physics of Solids, Germany

A large anomalous Nernst effect (ANE) is desirable for thermoelectric applications in transverse geometry, because it leads to simple thermoelectric device construction. $YbMnBi_2$, a topological antiferromagnet, was demonstrated to have a large ANE conductivity of ~ 10 A m^{-1} K^{-1}, with a magnetic field **B** applied along [100], temperature gradient ∇**T** applied along [001] and Nernst voltage $\mathbf{V_N}$ measured along [010], that exceeds observed values in most ferromagnets[1]. In this study, we investigated the Nernst effect and thermal Hall effect in a different configuration in which **B** is applied along canted ferromagnetic moment direction [110], ∇**T** along [1-10] and $\mathbf{V_N}$ along [001]. In this talk, we present here the experimental data showing that the ANE conductivity is even larger (30 ~ 70 A m^{-1} K^{-1}) than the previously reported value[1]. The thermal Hall effect is also anomalously large across the experiment range 40 K < T < 300 K and shows a step in field that suggests the existence of an Anomalous Thermal Hall Effect (ATHE).

Magnetically Self-Assembled Stretchable Thermoelectric Devices for Energy Conversion on Skin Byeongmoon Lee[1], Hyeon Cho[2], Heesuk Kim[1], Yongtaek Hong[2] and Seungjun Chung[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Compliant forms of thermoelectric devices (TEDs) can provide unprecedented opportunities for skin electronics to be completely untethered, enabling autonomous power systems. For efficient energy harvesting from soft and shape-changing heat sources such as the human body, the TEDs need to conform to complex three-dimensional (3D) surfaces without air gaps that would, otherwise, result in significant heat loss. However, most previous flexible TEDs show limited mechanical conformability due to their bulky inorganic thermoelectric (TE) legs and thick metal electrodes. Recently, soft interconnects such as liquid metals have been utilized to improve the flexibility of TEDs, but the high thermal impedance of elastomer passivation interferes with heat transfer from heat sources to TE materials, significantly reducing their energy harvesting performance.
In this presentation, we will introduce intrinsically stretchable components that can maximize the mechanical conformability and TE performance of compliant TEDs based on the magnetic self-assembly of inorganic particles in elastomeric matrices. Metal particles are magnetically self-assembled into vertical thermal paths in an elastomeric matrix, substantially increasing the through-plane thermal conductivity of elastic platforms. As stretchable interconnects, silver nanowire random networks embedded in the elastomeric platforms efficiently absorb strain energy between inorganic TE legs under deformation. Owing to the soft electrical and thermal conductors, TEDs based on the elastic platforms could form great mechanical and thermal contact with complex 3D heat sources, efficiently harvesting thermal energy from them [1]. In addition, we would like to show unprecedented fully soft TEDs,

where inorganic TE legs are replaced by elastomer composites with magnetically self-assembled TE particles. These results highlight the feasibility of our approach in the realization of high-performance compliant TEDs, paving a new route to fully self-powered electronic skin. The detailed methods and results will be discussed at the conference.

First-Principles Calculation of Thermoelectric and Thermomagnetic Transport Effects Using Phoebe Jennifer Coulter, Andrea Cepellotti and Boris Kozinsky; Harvard University, United States

As the need for energy-efficient devices has become more pressing, so has interest in finding ways to enhance the thermoelectric performance of materials. While first-principles methods based on density functional theory can describe these properties, the calculation of transport coefficients can be computationally demanding and memory intensive. To address this challenge, we present ongoing developments to Phoebe [1], a high-performance framework of phonon and electron Boltzmann transport equation solvers with the ability to predict the transport coefficients relevant to thermoelectric performance.

In particular, we will discuss the recent addition of magnetotransport predictions in Phoebe. While transport due to thermomagnetic effects can in some circumstances enhance thermoelectric performance, magnetotransport and thermomagnetic transport effects have rarely been computationally investigated. Using Phoebe, we calculate magneto and thermomagnetic transport coefficients to explore the physics underlying these effects in several materials.

Validating Experimental Measurement of Electrical Resistivity, Seebeck Coefficient, Hall Coefficient and Nernst Coefficient Using NIST SRM 3451 Matt Beekman, Andrew Jarymowycz, Chad Dutra, Matteo Benedetti, Travis Nichols, Christian Posadas and Kyle Thomson; California Polytechnic State University, United States

Measurement of the four transport coefficients, electrical resistivity, Seebeck coefficient, Hall coefficient, and Nernst coefficient has yielded important experimental insights into features of electronic structure and charge carrier scattering responsible for enhanced thermoelectric performance. While this powerful experimental technique, often referred to as the "method of four coefficients," remains underutilized in the thermoelectric materials research community, interest in its use has increased in recent years. Like all transport coefficients, thermomagnetic properties like the Nernst coefficient require careful measurement and validation of measurement accuracy, e.g. by using standards or through inter-laboratory comparison. While resistivity measurements can be validated using platinum or other standards, and Seebeck measurements can be validated using the NIST SRM 3451 or 3452, well-defined and widely available standards are not available for Hall or Nernst coefficient. Furthermore, Nernst coefficient measurements are not commonly performed in most research labs, making inter-laboratory comparison nontrivial. Here we describe a method for validating measurement of all four of the above coefficients using a single reference material, namely NIST SRM 3451, mounted for measurement in the same configuration as a research sample, in a single measurement cycle, without the need for inter-laboratory sample exchange. Data for all four coefficients in the temperature range 80 K to 400 K are reported, which will also be of use for researchers wanting to validate new or existing measurement systems in their own laboratory. A comparison of different measurement protocols will also be presented.

4:15 PM EQ01.02.09
New Trick for an Old Dog—From Prediction to Properties of "Hidden" Clathrates Kirill Kovnir; Iowa State University, United States

The zinc-antimony phase space has been heavily investigated due to the structural complexity and abundance of high-performing thermoelectric materials. Consequentially, the desire to use zinc and antimony as framework elements to encage rattling cations to achieve Phonon Glass Electron Crystal properties has remained an enticing goal. Guided by the Zintl electron count prediction we explored the *A*-Zn-*Pn* (*A* = cation; *Pn* = As, Sb) phase space via *in-situ* powder X-ray diffraction. *In-situ* studies reveal two "hidden" compounds which can only be synthesized in a narrow temperature range. The *ex-situ* synthesis and crystal growth exposed that compositionally and structurally unique new clathrate-like compounds formed. Single phase synthesis-enabled exploration of the transport properties confirming rattling of guest cations and revealed high Seebeck coefficients and low thermal conductivity. Further optimization of the figure of merit by aliovalent substitutions is computationally analyzed.

4:30 PM EQ01.02.11
Thermal Transport and Outstanding Thermoelectric Properties of 2D-3D Sb2Te3 Based Heterostructures with ZT>2.0 Khushboo Agarwal[1], Sergio Gonzalez-Munoz[1], Abhishek Ghosh[2], Mujeeb Ahmad[2], Bodh Raj Mehta[2] and Oleg V. Kolosov[1]; [1]Lancaster University, United Kingdom; [2]Indian Institute of Technology Delhi, India

While low dimensional and nanostructured materials are long proposed as potential candidates for high performing thermoelectrics (TE), the implementation of these is so far limited [1]. Here we report a large enhancement of the thermoelectric power factor and figure of merit, ZT, in Sb_2Te_3/MoS_2 multilayer structures and $Sb_2Te_3/AgSbTe_2$ composites with ZT exceeding 2.0 [2]. With thermal conductivity being a defining factor in ZT, we use a novel approach to simultaneously experimentally determine the values of in-plane (k_{xy}) and out-of-pane (k_z) thermal conductivities for multilayer and composite samples with characteristic layer thickness of few nanometres, using scanning thermal cross-sectional microscopy (xSThM). We create a fine near-atomically flat low angle wedge cut on the nanoscale multi-layered TE material via Ar ion beam exit nanopolishing followed by measurement of the local thermal conductance. A simple analytical model is then used to extract the quantitative values of anisotropic thermal conductivities, k_{xy} and k_z as well as to estimate the interfacial thermal resistance between the substrate and sample surface.

For Sb2Te3/MoS2 multilayer structure the thickness and number of layers was optimized to achieve extremely low values of thermal conductivity (0.7 ± 0.1 $Wm^{-1}K^{-1}$) along with higher values of power factor ($4.97 \pm 0.39 \times 10^{-3}$ $Wm^{-1}K^{-2}$) leading to high values of ZT of 2.08 ± 0.37 at 300 K. For 2D-3D Ag in $Sb_2Te_3/AgSbTe_2$ composite, the concentration was also optimized to increase values of ZT. Apart of discovering new highly efficient TE materials, the current methodology provides a powerful tool for quantifying the thermophysical properties in thin films and 2D materials with thicknesses on the order from few tens to several hundreds of nanometres, facilitating the search for new efficient thermoelectric and thermal interface and heat-spreading materials.

Mobility-Enhanced Thermoelectric Performance in Textured Nanograin Bi_2Se_3, Effect on Scattering and Surface-Like Transport Samaneh Bayesteh[1], Sebastian Sailler[1], Heike Schlörb[1], Ran He[1], Gabi Schierning[2,1], Kornelius Nielsch[1] and Nicolas Perez[1]; [1]IFW Dresden, Germany; [2]Universität Bielefeld, Germany

We report on the effect of artificially generated textures of Bi_2Se_3 in thermoelectric performance and low-temperature magnetoresistance [1]. A set of texturized nanograined Bi_2Se_3 samples was investigated, ranging from predominantly *c*-axis texture to random texture. *c*-axis oriented layered domains rendered the samples highly conducting due to drastically enhanced mobility, up to 1600 $cm^2V^{-1}s^{-1}$ at low temperature, and enhanced both carrier concentration and electrical conductivity. The largest power factor of 800 $\mu Wm^{-1}K^{-2}$ and highest 0.14 both at 300K were observed in a sample with a predominantly layered and c-axis oriented texture. The carrier scattering mechanism in the samples changed from mostly electron-phonon interaction at in the predominantly layered microstructure, to disorder-related scattering as the texture became random. The weak antilocalization effect was observed predominantly in the random textured samples, pointing towards enhanced surface-like transport channels. The phase coherence length evaluated using the Hikami-Larkin-Nagaoka model resulted in a high value of roughly 600 nm regardless of the texture. In the *c*-axis oriented layered Bi_2Se_3 oxidic insulating inclusions from either Fe_3O_4 or SiO_2 were incorporated. Both insulating phases reduced mobility. However, finely dispersed Fe_3O_4 secondary phase in Bi_2Se_3 resulted in a further increase of 0.2 due to much increased electrical conductivity. The combined effect of layered texture and Fe_3O_4 secondary phase resulted in an overall increase of around 50% compared to a non-textured polycrystal.

A General Approach for Exploiting X-Ray Dynamical Diffraction in Material Sciences and Biophysics Rafaela F. Penacchio[1], Maurício B. Estradiote[1], Milton S. Torikachvili[2], Cláudio M. Remédios[3], Guilherme A. Calligaris[4], Stefan Kycia[5] and Sergio L. Morelhao[1]; [1]Institute of Physics, University of São Paulo, Brazil; [2]San Diego State University, United States; [3]Federal University of Pará, Brazil; [4]Brazilian Synchrotron Light Laboratory, Brazil; [5]University of Guelph, Canada

Structural analysis with atomic resolution is, unequivocally, the cornerstone that underpins the development of fundamental areas of human knowledge such as structural biology and materials engineering. On a global scale, billions of dollars are invested annually in equipment and large facilities for structural analysis techniques. Even with all the existing know-how, there are still limits in the resolution of certain structural details capable of unraveling the exact origin of important properties of various organic and inorganic systems. It also applies to standard X-ray scattering and diffraction methods. One way to acquire more detailed structural information beyond that accessible by conventional crystallography is to exploit the X-ray dynamical diffraction (XRDD) phenomenon. It is well-known that XRDD allows direct measurements of diffracted wavefield phases, as extra information on top of the diffracted intensities. Although there are many examples of how to exploit phase measurements [1-4, and references therein], there are a few steps that can be quite difficult for the inexperienced user of the method as it is in its current conception: what are the structural details of a given system accessible by phase measurements only, and how to perform data acquisition and data analysis.
In this work, a general approach for exploiting XRDD in virtually any crystal system is presented as implemented into an open-source Python package (PyDDT - Python Dynamical Diffraction Toolkit). It allows experiment planning based on the available Crystallographic Information File (CIF) of the materials. Susceptibility of XRDD to structural details such as valence of chemical species, vacancies and anti-site occupation, internal strain due to foreign atoms, and relative differences in atomic displacement are easily investigated through a differential model structure generation tool inside the PyDDT. Optimum resonant diffraction conditions are also identified in this experiment planning step prior to the actual experiment. After a successful data collection, fast semi-automatic data analysis is carried out by the PyDDT for extracting all structure factor phase information available in the data set. Graphic tools for comparing experimental and theoretical phases conclude the application of the method by stating feasible model structures capable of explaining the XRDD data. Here the application of this approach is demonstrated in a few emblematic cases. Probing electron charges in silicon covalent bonds and in amino acid var der Waals bonds [3], as well as in using resonant diffraction to elucidate vibrational atomic displacements in a thermoelectric crystal [4]. In summary, the PyDDT is demonstrated for probing electronic density and atomic displacements of organic and inorganic crystals using laboratory and synchrotron radiation. This package establishes standard procedures for using this approach of X-ray dynamical diffraction, which now are reproducible by other researchers and transferable to other systems, being a big step toward the spread of the technique.

Challenges and Novel Strategies in High-Performance Thermoelectric Material Engineering Karan Giri, Yan-Lin Wang, Yu-Chieh Shih, Ling-Chun Chao, Chuan-Wen Wang, I-Jung Wang, Yi-Chen Chen, Cheng-Ju Yang, Pei-Hsuan Cho and Chun-Hua Chen; National Yang Ming Chiao Tung University, Taiwan

Thermoelectric (TE) materials have been recognized as promising materials and make a prime contribution to converting waste heat into valuable electrical energy without further loss. In recent decades, researchers have witnessed the development of new and efficient mechanisms/ strategies to optimize the figure of merit (*ZT*) of these materials to recover low-grade heat more efficiently. The TE materials and devices are of greater importance because of their small size (scalable), lack of moving parts, high reliability, feasibility for miniaturization, lack of noise and pollution, and lack of emission of greenhouse gasses. An application of such characteristics delivers exclusive TE technology for numerous fields or niche applications, such as sensing and wearable electronics, waste low-quality heat recovery, TE refrigeration, aerospace, cogeneration, medical thermostats, zero radiation, and solid-state operation. To fabricate high-performance TE materials, a balanced trade-off between TE parameters is indispensable to optimizing the *ZT* value and is the key challenge to engineering such thermoelectrics. To achieve the highest *ZT* value, the maximization of the TE power and the electrical conductivity, and the minimization of the thermal conductivity are essential. To some extent, the hit-and-trial method can be effective in optimizing TE properties. Practically, it is possible to enhance the power factor by aligning and converging the electronic bands, modifying the electronic structure, and creating resonance states. All-scale hierarchical scattering and entropy engineering incorporate all of these outcomes into a single material system. Band flattening and resonant levels are two commonly adopted ways to increase the effective mass which has a significant contribution to optimizing TE performance. The first one can be brought about via the endorsement of dopants accommodating highly localized orbitals which leads to a fall in the overlapped orbitals. The Kane-band model illustrates that band flattening can enhance the bandgap E_g through band dispersion. And in the latter approach, the excess density of states (DOS) can be achieved via electronic coupling and is more efficient at a lower temperature than at a higher temperature because of the variation in relaxation time. Low dimensionality and electronic structural modifications, such as electronic band structure engineering and the creation of extrinsic defects through alloying and nanostructuring to suppress the lattice thermal conductivity (k_l), are efficient strategies to enhance the *ZT* of TE materials. The confinement of the electrons in low dimensions (D) such as 1D or 2D can improve the performance of TE materials by abruptly altering the electronic DOS. Low-dimensionality strategy is a milestone to initiate the nanostructure (quantum-well, superlattice structures, nanowires) studies in TE materials. When the phonon has a longer mean free path (MFP) than the electron then nanostructuring is an appropriate technique for the optimization of TE properties. The grains or nanoinclusions of a suitable size can be introduced into the specimen to scatter more phonons than the electrons. In the specimen, the interfaces are rationally designed to reduce their effect on charge mobility (μ) and to decouple it with k_l. While adding hierarchical scattering centers into the heavy-band TE materials, the reduction of maintaining high μ is a key to optimizing *ZT*. For this, the size of these centers should have a dimension larger than the MFP of the charge carrier but smaller than that of the phonon. Some of the high-performance fabrications described in this review paper exhibiting exceptional TE performance include two-dimensional PbTe quadruple layers, both p-type and n-type materials with enhanced values of 2.39 and 2.44 in the mid-temperature range, respectively, and the hole-doped tin selenide polycrystalline samples with a value of ~ 3.1 at 783 K.

EQ01.03.05
P-N Conversion of CrN Films by Oxygen Incorporation and Their Thermoelectric Properties Yi Shuang and Yuji Sutou; Tohoku University, Japan

Thermoelectric properties have been widely studied in bulk materials compared to thin films. However, in some specific applications, such as flexible temperature sensors, small-scale power generation applications and on-chip energy harvesting, thermoelectric thin films are playing a significant role. Traditional thermoelectric thin films showing a high ZT value such as tellurides are limited for the applications at elevated temperatures due to their poor stability, low corrosion resistance and toxicity.[1,2] Therefore, in the recent years, the transition-metal nitrides and rare-earth nitrides have been developed as a new class of thermoelectric thin films due to their outstanding mechanical properties, relatively low thermal conductivity and a variable range of electrical properties. Among them, chromium nitride (CrN) exhibiting *n*-type conduction is one of the most promising candidates as they can show a low electrical resistivity together with a large absolute value of Seebeck coefficient. Besides, the high melting point of CrN makes it possible to be used in high-temperature thermoelectric applications. To practically use the *n*-type CrN into thermoelectric applications, *p*-type materials are also needed. The best choice of *p*-type materials is the material with similar crystal structure and thermal properties such as the thermal expansion. In addition, intermixing of atoms or chemical reactions should be avoided between *p* and *n* layers. Therefore, it is an ideal way to develop one thermoelectric material with both *n*- and *p*-type conducting properties. For example, *p*-type CrN can be made by alloying with a small amount of Al into *n*-type CrN.[3] The alloyed Al element can behave as an electron acceptor that reduces the carrier concentrations of pure CrN and leads to a *p*-type conducting eventually. Febvrier et al. also proposed a *p*-type CrN by controlling the stoichiometry without the need for dopants deposited by DC magnetron sputtering at 600 °C. They demonstrated that p-type conduction can be attributed from Cr vacancies, which pushes the Fermi level down in the valence band.[4] In this study, we proposed a much simpler method to convert the semiconducting type of CrN by introducing oxygen dopants into the CrN film using a radiofrequency (RF) magnetron sputtering at room temperature. By fixing the chamber base pressure to be 10^{-5} Pa and varying the N_2 gas flow rate (f_{N2}) during reactive sputtering, the oxygen content in the CrN films can be controlled from 6.8 to 12.4 at. %. The *n*-type CrN can be successfully converted into *p*-type by tuning the oxygen content. The crystal structure, electrical property and thermoelectric property of the obtained CrN_xO_y thin films were investigated and discussed. The present method to tune the *p-n* type of CrN_xO_y films is simple and reproducible, which could contribute to a *p-n* homo-junctions enabling a better application in not only thermoelectric devices, but also wider fields such as photodetectors, selector devices etc. What is more, the room temperature growth of thin film would be beneficial for the flexible and wearable energy-harvesting, and compatible to the MEMS processing.

Effect of Powder ALD Interface Modification on the Thermoelectric Performance of Bismuth Shiyang He, Amin Bahrami and Kornelius Nielsch; Leibniz Institute of Solid State and Materials Science, Germany

In thermoelectric materials, phase boundaries are crucial for carrier/phonon transport. Manipulation of carrier and phonon scatterings by introducing continuous interface modification has been shown to improve thermoelectric performance. In this paper, a strategy of interface modification based on powder atomic layer deposition (PALD) is introduced to accurately control and modify the phase boundary of pure bismuth. Ultrathin layers of Al_2O_3, TiO_2, and ZnO are deposited on Bi powder by typically 1–20 cycles. All of the oxide layers significantly alter the microstructure and suppressed grain growth. These hierarchical interface modifications aid in the formation of an energy barrier by the oxide layer, resulting in a substantial increase in the Seebeck coefficient that is superior to that of most pure polycrystalline metals. Conversely, taking advantage of the strong electron and phonon scattering, an exceptionally large decrease in thermal conductivity is obtained. A maximum figure of merit, *zT*, of 0.15 at 393 K and an average *zT* of 0.14 at 300–453 K were achieved in 5 cycles of Al_2O_3-coated Bi. The ALD-based approach, as a practical interfacial modification technique, can be easily applied to other thermoelectric materials, which can contribute to the development of high-performance thermoelectric materials of great significance.

Enhancement of Thermoelectric Properties by Magnetic Impurities in Lead-free Thermoelectric Materials Sujin Kim, Junphil Hwang and Sung-Jin Kim; Ewha Womans University, Korea (the Republic of)

Thermoelectric technology has attracted a lot of attention because it enables eco-friendly power generation. The enhancement of thermoelectric

performance is challenging due to its strong inverse interrelationship between electrical conductivity (σ) and Seebeck coefficient (S). In this study, we studied non-toxic IV-VI compound GeTe with magnetic impurities. Our experiments showed an improvement in thermoelectric performance by doping unfilled d-orbital elements. Some of unfilled d-orbital elements were added as magnetic impurities in the GeTe. Previously, we found that magnetic impurities generate exchange interaction and induce additional scattering, resolving their strong inverse correlation between electrical conductivity and Seebeck coefficient. The exchange interactions occur between the spin angular momentum of itinerant electrons and that of magnetic impurities. The exchange interaction between the spin angular momentum of magnetic impurities and itinerant electrons generates the superparamagnetic fluctuation inducing additional scattering reducing thermal conductivity. The magnetic impurities showed synergetic effects of the increasing powerfactor ($S^2\sigma$) and decreasing thermal conductivity (κ) in $zT = S^2\sigma T/\kappa$ resulting enhanced thermoelectric performance of GeTe.

EQ01.03.08
End-On Oriented PEDOT/Graphene Films for Photo-Magneto-Thermoelectric Effect Byeonggwan Kim, Cheolhyun Cho and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

Orientation control of conductive polymer chain on substrate has been explored for molecular self-assembly engineering, improving the charge transfer, controlling the optical and electronic properties for realizing next-generation flexible electronics. The ordering of conductive polymers in one direction is a key approach to obtain high electrical conductivity and carrier mobility for controlling magnetoresistance and megneto-thermoelectric effect of polymer film. We challenged to align the poly(3,4-ethylenedioxythiophene) (PEDOT) chains perpendicular to the substrate to form end-on orientation. The PEDOT chains were grown on a monomer-functionalized graphene surface that was prepared by using 3D tectons and surface-confined host-guest chemistry. A highly crystalline PEDOT film with end-on orientation showed a reversible magneto-thermoelectric effect and control carrier transport from hot to cold *via* external magnetic fields. The film showed a Seebeck coefficient enhancement and a large magneto-thermoelectric effect. Taking advantage of a high photothermal effect of the film, a photo-magneto-thermoelectric effect was demonstrated to control carrier transport in thin-film *via* external magnetic stimuli with a light source.

EQ01.03.09
Mass Production of $Cu_{2-x}Se$ Nanoparticle for Thermoelectric Bulk Materials with Nanosized Grains via High Concentration Metal Complex Precursor Cheol-hui Ryu[1], Myeongjun Ji[1], Jeong Hyun Kim[1] and Young-In Lee[1,2]; [1]Seoul National University of Science and Technology, Korea (the Republic of); [2]The Institute of Powder Technology, Korea (the Republic of)

Electrical energy consumption is closely related to the growth of economic activity. Energy from fossil fuels causes air pollution, climate change, and global warming due to the release of harmful substances during combustion, so it must be replaced with renewable energy as a result. In accordance with this trend, thermoelectric (TE) technology using waste heat is attracting a lot of attention as an eco-friendly mechanism with high efficiency, wide application temperature range, and high reliability without moving parts. Currently, the medium and high temperature (400-750K) waste heat generated in the industry is being dissipated in a high proportion of more than 60% due to the limit of energy efficiency. Therefore, $Cu_{2-x}Se$, which has recently been attracting attention among various thermoelectric materials, is a copper-based chalcogenide and has low toxicity and cost-effectiveness. In the high-temperature superion phase above 400K, Cu ions are very disordered and mobile, resulting in very low k_L and high zT values, so the TE efficiency is high in the medium and high-temperature regions. Furthermore, to maximize TE characteristics, a technique for further reducing thermal conductivity by increasing phonon scattering with nano-sized particles through a powder metallurgy process is attracting attention.
Although various synthetic methods including hydrothermal, solvothermal, and thermolysis to prepare $Cu_{2-x}Se$ nanoparticles have been developed, they require suitable conditions such as relatively low precursor concentration, high temperature, high vacuum, many numbers of reactants, special experimental arrangements to perform the synthetic procedures. This causes low yield and difficulties in process optimization and commercialization. According to homogeneous nucleation and growth theory, the critical nuclei radius and critical energy to generate specific nuclei depend on a precursor concentration in the reaction medium. In general, the nucleation rate is faster at high precursor concentrations, which means that smaller nanoparticles can be synthesized in large quantities. However, the actual synthesis process using high concentration precursors causes problems in which particles are uneven in size and increase in size. Therefore, a new methodology is needed to solve this problem.
In this study, a solution-based mass-production technology of $Cu_{2-x}Se$ nanoparticles was successfully developed using a high-concentration metal complex precursor and ultrasonic energy. This approach can prevent a particle agglomeration by introducing complex molecules and instantaneous uniform energy supply and recovery via ultrasound. Using this facile and cost-effective strategy, $Cu_{2-x}Se$ nanoparticles with an average diameter of 150nm were successfully synthesized at room temperature and atmospheric pressure. In addition, by adjusting the Cu/Se precursor ratio in the starting reaction solution, it was possible to easily control the alpha and beta phase fractions of $Cu_{2-x}Se$, which greatly contribute to the thermoelectric properties. Then, according to process variables, the physicochemical properties of synthesized nanoparticles were systematically investigated by various analysis methods. After the $Cu_{2-x}Se$ powder of each composition was sintered using Spark Plasma Sintering (SPS), a sample having a nano-sized grain was obtained. Then, the physicochemical properties of the samples prepared according to the Cu/Se composition were systematically analyzed, and the correlation between the composition and the thermoelectric properties was identified through various analysis methods.

EQ01.03.10
Organic Thermoelectrics Thusharika Muthumali and Ryan Chiechi; North Carolina State University, United States

Thermoelectric (TE) materials are a class of materials that can be used to generate electricity from waste heat. For practical TE applications, both p-type and n-type materials must exhibit comparable figures of merit, in order to operate in tandem in a TE generator device. However, n-type materials have so far lagged behind p-type materials. Molecular doping is the key, limiting process to enhancing the performance of n-type materials. It has been demonstrated that n doping efficiency can be increased by lowering the energy of the LUMO level and improving host dopant compatibility. These are, fundamentally, synthetic challenges and we aim to address them as such. In this contribution, we will present our strategies for designing and synthesizing new polymers and dopants to address key properties systematically.
The high doping levels required to maximize performance and the differences in polarity between the host backbone, pendant groups, and ionized dopant molecules can drive deleterious phase separation within the doped film. These challenges can be overcome by tuning the doping concentration and designing pendant groups that interact with and control the dispersion of polar dopants such as 1,3-dimethyl-2-phenylbenzimidozoline (DMBI). Improving dopant solubility will lead to uniformity of the films, higher doping efficiency, and increased conductivity.
The energy of the LUMO (conduction band) of the host polymer also plays an important role in increasing doping efficiency in polymeric n-type materials. Manipulating this energy can be achieved by tuning the electronic structure of conjugated polymers. However, electron transfer between the host polymer and the dopant can also be facilitated by introducing electron-rich donor moieties in the dopant, which is why we approach the synthetic challenges to both simultaneously.

EQ01.03.11
Synthesis of Graphene/Cu Nanoparticles by Photoreduction Method for Enhancing Thermoelectric Power Factor Koki Saito, Takashi Shimizu, Shunya Sakane and Hideki Tanaka; Chuo University, Japan

Thermoelectric materials that can directly convert heat to electricity are attracting attention. Their thermoelectric efficiency is usually evaluated by thermoelectric power factor ($S^2\sigma$), where S is Seebeck coefficient and σ is electrical conductivity. Graphene is a promising thermoelectric material due to its high electrical conductivity (σ) derived from its inherent high carrier mobility, good thermal stability and excellent mechanical strength. It has been reported that graphene composited with highly conductive precious metal nanoparticles (Pt, Au, Ag) forms conductive bridges and improves thermoelectric properties by increasing σ [1]. We have focused on copper as alternative metals to precious ones because copper is abundant in the earth and has as high electrical conductivity as precious metals. Therefore, the combination of graphene and copper nanoparticles (Cu NPs) is expected to improve the σ. In this study, we synthesized Graphene/Cu nanoparticles (Gr/Cu NPs) by the photoreduction method which does not require environmentally hazardous reductants [2], and evaluated their thermoelectric properties.
Mixed solution of copper acetate and graphene was irradiated with UV light. The resulting precipitates were spin coated and annealed on a glass substrate to form thin films (Gr/Cu NP films). Structure of the thin films was analyzed by X-ray diffraction (XRD), and cross sections and surfaces of the thin films were observed by scanning electron microscopy (SEM). Their electrical conductivity (σ) was measured by van der Pauw method. Their Seebeck coefficient ($S= \Delta V/\Delta T$) was determined by measuring the potential difference (ΔV) and temperature difference (ΔT) by our hand-made system.
SEM images of Gr/Cu NPs showed particles with several dozens of nanometers on the graphene sheet. Cross-sectional SEM images of the thin films showed the thickness of 50~70 nm on the glass substrate. From XRD pattern, the diffraction peak originating from Cu(111) appeared. These results indicate that the nanoparticles observed in the SEM images were Cu NPs. When the dependence on the amount of Cu NPs in the thin film was examined, the electrical conductivity σ showed the highest value at 10 wt%. This value is 1.5 times higher than the graphene thin film, and this indicates the formation of conductive bridges through Cu NPs on the graphene. On the other hand, S showed no significant dependence on the amount of Cu NPs in the thin film. As a result, the power factor ($S^2\sigma$) of the optimized Gr/Cu NP thin films was 1.5 times higher than the graphene thin film.

Testing the Validity of Wiedemann-Franz Law Using Thermoreflectance-Based Methods in Thin Copper Films Md. Rafiqul Islam[1], John A. Tomko[1], Md Shafkat Bin Hoque[1], Eric Hoglund[1], Sean W. King[2], Christopher Jezewski[2], Colin D. Landon[2], Daniel Hirt[1], Kiumars Aryana[1], Colin Carver[2], Thomas W. Pfeifer[1] and Patrick E. Hopkins[1]; [1]University of Virginia, United States; [2]Intel Corporation, United States

To determine the thermal properties of thin metal films, a common approach is to measure their electrical resistivity and then calculate in-plane thermal conductivity employing the Wiedemann- Franz (WF) law and the bulk metal's Lorenz number. However, the implementation of the WF law in calculating thermal conductivity can be refuted because of the Lorenz number deviating from its bulk value owing to thickness-dependent microstructure, inelastic electron-phonon scattering events, and/or point defect density. In this work, we address the dearth of understanding of how thermal and electrical properties of copper (Cu) films scale at nanometer dimensions via independent measurements of the thermal and electrical transport properties. We perform sheet resistance and thermoreflectance-based nanoscale thermal conductance measurements on Cu films ranging from 25 to 500 nm thick, grown by physical vapor deposition (PVD) and electroplating methods. We directly measure the in-plane thermal conductivity of the Cu thin films via time-domain thermoreflectance and steady-state thermoreflectance techniques. We find the in-plane thermal conductivity of thin films deviates at least 15% from the WF law-derived thermal conductivity. This deviation in thermal conductivity of thin films can be attributed to their columnar grain structures and more electron-phonon scattering events compared to the bulk one.

EQ01.03.13

Synthesis of Single Phase α-Cu_2Se Nanowires by Photoreduction Method for Thermoelectrical Application Tatsuki Miura, Kazuki Munakata, Shunichiro Miwa, Shunya Sakane and Hideki Tanaka; Chuo University, Japan

Cu_2Se, a low-toxicity and low-cost p-type semiconductor, has attracted attention for various applications such as thermoelectric materials, photocatalysts, and solar cells due to its optical and electrical properties. Especially, there have been many reports that Cu_2Se exhibited high thermoelectric performance. For further enhancement of thermoelectric performance of Cu_2Se, nanostructuring is effective due to phonon scattering at nanostructure interfaces leading to thermal conductivity reduction. Recently, various Cu_2Se nanostructures have been synthesized. However, Cu_2Se usually shows a complex phase structure depending on temperature and Cu defects because Cu_2Se undergoes a reversible phase transition between the low-temperature phase α-Cu_2Se (monoclinic) and the high-temperature phase β-Cu_2Se (cubic) in the 350-410 K temperature range. Therefore, this makes it difficult to synthesize single-phase Cu_2Se nanostructures. We have focused on the photoreduction method as a synthesis of nanostructures. In the photoreduction method, strong reductant or toxic agent are not used, and the reaction speed is slow. In the synthesis of Cu_2Se nanostructures, the phase structure can be controlled by adjusting the light intensity and irradiation time due to the slow reaction. In this study, we aim to synthesize single-phase α-Cu_2Se nanowires (NWs) by photoreduction method and to evaluate their electronic structures.
Cu_2Se NWs were synthesized by following method briefly. Selenium dioxide and β-cyclodextrin were mixed in distilled water and sonicated . This solution was slowly mixed with L(+)-ascorbic acid solution under continuous stirring. Obtained precipitates were centrifuged and washed. Se NWs were synthesized by redispersion of this precipitates in ethanol [1]. The synthesized Se NWs and copper acetate were mixed in ethanol solution and irradiated with UV light. The product was obtained by centrifugation and Cu_2Se NWs was synthesized. Structural characterization of the prepared samples was performed using scanning electron microscopy (SEM), X-ray diffraction (XRD), energy dispersive X-ray analysis (EDX), and diffuse reflection UV-visible spectroscopy (DR UV-vis).
SEM images showed a nanowire structure with a diameter of about 500 nm and a length of several micrometers. It was found that the nanowire structure was maintained even after photoreduction. The EDX mapping results showed that the nanowires were composed of Cu and Se, and the atomic number ratio of Cu and Se was found to be about 2:1. The diffraction peaks in the XRD pattern of synthesized samples were attributed to α-Cu_2Se. These results indicate that α-Cu_2Se NWs were synthesized from Se NWs by photoreduction method.
DR UV-vis spectra of the synthesized α-Cu_2Se NWs were measured. In the UV-vis absorption spectrum of α-Cu_2Se, the absorption due to the interband excitation from the valence band to the conduction band appears at <800 nm, while the absorption due to the intraband electron excitation in the valence band appears at >800 nm. For the region below 800 nm, the band gap of the sample was obtained by using the equation of Tauc et al [2]. The band gap of synthesized α-Cu_2Se NWs was found to be 1.17 eV. This band gap value was in good agreement with that of bulk α-Cu_2Se (1.20 eV [3]).

Enhanced Thermoelectric Properties of $CoSb_3$-Based Skutterudite by Incorporating Reduced Graphene Oxide Mun Hwi Lee[1,2], Woo Hyun Nam[1], Jung Young Cho[1] and Young Soo Lim[2,2]; [1]Korea Institute of Ceramic Engineering & Technology, Korea (the Republic of); [2]Pukyong National University, Korea (the Republic of)

We report a strategy for enhancing thermoelectric properties in $CoSb_3$-based skutterudite through the incorporation of reduced graphene oxide (RGO). Double-filled *n*-type $CoSb_3$ (SKD) powder was obtained by encapsulated induction melting and grinding. The SKD-RGO hybrid powder was prepared by coating graphene oxide (GO) onto the SKD powder and followed by a chemical reduction process. The hybrid powder was consolidated into the SKD-RGO bulk composites by spark plasma sintering. Advantageous effects of the RGO incorporation both on the charge and phonon transports were observed in the composites. The electrical conductivity of the composites increased with increasing the RGO content. Although the incorporation of RGO reduced the Seebeck coefficient due to the increase in the carrier concentration, the composites exhibited an improved power factor. Furthermore, lattice thermal conductivity in the composites decreased due to an additional phonon scattering at SKD/RGO interfaces. This study suggests that the incorporation of carbon nanomaterials is a promising way to the simultaneous control of the charge and thermal transports for realizing high thermoelectric performance in skutterudite materials.

Carboxylic Acid Terminal Group Remarkably Enhances Thermopower of Aliphatic Monolayers Jiung Jang and Hyo Jae Yoon; Korea University, Korea (the Republic of)

In molecular thermoelectrics, study of thermopower in molecular junction permits access to physical-organic information about nano-scale thermoelectric energy conversion. Whereas π-extended building blocks have been considered as efficient thermoelectric materials, aliphatic molecules are usually avoided, and the related mechanism of thermoelectric energy conversion remains unclear. In this presentation, we show that replacement of methyl terminal group with carboxylic acid significantly enhances thermopower in self-assembled monolayer (SAM)-based large-area molecular junction. Using the liquid metal junction technique, we formed non-damaging contacts over the delicate surface of SAMs and examined length dependence of Seebeck coefficient. We focused on the following three different series of aliphatic molecules and compared their Seebeck coefficient: mercaptoalkanes ($HS(CH_2)_{n-1}CH_3$; n=2-10, 12, 14, 16, 18), mercaptoalkanoic acids ($HS(CH_2)_{n-1}CO_2H$; n=2-8, 11, 12, 16), and methyl mercaptoalkanoates ($HS(CH_2)_{n-1}CO_2CH_3$; n=2-8, 11, 12). Two interesting features were observed. i) The alkanoic acid molecules led to significant increases in the Seebeck coefficient by up to ~250 %, compared to the alkane molecules of similar lengths. ii) Rather surprisingly, in the short molecular-length regime ($n \leq 5$), Seebeck coefficient of alkanoic acid molecules increased as the length of aliphatic backbone increased, whereas the others (mercaptoalkane and mercaptoalkanoate molecules) exhibited linear regression of Seebeck coefficient with increasing the length. Structural analysis over the SAMs and theoretical calculations suggested that the unusual thermoelectric behaviors were attributed to the interplay between the supramolecular disorder in SAM and the electronic interaction between the carboxylic acid terminal group and top electrode, which had significant influence on the energy offset between Fermi level and energy level of accessible occupied molecular orbital.

EQ01.03.19
Moreau Relation and the Nernst Effect in Semiconductors Jean Ghantous, Max Buskirk and Matt Beekman; California Polytechnic State University, United States

An empirical relation first proposed by Moreau and later by Bridgman expresses the Nernst coefficient of a metal as the product of the Thomson coefficient, electrical conductivity, and Hall coefficient. Thus a feature of this relation is that the Nernst coefficient changes sign whenever the slope of the Seebeck coefficient changes sign, behavior that has been observed to hold not only in metals but also in some semiconductors. Here, within the Boltzmann transport theory, we provide an evaluation of the extent to which the Moreau relation applies to semiconductor materials more generally, and specifically in the case of Bi_2Te_3. Implications for interpretation of Nernst measurements for determining charge carrier scatting mechanisms, as well as applications in thermomagnetic energy conversion, will also be discussed.

Progress of Fabricating Heritage Silicon Germanium Unicouples Billy C. Li[1], Sutinee Sujittosakul[1], Vilupanur Ravi[1,2], Ike Chi[1] and Jean-Pierre Fleurial[1]; [1]Jet Propulsion Laboratory, United States; [2]California Polytechnic State University, Pomona, United States

NASA has successfully demonstrated Radioisotope Thermoelectric Generators (RTGs) as an effective power system to support numerous scientific deep space explorations. RTGs have consistently demonstrated their extraordinary reliability and longevity (40 years of continuous operation for Multi-Hundred Watt Radioisotope Thermoelectric Generator (MHW-RTG) on Voyager 1 and 2) while relying on thermoelectric materials and device technologies that were developed in the 1960s and 1970s. Recently, NASA announced plans to reestablish the General Purposes Heat Source-Radioisotope Thermoelectric Generator (GPHS-RTG) with Silicon-Germanium Unicouple(s) for potential future deep-space missions. However, the Silicon-Germanium unicouple production line in industry was discontinued in the late 1990s, resulting in loss of facilities, a combination of legacy equipment obsolescence and scattering of remaining legacy equipment to various government entities, bulk storage of legacy build-to-print procedures, loss of trained and knowledgeable personnel, and a likely loss in qualified vendors. To reduce potential risks due to this obsolescence, NASA's Radioisotope Power Systems program established a SiGe Task Force (NASA RPS DIR-006) in support of the Next-Generation RTG Project (Mod 1). The focus of task force support at NASA's Jet Propulsion Laboratory (JPL) has been on identifying and assessing initial key risks and exploring options relative to reestablishing the GPHS-RTG SiGe unicouple production line. To this end, JPL utilized its existing capabilities and heritage procedures of legacy SiGe unicouple production to conduct "heritage build-to-print" SiGe unicouple fabrication. Performing this "heritage" unicouple assembly and pellets/segments fabrication steps enabled JPL to identify critical processes and evaluate their robustness to variations from available legacy documentation and processes. Here, we report on the results of JPL SiGe unicouple assembly pathfinder practices using Cassini RTG production line ready-to-use parts.

Electrical Alignment of Single-Walled CNTs in Polymer Matrix Toward High Thermoelectric Performances Hyunjin Joh[1], Gophinathan Anoop[1], Seunghyun Jo[1], Hye Jeong Lee[2,1], KwangSup Eom[1] and Ji Young Jo[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of)

A Thermoelectric generator (TEG), which can convert thermal energy directly to electrical energy, is a promising candidate for renewable energy

converter. Flexible TEGs can easily be attached to heat sources order to reduce heat loss at interfaces rather than rigid inorganic-based TEGs, but their low thermoelectric performance still hinders their being commercialized. The performance of the TEGs can be expressed by thermoelectric figure of merit (ZT, where $ZT=S^2\sigma T/\kappa$, Seebeck coefficient (S), electrical conductivity (σ), and thermal conductivity (κ)). These parameters are highly entangled via carrier concentration in -preexisting homogeneous thermoelectric materials, which sets a fundamental limit of ZT in TEGs [1]. A composite consisting of insulating polymer and conducting nanoparticles are suggested to enhance the ZT in flexible thermoelectrics. Such composites provide a high σ *via* the formation of conducting paths based on nanoparticles and a low κ arising from the energy filtering effect [2]. We chose poly(vinylidene fluoride-trifluoroethylene) (P(VDF-TrFE)) for the polymer matrix and single-walled carbon nanotubes (SWCNTs) as the conducting reinforcement nano-material. In addition, we applied an alternating voltage to align the SWCNTs in the polymer matrix, which provides the high σ as well as the high thermoelectric ZT. Here, we successfully fabricated the freestanding P(VDF-TrFE)-SWCNT composite films with excellent flexibility. At 11.3 CNT wt % sample, thermoelectric Power Factor (PF, where $PF=S^2\sigma$) was measured as 1.25 $\mu W/m*K^2$. After inducing an electric field during the solution process to enhance PF, SWCNTs were aligned in the P(VDF-TrFE) matrix. Therefore, σ was increased (~500 S/m) much higher than non-aligned samples, while S decreased slightly (60 μV/K) resulting in PF increase up to 1.79 $\mu W/m*K^2$. PF of this composite film remained above 97% even in a highly bent condition (at bending radius under 5 mm), and also remained more than 95% after the 10^5 cycles of the bending test. The freestanding and flexible P(VDF-TrFE)-SWNT composite films can be attached to any surface and find applications in high-performance flexible thermoelectrics such as wearable devices.
To fabricate the thermoelectric composite film, various amounts of powder-type SWCNTs were dispersed in N, N-dimethylformamide (DMF) by magnetic stirring. P(VDF-TrFE) powder was added to the suspension and dissolved. After 24 hours of stirring at room temperature, the suspension was poured into Teflon mold and dried on a hot plate at 60˚C under an AC voltage. After 24 hours of drying, P(VDF-TrFE)-CNT sheet is fully dried and peeled off from the mold to be cut into a piece. Raman spectroscopy was used to investigate the alignment of CNTs, and a semiconductor caracterization system(Keithley 4200) and Seebeck measurement system was used for the electrical measurement. Differential scanning calorimeter(DSC) and an in-plane thermal diffusivity tester was measured to calculate κ of the film.

EQ01.03.22
SiGe and Mg_2Si Nanostructured Fibers as Thermoelectric Materials for Energy Harvesting Carolina Duque Sierra[1], Jose M. Sojo Gordillo[1], Merce Pacios[2], Alex Morata[1] and Albert Taracón[1]; [1]Catalonian Institute of Energy Research, Spain; [2]Universitat Autònoma de Barcelona, Spain

The enormous increase in energy demand for expanding the internet of things (IoT) to create more sustainable cities and communities has led to a much-needed boost in energy sources for low-power microelectronics. Thermoelectric (TE) materials present a versatile and environmentally beneficial option to harvest energy from ambient waste heat to power this transition. Moreover, thanks to nanostructurization, commonly poor TE materials (i.e., silicon) have remarkably enhanced their TE properties; this is the case for nanowires and Si-based fabrics made of nanotubes. Nonetheless, the scalability of Si-based nanostructured materials remains a challenge.
The present work studied Silicon-alloys (SiGe and silicides) nanotube-based fibers due to their integrability in the electronics industry and the abundance and low extraction environmental impact of the herein-used materials. Most importantly, the fabrication of TE nanotubes was up-scaled to large areas. The nanotube-based fabric was fabricated using an electrospun fiber template and chemical vapor deposition (CVD) in a bottom-up approach, allowing the tailoring of the orientation and thickness of nanotubes and the final fabric.
Different strategies to improve Silicon-alloys performance as
TE materials were explored in order to optimize their *Figure of Merit,* $zT = S^2\sigma/\kappa$. The thermal conductivity, κ, was tuned by rapid thermal treatments (RTP) techniques and studied employing Laser Flash Measurements; the Seebeck coefficient, S, was modified by varying the ratio between silicon and the alloying elements and characterized using Seebeck-coefficient equipment. We have also studied the change of the electrical conductivity, σ, by controlling the material's doping and the thickness of the nanostructures. Likewise, a complete morphological and compositional characterization was performed using electron microscopy techniques, EDX, and XRD.
Thus, the suitability of electrospinning and CVD to fabricate large-area TE materials was successfully accessed. Furthermore, the TE properties were investigated, and steps to optimal morphology and compositional conditions of the Si-alloy materials were found.

EQ01.03.23
Effects of PEDOT:PSS Microstructure on the Charge Transport and Thermoelectric Properties Juhyung Park[1], Jae Gyu Jang[2], Sung Hyun Kim[2] and Jeonghun Kwak[1]; [1]Seoul National University, Korea (the Republic of); [2]Wonkwang University, Korea (the Republic of)

Conducting polymer-based thermoelectric (TE) device, which can harvest low temperature waste heat, have great potentials as energy sources for operating various low-power electronic devices. Among various conducting polymers, poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) is one of the most attracting candidates owing to its high electrical conductivity, solution processability, flexibility, and air stability. Various post-treatments have been introduced to increase the thermoelectric properties of the PEDOT:PSS films. These methods have been known to change the crystallinity and relative PSS composition of the PEDOT:PSS films, which determines charge transport. However, how both the crystallinity and composition of the PEDOT:PSS films correlated to their charge transport and thermoelectric properties has not been intensively studied. Here, we present the interdependence of the microstructure (i.e. crystallinity and PSS composition), charge transport and TE properties using PEDOT:PSS films post-treated with various methods. The crystallinity and the composition of the PEDOT:PSS films were carefully characterized with both the grazing incidence wide angle spectroscopy (GIWAXS) and X-ray photoelectron spectroscopy (XPS). The charge transport properties of the films were investigated using theoretical models and the temperature-dependent electrical conductivity.

EQ01.03.25
Preparation and Characterization of Cu-Te Phases Synthesized by Focused Ion Beam Method Nils Braun[1], Vladimir Roddatis[2], Agnes Mill[1], Sonja Cremer[1], Hagen Bryja[1], Lennart Voß[3], Suyang Sun[4], Lorenz Kienle[3], Wei Zhang[4] and Andriy Lotnyk[1,5,6]; [1]Leibniz Institute of Surface Engineering (IOM), Germany; [2]GFZ German Research Centre for Geosciences, Germany; [3]University of Kiel, Germany; [4]Xi'an Jiaotong University, China; [5]The Research Institute of Advanced Technologies, China; [6]Harbin Engineering University, China

Specimen preparation for transmission electron microscopy (TEM) using focused ion beam (FIB) is a commonly used method [1]. An advantage over other methods is site specific specimen preparation that only damages a small area of the sample. However, it also suffers from many disadvantages. Artifacts induced by FIB range from ion implantation and resulting amorphization to thermal effects like phase transitions [2,3]. In this work, we prepared different nanoscale Cu-Te phases from Cu (electrodes) - Sb_2Te_3 (thin films) system [4] using FIB method. Copper chalcogenides have shown promising thermoelectric properties, e.g. high efficiency and tunability, which are key motivations for research on these materials [5].

Sb_2Te_3 thin layers with thicknesses of 17 or 100 nm are epitaxially grown on p-type Si (111) substrates. Samples with a 24 nm thick polycrystalline Sb_2Te_3 thin film are grown on a SiO_2 coated wafer using pulsed laser deposition (PLD) [4]. Cu, Pt/Cu and Cr layers are deposited by magnetron sputtering on top of the Sb_2Te_3 layers. TEM specimens are prepared at varied beam currents using a standard cross-section FIB preparation method [1]. Ion beam parameters are varied and lowered up to 15 kV, 250 pA for the trenching step before lift out. FIB specimens are investigated using advanced methods of aberration-corrected scanning TEM such as atomic-scale HAADF imaging and atomic-scale chemical analysis (EDX and EELS). In situ x-ray diffraction heating of

the Cu-Sb_2Te_3 thin film is performed to confirm structural changes.

Dependent on beam current used during FIB lamella preparation and Sb_2Te_3 layer thickness, hole formation in the Cu layer, thickness change and chemical changes of the Sb_2Te_3 layers are observed. Layer thickness after FIB specimen prepared at normal milling parameters are 28 nm and 23 nm for reduced parameters in a sample with originally 17 nm Sb_2Te_3. Hole formation is also decreased indicating less material transport. The structural changes are confirmed by in situ x-ray diffraction heating in addition. Samples with a 17 nm Sb_2Te_3 layer showed uniform intercalation of Cu while a sample with 100 nm thick Sb_2Te_3 layer exhibited differential intercalation behavior. In specimen prepared from the in situ heated samples Sb_2Te_3 and Cu-Te grains are observed. The introduction of a Pt layer between the Cu electrode and Sb_2Te_3 layers hindered structural changes caused by FIB. The same effect is observed in the heated sample where a Sb layer was formed between the Cu and Sb_2Te_3 layer. Moreover, Cr-Sb_2Te_3 and a Cu-GeTe layer systems showed no modifications of Sb_2Te_3 and GeTe thin films during FIB preparation. In polycrystalline Sb_2Te_3 specimen the intercalation of Cu and formation of new Cu-Te phases was also observed. Here a formation of a tetragonal Cu_2Te phase is found.

This work shows that structural changes in Sb_2Te_3 thin film systems can be induced during FIB specimen preparation of Cu (electrode)-Sb_2Te_3 (thin films) systems. The influence of different factors such as ion beam current, layer stacking sequence, Sb_2Te_3 structure and layer thickness on the formation of Cu-Te phases are evaluated. The changes are thermally induced transitions caused by FIB process, while redeposition of Cu plays a minor role. Similar thermal effects can be observed in heated samples. Other studied systems show no modifications.

Electron Band Engineering for Thermoelectric Semiconductors G. J. Snyder; Northwestern University, United States

Thermoelectric semiconductors typically have complex electronic band structures as it leads to improved performance. This complexity arises from orbital chemistry as well as structure. Band inversion and warping can also lead to complex band structures and unusual electronic properties beyond thermoelectrics such as topological insulating behavior.
The DOS and transport effective masses are commonly used to describe electronic transport in semiconductors using a classical analogy to the kinetic theory of gasses. The Seebeck coefficient can be used conductivity and Hall measurements to characterize the DOS mass [1] and DOS weighted mobility [2] to provide direct experimental characterization of DOS and mobility at room temperature and above. In materials with complex electronic structures the DOS and inertial masses can vary significantly. For example, in many valley electronic structures such as PbTe, with N_V isolated valleys in the Fermi surface, the DOS mass can be high and inertial mass low for high thermoelectric quality factor. High valley degeneracy has been found in many high zT systems such as Bi_2Te_3, $Mg_2(Si,Sn)$, $CoSb_3$ skutterudites and some Half Heuslers.
In some systems the Fermi surface pockets can be anisotropic and even non-ellipsoidal, such as the tubes of Fermi surface found in $SrTiO_3$. Tubes or sheets of Fermi surface rather than ellipsoidal pockets leads to a density of states like 1D or 2D low dimensional materials. By engineering the orbital chemistry complex behavior and unusual properties can be devised even in 3D materials.

Discovery and Characterization of an Off-Stoichiometric Stability Region in Combinatorial (Nb,Ta)FeSb Half Heusler Thin Films Dylan J. Kirsch[1,2], Joshua Martin[1], Nathan Johnson[3,4], Rohit Pant[2], Ichiro Takeuchi[2] and Apurva Mehta[4]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]Stanford University, United States; [4]SLAC National Accelerator Laboratory, United States

The NbFeSb ternary system is one of the higher performing p-type Half Heusler (HH) thermoelectrics but has a relatively high thermal conductivity. Several theoretical and experimental reports suggest that forming a solid solution mixture between Nb and Ta could lower lattice thermal conductivity without negatively affecting the electrical transport. Experimental investigations have studied (Nb,Ta)FeSb solid solution mixtures up to $(Nb_{0.6}Ta_{0.4})FeSb$, which is the Nb/Ta ratio that was found to exhibit the highest thermoelectric figure of merit. However, the effects of an excess or a deficit of Fe or Sb on both the electrical and thermal transport properties have been largely unexplored. There could be additional alloy stoichiometries with more optimized properties. Combinatorial thin film deposition provides an efficient route to synthesize a wide range of stoichiometries on a single substrate, enabling rapid screening of composition/structure/transport property relationships. Here we used combinatorial sputter deposition to investigate thin film mixtures of Sb, Fe, and a $Ta_{0.4}Nb_{0.4}Ti_{0.2}$ alloy target. Room temperature electrical and thermal transport properties were mapped as a function of atomic composition (micro-X-ray Fluorescence) using our custom-built suite of high-throughput measurement instrumentation, which includes a scanning Seebeck coefficient and 4-probe resistivity probe, and a scanning frequency domain thermoreflectance (FDTR) instrument. The structural properties were examined using a high throughput synchrotron X-ray diffraction (XRD) at Stanford Synchrotron Radiation Lightsource. Rietveld refinement of the single phase XRD patterns provide key insights into the role of excess Fe or Sb on the site occupancy and atomic ordering of the HH phase and the resulting electrical and thermal transport properties. A region of off-stoichiometric HH phase stability was identified that exhibits electrical and thermal transport properties which agree with bulk values reported in literature.

9:15 AM EQ01.04.04
Low Thermal Conductivity and Thermoelectric Performance of Zintl $Yb_{10}MnSb_9$ Leah E. Borgsmiller and G. J. Snyder; Northwestern University, United States

The recently discovered Zintl compound $Yb_{10}MnSb_9$ is a thermoelectric material very close in compositional space to high performing materials such as $Yb_{14}MnSb_{11}$ and $Yb_{21}Mn_4Sb_{18}$, making it an interesting candidate for high temperature thermoelectric applications. While others have characterized this material's crystal structure, here we measure and report electronic and thermal transport data for bulk polycrystalline $Yb_{10}MnSb_9$ up to 825K. We show that this material has ultralow thermal conductivity, likely due to the previously reported complicated crystal structure with partial occupancies. This ultralow lattice thermal conductivity in conjunction with a higher Seebeck coefficient than in other Yb-Mn-Sb compounds, leads to a moderate zT (thermoelectric figure of merit) of about 0.34 at 825K and is likely to peak at a higher value via material optimization. We approximate a bandgap of about 0.4 eV and expect the zT to be able to reach values as high as 0.33 at 725K given adequate doping (which is comparable to $Yb_{14}MnSb_{11}$ at that temperature) using a thermoelectric quality factor analysis. Additionally, we suspect that the zT has the potential to reach even higher values by improving the quality factor, B, through grain boundary engineering making it possible to surpass performance of $Yb_{14}MnSb_{11}$. Here we provide suggestions for future studies to improve thermoelectric performance. We also suggest that other undiscovered 10-1-9 Zintl compounds with thermoelectric potential likely exist, particularly $Yb_{10}MgSb_9$. This work is the first report of thermal conductivity, approximate bandgap, and zT for this $Yb_{10}MnSb_9$ compound, and we discuss implications of this material for future thermoelectric study through comparisons to the leading $Yb_{14}MnSb_{11}$ material.

9:30 AM EQ01.04.05
High-Entropy Chalcopyrite Materials with Ultralow Thermal Conductivity Somnath Acharya[1], Junphil Hwang[2], Kwangrae Kim[1], Woohyun Hwang[1], Aloysius Soon[1] and Woochul Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Ewha Womans University, Korea (the Republic of)

Currently, high-entropy alloys are of great interest in material science and engineering research. Unlike conventional alloys, which consist of two or three elements, high-entropy alloys contain multiple principal elements to form a single-phase solid solution with stable crystal structures. Because of its high configuration entropy, high-entropy materials can be more stable at elevated temperatures due to the minimization of Gibbs free energy ($G = H - TS$, where H is enthalpy, S is entropy, and T is temperature). In the context of thermoelectric material, the performance can be greatly improved by optimizing the entropy through lattice thermal conductivity suppression and via improving the crystal structure symmetry resulting in large Seebeck coefficients. Chalcopyrite compounds [(Cu/Ag)(In/Ga)Te_2] have been considered a promising thermoelectric material with high Seebeck coefficients and decent electrical conductivity. Here, we have studied $CuGaTe_2$-based multicomponent chalcopyrite to investigate their thermal and electrical transport properties. The major drawback of the $CuGaTe_2$-based compound is high lattice thermal conductivity due to its diamondoid structure. In this study, we observe that Ag and In alloying in $Cu_{1-x}Ag_yGa_{0.8}In_{0.2}Te_2$ leads to the enhancement of power factor and significantly reduces the lattice thermal conductivity. The transport studies and DFT calculation suggest that the power factor enhancement can be justified by the increase of charge carriers while the low lattice thermal conductivity has been explained through a strong phonon coupling between low-frequency optical phonons and heat-carrying acoustic phonons. Additionally, manipulating the configuration entropy via introducing Zn in $Cu_{1-x}Ag_yGa_{0.8}In_{0.2}Te_2$, lowers further lattice thermal conductivity to ~ 0.38 W/m-K at 850 K due to the strengthening of phonon scattering. Therefore, entropy engineering leads to significance improved thermoelectric performance of $CuGaTe_2$-based material.

Opportunities in Nanoscale and Nanocomposite Thermoelectrics Ali Shakouri; Purdue University, United States

An overview of thermoelectric effects in nanoscale devices and in bulk nanocomposites will be given. Some of the key ideas to increase the material figure-of-merit and the impact on the performance metrics of the energy conversion devices and systems are described. The role of geometry, dimensionality and non-equilibrium effects will be discussed.

10:45 AM EQ01.04.07
Defect Chemistry of Promising N-Type Thermoelectric $Y_2Ti_2O_5S_2$ Katarina Brlec and David O. Scanlon; University College London, United Kingdom

One of the many pathways to decreasing the impact of climate change is to increase the efficiency of current fossil fuel based systems. Even the best internal combustion engines suffer from thermal losses where up to 70% of energy is lost as exhaust heat. These losses can be offset to an extent by thermoelectric devices which convert waste heat into useful electrical energy via the Seebeck effect. The efficiency of thermoelectric materials is typically evaluated using the figure of merit (ZT), with some of the best performing materials reaching ZTs of > 2.[1] However, current state-of-the-art thermoelectric materials contain rare or toxic materials, making them commercially unappealing.

$Y_2Ti_2O_5S_2$ has been experimentally and computationally studied as a potential battery anode and photocatalyst for water-splitting.[2-4] Our recent work shows the intrinsically n-type $Y_2Ti_2O_5S_2$ is also a promising high temperature thermoelectric, with ZT exceeding 1 above 850 K at charge carrier concentrations of 10^{19}–10^{20} cm^{-3}.[5] Using hybrid density functional theory we investigate the intrinsic defect chemistry to determine the doping potential. Select n-type extrinsic dopants were considered to establish whether the charge carrier concentrations required for high ZT are indeed achievable.

New High Performance N-Type Bi_2Te_3-Based Thermoelectric Systems In Chung; Seoul National University, Korea (the Republic of)

Bi_2Te_3 has served as a representative thermoelectric system operating near the room temperature regime. It has been extensively studied to obtain higher thermoelectric figure of merit, ZT. However, there are two major tasks that have to be addressed for broad commercial application of this material system. First, effective doping or alloying for Bi_2Te_3 is so difficult that only few related phases show high thermoelectric performance. As a result, efficient performance-enhancing strategies have been developed in comparison with PbQ (Q = chalcogen) which is a canonical thermoelectric system for intermediate temperature range (500 – 900 K). Second, its n-type performs much inferior to the p-type counterpart, making it challenging to develop their high performance thermoelectric devices. In this presentation, I will present new synthesis methods to stabilize a wide range of new Bi_2Te_3-based materials. The temperature of a peak ZT can be readily tunable by changing the chemical composition of these series systemically. The best composition exhibits a ZT greater than 1.4, a record-high for n-type thermoelectric materials around atmosphere temperature.

11:30 AM EQ01.04.10
Investigating the Effects of Defect Energetics on Phase Boundaries Shapes Adetoye H. Adekoya and G. J. Snyder; Northwestern University, United States

Thermoelectric (TE) devices which offer a route for energy recovery/production often need to be optimized by doping with other elements to improve the thermoelectric figure of merit (zT), which qualifies the device's efficiency. The solubility of these elements in the bulk system is usually in such dilute concentrations that they can best be described as 0-D defects in an otherwise essentially uniform crystal. Though dilute, the defects can nevertheless be visualized on a phase diagram as providing some width to nominally single-phase regions or so-called line compounds. The width of these phases is known to be set directly by the defect energy of the defects, however, little attention is paid to the shape of these regions despite the fact that the shape of the region directly sets the solubility limits and thus the maximum concentration of defects in addition to providing an understanding of the dominant defects in that system. We discuss the thermodynamic factors that impact the shape of the phase diagrams and show how they can provide a guide to the optimal doping of semiconductors.

High-Temperature Elastic Moduli—A Tool for Understanding Chemical Bonding and Thermal Transport in Thermoelectric Materials Alexandra Zevalkink; Michigan State University, United States

Measurements of elastic moduli, in particular as a function of temperature, can play a key role in interpreting trends in lattice thermal conductivity. In addition to providing an accurate measure of sound velocity, the elastic moduli can be used to estimate a thermodynamic Grueneisen parameter using several different approaches. As a case study, this presentation will focus on high-temperature resonant ultrasound spectroscopy measurements of GeSe-$AgBiSe_2$ alloys. Recently, alloys between IV-VI and I-V-VI_2 semiconductors have been the object of intense investigations, owing to reports of lone-pair induced anharmonicity, ferroelectric instabilities, and spontaneous formation of nanostructures, all of which can contribute to their low thermal conductivity. The GeSe-$AgBiSe_2$ system is of interest because, within a narrow compositional window, the crystal structure progressively transitions from an orthorhombic structure (*Pnma*), to rhombohedral (*R3m*), to cubic rock salt (*Fm-3m*), with marked consequences on the lattice thermal conductivity. By studying the elastic behavior of the GeSe-$AgBiSe_2$ system, we can decouple the impact of composition and crystal structure on the sound velocities and phonon scattering rates. Within a given structure type, alloying with Ag and Bi leads to both softening and increased point-defect phonon scattering. However, the transition from rhombohedral to cubic symmetry causes a drastic step-like increase in the elastic moduli, and a corresponding increase in thermal conductivity. Overall, an improved understanding of the elasticity and anharmonicity of complex rock salt alloys may be useful in guiding the design of thermoelectric materials with tailored thermal properties.

Thermoelectric Properties of Thin Film of Metal Chalcogenides Grown on Flexible Substrate by MOCVD and Role of Energy Filtering at Grain Boundaries Giuseppina Pace[1,2], Arun Kumar[1,3], Pietro Rossi[2], Mario Caironi[2], Jean-Luc Battaglia[4] and Claudia Wiemer[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Università degli Studi di Salerno, Italy; [4]Université de Bordeaux, France

In many industrial processes more than 60% of the energy consumption is wasted into heat. [1] Recovery such heat as well as providing new solution for heat conversion into electricity is a “must be done” effort to contribute to novel green energy solution. This compelling request for sustainable and environmentally friendly energy supplies is driving the study of novel materials to be integrated into thermoelectric generators (TEGs). TEGs have attracted great interest in diverse fields, ranging from electronics to energy storage and conversion. Commercial TEGs are mostly based on bulk thermoelectric materials, providing flat and rigid module devices. However, to enlarge the field of application of such technology, such as micro-cooling ability for solving heat dissipation issues in electronics and light mobile devices for harvesting human body heat, the thermoelectric properties of thin film need to be improved and further investigated. Furthermore, curved and flexible module devices, offer potential for conformable devices enabling the versatile energy harvesting from heat sources of arbitrary geometries. [2]
Here we investigate the thermoelectric properties of Sb_2Te_3 thin films based on phase change metal chalcogenides deposited by Metalorganic Chemical Vapour Deposition (MOCVD) on flexible substrates. [3,4] Differently from other deposition techniques MOCVD enables large area applications, and it is therefore prone to scalable application. The Sb_2Te_3 thin-film growth on the flexible substrate is not commensurate, nevertheless good crystallinity is achieved and an out of plane 00*l* preferential orientation is achieved also at room temperature. We observed that the electrical and thermal properties of the flexible thin film are preserved even after mechanical stress cycling.
The improvement of the Seeback coefficient and the increased electrical conductivity following thermal annealing is explained in terms of an energy filtering effect, induced by the formation of larger Sb_2Te_3 crystalline domains contoured by a Te poor boundary phase. Our work highlights the importance of acquiring fundamental knowledge on the proper design of the boundary states and on the optimal interphase engineering, that can reveal to be key aspects to be controlled for the further improvement of thermoelectric performances of novel materials.

Investigating the Role of Vacancies on the Structure, Bonding and Thermoelectric Properties of $EuCu_{1-x}Zn_xSb$ Sevan Chanakian and Alexandra Zevalkink; Michigan State University, United States

The ZrBeSi structure type, consisting of alternating planar hexagonal nets intercalated by a cation layer, can accommodate large vacancy concentrations - up to 50% of the metal species which help form the hexagonal nets. Their tolerance for disorder and varying structural complexity provide routes to

amorphous-like lattice thermal conductivity, making them exciting for thermoelectric applications. Here, we investigate the impact of vacancies on the temperature dependent structural, thermal, and electronic properties of $Eu_2M^{1+}_{2x}M^{2+}_{1-x}Sb_2$ (M^{1+} = Cu, M^{2+} = Zn). The transition from a fully-occupied hexagonal net to one with a quarter of the atoms missing has wide-ranging consequences, particularly for the structural and phononic properties. With increasing vacancy concentration, we observe a non-linear expansion of the hexagonal net and simultaneous contraction in the perpendicular direction. Despite the absence of long-range ordering, pair distribution function analysis from synchrotron X-ray diffraction reveals significant local structural distortions caused by *M*-vacancies, which leads to strong phonon scattering. It is observed that while the fully-ordered compound, EuCuSb, is a stiff material with moderate thermal conductivity, its half-filled analogue, $EuZn_{0.5}Sb$ exhibits soft bonding which corresponds to the decrease in sound velocity. This, combined with increased scattering, leads to a precipitous drop in lattice thermal conductivity in the vacancy-rich $EuZn_{0.5}Sb$ samples (0.6 W/mK and 300K). The connection between structure, bonding and electronic properties are not as straightforward. Models incorporating different scattering mechanisms paint varied pictures into the compositional trends in electronic properties, particularly the mobility. These varied explanations of experimental observations warrant further investigation to truly understand how the stability of the planar hexagonal nets influences the electronic properties in the ZrBeSi family of materials.

Metrology, Certification and Release of SRM 3452—High-Temperature Seebeck Coefficient Standard (295 K to 900 K) Joshua Martin[1], Zhan-Qian Lu[1], Winnie Wong-Ng[1], Sergiy Krylyuk[1], Dezhi Wang[2] and Zhifeng Ren[2]; [1]National Institute of Standards and Technology, United States; [2]University of Houston, United States

To enable instrument validation and interlaboratory data comparison at high temperatures relevant to thermoelectric waste heat recovery, we have completed the development and certification of Standard Reference Material (SRM) 3452: *High-Temperature Seebeck Coefficient Standard* (*295 K to 900 K*), now available to the public. SRM 3452 is bar-shaped p-type boron-doped polycrystalline silicon-germanium alloy with a nominal composition of $Si_{80}Ge_{20}$. For the SRM 3452 material, we describe the synthesis, anneal-quench procedure, and structural and physical characterization. For the certification measurements, we describe the custom measurement instrumentation, measurement protocols, statistical analysis, the certified Seebeck coefficient values, comprehensive uncertainty budgets, and metrological traceability. Our extensive efforts to identify, reduce, and quantify measurement uncertainties will be emphasized. SRM 3452, together with complimentary SRM 3451: *Low-Temperature Seebeck Coefficient Standard* (*10 K to 390 K*), now provide certified reference materials traceable to the International System of Units for Seebeck coefficient measurements within the temperature range 10 K to 900 K with a broad overlap region (295 K to 390 K).

2:45 PM EQ01.05.05
Precision Interface Engineering by ALD in CuNi Alloys Towards High Thermoelectric Performance Shiyang He, Amin Bahrami and Kornelius Nielsch; Leibniz Institute of Solid State and Materials Science, Germany

Phase boundaries play a critical role in the carrier/phonon transport in thermoelectric materials. Herein, a novel technique for surface engineering of thermoelectric materials based on powder atomic layer deposition (pALD) of single/multi-layers of second phase on CuNi powders is presented. Ultrathin layers of various oxides (10–100 cycles of ZnO and Al_2O_3) are uniformly formed on the surface of CuNi alloy particles to validate or refute this idea. The formation of energy barriers and hierarchical interface modifications emerge from the deposition of ZnO/Al_2O_3 layers, leading in a considerable increase in the Seebeck coefficient. Although there is a slight decrease in electrical conductivity after 50 ALD cycles of ZnO, the increased Seebeck coefficients compensate for the loss and result in a 45% increase in power factor when compared to the pristine sample. In addition, the $ZnO/Al_2O_3/ZnO$ multilayer structure was designed to improve electrical resistance at phase boundaries. In coatings with a high cycle number of samples (> 25 cycles ZnO/5 cycles Al_2O_3/ 25 cycles ZnO cycles), the multi-layer structure retained an enhanced power factor while dramatically reducing heat conductivity. At 673 K, a maximum figure of merit (zT) of 0.22 was attained in 44 cycles ZnO/11 cycles Al_2O_3/ 44 cycles ZnO cycles multi-layer samples. When compared to pure CuNi, the zT value increased 144% due to pALD decoupling of thermoelectric parameters, which is comparable to the highest value ever recorded. The pALD technique to surface modification may readily be extended to different thermoelectric materials, assisting in the creation of high-performance thermoelectric materials.

Interface-Dominated Topological Transport in Nanograined Bi_2Te_3 Gabi Schierning[1], Sepideh Izadi[1], Sarah Salloum[2], Ahana Bhattacharya[2], Jeong W. Han[2], Lauritz Schnatmann[1], Stephan Schulz[2,2] and Martin Mittendorff[2]; [1]Bielefeld University, Germany; [2]University of Duisburg-Essen, Germany

Bismuth telluride is an excellent thermoelectric material and also belongs to the class of three-dimensional topological insulators. Therefore, surface charge carriers with extremely high mobility exist at the crystal surfaces. This is particularly visible in nanoparticulate samples, provided that the nanoparticles used have sufficient surface purity. Compacted nanoparticulate bulk samples exhibit a high density of interfaces. These samples show a pronounced weak anti-localization in the low-temperature transport behavior as well as a kink in the electrical resistance at about 5 K. Evaluation of the magnetotransport data using the Hikami-Larkin-Nagaoka model yields coherence lengths of up to 200 nm, which is significantly larger than the average grain size in the studied samples. Using terahertz spectroscopy, the average mobility of the surface charge carriers can be estimated to be about 1000 to 10000 $cm^2V^{-1}s^{-1}$ at room temperature. This means that good thermoelectric properties of nanoparticulate Bi_2Te_3 near room temperature are also determined in part by the existence of surface charge carriers.

4:00 PM EQ01.05.08
Phonon Channel Engineering Through Crystal Chemistry and Defects Matthias T. Agne; WWU Münster, Germany

Effective control over thermal transport is often a limiting factor in the development of energy efficient thermal/optical/electronic devices, especially thermoelectric materials that require ultra-low thermal conductivity. In the classic theory of thermal transport by atomic vibrations (phonons) in crystalline materials, heat moves in a manner analogous to a gas, described by a velocity and by scattering events. This is known as the phonon gas model. Thermal transport in amorphous materials is fundamentally different, where heat moves in a manner analogous to an atomic-scale random walk. These phonons can be called diffusons. Only recently have these two perspectives been unified within one theoretical framework, which subsequently shows that phonons in complex crystalline materials can exhibit both gas-like and diffuson-like character. Effective tuning of thermal conductivity thus requires an understanding of both transport “channels.” This talk will discuss materials design strategies in the context of two-channel transport. It will be shown that many ultralow thermal conductivity materials likely have both types of phonon transport, whose relative contributions depend strongly on temperature. Furthermore, factors like chemical composition and material defects may be used to prefer or suppress one channel or the other. This is experimentally demonstrated in several novel thermoelectric materials such as silver argyrodites.

4:15 PM EQ01.05.09

Bipolar Doping of Diamond-Like Semiconductor Hg2GeTe4 Claire Porter[1] and Jiaxing Qu[2]; [1]Colorado School of Mines, United States; [2]University of Illinois at Urbana-Champaign, United States

We are in era of unprecedented materials discovery, ushered by the development of rich computational techniques to generate new compositions and structures. However, to create useful state of the art electronic devices, many of these discovered semiconductor compounds require doping to obtain an optimal electronic carrier concentration. In this work, we conduct a thorough investigation of the extrinsic doping of recently discovered candidate thermoelectric material Hg_2GeTe_4, considering the presence of native defects, synthetic growth conditions, and dopant solubility limits.

We start by carrying out a computational analysis of 12 candidate extrinsic dopants, aiming to achieve both high p- and n-type carrier concentrations. Hg_2GeTe_4 is a recently discovered ordered vacancy compound with established regular vacancies in its crystal lattice; our doping strategy focuses on this large interstitial site as an opportunity to introduce donor defects (n-type doping) while suppressing compensating native defects through deliberate synthetic conditions. For p-type doping, we find that Hg-poor growth conditions offer a low energy entry to doping Group 11 dopants on the Hg site, introducing acceptor defects (p-type doping). Experimental results are in good agreement with computation, and we discover that even the most effective n-type dopants (Ga, Zn, In, Sc) are incapable of rendering Hg_2GeTe_4 n-type due to the discrepancy in electronic band effective mass (m^*_{DOS}) between its heavy valence and light conduction band. P-type doping is successful. While Hall data (carrier concentration, Hall mobility) are negative for our most successful n-type dopants, Seebeck coefficients are positive. These anamalous results point to the difficulty in bipolar doping in a material with widely different band masses.

P-type doping of Hg2GeTe4 is best realized with Group 11 dopants, of which Ag is the most successful (zT of 0.4 at 200°C). Au is also quite promising, however dopant solubility is impeded by the formation of AuTe2. Doping Hg2GeTe4 with Ag results in the discovery of a Ag quaternary compound (currently undergoing structure/charge flipping analysis to determine the structure of this unknown compound). Cu forms a full solid solution with Hg2GeTe4 and has been well studied. We perform a thorough structural analysis of the compound and offer explanations for the different behavior of these 3 Group 11 dopants, including evidence of a C2v distortion in Au-doped HGT analagous to the distortion observed in Au-doped silicon.

N-type doping is more difficulty due to the alloying of the dopant with binary impurity phases in Hg2GeTe4, in direct competition with formation of electron-donating defects. Zn, Sc, and In are the best n-type dopants according to theory, and experiment confirms these predictions. N-type Hall carrier concentration is realized, but Seebeck coefficents are always positive, suggesting insufficient pushing of the Fermi level into the conduction band. This anamalous result has been well documented in other chemical systems.

Finally, doping strategies are offered for ordered vacancy compounds, where the presence of the vacancy can cause unwanted counter-doping. We also emphasize the importance of paying attention to m^*_{DOS} when attempting bipolar doping.

4:30 PM EQ01.05.10
Selenium Vapor Annealing in Multinary Cubic Selenides Reveals p-Type Dopability via Regulating Hole-Killer Antisite Defects Hanhwi Jang[1], Michael Toriyama[2], Stanley Abbey[3], Brakowaa Frimpong[3], James P. Male[2], G. J. Snyder[2], Yeon Sik Jung[1] and Min-Wook Oh[3]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Northwestern University, United States; [3]Hanbat National University, Korea (the Republic of)

Multinary ABX_2-type cubic chalcogenides have attracted significant attention as a promising thermoelectric material because of their intrinsically low lattice thermal conductivity. However, compared to conventional thermoelectric materials, the electronic transport properties of ABX_2 compounds are still poorly understood. For example, it is not clear what types of point defects generate excess carriers in these compounds, resulting in a time- and cost-consuming trial-and-error process for a material discovery. In addition, it is difficult to reproduce the thermoelectric properties of some ABX_2 compounds because the properties of these compounds are highly sensitive to the synthesis environment. Taking $AgBiSe_2$ as an example, the reported Seebeck coefficient ranges from -450 to 550 μV/K, implying an uncontrolled carrier concentration and conduction type. Moreover, p-type conductivity of $AgBiSe_2$ is completely lost above 550 K, implying a generation of unknown hole-killer defects at an elevated temperature. Therefore, a systematic investigation of the electronic properties of these compounds is required. In this presentation, we reveal that Bi-on-Ag antisite defects (Bi_{Ag}) are responsible for low p-type dopability of $AgBiSe_2$-based cubic thermoelectric materials by first-principles calculations and experimentally demonstrate how to suppress those charged antisite defects via Se vapor annealing to achieve p-type conductivity in $AgBiSe_2$-based compounds. We rationalize the mechanism of Se vapor annealing to stabilize p-type conductivity by defect formation energy calculations which clearly show an increased Bi_{Ag} formation energy in Se-rich conditions. Moreover, we elucidate the importance of controlling self-doping via the annealing process to capture a signature of band convergence with alloying. This work will pave a way for rationalizing the electronic transport properties of several thermoelectric chalcogenides that suffer from significant phase boundary effects and uncontrolled properties.

SESSION EQ01.06: Device Design, Fabrication and Application I

8:15 AM *EQ01.06.01
Distributed Transport Properties (DTP)—Optimally Structured Thermoelectric Material Maximizes Solid State Heat Pump Performance Doug Crane, Bob Madigan and Lon Bell; DTP Thermoelectrics, United States

The novel and optimal structuring of spatially distributed transport properties (DTP) within thermoelectric (TE) elements is introduced and discussed. Using this structuring with currently available materials can produce TE systems with an increase in single-stage maximum temperature differential up to 35% in addition to up to 150% increase in coefficient of performance (COP) and up to 200% increase in heat pumping capacity. A conventional single-stage thermoelectric module operating in cooling mode has a maximum temperature difference of 73K (Th = 300K), whereas a two-stage cascaded device can increase this value up to 107K. One current manufacturer of conventional thermoelectric devices manufactures two-stage cascaded devices with maximum temperature differences that range from 86K to 101K. With DTP, a single-stage device can provide a comparable maximum temperature difference to the conventional two-stage cascaded devices with the potential to reach 100K. The creation of a position-dependent Thompson effect within the elements can partially offset detrimental distortion of the temperature profiles that Joule heating produces. This, combined with locally optimized thermal and electrical transport properties, increases TE element efficiency and thermal power pumping capacity. Closed-form analytic governing equations are presented for TE systems with optimally performing DTP. The unique behavior of DTP TE material systems is described: TE elements

incorporating available TE material with peak ZT at higher temperatures are used at the low temperature side in combination with material with peak ZT at colder temperatures at the high temperature side. Theoretical, numerical, and recent experimental results are reported that quantify performance improvements in maximum temperature difference, COP, and cooling capacity. The development of materials specifically optimized for DTP purposes is discussed along with their projected impact on TE device performance.

8:45 AM EQ01.06.02
Mastering Capillary Forces to Move Silicon Nanowires from Nano to Macro Dario Narducci, Stefano Magagna and Federico Giulio; University of Milano Bicocca, Italy

Silicon nanowires (SiNWs) have been a milestone in the exploitation of nanotechnology as a tool to develop efficient thermoelectric materials. By breaking the unfortunate tie between thermal and electric conductivity, the making of quasi-1D nanostructures let improve Si figure of merit (ZT) at room temperature from a meager 0.01 up to ≈ 1 [1, 2]. Nonetheless, usability of SiNWs in real-world devices has met the hurdles commonly encountered by nanostructures. As noted [3], for most applications thermoelectric devices need bulk materials, exchanging heat over large areas and across macroscopic distances. For SiNWs obtained by extreme lithography [2] this can be hardly obtained at acceptable costs. Instead, bottom-up approaches such as metal-assisted chemical etching (MACE) disclose the possibility of preparing wires with arbitrary lengths over large surfaces, enabling in principle full scalability from the nanoscale to macroscopic systems. However, on the MACE route three issues must be cleared, namely (1) the possibility of obtaining crystalline highly doped SiNWs; (2) the control of capillary forces bundling wires; and (3) the series resistance of the substrate. In this communication we report about the optimization of one-pot MACE to prepare SiNWs with lengths in excess to 0.1 mm [4]. Single-crystalline Si (100) wafers, both p and n-type with doping levels between 10^{15} and 10^{19} cm^{-3}, were etched in $HF/AgNO_3$ solutions at temperatures between 15 and 25 °C. We show that, contrary to previous reports, highly doped SiNWs are crystalline, with an encapsulating amorphized layer of only a few nanometers [4] that may be successfully removed (when needed) by wet etching. Quite independently of the doping, as-prepared SiNWs display bundling because of the capillary forces due to the solvent-wire interaction, ultimately causing SiNWs to bind to each other at their free ends. When supported SiNWs are supposed to act as thermoelectric legs in a device, bundling degrades system performances, as it increases the electrical resistance per area unit. An easy procedure to minimize capillary forces and the subsequent folding of SiNWs will be presented, making a combined use of chemical etching to control SiNW hydrophilicity and of solvent of graded polarity to control solvent-surface interactions. Non-bundled SiNWs also display enhanced (lower) electrical and thermal contact resistances, enabling the fabrication of thermoelectric devices with the conventional Π-type geometry [5]. However, capillarity is not always a negative feature. We will report for the first time about the making of unsupported, substrate-free Si 'nanofelts', where SiNWs are kept together by random bundling at their opposite ends. Lack of the series thermal and electric substrate resistance along with possibility of obtaining intertwined thick SiNW assemblies discloses exciting novel opportunities to scale thermoelectric nanosystems to the macroscopic scale.

Direct Measurement of Peltier Coefficient in Thermoelectric Materials and Devices Mark Lee[1], Hari P. Panthi[1], Ruchika Dhawan[1,2], Orlando Lazaro[2], Andres Blanco[2] and Hal Edwards[2]; [1]The University of Texas at Dallas, United States; [2]Texas Instruments, United States

Development of thermoelectric (TE) materials and device technology requires the ability to measure fundamental electrical and thermal physical properties such as electrical resistance (R), thermal conductance (K), Seebeck coefficient or thermopower (α) and Peltier coefficient (Π) at both device and constituent material levels. The thermopower α governs TE generator operation and is routinely measured by the straightforward procedure of recording open-circuit voltage, V_{oc}, as a function of applied temperature difference ΔT across a sample. Although Π is the property that governs TE cooler operation, it is rarely actually measured because of difficulties isolating the Peltier heat flow, $I\Pi$, from often much larger non-Peltier heat sources and flows such as Joule heating, I^2R, and passive Fourier thermal conduction $K\Delta T$, where I is the electrical current through a sample. Instead, the value of Π is almost always inferred from the measured α using a theoretical Kelvin relation $\Pi = \alpha T$, where T is the absolute temperature. We recently developed a method for directly and independently determining Π on any TE material or device via measurements of the short-circuit current, I_{sc}, and the difference in heat flows between a thermopile held in open-circuit versus short-circuit conditions. This method has several advantages over previous Peltier coefficient measurements; it determines Π solely from conventionally measured performance parameters, self-corrects for non-Peltier heat effects, does not require knowing any other material property values, is nondestructive, and does not assume validity of the Kelvin relation. We demonstrate this procedure by measuring Π on Bi_2Te_3 near room temperature using a Bi_2Te_3 TE generator. Combined with an independent measurement of α on the same device under the same conditions, we can empirically verify consistency with the Kelvin relation under near-equilibrium conditions to good accuracy. Our method also permits testing the Kelvin relation in TE systems held far from equilibrium.

9:15 AM EQ01.06.05
Barium Titanate Based Materials for Intelligent Thermoelectric Converters with Dynamic Workload Management Mohammad Althehaiban[1], Andrey Berenov[1], Vladimir Getov[2] and Peter K. Petrov[1]; [1]Imperial College London, United Kingdom; [2]University of Westminster, United Kingdom

Mobile devices are nowadays an all-pervasive technology. Their number is expected to reach 17.72 billion worldwide by 2024, an increase of 3.7 billion devices compared to 2020 levels[1]. A typical cell phone gives off around 0.2 Watts of heat when idle, and closer to a Watt while making a call or running processor-intensive applications. The heat generated by a tablet or laptop is much higher. Almost all this heat is never recovered.
Currently, high and medium-grade heat are the easiest to recover. In contrast, the low-grade heat is usually wasted in the environment, although, it is approximately more than 50% of the entire wasted heat[2]. This is because i) the currently achieved efficiency of the heat to electricity conversion at these temperatures is very low and ii) because, under the condition of constant heat flux generation, it is challenging to maintain a temperature gradient (or heat oscillation) required for the operation of the conventional thermoelectric converters.
In this paper, we will present our latest achievements in developing barium titanate-based materials that could be used to build an intelligent thin film thermoelectric (TFTE) converter attached to a digital system/device with dynamic workload management.
We will review the requirements imposed on the active materials and will compare them with our current results. We will further discuss in detail

materials' structural properties examined using SEM and x-ray diffraction, and their dielectric properties (dielectric permittivity and P-E hysteresis loops) measured in a temperature range between 80-450K at frequencies up to 1MHz.
Due to the small heat mass of our TFTE converter, it is possible to achieve a rapid heating-cooling cycle and therefore to recover substantial wasted heat per unit time.

Effects of Infill Pattern on Thermoelectric Transport in Extrusion-Based Additively Manufactured Elemental Ni and Bi Victoria J. Stotzer, Christian Apel, Eleanor Scott, Sarah J. Watzman and Ashley Paz y Puente; University of Cincinnati, United States

Conventional synthesis and manufacturing of thermoelectric materials is often tedious, time-intensive, wasteful, and expensive with severe limitations in terms of resultant sample geometry and size. While traditional growth techniques have been used for many years in the field, as the interest in thermoelectric devices and environmental efficiency has increased, processing limitations have become abruptly apparent. However, recent popularity for additive manufacturing offers the potential to decrease fabrication time, although success in additive manufacturing has been majorly limited to metals and polymers, while the manufacture of thermoelectric semiconductors has identified many limitations [1]. Current work has not extensively studied how additive manufacturing techniques alter thermoelectric transport. In this work, we approach the problem starting with Ni, whose thermoelectric properties are well established [2], albeit less compelling than those of conventional thermoelectric materials. Specifically, we focus on the particle-laden ink extrusion printing process, which has proven successful with producing bulk Ni samples [3]. Previously, we have shown that extrusion-based additive manufacturing does not alter thermoelectric transport properties of Ni [4]. Through altering printing parameters and sintering techniques, we study the microstructure of printed samples with a specific focus on densification, composition, and pore and crack concentration caused by three distinct infill patterns. We report the effect of these infill patterns on thermoelectric transport through measurements of the temperature-dependence of thermopower, electrical resistivity, and thermal conductivity. We then extend this work to elemental Bi as a more efficient thermoelectric material. Pure Bi has not previously been printed using extrusion-based additive manufacturing; therefore, we present a newly-developed low-temperature method.

Leveraging Additive Manufacturing to Tailor Thermoelectric Device Configuration, Leg Shape and Transport Properties Saniya LeBlanc; The George Washington University, United States

Additive manufacturing enables unprecedented customization of thermoelectrics at multiple lengths scales – from nanoscale inclusions to macroscale device shape – potentially all with one manufacturing process. We explore the process-structure-property relationship for laser-based additive manufacturing (specifically laser powder bed fusion) of thermoelectric materials for low and high temperature applications. We determined the process parameters required to form high density parts, and we characterized the nano- and micro-structural features formed in the printed parts. Simulations of the spatial and temporal temperature gradients during processing were used to determine solidification rates and thus predict grain structure, such as the distribution of equiaxed versus columnar grains; the predicted grain structure was compared to the experimentally observed grain structure. Thermoelectric properties (Seebeck coefficient, electrical conductivity, and thermal diffusivity) of printed bulk parts were measured as a function of temperature. The results provide insight about how additive manufacturing can be used to engineer thermoelectric materials and devices at multiple length scales.

10:45 AM EQ01.06.08
Scalable Manufacturing of Textured Thermoelectric Thin Foils of Na_xCoO_2 Nanosheets Rana Ucuncuoglu, Abdelhakim Elmhamdi, Esra B. Karatas Ozkaraca, Elif S. Gur, Ceren Egemen and Mahmut Aksit; Gebze Technical University, Turkey

A novel, industry-compatible nanomaterial processing technique is reported for producing polycrystalline thermoelectric (TE) foils of Na_xCoO_2 nanosheets. In-house produced Na_xCoO_2 nanosheets are chemically modified and coated on polymeric substrates using shear force. By post-heat treatment, Na_xCoO_2 nanosheets in the coated film are re-crystallized into thermoelectric $Na_{0.7}CoO_2$ phase while simultaneously burning away the polymer substrate resulting in self-standing textured thin foils of thermoelectric $Na_{0.7}CoO_2$ nanosheets. X-ray diffraction (XRD) with point and area detectors is used to confirm the crystalline phase and texturing of the resulting foils. Scanning electron microscopy (SEM) results also indicate the good alignment of Na_xCoO_2 nanosheets in the foil structure. According to SEM images, the thickness of nanosheets in the foil typically varies between 100 and 400 nm. The thickness of the foil can be altered between 9 and 70 μm as measured by cross-sectional SEM. Lateral lengths up to 10 cm can be readily achieved for the produced foils without any obvious indication of potential fundamental limitations to produce even larger foils. Structural changes in Na_xCoO_2 nanosheets are analyzed in detail by Transmission electron microscopy (TEM) after each step of the novel nanomaterial processing method. Finally, thermoelectric properties of the produced foils are measured from 160K to 340K using an in-house built thermoelectric measurement apparatus. Room temperature electrical resistivity of the produced foils can be as low as 3,21 milliohm.cm, whereas their Seebeck coefficients are larger than 65 μV/K in the same conditions.

Scalable Manufacturing of Textured Thermoelectric Thin Films of Bi_2Te_3 Nanosheets Abdelhakim Elmhamdi, Ahmet Furkan Gamli, Elif S. Gur, Esra B. Karatas Ozkaraca, Rana Ucuncuoglu and Mahmut Aksit; Gebze Technical University, Turkey

Many thermoelectric materials have layered crystal structures with anisotropic transport properties. They typically require a high degree of texturing to fully benefit from inherently good thermoelectric properties and possible thermoelectric enhancements from micro-nano structuring. A novel, scalable nanomaterial processing technique is reported for producing textured, polycrystalline thermoelectric foils of Bi_2Te_3 nanosheets. Bi_2Te_3 nanosheets are prepared in-house using a simple solvothermal method. Textured films are then prepared by spraying isopropyl alcohol (IPA) dispersions of the nanosheets on polymeric substrates, followed by shear force application parallel to the substrate plane. The films are then subjected to post-heat treatments to optimize their thermoelectric properties. X-ray diffraction (XRD) patterns of Bi_2Te_3 nanosheets match with JCPDS 15-0863 Bi_2Te_3 reference both before and after

the film preparation and post-heat treatment. The inherently weak [006] peak is almost non-existent in the powder form. In contrast, it is the dominant peak in the post-heat-treated film, indicating the strong orientation of the nanosheets along the substrate plane. The strong texturing in the films is also confirmed with area detector XRD measurements. According to scanning electron microscopy (SEM) images, the Bi_2Te_3 nanosheets have hexagonal shapes with less than 200 nm lateral length. The average nanosheet thickness is ~12 nm as calculated by XRD-Scherrer Broadening crystal size analysis on (006) peak. The thickness of the prepared films can be between 500 to 900 nm. Lateral lengths of more than 5 cm can be achieved for the produced films. Transmission electron microscopy (TEM) is used to observe structural changes in Bi_2Te_3 nanosheets after each step of the novel nanomaterial processing method. The Seebeck coefficient (S) and electrical conductivity (σ) of the produced films are measured from 300K to 350K using an in-house built thermoelectric measurement apparatus. The room temperature S and σ of the produced films are -102 μV/K and 1.21 10^4 S/m, respectively. According to the mechanical flexibility test, the films Can maintain >95% of their initial σ after 1000 bending cycles.

SESSION EQ01.07: Device Design, Fabrication and Application II

Wearable Thermoelectric Generator for Wearable Medical Solutions Jiyong Kim, Eun Kyu Kim, Gimin Park, Bo Min Kang, Hyo Geon Lee, Salman Khan, Seungjai Woo, Sungjin Park, Hyeong Min Yoon, Jae Hyun Kim, Jae Woo Jung, Jun Young Yoon and Woochul Kim; Yonsei University, Korea (the Republic of)

Patients with medical conditions, including diabetes, require continuous monitoring of the subject's health condition and immediate treatment (*e.g.*, drug injection) to maintain their wellbeing. Nowadays, the development of wearable electronics has made continuous health monitoring possible; for instance, continuous glucose monitors (CGMs) track the glucose level of the wearer and inject insulin *via* insulin pump patches. Nonetheless, conflict arises in terms of their lifetime, such devices should be self-powered so that the external power source need not be replaced. Previously, we have demonstrated that body heat harvesting through a wearable thermoelectric generator (WTEG) allows the operation of a commercial CGM [1] and showed improvement in its power density by attaching a radiatively cooled heat sink [2]. As mentioned before, health monitoring should be followed by immediate treatment of the illness. This study focuses on operating a micropump for drug injection fully powered by a WTEG. The WTEG was carefully designed by integrating the bioheat transfer and thermoelectric phenomena at various environmental conditions. The fabricated WTEG demonstrates power densities up to 13.5 $\mu W/cm^2$ when the ambient air temperature is 292 K. Also, a handmade low-power micropump consists of a bi-stable electromagnetic actuator wrapped around an energy-storing elastic tube with passive valves. The electromagnetic actuator, capable of injecting 1.5 μL per 3.76 mJ, can be powered by the stepped-up voltage provided by the WTEG. As the WTEG generates a sufficient amount of power to operate the micropump solely harvested from the human body heat, this study leaps toward a continuous closed-loop diabetes solution.

Geometric Study of Micro Thermoelectric Device with Optimized Contact Resistance Nithin B. Pulumati[1,2], Aditya S Dutt[1,2], Kangfa Deng[1], Kornelius Nielsch[1,2] and Heiko Reith[1]; [1]Leibniz Institute for Solid State and Materials Research, Germany; [2]TU Dresden, Germany

Generation of electricity without leaving a vast carbon footprint represents one of the critical challenges of the 21st century. Around 60% of energy is dissipated in the form of heat while burning fossil fuels. Thermoelectric devices have drawn a wide interest because of its potential to convert waste heat into clean electricity and vice-versa. For applications like in biomedical and Internet of things, μTEDs need to have a robust packaging so that the devices can be brought in direct thermal contact with the target heat sink and source. The packaging technology developed for macroscopic modules needs improvement as it cannot be applied to μTEDs due to a large thermal resistance between the capping material and the device which deteriorates its performance. Here, we develop μTEDs using optimized geometry and contact resistance combined with a novel packaging technique that is fully compatible with on-chip integration.
We developed a process for the fabrication of μTEDs with vertically free-standing leg pairs without a top plate. The fabricated μTEDs were embedded in a photoresist for using the device in applications.
The fabrication of the μTED is based on the combination of photolithographic patterning process with electrochemical deposition of $Bi_2(Te_xSe_{1-x})_3$ and Te as n-type and p-type thermoelectric materials respectively. Using the optimized geometry and contact resistance, the maximum net cooling temperature and the cycling reliability were enhanced. The geometrically optimized μTED with low contact resistance showed a maximum cooling of around 10.8K at an applied electrical current of 235mA, a rapid response time of 700μs and survived over 100 million cooling cycles in our reliability studies [1]. The fabricated μTED can be used to scavenge waste heat to provide solid-state electricity for powering electronics and have potential applications in wearable electronics, and wireless sensors. These embedded, optimized, stable and easily scalable μTEDs open new avenues for widespread applications in biomedical applications, powering internet-of-things devices, and local heat management.

Development Status of Skutterudite-based Thermoelectric Technology for Integration into a Potential Skutterudite-Multi Mission Radioisotope Thermoelectric Generator Thierry Caillat; Jet Propulsion Lab, United States

The flight-proven Multi-Mission Radioisotope Thermoelectric Generator (MMRTG) is currently powering NASA's Mars Curiosity and Perseverance rovers and selected for NASA's Dragonfly mission. The MMRTG design includes sixteen thermoelectric converter modules, each composed of 48 couples of PbTe/TAGS (Lead-Telluride/Tellurium-Antimony-Germanium-Silver) packaged in fibrous insulation and is operated under inert gas in a hermetically sealed environment. The skutterudite (SKD)-MMRTG design in development would be nearly identical except for upgraded 48-couple modules using skutterudite-based couples. While preserving the majority of the flight-qualified MMRTG design, fabrication tooling and flight support equipment, the new skutterudite-based couples would provide a substantial improvement in power output over time.

A team composed of Aerojet Rocketdyne (AR), Teledyne Energy Systems, Inc. (TESI), and NASA's Jet Propulsion Laboratory (JPL) team has been

maturing the SKD technology for integration into a potential SKD-MMRTG. From JPL-transferred skutterudite technology, TESI has developed manufacturing capabilities for skutterudite-based couples as well as 48-couple modules, a building block of the SKD-MMRTG. Life assessment testing of SKD couples is underway at JPL and TESI, with some couples achieving more than three years of continuous time-on-test. Testing of SKD couples and a 48-couple module has shown that their power output is in good agreement with the predicted values. Physics-based life performance prediction models developed at JPL, and a newly developed one at TESI, utilize the couple test data results and analysis to forecast the generator power output. The current best-estimate power predictions for the SKD-MMRTG meets specification requirements and offers up to about 37% more power at End-Of-Design-Life (EODL) than the MMRTG at equivalent operating conditions. The SKD-MMRTG would provide a substantial improvement in power output in the out years, making it ideal for many long-duration, deep-space missions.

Direct Ink Writing of Three-Dimensional Thermoelectric Materials and Devices Jae Sung Son, Seungjun Choo, Seong Eun Yang, Jungsoo Lee, Keonkuk Kim and Hyunjin Han; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Heat is omnipresent in natural and artificial environments, more than 60% of which is dissipated. Thermoelectric (TE) power generation can provide a unique solution to convert this dissipated, wasted heat into useful energy, that is, electricity. Generally, TE conversion efficiency depends on the material properties and design of the module structure. The geometrical design of thermoelectric legs in modules is important to ensure high power generation but cannot be easily achieved by traditional fabrication processes. At this moment, three-dimensional (3D) printing technology can maximize the flexibility in the design and fabrication of TE modules into more efficient structures. Furthermore, the printing process can significantly reduce the processing cost for the fabrication of TE modules owing to lower energy input and a simplified assembly process. Herein, I present the development of the 3D direct ink writing process applied to a range of different TE materials of Bi_2Te_3, BiSbTe, PbTe, and Cu_2Se-based inorganic alloys. Surface states of TE particles were precisely optimized with the controllable charge states in the presence of anionic inorganic binders, achieving the suitable viscoelasticity of the TE inks to the direct ink writing. The geometrically designed 3D-written TE materials were assembled into power generating systems, in which high efficiencies of energy conversion were achieved by the optimization of heat transfer.

Electron Transport in Double-Barrier Semiconductor Heterostructures for Thermionic Cooling Xiangyu Zhu[1], Marc Bescond[2], Toshiki Onoue[1], Gerald Bastard[3], Alwin Philippe[3], Carosella Francesca[3], Robson Ferreira[3], Naomi Nagai[1] and Kazuhiko Hirakawa[1]; [1]Institut of Industrial Science - University of Tokyo, Japan; [2]IM2NP - Aix Marseille Université, France; [3]Laboratoire de Physique de l'ENS, France

Progress in ultrahigh-density ultrahigh-speed electronic-photonic devices has come along with the tremendous generation of heat, resulting from thermalization of hot carriers generated by high electric fields. Cooling technologies are, therefore, indispensable for the continuous development of high-performance devices. Solid-state physics may provide relevant alternative approaches to go beyond the standard cooling techniques based on liquid or air (fans). So far, most of the solid-state solutions rely on the thermoelectric Peltier effect. However, thermoelectric devices operate in the near-equilibrium regime. Furthermore, the cooling efficiency deteriorates due to scattering induced internal Joule heating. Recently, thermionic cooling, which is based on the thermionic emission process, is attracting considerable attention [1]. The thermionic cooling devices operate far from thermal equilibrium. Recently, Chao et al. proposed a thermionic cooling structure with asymmetric double barriers [2]. In this structure, a quantum well (QW) is sandwiched between two potential barriers. The left barrier (the “emitter” barrier) is designed to be thin and tall. Since the emitter barrier is thin, electrons can tunnel from the emitter electrode into the QW by resonant tunneling, which allows only cold electrons to enter the QW. This selective electron injection is the key for enhancing the cooling efficiency. The second barrier (the “collector” barrier) is thick and low. Since the collector barrier is thick, electrons cannot escape the QW by tunneling; instead, they are forced to surpass the collector barrier thermionically (thermionic emission). Indeed, we recently demonstrated that (Al,Ga)As/GaAs asymmetric double-barrier thermionic cooling structures could reduce the electron temperature, Te, from 300 K down to 250 K by applying a bias voltage to the structure [3,4]. To improve the cooling performance, an understanding of electron transport and optimization of structural parameters are needed.
Here, we investigate electron transport in asymmetric double-barrier (Al, Ga)As/GaAs thermionic cooling heterostructures. Measurements of temperature-dependent current-voltage characteristics confirm that the dominant electron-transport process is a sequential process of resonant tunneling injection into and thermionic emission from the QW cooling layer. The thermal activation energy of the current is found to be strongly dependent on the bias voltage. Furthermore, instead of showing simple thermal activation behavior, the current exhibits rather complicated temperature and voltage dependence, particularly when the thermionic emission barrier is low. To establish a quantitative understanding, we develop an intuitive analytical model for sequential electron transport that explicitly takes into account scattering effects in the thermionic emission process from the two-dimensional QW states to the three-dimensional above-barrier states. The observed temperature dependent sequential current is well explained by the present theory [5].

Direct Ink Writing of Highly Integrated 3D Thermoelectric Generators with Selectively Doped Carbon Nanotubes Seongkwon Hwang[1], Doojoon Jang[1], Byeongmoon Lee[1], Heesuk Kim[1], Jeonghun Kwak[2] and Seungjun Chung[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

With an increase of interest in self-powered electronics, thermoelectric generators (TEGs) have been regarded as the most promising sustainable energy harvesting device to power them due to their reliable energy conversion from heat to electricity regardless of individual circumstances. One of the key requirements of high efficient TEGs is to achieve conformal interfaces on arbitrary-shaped or shape-changing 3D heat sources such as the human body by minimizing heat loss through undesirable air gaps. Specifically, because the temperature difference across thermoelectric (TE) legs would be mostly given in the through-plane in reality, the development of 3D-structured TEGs which could be attached to various types of heat sources is highly desirable. In the last decade, although 3D wavy-structured TEGs or introducing 3D bulk TE legs into deformable platforms have been proposed, still low integration density or limited flexibility would be a bottleneck to achieve maximized energy conversion efficiency.

In this presentation, we will introduce highly integrated 3D TEGs with direct ink writing (DIW) of carbon nanotubes (CNTs) onto an elastomeric substrate and their potential applications. High-performance viscoelasticity p- and n-type CNT inks were prepared by conducting selective chemical doping, and their rheological properties such as dynamic viscosity, storage modulus and shear yield stress were systematically analyzed according to the concentration of CNTs, which is a key requirement to optimize the DIW process resulting in high-resolution CNT legs. Especially, we directly print CNT inks onto the 3D TEG platforms with 1mm-thick thermal insulators, which can deliver the large temperature difference in the through-plane via optimizing the heat transfer model. Therefore, our TEGs can convert waste heat into electricity by just attaching them to arbitrary-shaped 3D heat sources without any structural assistance.
To deliver improved TE performance, interfacial properties between the TE legs and interconnects and their mechanical properties simultaneously, we have introduced all CNT-based 3D TEGs, which exhibit excellent output power of 32 nW/cm^2 at $\Delta T = 15$ K. In addition, mechanical reliability and deformability under tensile strain were demonstrated owing to the use of intrinsically soft TEG platforms. To the best of our knowledge, it is the first to employ 3D DIW directly to realize all-CNT-based TEGs to exploit waste heat in the direction of the through-plane. We believe our results pave a promising pathway to realize highly efficient 3D TEGs with a high degree of design freedom for self-powered flexible/or wearable applications. The detailed methods and results will be discussed at the conference.

Thermally Programmable Liquid-Crystalline Thermoelectric Ionogels Byeonggwan Kim, Sienoh Park, Cheolhyun Cho, Kyung Tae Park, Wooyoung Lee and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

Ionic thermoelectric effect has emerged as a new realm for ionic thermoelectric supercapacitors, energy harvesters, fluorescence ion sensing, and self-healable materials. However, despite significant improvement of ionic thermoelectric performance and several attempts to extend to include other mechanical properties, a temperature-programmable function has not been integrated with ionic thermoelectric materials. Herein, we synthesized thermally programmable ionogels *via* photopolymerization of ionic monomers and hydrophobic nematic monomers in the presence of an ionic liquid. A liquid-crystalline ionogel film showed reversible temperature programmability at designed temperature, at which temperature the nematic-isotropic phase transition occurs by monitoring with polarized optical microscope. The liquid-crystalline ionogel film showed a phase-controlled ionic Seebeck coefficient. To enhance the carrier transport for thermoelectric performance, doped carbon nanotubes were introduced for thermoelectric ionogel device. Taking advantage of high thermoresponsive thermoelectric output, the liquid-crystalline ionogel film was used to demonstrate a self-detectable and wireless fire alarm, which enables detection of elevated temperatures with the naked eye by integrated as a thermal switch for an electrochromic window, a liquid crystal display, or a light-emitting diode. The ionogels could benefit in exploiting autonomous thermoresponsive electronics that can be used to detect and view temperature changes in the environment.

Efficient Methods for Accurately Calculating Thermoelectric Properties—Electronic and Thermal Transport Anubhav Jain; Lawrence Berkeley National Laboratory, United States

We describe our efforts to aid in new thermoelectric materials discovery through theory-driven approaches. In particular, we focus on two efforts. The first is a new model of carrier transport called AMSET that allows one to model the temperature-dependent Seebeck coefficient and mobility from first-principles at reasonable computational cost. This is achieved by adapting classical scattering equations previously developed for 1D parabolic band semiconductors to complex density functional theory band structures. We will explain the theory behind AMSET as well as comparison against experiment and constant relaxation time approaches typically used in the field. Next, we will describe efforts to efficiently calculate thermal transport using compressed sensing lattice dynamics. Such approaches offer the possibility to calculate temperature-dependent thermal conductivities at a fraction of the computational cost of explicit approaches. For both methods, we will offer comparisons to experiments and offer a perspective on their potential role in uncovering and understanding thermoelectric materials.

8:45 AM EQ01.08.03
Band Inversion-Driven High Valley Degeneracy Michael Toriyama and G. J. Snyder; Northwestern University, United States

Thermoelectric materials can convert thermal energy to electrical energy and vice versa, enabling low-carbon alternatives for cooling and waste heat recovery. Yet, the low power conversion efficiencies of existing thermoelectric materials remain a challenge. One method to improve the thermoelectric performance of a material is by tuning the valley degeneracy, which we can control by modifying the degree to which the bands are inverted. We generalize this concept of "band inversion-driven high valley degeneracy" and derive simple rules for when inverted-band materials exhibit high thermoelectric performance. Using a combination of *k.p* perturbation theory and Density Functional Theory calculations, we show that electronic bands must be inverted to a critical degree for a material to possess high valley degeneracy. We apply this rule to discover potentially high-performing thermoelectric materials within the *ABX* chemical space of materials. We find that NaCaBi (space group: $P6_3/mmc$) is a promising candidate with a degeneracy of 6 for both the conduction and valence bands, resulting from the high degree of band inversion in the material. Through detailed Boltzmann transport theory-based calculations, we find that NaCaBi can reach zT between 0.4 and 0.8 at 300 K. Our study therefore demonstrates that band inversion is a rational descriptor for identifying high-performing thermoelectric materials.

9:00 AM EQ01.08.04
Substitution of High Oxidation State Cations in *N*-Type Chalcopyrite Anthony V. Powell, Sahil Tippireddy and Paz Vaqueiro; University of Reading, United Kingdom

Metal sulphides are attractive candidate materials for thermoelectric energy harvesting. In addition to the greater abundance of sulphur compared to its heavier congeners selenium and tellurium, sulphur is also less toxic. There have been significant advances in the performance of *p*-type sulphides, including the binary sulphide, $Cu_{2-d}S$ and materials related to the minerals tetrahedrite, bornite and colusite. However, progress in the *n*-type counterparts has been more modest, with few materials exceeding ZT = 1, while the highest performance typically occurs in materials containing toxic elements such as lead.

A major focus of our work on new *n*-type sulphides containing Earth-abundant elements is materials derived from chalcopyrite. Chalcopyrite contains the same CuS_4 building block as in the high-performance binary phase. The presence of additional (Fe) cations suppresses the cation mobility that characterizes phonon liquid electron crystal (PLEC) type behaviour. Although the PLEC character of $Cu_{2-d}S$ contributes to a remarkably low thermal conductivity, it also facilitates copper-ion migration under operating conditions, leading to degradation.

We have sought to utilise substitution with high-oxidation state cations at Cu and Fe sites to manipulate the carrier concentration and hence transport properties of chalcopyrite. Cations such as Sn^{4+}, Ge^{4+} and Cr^{3} can effect larger changes in carrier concentration per unit of substitution than the more usual dispositive substituents. Figures of merit of ZT» 0.3 at 673 K have been achieved in Sn- and Cr-substituted phases, while values approach ZT = 0.4 on Ge-substitution. These represent a 4- to 5-fold improvement over the stoichiometric end-member phase. However in all cases, substitution leads to increases in carrier concentration that are substantially lower than expected on the basis of formal oxidation states. By application of a range of experimental and computational approaches, we have investigated the origin of this unexpected result. This has led us to identify a variety of new features that introduce additional complexity into the substituted phases.

In $Cu_{1-x}Sn_xFeS_2$, substitution leads to the formation of small polarons through partial reduction of Fe^{3+} to Fe^{2+}. Localized Fe^{2+} states reduce the free-carrier concentration from the expected value, contributing to the maintenance of a relatively high Seebeck coefficient, despite the reduction in electrical resistivity. Substitution also induces a high level of mass and strain-field fluctuation, resulting in lattice softening and enhanced point-defect scattering. This, together with microstructural changes, leads to scattering of phonons with a wide range of mean free paths, and to the observed substantial reductions in thermal conductivity. When iron is partially substituted by germanium however, X-ray photoelectron spectroscopy suggests the lower-than-expected increase in carrier concentration is associated with the presence of germanium in two oxidation states (Ge^{2+}/Ge^{4+}) in the substituted phases. The $4s^2$ lone pair of Ge^{2+} also results in different bonding characteristics to that of the closed-shell Ge^{4+} species. This results in a local structural distortion, identified through Pair Distribution Function analysis of synchrotron powder X-ray diffraction data, whereby some germanium cations are displaced from the centre, towards the face of a metal-centered tetrahedron. This local distortion contributes to the observed reduction in thermal conductivity. Collectively, these results reveal an unexpected richness in composition-structure-property relations in *n*-type chalcopyrites that may offer scope for the development of future design strategies for *n*-type sulphide thermoelectrics.

9:15 AM EQ01.08.05
Theoretical Investigation into the Chemical Origins of High Valley Degeneracy in n-type Mg_3Sb_2 for Thermoelectric Applications Madison Brod[1], Shashwat Anand[2] and G. J. Snyder[1]; [1]Northwestern University, United States; [2]Lawrence Berkeley National Laboratory, United States

Mg_3Sb_2-based alloys have attracted much attention in recent years as high-performing, low-temperature n-type thermoelectrics that are competitive with state-of-the-art Bi_2Te_3. The high valley degeneracy of the conduction band (CB) edge is largely responsible for the excellent thermoelectric performance of Mg_3Sb_2. This high valley degeneracy is due to the fact that the conduction band minimum (CBM) is located at a low-symmetry point in the ΓALM plane of first Brillouin zone, which has six-fold degeneracy. Moreover, it has been found that alloying Mg_3Sb_2 with Mg_3Bi_2 can further improve thermoelectric performance by increasing the curvature of the conduction band edge, and hence, increasing the electron mobility. In prior works, the highly degenerate CBM in Mg_3Sb_2 has been attributed to interactions between Mg-s orbitals. However, the Mg-s/Mg-s interactions alone cannot explain the changes in transport properties observed upon substitution of Sb with Bi. In this work, we aim to elucidate the chemical origins of the low-symmetry CBM using a combination of density functional theory (DFT), crystal orbital Hamilton population (COHP) calculations, and tight-binding. While, prior studies have not fully considered the importance of Mg/Sb interactions, here, we show that Mg-s/Sb-p interactions play a large role in the formation and shape of the low-symmetry CBM. DFT and COHP calculations show that the strength of Mg-s/Sb-p anti-bonding interactions reach a local minimum near the CBM. Additionally, it is possible to reproduce the low-symmetry CBM using a tight-binding model that considers Mg-s/Sb-p but does not consider Mg-s/Mg-s interactions. Additionally, unlike the Mg-s/Mg-s interactions, Mg-s/Sb-p (and Mg-s/Bi-p) interactions can explain the increase in curvature near the CBM upon Bi alloying on the Sb-site. The findings of this work will allow for improved insights into strategies for tuning electronic transport in Mg_3Sb_2-based alloys and for developing similar materials with high valley degeneracy.

9:30 AM EQ01.08.06
Limits of Thermoelectric Performance with a Bounded Transport Distribution Jesse Maassen; Dalhousie University, Canada

Band engineering is an important strategy that seeks to tailor a material's electronic and scattering properties to improve its thermoelectric performance. This effectively alters the material's transport distribution (TD), which is the central quantity that determines the electronic conductivity, Seebeck coefficient and electronic thermal conductivity. The seminal work of Mahan and Sofo [1] concluded that the thermoelectric figure of merit, ZT, is maximized with a delta function TD – an unbounded distribution. Later studies by Zhou et al. [2] and Jeong et al. [3], exploring different band structures and scattering models, found that ZT is maximized when the width of the TD is finite and that the TD always remains bounded. Assuming a bounded TD, a genetic algorithm search by Fan et al. [4] determined that a boxcar TD is best for ZT.

This talk presents a study that theoretically derives what is the optimal bounded TD and its implications on the limits of thermoelectric performance [5]. To maximize the figure of merit and the power factor the ideal transport distributions are boxcar and Heaviside functions, respectively – the edges of which must be located at specific energies. The optimal power factor is simply limited by the magnitude of the Heaviside TD, and reaches ZT values between 4-5. The optimal figure of merit, which can approach the Carnot limit, is uniquely determined by a key quantity that is proportional to the TD magnitude and temperature, and inversely proportional to the lattice thermal conductivity. These results suggest two general approaches to enhance thermoelectric performance: identify or design materials with TDs that have large magnitude (large distribution of modes, high velocities and/or low scattering) and that possess the ideal boxcar or Heaviside shape (controlled by band structure shape, scattering profile and dimensionality). This study can help guide the search for better thermoelectrics by establishing practical upper limits on performance, and by providing target TDs to guide band and scattering engineering strategies.

10:15 AM EQ01.08.07
Inverse Design of Nanoarchitected Three Dimensional Materials for Thermal Transport Applications Giuseppe Romano; Massachusetts Institute of Technology, United States

Owing to phonon-boundary scattering, nanoarchitected materials are a promising platform for tuning thermal transport. Engineering these systems, however, is challenging because the underlying physics must capture momentum-resolved transport, typically addressed by the Boltzmann transport equation (BTE). Borrowing concepts traditionally applied to mechanical compliance optimization, we develop a topology optimization framework for nanoscale heat transport, based upon density-based topology optimization [1]. In practice, the geometry is discretized in pixels (or voxels in three dimensions), to which a fictitious density is assigned. Then, this density is optimized to minimize a given objective function, under constraints. The key aspects of our method are a novel material interpolation method, the Transmission Interpolation Method (TIM), and the solution of the adjoint BTE. In contrast with standard topology optimization methods, where the density is linked to a bulk-related property (e.g. the thermal conductivity), TIM parametrizes an interfacial transmission coefficient. I will show how this approach is able to guarantee a smooth transition between solid and void regions, while ensuring energy conservation along adiabatic walls. After a brief introduction on technical details, I will provide examples on tailoring the effective thermal conductivity tensor in two- and three- dimensional nanoarchitected materials. Conclusion and final remarks will conclude the talk.

10:30 AM EQ01.08.09
Finite Element Simulation Approach to Optimize Thermal Behavior in Thermoelectric Interconnected Nanofiber 3D Networks Germán Alcalá[1], Pablo Cerviño[2], Marisol Martín-González[2] and Olga Caballero-Calero[2]; [1]Complutense University of Madrid, Spain; [2]Micro and Nanotechnology Institute (CSIC), Spain

The fabrication of interconnected nanostructures of thermoelectric materials by means of electrochemical growth inside nanoporous templates has been explored recently [1-2]. The production of these networks, especially those produced in high ordered 3D nanoporous alumina templates, have been reported as an excellent method to reduce thermal flux along thermoelectric materials [3]. This approach would allow increasing thermoelectric efficiency by reducing thermal conductivity while having a small effect on electric conductivity.
In the present work we focussed on the fabrication of interconnected nanostructures, using commercial nanoporous filters as templates. In order to optimize the type of structure, and geometrical parameters having an influence on the thermal conductivity of the structure, the thermal behaviour of such nanostructures has been studied using the finite elements method. The use of python script has been a key tool in order to produce the actual geometries, due to the high randomness in parameters such as nanowire section radii, nanowire positions or nanowire orientations. Thermal losses in the nanowire walls have been simplified to a convection model, allowing qualitative comparison between the studied geometries, and facilitating the analysis of the individual geometrical parameters in order to spot the optimal 3D interconnected nanonetwork. This allowed us to determine the optimal parameters leading to the lowest thermal transfer and thermal conductivity, and thus increasing the thermoelectric efficiency.

Thermoelectric Performance of $CuInTe_2$ from First Principles Using Hybrid-DFT and Lattice Dynamics Sabrine Hachmioune[1,2,2], Maheswar Repaka[2], Zhai Wenhao[2], Kedar Hippalgaonkar[2,3] and David O. Scanlon[1,4]; [1]UCL, United Kingdom; [2]Agency for Science, Technology and Research, Singapore; [3]Nanyang Technological University, Singapore; [4]Thomas Young Centre, United Kingdom

Fossil fuels provide 80% of the world's energy[1] and of that energy, an estimated 80% is wasted in the form of heat.[2] This has motivated world leaders to invest in alternative forms of energy generation.[3] One such alternative to be explored is the use of thermoelectric materials (TE).
Thermoelectric materials can convert heat into electricity through the Seebeck effect allowing them to increase the overall efficiency of existing processes, as well as serve as a clean source of electricity. Materials in use today are composed of toxic elements like lead or are plagued by low efficiencies. To measure thermoelectric efficiency, we use the figure of merit, ZT. For comparison, the average ZT of a well-known TE that has been used in many NASA space missions, PbTe is 1.4.[4]
In this work, we explore a chalcopyrite semiconductor, $CuInTe_2$ (CIT) with an experimental ZT of 1.18 at 850 K[5] which has been predicted to increase up to 1.72 (10^{18} carriers cm^{-3}).[6] The hybrid-DFT functional (HSE06) with spin-orbit coupling (SOC) is used to accurately predict the band structure and the AMSET code[7] is used to calculate the Seebeck coefficient, electrical conductivity, electronic thermal conductivity, and mobility. We use the supercell approach employed by Phono3py[8] to calculate third-order phonon-phonon interactions and determine the lattice thermal conductivity. These results allow us to fully calculate the ZT of CIT from first principles where previous theoretical studies have used a semi-empirical approach.[6]
A fundamental understanding of the dopability is key to yielding a proper prediction of the thermoelectric performance, therefore, a study of the full defect chemistry using hybrid-DFT will give insights into realistic doping concentrations by calculating the self-consistent fermi level. We will also assess the effect of different dopants on ZT. This can help guide experimental studies by screening a range of dopants that haven't been studied before in this system such as Sb.[9]

Unlocking the Thermoelectric Potential of the $Ca_{14}AlSb_{11}$ Structure Type—The Case of $Yb_{14}ZnSb_{11}$ Geoffroy Hautier[1,2], Andrew Justl[3], Francesco Ricci[2], Andrew Pike[1], Giacomo Cerretti[4], Sabah Bux[4] and Susan Kauzlarich[3]; [1]Dartmouth College, United States; [2]University Catholique de Louvain, Belgium; [3]University of California, Davis, United States; [4]NASA Jet Propulsion Laboratory, United States

$Yb_{14}MnSb_{11}$ and $Yb_{14}MgSb_{11}$ are among the best p-type high temperature (>1200 K) thermoelectric materials, yet other compounds of this structure type have not matched their stability and efficiency. Here, we show with first principles computations that the electronic structure features that make these compounds exceptional thermoelectric materials are present across a wide range of chemistries, including materials such as $Yb_{14}ZnSb_{11}$ that have shown poor performances. In fact, we show that $Yb_{14}ZnSb_{11}$ when phase pure is a high-performance thermoelectric materials. We synthesized phase pure $Yb_{14}ZnSb_{11}$ through a new synthetic route utilizing binary precursors which revealed the exceptional high temperature thermoelectric properties, reaching a peak zT of 1.2 at 1175 K. Experimental and theoertical analysis link the previously reported poor performances to the 9-4-9 impurity phase that our new synthesis route eliminated.

SESSION EQ01.09: Thermoelectric Transport in Organic and Composite Materials
Session Chairs: Je-Hyeong Bahk and Heng Wang
Thursday Afternoon, December 1, 2022
Sheraton, 2nd Floor, Back Bay A

1:30 PM *EQ01.09.01
Thermoelectric Transport in Nanotube and Nanowire Network-Based Composites Je-Hyeong Bahk[1], Oluwasegun I. Akinboye[1], Fan Yang[2], Yu Zhang[1] and Yue Wu[2]; [1]University of Cincinnati, United States; [2]Iowa State University of Science and Technology, United States

High thermoelectric (TE) efficiency of a material can be achieved by promoting high-energy charge carrier transport while simultaneously suppressing thermal transport in the material. This is, however, extremely difficult to achieve in a bulk material because there is a trade-off relationship between the charge and thermal transport. In this talk, we present several strategies of decoupling the charge and thermal transport with nanowire and nanotube networks to enhance the TE efficiency. We focus on carbon nanotube network-based composites, where the three-dimensional nanotube networks provide high-conduction pathways for charge carriers, while the polymer matrix occupying the majority material volume offers suppressed thermal transport. The (sub-)nanoscale junctions between nanotubes can also induce efficient energy-dependent carrier transport via tunneling and energy filtering to enhance the power factor, while suppressing phonon transport across them. We present a comprehensive study on nanotube and nanowire network-based composites including the effects of nanotube doping, modified interfaces with additional nano-inclusions such as bismuth telluride nanoparticles, and the change of network microstructure with excluded volume created by micro-particles.

2:00 PM EQ01.09.02
Thermoelectric and Mechanical Properties of PEDOT:PSS-Coated Ag_2Se Nanowire Composite Fabricated via Digital Light Processing Based 3D Printing Dabin Park and Jooheon Kim; Chung-Ang University, Korea (the Republic of)

In this study, we present a digital light processing (DLP)-based 3D printing method to produce thermoelectric (TE) composites. The UV-curing photoresins are composed of isobornyl acrylate (IBOA), diurethane dimethacrylate (DUDMA), and Phenylbis(2,4,6-trimethylbenzoyl) phosphine oxide (BAPO) is used as the photoinitiator. As TE fillers, poly(3,4-ethylenedioxythiophene)-poly(4-styrenesulfonate)-coated (PEDOT:PSS-coated) silver(I) selenide (Ag_2Se) nanowires (NWs) were used. UV curable photoresins with P-Ag_2Se(2) fillers were then printed with a DLP-based 3D printer. Ag_2Se is widely used as TE materials because of its high electrical conductivity. However, high-electrical conductivity is usually accompanied with high thermal conductivity. Thus, to keep the composite with high electrical conductivity and meanwhile with low thermal conductivity, PEDOT:PSS coating was chosen because PEDOT has an low thermal conductivity. The in-situ synthesis method enables the strong binding of inorganic Se NWs and organic PEDOT:PSS. After synthesizing the P-Se NWs, the P-Ag_2Se composite was formed through the reaction of P-Se and the silver (Ag) precursor solution. As the amount of PEDOT:PSS used in the experiment increased from 1 mL to 3 mL, the composite were named P-Ag_2Se(1), P-Ag_2Se(2), and P-Ag_2Se(3).
The successful synthesis of pristine Ag_2Se NWs and P-Ag_2Se was confirmed via field-emission transmission electron microscope (FE-TEM) analysis. The lattice spacing agrees closely with the (200) plane spacing of orthorhombic Ag_2Se with an interplanar spacing of 0.35 nm. It was confirmed that the thickness of the P-Ag_2Se composite coating layer increased as the amount of PEDOT:PSS increased. The temperature-dependent TE properties of prepared P-Ag_2Se composite with different PEDOT:PSS contents were investigated. The electrical conductivity (σ) of the P-Ag_2Se composite increased with an increase in the PEDOT:PSS contents because the PEDOT:PSS can form an electrically conductive network in the PEDOT:PSS-coated Ag_2Se NW, resulting in a high σ. In contrast with the tendency of σ, the absolute value of S of the P-Ag_2Se decreases with increasing PEDOT:PSS contents. The maximum power factor of ~429.18 μW/m K^2 was achieved for the P-Ag_2Se composite with ~9 wt.% of PEDOT:PSS contents (P(2)-Ag_2Se). Due to its outstanding TE properties, P-Ag_2Se(2) fillers were added to the photoresin as a TE filler with high TE performance. The cured photoresin with 30 wt.% TE fillers are analyzed via FE-SEM. These images illustrate the layered structure of a cured composite and its uniform thickness. Additionally, the FE-SEM images highlight the presence of a large number of wire structures in photoresins.
The mechanical properties of photoresins with various P-Ag_2Se(2) contents are measured. When the filler loading increases, the tensile stress decreases because the P-Ag_2Se(2) filler in the photoresin matrix renders the composite resin brittle. The room-temperature σ of cured composite samples with various TE filler contents (0, 10, 20, and 30 wt.%) are analyzed. The σ of the cured sample increased with ~2.87 S/cm to ~117.39 S/cm as the amount of TE filler increased from 0 to 30 wt.%. The highest σ value of ~117.39 S/cm was obtained in the cured composite with 30 wt.% of P-Ag_2Se(2) fillers, which is much larger than those of photoresins without fillers. The Seebeck coefficient (S) of the composite sample was investigated at room temperature with various P-Ag_2Se(2) contents. The S increases as the contents of P-Ag_2Se(2) increase. The maximum S value of ~-81.94 μV/K is found in the cured composite with 30 wt.% of P-Ag_2Se(2). The thermoelectric ZT is calculated with S, σ, and κ. 5d. The maximum ZT of ~0.02 was achieved from the cured resin with 30 wt.% of P-Ag_2Se composite.

Fully Conjugated Ladder Polymers and Novel Dopants for N-Type Organic Thermoelectrics Donato Ottomano[1], Ryan Chiechi[2] and Remco W. Havenith[1]; [1]University of Groningen (RUG), Netherlands; [2]North Carolina State University, United States

Organic thermoelectric materials are systems capable of converting thermal differences into voltage differences. Within a thermoelectric device, the transition between thermal gradient and electric potential results from the diffusion of charge carriers towards the hot side and away from the cold side. This phenomenon is identified as the Seebeck effect, and its coefficient quantifies how rapidly a material responds to a perturbation. The thermoelectric efficiency is directly related to a high electrical conductivity. In contrast, a large thermal conductivity translates in a volatile temperature gradient, which minimizes the voltage difference and limits the diffusion of charge carriers. For these reasons, semiconducting organic polymers are excellent candidates for non-toxic, greener and more versatile thermoelectric applications. To further improve their efficiency, additional charge carriers are injected into these devices via doping. In organic semiconductors, charge carriers move from the frontier orbitals of the dopant towards the undoped species. Therefore, a

greater energy difference between the frontier orbitals of the two species not only guarantees a higher doping efficiency, but enhances the overall thermoelectric performance. In this work, we investigate fully conjugated ladder polymers as n-dopable thermoelectric candidates. Ladder polymers have been shown to perform well as n-type materials in thermoelectric devices, not only on account of their high electrical conductivity, but also their low lying LUMOs rendering them susceptible to reduction by conventional n-dopants. However, they tend to be insoluble and difficult to process. We address these shortcomings by designing and synthesizing novel ladder polymers with solubilizing groups that do not sacrifice performance. Unlike previous reports, we are employing slightly electron donating linkers to avoid overly unreactive monomers which are known to impede the polymerization. In addition, we are incorporating highly electron deficient functionalities within the polymer backbone to further lower the frontier orbitals and improve the doping efficiency. Finally, there is a paucity of n-type dopants and the mechanism of the best-performing dopants remains unclear. We are investigating a class of dopants with readily tunable oxidation potentials that minimally affect their structure, steric bulk and polarity to investigate the role of oxidation potentials without altering other relevant variables. With a deeper understanding of doping mechanisms and with highly electron deficient fully-conjugated ladder polymers, our group points towards record performances in the field of n-type organic thermoelectrics.

2:30 PM EQ01.09.04
Mixed Ionic-Electronic Conducting PEDOT/PAMPS Polymer Composite Films for Transparent and Self-Healable Thermoelectric Harvesters
Cheolhyun Cho, Byeonggwan Kim and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

In these days, a lot of effort is put on energy harvesting technologies. As one of them, thermoelectric (TE) technology which harvests energy through conversion from heat to electricity is a future-oriented technology that contributes to energy reuse and environmental friendliness. However, the existing TE materials have low heat-to-electricity efficiency, so it is difficult to use their harvested energy for operating other devices. As an alternative, ionic polymer could be a promising candidate because it has an excellent energy harvesting property based on the Soret effect. In addition to excellent thermoelectric property, ionic thermoelectric materials (iTE) have the advantages of low-cost production, light weight, scalability, and environmental friendliness. However, the lack of electrical properties in the iTE devices is critical because there is little actual energy transfer. In addition, researches on n-type iTE materials have not been progressed much, and they showed lower energy harvesting performance than p-type iTE materials due to the difficulty of the transport of large-sized negative ion carriers.
In this study, we developed mixed ionic-electronic conductor (MIEC) based TE material for better energy harvesting property. Poly(3,4-ethylenedioxythiophene) (PEDOT), an electrical conductive polymer, was co-polymerized in poly(2-acrylamido-2-methyl-1-propanesulfonic acid) (PAMPS), an ionic polymer-based media using ammonium persulfate (APS) as an initiator. Through transmission electron microscopy (TEM) analysis, the core-shell structure of PEDOT-PAMPS and the pi-pi interaction of the PEDOT domain acting as an electrical channel were characterized. We focused on finding an optimized PEDOT concentration that maintains MIEC characteristics while maintaining transparency in a thin film state. APS was additionally doped to the synthesized PEDOT-PAMPS polymer composite, resulting in n-type PEDOT-PAMPS (NPP) composite where bisulfate acts as anionic carrier. A novel n-type ion transport mechanism was designed in consideration of the deprotonation of the sulfonate group of PAMPS and polymer-polymer, polymer-ion interaction. The mechanism was scientifically elucidated through Raman spectroscopy and X-ray photoelectron spectroscopy (XPS) analysis, and bisulfate generation and ion transport were characterized using time-of-flight secondary ion mass spectrometry (ToF-SIMS) and nuclear magnetic resonance (NMR) analysis. In addition, bisulfate-detecting fluorescent material was synthesized to visually show the bisulfate transport in real time when a temperature gradient (ΔT) was given.
The TE properties of NPP films were measured considering humidity, different ΔT, and concentration of components. The optimized NPP film showed a negative ionic Seebeck coefficient of -25.0 mV K^{-1}, ionic power factor of 9.94 mW m^{-1} K^{-2}, and an ionic figure of merit of 7.2 at 80% relative humidity and room temperature, which exhibited the highest TE performance in organic materials at room temperature. In addition to excellent TE properties, NPP film with Young's modulus similar to human skin and self-healing property of hydrogel-based composite could be applied to a flexible organic TE module. The TE module with 20 legs generated -2.75 V at a ΔT of 5.5 K, and the flexible band-type TE module attached to the human wrist generated -1.88 V. To emphasize energy harvesting property and transparency, we succeeded in turning on the LED using the capacitor charged by the TE module for the first time using an organic-based TE device, and fabricated a TE module composed of legs dyed with water-soluble ink. In addition, by fabricating a photothermal-thermoelectric combined device, photothermal-to-thermoelectric voltage according to laser power was observed using a light source instead of heat. Various applications using NPP films have demonstrated the practicality and multifunctionality of this novel TE material, and its potential as a promising energy harvester.

2:45 PM EQ01.09.05
Significant Enhancement in the Thermoelectric Propoerties of Polymers via Ionic or Molecular Energy Filtering Jianyong Ouyang; National University of Singapore, Singapore

Intrinsically conducting polymers such as PEDOT:PSS can exhibit high thermoelectric properties because of their high electrical conductivity. However, their Seebeck coefficient is usually 10^0-10^1 μV/K. Although dedoping can increas the Seebeck coeffiicent, it is achieved at the sacrifice of the electrical conductivity. A remedy is via energy filtering that can greatly increase the Seebeck coefficient while only slightly affect the electrical conductivity. Here, I will report several novel methods to significantly enhance the thermoelectrical properties of polymers by forming composites with ions or organic moleucles that can induce energy filterting. The polymer composites can exhibit a very high zT value at room temperature.

3:00 PM BREAK

3:30 PM DISCUSSION TIME

4:00 PM EQ01.09.07
Single Ether-Based Polar Side Chain—A Tool for Controlling the Microstructure and Dopant Location in Polymer Semiconductors for Organic Thermoelectric Devices Nicolas Leclerc[1], Pablo Durand[1] and Martin Brinkmann[2]; [1]ICPEES-CNRS, France; [2]Institute Charles Sadron, France

Combining side chain engineering and controlled alignment of semiconducting polymers is an effective strategy to produce oriented thin films with improved thermoelectric performances. In this contribution, we demonstrate that the substitution of standard linear alkyl side-chains with a chain of identical length including an ether function leads to a new class of slightly polar PBTTT polymers, preserving the ease of synthesis and air stability of alkylated PBTTTs. This side-chain modification improves the structural order of PBTTT backbones and the thermomechanical properties of the polymer. Such polymers can be thus oriented by high temperature rubbing to reach very high dichroic ratios up to 20 thanks to enhanced cohesive forces within side-chain layers. The side chain polarity helps to tune the polymer-dopant interactions. In addition, the single ether-based side-chain approach allows to adjust the ether function position along the side chain, tuning the physico-chemical and TE properties. The conjugation of improved alignment and random orientation of intercalated F_6TCNNQ dopants helps reach a very high charge conductivity of 10^4 S/cm and a record power factors for organic materials of 2.9 $mWm^{-1}K^{-2}$ in the polymer chain direction.

4:15 PM EQ01.09.08

Thermoelectric Power Factor Enhancement of PEDOT:PSS by Formation of Cu_2Se Nanowire Network Structures Shunya Sakane[1], Shunichiro Miwa[1], Tatsuki Miura[1], Kazuki Munakata[1], Takafumi Ishibe[2], Yoshiaki Nakamura[2] and Hideki Tanaka[1]; [1]Chuo University, Japan; [2]Osaka University, Japan

Thermoelectric power factor is represented with $S^2\sigma$, where S and σ are Seebeck coefficient and electrical conductivity, respectively. Recently, organic thermoelectric materials have been attracting attention for their low cost, eco-friendly, and flexibility. For thermoelectric power factor enhancement of organic materials, introduction of inorganic nanostructures is effective. Especially, nanowires (NWs) can bring percolation effect by forming NW network structures, leading to power factor enhancement. As inorganic nanostructures, we focused on Cu_2Se NWs. Cu_2Se is composed of low-cost and abundant elements, and exhibits high thermoelectric power factor at room temperature (RT). In this study, we prepared PEDOT:PSS films containing the Cu_2Se NWs synthesized by photoreduction method [1] for the enhancement of thermoelectric power factor.

Cu_2Se NWs were synthesized as following method. Se NWs were synthesized by mixing SeO_2, β-cyclodextrin, and ascorbic acid, stirring the solution for 4 hours, and redispersing it in ethanol for 4 hours [2]. The Se NWs, ethanol, and copper acetate were added into Milli-Q water, and the solution was irradiated by UV light, forming Cu_2Se NWs (photoreduction method). After that, PEDOT:PSS solution and ethanol dispersion of Cu_2Se NWs were spin coated and annealed at 80 °C alternately on glass with various spin coating number of Cu_2Se NWs. The reference sample of PEDOT:PSS thin film without Cu_2Se NWs was also synthesized. The structures of the NWs and films were confirmed by X-ray diffraction (XRD), scanning electron microscopy (SEM), energy dispersive X-ray spectrometry (EDX). S was measured by hand-made system and σ was measured by van der Pauw method. The S values were also revised by ZEM-3 (ADVANCE RIKO).

From the surface SEM-EDX analysis of PEDOT:PSS/Cu_2Se NWs thin films, Cu, Se and S (from PEDOT:PSS) were observed, indicating that Cu_2Se NWs were covered with PEDOT:PSS. The SEM-EDX image also showed that Cu_2Se NWs were connected to each other, which is NW network structure. Quantitative analysis of EDX demonstrated that the amount of Cu_2Se increased as the spin coating number of Cu_2Se increased. For thermoelectric performance, PEDOT:PSS/Cu_2Se NWs thin films exhibited drastic increase of σ at ~40 wt% as the Cu_2Se amounts increased. This is due to the formation of Cu_2Se NW network structures. This σ value was much higher than that of PEDOT:PSS single thin film. As a result, PEDOT:PSS/Cu_2Se NWs thin films exhibited the enhancement of power factor by formation of Cu_2Se NW network structures.

Phonon Scattering and Vibrational Localization in 2D Embedded Nanoparticle Composites Ongira Chowdhury and Joseph P. Feser; University of Delaware, United States

In this work, a Landauer approach enabled by the Frequency Domain Perfectly Matched Layer Method (FDPML) is used to study phonon transport in a series of large 2D domains with randomly embedded nanoparticles over a wide range of nanoparticle loadings and wavelengths. The effect of nanoparticle packing density on the mean free path and localization length is characterized. We observe that in the Mie scattering regime, the independent scattering approximation is valid up to volume fractions exceeding 10% and often higher depending on the scattering parameter, indicating the mean free path can usually be calculated much less expensively using the number density and the scattering cross-section of a single scatterer. We also study localization lengths and their dependence on particle loading. In the case of heavy particles in a lighter matrix, we have been able to observe localization only at volume fractions >30% using the Landauer approach and only for high frequency modes, exceeding the vibration frequencies of the embedded nanoparticles. Using modal analysis we show that localization in nanoparticle laden materials is primarily due to energetic confinement rather than Anderson localization. Subsequently, we show that by using light particles in a heavy matrix the fraction of confined modes can be substantially increased.

4:45 PM EQ01.09.10

Linking Polaron Signatures to Charge Transport in Doped Thiophene Polymers Anas I. Abutaha[1], Vijila Chellappan[2], Pawan Kumar[2] and Kedar Hippalgaonkar[2,3]; [1]Qatar Environment and Energy Research Institute (QEERI), Hamad Bin Khalifa University (HBKU), Qatar; [2]Institute of Materials Research and Engineering, Agency for Science Technology and Research, Singapore; [3]Nanyang Technological University (NTU), Singapore

Carrier doping and structural morphology are key knobs to tune thermoelectric transport in conducting polymers. Several characterization methods such as Grazing-Incidence Wide-Angle X-ray Scattering (GIWAXS), Ultraviolet photoelectron spectroscopy (UPS) - inverse photoemission spectroscopy (IPES), and Absorption spectroscopy (Visible- Near Infrared (NIR) spectral region) are required to fully study these knobs. Here, we focus on absorption spectroscopy to understand thermoelectric transport in conducting polymers. Optical signatures of doping are correlated with thermoelectric properties of conducting polymers. Thus, we quantitatively extract the carrier concentration from optical absorption signatures of polarons by linking the absorption ratio of the low energy polaronic peak and neutral excitons in doped thiophene-based films with electrical conductivity and Seebeck coefficient under Boltzmann transport equations (BTE). The rate of change of electrical conductivity with carrier concentration (absorption ratio) differs with variation in doping and/or processing conditions, whereas the Seebeck coefficient decreases monotonically with carrier concentration regardless of doping method as expected. The correlation confirms that charge mobility is a key parameter to improve the thermoelectric performance where the method of doping or process conditions creates wide range of structural disorder controlling charge transport.

Progress in Transverse Thermoelectric Conversion Using Spin Caloritronics Ken-ichi Uchida[1,2]; [1]National Institute for Materials Science, Japan; [2]Tohoku University, Japan

Spin caloritronics is the fusion research field based on the combination of spintronics, thermoelectrics, and thermal energy engineering, in which the interplay between spin, charge, and heat currents has been extensively investigated. In this field, many experimental and theoretical studies have focused on the transverse thermoelectric conversion using magnetic materials to clarify its mechanism and utilize unique functionalities [1]. In this talk, we review fundamentals of spin caloritronics and recent progresses in basic and applied studies on the transverse thermoelectric conversion using magnetic materials, *i.e.*, the anomalous Nernst/Ettingshausen effects [2-5] and the Seebeck-driven transverse thermoelectric generation [6-8].

8:30 AM EQ01.10.02
Globally Optimal Band Structure for Thermoelectrics in Realistic Systems Junsoo Park; NASA Ames Research Center, United States

Observation is made that a linear dispersion in any dimension under acoustic-phonon-deformation-potential scattering theoretically prescribes a constant charge transport distribution, required for the boxcar profile known to maximize the thermoelectric figure of merit. A linear dispersion squeezed by two transport gaps under scattering by phonon deformation then theoretically constitutes a globally optimal qualitative band structure that may arise in realistic materials. Optimum bandwidth and electron velocity are also determined under deformation-potential scattering in three dimensions. The prescriptions lead to constant zT for all temperatures for a given value of lattice thermal conductivity, in agreement with purely analytic results from a boxcar transport distribution. This indicates that for a truly optimal band structure, the electronic part of the performance is temperature-independent, and the temperature-dependence of zT owes solely to that of lattice thermal conductivity.

8:45 AM *EQ01.10.03
Utilizing Band Anisotropy to Enhance the Thermoelectric Power Factor Chenguang Fu, Tiejun Zhu and Airan Li; Zhejiang University, China

The electronic band structure is a “gold mine” for exploring novel strategies that will promote the discovery of good thermoelectrics. Band anisotropy is a key characteristic of electronic structure that broadly exists in a lot of solid materials. Theoretically, valley anisotropy was proposed to benefit the electrical transport of TE materials [1,2]. However, there is still no experimental demonstration to confirm this prediction due to the challenge of the selection of suitable material as a model. Here, taking advantage of the single anisotropic Fermi pocket in p-type Mg_3Sb_2, a feasible strategy of utilizing the valley anisotropy to enhance the thermoelectric properties was demonstrated by synergistic studies of single crystals and textured polycrystalline samples. Compared to the heavy-band direction, improved carrier mobility by a factor of 3 is observed along the light-band direction while the Seebeck coefficient remains similar. Together with lower lattice thermal conductivity, increased room-temperature zT by a factor of 3.6 was found in the light-band direction of the single crystal. Further analysis revealed that the pz orbital, which overlaps more along the light-band direction, leads to the anisotropic valence band. With this knowledge, first-principles calculations of 66 isostructural Zintl phase compounds were conducted and 9 of them were found to display a pz orbital-dominated valence band, which are useful for guiding the development of high-performance p-type Zintl phase TE materials [3].

Thermoelectric Materials Assembled from Nanocrystals Dmitri V. Talapin; University of Chicago, United States

Nano- and mesostructuring of thermoelectric (TE) materials have emerged recently as a new paradigm to enhance the efficiency and manufacturability of TE modules. Switching from materials with large crystal grains to nano- and mesostructured compounds brings to the spotlight fundamentally important problems of morphological stability, grain growth, and inter-grain transport. The chemistry and physics of interfaces in TE devices remain largely underexplored. This is in stark contrast to, e.g., thin-film photovoltaics where grain boundaries have been studied in-depth for many years.
We will first discuss the effect of interfaces on charge and heat transport in arrays of semiconductor nanocrystals (NCs) that represent a convenient model of nanostructured TE materials. Next, we will cover new chemical approaches for the rational design of the interfaces in nanostructured TE materials. The NCs themselves can serve as a “solder” for nano- and mesoscopic grains. During mild heat treatment, NCs fill up the voids between particles and act as a “glue” joining grains in hot-pressed pellets or solution-processed films. The chemical design of NC glue allowed for the selective enhancement or reduction of the majority carrier concentration near the grain boundaries, and thus resulted in doped or de-doped interfaces in granular TE materials. Chemically engineered interfaces can be further designed to optimize power factor and thermal conductivity.

Design and Fabrication of Tetradymites Based Vertically-Oriented Thermoelectric Generators (TEGs) Mamadou T. Mbaye; Norfolk State

University, United States

As the world governments and lawmakers shift to concerted environmentally-friendly policies to achieve net zero in carbon emissions by the year 2050, much interest and discourse are being displayed in scientific fora on how research in renewable energy materials and devices can pave the way to a more sustainable planet. In light of that, thermoelectric materials and devices based on Bi_2Te_3 and its alloys have received renewed attention from industry and academia due to their renewability, large scalability, and commercial viability in producing electricity from waste heat for niche applications in micro refrigeration and small power generation. These materials exhibit the dimensionless figure of merit ZT values around 1, at room temperature and can be utilized to design and fabricate novel, vertical, flexible, wearable, and portable thermoelectric devices. However, for thermoelectric devices to be competitive with fluid-based and other energy-related devices, $ZT \geq 2$ is usually sought. The complexities of achieving high ZT reside in the fact that the dimensionless figure of merit presents a number of conflicting parameters. One cannot change one parameter without the detrimental effect of impacting the others. How then do we navigate the delicate and intricate relationship between the Seebeck coefficient or thermopower S, the electrical conductivity α, and the thermal conductivity K in order to achieve high ZT? From band engineering to grain boundary scatterings, to multilayer superlattice (SL) structures, thermoelectric researchers worldwide are investigating a plethora of options combined with state-of-the-art techniques to achieve just that.
In this work, we designed vertical and flexible thin-film thermoelectric generators (TEGs) based on n-type Bi_2Te_3, p-type Sb_2Te_3, and their ternary chalcogenide n-type $Bi_2Te_{2.83}Se_{0.17}$ and p-type $Bi_{0.4}Sb_{1.6}Te_3$ in the form of multilayer superlattice nanostructures using RF magnetron sputtering deposition method. The inclusion of interstitial atoms (Sb and Se) in these nanostructured ternary chalcogenides provides a two-fold benefit as it can greatly reduce the thermal conductivity of the material, due to scattering events of a wide range of phonons carrying heat but also improve the power factor through modification of the electronic structure of the material. In addition, if the layer thickness is in close proximity to the phonon's mean free path (MFP), heat-carrying phonons of different wavelengths (short, medium, or long) can be scattered more effectively at the superlattice interfaces, thereby resulting in the decrease of the lattice thermal conductivity of the material and subsequently the enhancement of the thermoelectric figure of merit. Furthermore, we investigated the optimal growth parameters for each material that will render high thermopower, S, and suitable electrical conductivity, α.

PRESENTED ON-DEMAND ONLY: Flexible Thermoelectric Generator with Moisture Re-Absorbable Hydrogel Heatsink Jeong Hun Kim, Jong-Pil Im, Seung Eon Moon and Yeriaron Kim; Electronics and Telecommunications Research Institute, Korea (the Republic of)

A thermoelectric generator (TEG) is promising energy harvesting device that can convert heat generated from power plant, furnace and combustion engine to electric energy. Because of the demands for pollutant-free energy source, researches about thermoelectric materials has been widely conducted to utilize it as a renewable energy source. In particular, since many heat sources have a curved shape, interest in flexible TEG (f-TEG) that can be applied here is growing.
In this paper, we made a BiTe-based flexible TEG that can be applied to curved surfaces using a polyimide PCB substrate. By designing the performance of the F-TEG according to the height of the TEG leg (1.5 ~ 3 mm) and the number of pairs (31 ~ 58 pair), and verifying it experimentally, an optimized structure could be derived.
In the case of f-TEG, it is difficult to apply a general fin-type heatsink made of metal, so a hydrogel-based flexible heatsink that can replace it was produced. In the case of utilizing the latent heat of water, high power generation output can be obtained initially, but the performance gradually decreases as water evaporates. To solve this problem, a hygroscopic ion that can reabsorb moisture in the absence of a heat source was introduced. In addition, by controlling the ratio of monomer and crosslinker and solvent, it was confirmed that stable attachment to the f-TEG surface was possible and cracks did not occur even during evaporation. Also, it was confirmed that the f-TEG to which the hydrogel heatsink was applied improved the power generation performance for more than 5 hours, and recovered more than 90% of the initial performance after one night in the atmospheric condition.
The f-TEG was manufactured in the form of an array to produce a system capable of mW-level power generation, and it was confirmed that the voltage was boosted through the power management device to drive the sensor and transmit information using bluetooth.
It is expected that this will be used as a power source for wearable devices and mobile systems that can be driven by themselves using various heat sources including body temperature in the future.

DLC Interlayers Functionalized Bi–Sb–Te-Based Nanoarchitectured Films for Achieving High Thermoelectric Performance Karan Giri, Yan-Lin Wang, Yu-Chieh Shih, Chuan-Wen Wang, Ling-Chun Chao, Yi-Chen Chen, I-Jung Wang, Pei-Hsuan Cho, Cheng-Ju Yang and Chun-Hua Chen; National Yang Ming Chiao Tung University, Taiwan

Nanostructuring has become one of the most practically proven and effective strategies in enhancing the thermoelectric figure of merit, which significantly propels thermoelectric materials to the forefront of progress in fundamental research and advanced applications. Accompanied with nanostructuring, heterogenization, which frequently shows excellent synergistic effects with nanostructures, has appeared as an appendable and feasible solution for a further breakthrough. Among numerous hetero-additives, diamond-like carbon (DLC), composed of sp^3 and sp^2 hybrid carbon atoms, is a type of amorphous carbon. Because of its relatively low tuneable thermal conductivity $\sim 10^{-1}$–10^{-2} $Wm^{-1}K^{-1}$, it may be applied as a potential candidate to suppress the thermal conductivity of the thermoelectric matrix without seriously affecting the overall conductivity.
In this work, we developed a new design concept and methodologies for building quasi-superlattice-like structurally ordered hetero-nanocomposite films for potentially realizing high-thermoelectric performance. According to this design concept, a series of superarchitectures consisting of longitudinally periodic DLC interlayers in latitudinally well-aligned Bi-Sb-Te (BST) based nanostructures were successfully demonstrated for the first time by using dual-beam pulsed laser deposition. The optimized Seebeck coefficient of ~500 μVK^{-1} and the corresponding power factor of ~40 $\mu Wcm^{-1}K^{-2}$ achieved are comparable to or higher than the reported values for BST or BST-based nanocomposites, which evidently originated from the periodically added DLC interlayers, as clarified in the Pisarenko plot. Besides, the periodic presence of the DLC additives was found to instantly refine the grain size of the simultaneously deposited local BST layer and thus effectively reduce the thermal transport as qualitatively evidenced by micro-Raman characterizations. The present work provided a direct insight into the fundamental understanding of the utilization of DLC as functional hetero-additives for structural modulation and thermoelectric enhancement.

"Defects" as Emitters for Quantum Photonics—Imperfections Creating Opportunities Evelyn Hu; Harvard University, United States

We have typically sought out "perfect" materials is to produce the best emitters for nano-photonic devices. Recently, however, defect states in wide bandgap semiconductors are defining a new frontier for nano-photonics. This talk will focus on a particular defect state: silicon vacancies in 4H-SiC. Integration of such defects within nanobeam photonic crystal cavities have shown an 80-fold optical enhancement of a Si-vacancy transition with emission at about 860 nanometers. The emitter-cavity coupling produces significant photonic signal amplification, and can serve as a building block, quantum repeater for larger-scale quantum information networks.
The photonic crystal cavities can also serve as "nanoscopes" that allow us to better understand the local environment of the silicon vacancies, the other defects that they encounter, the possible interactions with those defects and pathways to better processing and control of the defects. We will discuss insights provided by the cavities as nanoscopes. The accompanying spin signatures of the silicon vacancies, and the correlations between photon emission and spin modulation provide insights into further applications of these new nanophotonic emitters.

11:00 AM EQ02.01.02
Excitonic Halide Perovskites—A New Room-Temperature Materials Platform for Quantum Simulations. Wei Bao; University of Nebraska–Lincoln, United States

Exciton polaritons, the part-light and part-matter quasiparticles in semiconductor optical cavities, are promising for exploring Bose–Einstein condensation, non-equilibrium many-body physics and analogue simulation at elevated temperatures. However, a room-temperature polaritonic platform on par with the GaAs quantum wells grown by molecular beam epitaxy at low temperatures remains elusive. Here, we address this challenge by adopting a method based on the solution synthesis of excitonic halide perovskites grown under nanoconfinement. Such nanoconfinement growth facilitates the synthesis of smooth and homogeneous single-crystalline large crystals enabling the demonstration of XY Hamiltonian lattices with large sizes. Next, we report the first observation of polariton superfluidity in a Wannier-Mott exciton system at room temperature. Specifically, we demonstrate transitions from a normal fluid to superfluidity and supersonic fluid in both two- and one-dimensional cases in halide perovskite microcavities. In the two-dimensional case, we demonstrated a landmark zero-viscosity superfluid and a supersonic Čerenkov wave pattern at room temperature, on a par with low-temperature GaAs cases for the first time. In the one-dimensional case, we show that the back-reflection can be fully suppressed outside the superfluidity healing length when the polariton superfluid hits a hard potential wall under the critical velocity. With these demonstrations, we further establish perovskites as a promising platform for room temperature polaritonic physics and pave the way for the realization of robust mode-disorder-free polaritonic devices at room temperature.

Topological Hydrodynamic Circulator in Graphene's Viscous Hall Fluid Wenbo Sun, Todd Van Mechelen, Ashwin K. Boddeti, Sathwik Bharadwaj and Zubin Jacob; Purdue University, United States

Viscous Hall electron fluid in graphene has emerged at the forefront of many-body interacting electron systems due to its low dimensionality and impurity density. It is the first candidate for a non-local topological electromagnetic phase of matter. This 2D topological viscous Hall insulator is characterized by an optical N invariant, fundamentally different from the Chern and quantum spin Hall insulators. Here, we show that this viscous Hall fluid is in a topological electromagnetic phase arising from the repulsive nature of Hall viscosity. This feature is evident by studying the edge magneto-plasmons, which close the low-frequency electromagnetic bandgap for graphene. Based on the unidirectional topological edge plasmons, we design and simulate a topological circulator, which is a chiral quantum radio-frequency (RF) circuit component crucial for information routing and interfacing quantum-classical computing systems. Our work opens practical applications of graphene's viscous Hall fluid and simultaneously provides an experimental platform for studying topological hydrodynamics of light.

Creating Bound States in the Continuum Using Superstructure Photonics Alexander Cerjan; Sandia National Laboratories, United States

In the past decade, symmetry-protected bound states in the continuum (BICs) have proven to be an important design principle for creating and enhancing devices reliant upon states with high-quality (Q) factors, such as sensors, lasers, and those for harmonic generation. However, as I will discuss, it is possible to prove using representation theory that current implementations of symmetry-protected BICs in photonic crystal slabs can only yield BICs at the center of the Brillouin zone and below the Bragg diffraction limit, which fundamentally restricts their use to single- or few-frequency applications. Instead, this limitation must be overcome by altering the system's radiative environment. In this talk I will discuss two separate methods for creating lines of BICs by altering the radiative environment surrounding a photonic slab, i.e., by using a superstructure: First, by using the symmetry of the environment to create a symmetry bandgap in the environment's radiative channels in which slab states with un-represented symmetries are necessarily BICs [1]. Second, by using the environment to reduce the number of radiative channels, enabling the formation of lines of BICs accidentally [2]. The ability to create continuous lines of BIC may have ramifications for enabling multi-frequency and multi–wave vector applications in technologies that leverage these high-Q states.

1:30 PM *EQ02.02.01
Plasmonics in Electronic Topological Materials Stephanie Law; University of Delaware, United States

Topological insulators (TIs) are materials with an electronic bulk bandgap crossed by surface states that exhibit linear dispersion and spin-momentum locking. Electrons occupying these surface states have low mass and large Fermi velocity due to the linearity of the band structure. The spin-momentum locking of the surface states leads to a reduction in electron scattering, since a change in momentum requires a spin flip. Among other interesting properties, two-dimensional Dirac plasmon polaritons (DPPs) can be excited from these surface electrons. These plasmon polaritons exhibit resonances in the terahertz (THz), a frequency range of interest for chemical identification, imaging, and communication. The TI plasmons inherit the unusual properties of their constituent electrons: the excitations are two-dimensional and massless, similar to those found in graphene. Unlike graphene, TI plasmons should also exhibit spin-momentum locking, leading to a reduction in scattering and an increased plasmon lifetime.
In this talk, I will summarize our past work on exciting DPPs in TI thin films, demonstrating record-high mode indices and long plasmon lifetimes. I will then discuss more recent work on coupling DPPs in adjacent microribbons to tune their frequency, exploring how the DPPs evolve as the TI film thickness is tuned through the topological transition, and synthesizing TI/normal insulator superlattices that house complex DPP modes. I will close by showing evidence for a transition to a THz Dirac hyperbolic metamaterial in multilayer stacks of TIs and normal insulators. These materials have the potential to be powerful components in future THz photonic devices.

2:00 PM EQ02.02.02
Ultra-Low-Loss Anisotropic Image Polaritons in α-MoO_3 Sergey Menabde[1], Junghoon Jahng[2], Sergejs Boroviks[3,4], Jongtae Ahn[5], Jacob Heiden[1], Do Kyung Hwang[5], Eun Sung Lee[2], N. Asger Mortensen[4,4] and Min Seok Jang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of); [3]Swiss Federal Institute of Technology Lausanne, Swaziland; [4]University of Southern Denmark, Denmark; [5]Korea Institute of Science and Technology, Korea (the Republic of)

Polaritons in van der Waals crystals possess a high degree of field confinement, allowing for the strong light-matter interaction and light manipulation at nanoscale. At the same time, when a polaritonic van der Waals crystal is placed in proximity to a highly conductive metal, the coupling between the collective charge oscillations and their images in the metal results in a manifestation of an even more compressed low-dimensional mode – the image polariton.
We use the near-field optical microscopy and the photo-induced force microscopy to study the hyperbolic image phonon-polaritons (HIP) in orthorhombic molybdenum trioxide (α-MoO_3) – a recently discovered polaritonic van der Waals crystal that supports strongly anisotropic mid-infrared phonon-polaritons. As a low-loss substrate for the image modes, we employ the atomically-flat monocrystalline gold flakes. By leveraging the unique physical properties of the gold crystals, we systematically probe different momentum states on the isofrequency surface and measure the full complex-valued propagation constant of the HIP propagating at different angles to the crystallographic axes of α-MoO_3.
We report an exceptionally long lifetime of phonon-polaritons in α-MoO_3: 4.2 ps and 9.7 ps in the second and the third Reststrahlen bands, respectively, owing to the suppression of all substrate-mediated loss channels in our samples. In contrast, the less confined phonon-polaritons in the α-MoO_3 on SiO_2 substrate have been shown to have a significantly shorter lifetime of ~2 ps in the second Reststrahlen band.
Furthermore, our study reveals the drastically different dispersion properties of the HIP with opposite signs of the group velocity: only the modes with positive group velocity (in the second Reststrahlen band) have both significantly larger momentum and lifetime compared to their counterparts on a dielectric substrate, while the image modes with anomalous dispersion (in the third Reststrahlen band) possess smaller momentum.
Summarizing, our near-field study demonstrates a unique combination of the in-plane anisotropic phonon-polaritons in α-MoO_3, the image mode, and the monocrystalline gold substrate, leading to a manifestation of the hyperbolic image phonon-polaritons with simultaneously greater field compression and larger lifetime compared to the phonon-polaritons in α-MoO_3 on a dielectric substrate. Our results spotlight the HIP in α-MoO_3 as an appealing platform for versatile nanophotonic applications.

2:15 PM *EQ02.02.03
Strong Coupling and Extreme Anisotropy in Infrared Polaritonic Media Joshua D. Caldwell; Vanderbilt University, United States

The field of nanophotonics is based on the ability to confine light to sub-diffractional dimensions. In the infrared, this requires compression of the wavelength to length scales well below that of the free-space values. While traditional dielectric materials do not exhibit indices of refraction high enough in non-dispersive media to realize such compression, the implementation of polaritons, quasi-particles comprised of oscillating charges and photons, enable such opportunities. Two predominant forms of polaritons, the plasmon and phonon polariton, which are derived from light coupled with free carriers or polar optic phonons, respectively, are broadly applied in the mid- to long-wave infrared. However, the short scattering lifetimes of free-carriers results in

high losses and broad linewidths for the former, while the fast dispersion and narrow band of operation for the latter result in significant limitations for both forms. Here we will discuss the opportunity to implement polaritonic strong coupling between different media in an effort to dictate the polaritonic dispersion relation, and thus, the propagation and resonant properties of these materials. Further, by employing the extreme anisotropy of crystals ranging from two-dimensional materials such as hexagonal boron nitride and transition metal dichalcogenides to low-symmetry monoclinic to triclinic materials, novel optical phenomena such as hyperbolicity and shear polaritons are observed. The talk will highlight ultra-strong coupling between both forms of polaritons in the context of infrared emitters, as a means to control planar propagation using hyperbolic polaritons, an modifying thermal dissipation at ultrafast time scales.

2:45 PM EQ02.02.04
Engineered Near- and Far-Field Optical Response of Dielectric Nanostructures Using Focused Cylindrical Vector Beams Martin Montagnac[1], Gonzague Agez[1], Sebastien Weber[1], Arnaud Arbouet[1], Aurelien Cuche[1], Guilhem Larrieu[2], Yoann Brûlé[3], Gerard Colas des Francs[3], Bruno Masenelli[4], Vincent Larrey[5] and Vincent Paillard[1]; [1]CNRS-CEMES, France; [2]CNRS-LAAS, France; [3]ICB, France; [4]INL, France; [5]CEA-LETI, France

We present near- and far-field optical properties of silicon nanostructures (Si-NS) under linear polarization (Gaussian beam), and azimuthally or radially focused cylindrical vector beams investigated by finite-difference time-domain method (FDTD) in Meep open-source software.
In addition to the preferential excitation of specific electric or magnetic resonance modes as function of the excitation beam polarization, we show in the case of spheroids that shape anisotropy affects the resonance wavelength and the dipole orientation of the magnetic or electric dipole mode. Depending on the spheroid symmetry axis with respect to the electric field orientation, the electric dipole resonance can be split in two peaks, giving quasi-unidirectional scattering, separated by an anapole mode. The optical properties in both the far-field (scattering pattern) and near-field (electric and magnetic field hot spots) can be tuned by changing the excitation polarization at a fixed wavelength and selecting properly the spheroid shape and dimensions. Similar behavior is obtained on nanostructures such as nanocylinders with circular or elliptic section that could be produced by top-down fabrication techniques.
As magnetic and electric near field hotspots can be engineered, we present photoluminescence (PL) mappings of Eu^{3+}-doped homogenous thin films deposited on Si nanostructures produced by electron beam lithography and reactive ion etching of silicon on silica substrate.
On the one hand, we show that the PL enhancement depends on the Si-NS resonance mode at the excitation wavelength. We also evidence that PL maps exhibit a very specific behavior as function of the shape and polarization of the excitation beam. In other words, the PL intensity distribution can be spatially shaped by the near-field, itself shaped by both the excitation beam polarization and the Si-NS properties.
On the other hand, we investigate how the PL maps at the emission wavelength for the different kind of emitting dipolar transitions (magnetic dipole at about 590 nm and electric dipole at about 610 nm) are influenced by either the electric or magnetic Local density of States (LDOS).
Such work constitutes a first step in the design of Si-NS coupled to quantum emitters that can be optimized for many parameters: both excitation and emission wavelengths, emitting dipole nature and orientation, and emission directivity.

Collective Multipole Resonances in Lossy Materials Amanda Romero, Erik Boldt, James Toomey and Viktoriia Babicheva; University of New Mexico, United States

There is a lot of interest in utilizing metamaterial perfect absorbers and transforming electrodes into hybrid photodetectors, which can enhance their performance. Due to their exceptional properties, lossy materials, such as titanium, nickel, and others, have been a focus of large research efforts. However, because of the high losses, achieving high light confinement and harvesting in the nanostructures of such materials is challenging.
We design resonant nanostructures to achieve efficient light control and dynamic tuning of nanophotonic elements. We have achieved the excitation of strong lattice resonances and larger absorption in the arrays of lossy nanoparticles, which can result in a higher generation of hot electrons. We explore the optical properties of novel nanostructures, intending to use them in laser devices and for enhanced emission.
A universal approach is developed to achieve the design goals of layered nanostructures with low optical losses and high performance. We have shown that further narrowband and broadband photodetector functionality can be improved using a multiple-period array of nanoparticles by manifesting enhancement in the resonances and absorption profiles. These nanostructures can provide high-efficiency hot-electron photoconversion and be applied in hybrid devices and photodetectors.
This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science by Los Alamos National Laboratory (Contract 89233218CNA000001) and Sandia National Laboratories (Contract DE-NA-0003525). The work is also supported by Contract DE-2375849.

Metal-Halide Perovskite Hyperbolic Metamaterials Jacob Scheuer; Tel Aviv University, Israel

Hyperbolic metamaterials (HMM) are artificially engineered anisotropic materials. These materials are characterized by their hyperbolic dispersion relation where the in-plane dielectric constants have an opposite sign to the out-of-plane dielectric constants. Recently, HMMs received much attention due to their potential applications in super resolution imaging, absorber, biosensors, extreme polarization anisotropy of photoluminescence just to name a few. Metal-halide perovskites have emerged in recent years as a powerful material system in the field of photonics. Due to their promising electronic and optical properties, tremendous progress has been made in perovskites solar cell performance. In this presentation, I will demonstrate the first realization of HMM using solution processable methyl ammonium lead iodide ($MAPbI_3$) and plasmonic metal, Au. I will discuss the properties of the HMM within the available parameter space (geometry, wavelength, etc.) in the context of effective medium theory as well as the potential applications

4:15 PM *EQ02.03.03
Extreme Strain Engineering to Control Photon, Electron, Phonon and Polariton Transport in Materials for Energy Applications Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

I will discuss the opportunities and applications enabled by strain-induced deformations in semiconductor and polymer materials. One such application is persistent electric energy generation in flexoelectric devices that can be achieved by harnessing absorption and radiative heat emission in narrow-gap semiconductors with inversion symmetry broken by inhomogeneous strain [1]. Another is static and dynamic control of directional surface plasmon polariton modes propagation in Weyl semimetals or semiconductors under strain [2,3]. I will outline strategies to engineer and characterize the effects of the externally-induced or in-situ strain on the material structure, polarization, and energy transport properties. Finally, I will discuss the opportunities for solid-state cooling and heating applications based on elastocaloric and twistocaloric effects in strain-activated polymer fibers engineered to achieve temperature control, energy storage, and thermal conductivity modulation.

This research has been supported in part by the MIT Lincoln Laboratory under award No.ACC-777 (for the flexoelectric energy harvesting), the Army Research Office under award No. W911NF-19-1-0279 (for the near-field radiative energy transfer), the DOE-BES program under award No. DE-FG02-02ER45977 (for the strain-controlled thermal conductivity) and the MIT-SUSTech Program (for the elastocaloric effects).

Hyper-Doped Silicon Nanoantennas and Metasurfaces for Tunable Infrared Plasmonics Jean-Marie Poumirol[1], Caroline Bonafos[1], Clément Majorel[2], Peter Wiecha[3], Richard Monflier[3], Guilhem Larrieu[3], Fuccio Cristiano[3], Anne-Sophie Royet[4], Pablo Acosta Alba[4], Sébastien Kerdiles[4] and Vincent Paillard[1]; [1]CEMES-CNRS, Université de Toulouse, CNRS, France; [2]CHREA-CNRS, France; [3]LAAS-CNRS, Université de Toulouse, CNRS, France; [4]CEA-LETI, France

The use of plasmonic or high refractive index dielectric nanoantennas or metasurfaces is a common strategy for increasing optical absorption and scattering and for localizing light at subwavelength dimensions. Because of their low losses and direct compatibility with large-scale production techniques from microelectronics, semiconductor nanostructures and full noble metal nanostructures are attracting increasing interest in the visible spectrum. Those techniques have limitations in the mid-infrared (MIR), namely at wavelengths ranging from 2 to 15 µm, which is the region of relevance for chemical or biological sensing and thermal imaging.
Doped semiconductors[1-2], in addition to other properties like shape and size, are a promising choice for plasmonics encompassing a broad infrared spectrum, since their LSPR can be controlled by dopant concentration as well as other parameters like shape and size. Massively doped silicon (Si) nanostructure arrays are logical candidates for mass-producing highly integrated low-cost MIR plasmonic devices.
In this framework, we developed all-silicon-based plasmonic metasurfaces generated by submicrometer tiny doped-Si nanodisks (Si-NDs) by processing hyper-doped overlayers of SOI substrates[3]. We showed that such nanostructures can support localized surface plasmon resonances that are controlled by the Si free carrier density. By modulating the free carrier concentration between 10^{20} and 10^{21} cm^{-3}, the plasmon can be tuned in a spectral window between 2 and 5 µm[4]. Active dopant concentrations exceeding 10^{21} cm^{-3} are required to reach the NIR regime. We showed that, despite a large mismatch between the wavelength (25.5 µm) and the Si-ND diameter (100 nm), the LSPR allows for a substantial interaction with IR light, resulting in a loss in transmittance of up to 10% at the resonance[4]. We evaluated the optical characteristics of a single nanodisk as well as the entire metasurface using numerical simulations[5]. They demonstrate excellent agreement with the experimental findings and provide physical insights into the influence of nanostructure form and near-field effects on the metasurface's optical characteristics. Our results open highly promising perspectives for integrated all-silicon-based plasmonic devices for instance for chemical or biological sensing or for thermal imaging.

A Near-Field Tunable Magnetocaloric Thermal Switch Simo Pajovic and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

The magnetocaloric effect is the phenomenon in which some magnetic materials experience a change in temperature upon an adiabatic change in magnetization. It is well-known that this process can be exploited to achieve magnetic refrigeration and has other potential applications including drug delivery (particularly controlled release) and hyperthermia to treat cancer [1]. In recent years, there has also been an interest in using magnetic fields to manipulate radiative heat transfer, especially in the near-field, where length scales are approximately less than the peak wavelength of the blackbody spectrum and evanescent modes dominate. For example, it is possible to tune the near-field radiative heat transfer between planar doped semiconductors by applying a magnetic field and modulating its magnitude and direction [2]. This is because the applied magnetic field induces off-diagonal elements in the dielectric tensor, which are linked to nonreciprocal modes and magneto-optic effects, as well as uniaxial or biaxial anisotropy, which can give rise to hyperbolic modes. In this work, we have combined the magnetocaloric effect and magnetic control of radiative heat transfer to model a near-field tunable magnetocaloric thermal switch. We have shown that the heat flux between a magnetocaloric material and a magneto-optic material can be controlled via two mechanisms: the temperature change originating from the magnetocaloric effect; and modes such as surface plasmon polaritons and hyperbolic modes that depend on both the magnitude and the direction of the applied magnetic field. Thus, we predict the applied magnetic field enables control over the

directionality of the heat flux—from the magnetocaloric material to the magneto-optic material and vice-versa—and its magnitude, both spectrally and totally. Our work points toward a new class of thermal switches with a potentially wide range of operating temperatures dependent on the Curie temperature of the magnetocaloric material. This work is supported by an ARO MURI (Grant No. W911NF-19-1-0279) via the University of Michigan.

Narrow Bandwidth Polymers and Metal Oxide Interlayers to Improve an Artificial Retina Leslie Askew and Maxim Shkunov; University of Surrey, United Kingdom

Recent advances in biomedical engineering have led to a growing worldwide effort to develop a retinal prosthesis designed to restore vision to people suffering from retinal dystrophies such as age-related macular degeneration (AMD) and retinitis pigmentosa (RP). Some of this work has involved interfacing degenerative retinas with organic-semiconductor based devices to elicit an electrical response upon illumination in order to initiate a transduction of stimuli through the remaining retinal network, and thus provide a capability to restore vision. Previous work done by our group has demonstrated several conjugated polymers and small molecules with different bandgaps used towards a device prototype for potential vision restoration in full colour by emulating the each photoresponse from the rods and cones of the human eye.[1]
Commercially available prosthetics to date have been designed primarily as solid-state devices requiring transcranial wiring and associated ancillary optical and power components. Recent research into less invasive and more comfortable devices has turned to organic photovoltaic materials that are lightweight, flexible, and relatively low-cost. Moreover, using organics capitalises on their potential biocompatibility and their electrical properties to create arrays of miniature photovoltaic pixels to stimulate neurons in the retinal pathway and may provide a straightforward and reliable basis for durable visual prosthetics.
However, challenges in using carbon-based semiconductors to elicit enough photocurrent to stimulate a cell in the retinal network remain. Firstly, the power conversion efficiency of thin film organic photovoltaics has only recently exceeded 12%,[2-4] a value that is woefully small. Increasing excitation power until a photocurrent is detectable is a common work-around, however, while it might prove functional in a laboratory setting, the unnaturally powerful source may result in catastrophic damage to a prosthetic device in a human body. It would be much more favourable to utilise the electronic properties of additional interfacial materials to improve device performance.
In this study, we report on the characteristics of devices fabricated with a range of organic semiconductor polymers for active layers as part of our development of an artificial retina prototype. Previous work has identified a range of promising small molecules that emulate trichromatic vision (rods and three cones); here we describe improvements made with “off the shelf” polymers with narrow absorption bands that suitably match those of human photoreceptors. Importantly, we employ electron-transporting / hole-blocking metal oxide interlayers at the current collecting electrode to elicit capacitive charge transfer of sufficient magnitude for neuronal stimulation. By reducing the difference in work functions of the electrode and LUMO level of the active materials, a significantly higher photoinduced current can be produced for all of the molecules in this study, and the resulting capacitive nature of charge transfer can help to dramatically reduce peroxide-induced Faradiac reactions in device-neuron interfaces.[5]

Spatial Modulation of Radiative Decay Dynamics of Exciton Complexes in WSe_2 Monolayer Jaeyu Kim, Sanghyeok Park, Dongha Kim and Min-Kyo Seo; Korean Advanced Institute of Science and Technology, Korea (the Republic of)

Excitons in transition metal dichalcogenides (TMDs) monolayer possess strong binding energy, valley selectivity, and high quantum efficiency, which are useful for various applications in excitonics, quantum many-body physics, and optoelectronics. TMDs support not only excitons but also a variety of exciton complexes such as biexcitons, charged excitons, and dark excitons that have distinct features and capabilities from excitons: Biexcitons in TMDs have high valley selectivity. Charged excitons can be effectively controlled by the application of electric fields. Dark excitons have a longer intrinsic lifetime and thus can diffuse a longer distance. It has therefore been essential to examine and understand the radiative decay dynamics of exciton complexes in various environmental conditions. The Purcell effect in terms of vacuum field interference has been widely used to control the radiative decay rate of the exciton complexes. However, the radiative decays of the exciton complexes occur at different emission wavelengths and their detailed properties vary from specimen to specimen. The conventional planar mirrors or resonators are not practical to provide the target TMD material with various optical environments depending on the position and emission wavelength at the same time, which is required for investigating the decay dynamics of the exciton complexes systematically.
In this research, we present the spatial modulation of radiative decay dynamics of exciton complexes in the WSe_2 monolayer employing a gradient-thickness mirror (GTM). Our GTM structure consists of the Si/Al (80 nm)/SU8 multilayer. The Al layer acts as a bottom mirror, and the thickness of the SU8 layer gradually changes from 80 to 500 nm over a horizontal distance of 20 micrometers with a slope of ~1°. The flake of hBN (150 nm)/WSe_2 monolayer/hBN (70 nm) was transferred onto the surface of the GTM structure. At a given wavelength, the vacuum field interference and the Purcell effect depend on the thickness of the dielectric SU8 layer. The GTM structure supports a white light interference pattern, in which the constructive/destructive interference conditions for the different emission wavelengths of the exciton (720 nm), biexciton (730 nm), and dark exciton (740 nm) in the WSe_2 monolayer appear at different spatial positions and repeat with different spatial frequencies. As a result, the radiative decay dynamics of each exciton complexes can be modulated in different manners along the direction of the thickness gradient, which enables us to examine the decay dynamics of exciton complexes in the identical WSe_2 monolayer under a variety of conditions.
We measured the photoluminescence (PL) spectrum from the exciton complexes in the WSe_2 monolayer pumped with He-Ne laser via a confocal scanning microscopy. The PL intensity ratio between the exciton complexes, related to their relative radiative decay rates, change depending on the position along the thickness gradient of the GTM structure. We demonstrated that the relative PL intensity ratio of biexcitons to bright excitons spatially changes from ~0.28 to 2.1 with one order of magnitude. We also demonstrated an optical situation where the emission from dark excitons dominates in those of other exciton complexes, which have been difficult to realize due to the weak radiative recombination of the dark exciton. In addition, we were able to systematically investigate the Lamb shift of the bright exciton emission spectrum depending on the vacuum field interference strength.

Thermodynamic Limits of Photon-Multiplier Luminescent Solar Concentrators Tomi Baikie, Arjun Ashoka, Akshay Rao and Neil Greenham; University of Cambridge, United Kingdom

Luminescent solar concentrators (LSCs) are theoretically able to concentrate both direct and diffuse solar radiation with extremely high efficiencies. Photon-multiplier luminescent solar concentrators (PM-LSCs) contain chromophores which exceed 100\% photoluminescence quantum efficiency. PM-LSCs have recently been experimentally demonstrated and hold promise to outcompete traditional LSCs. However, we find that the thermodynamic limits of PM-LSCs are different and are sometimes more extreme relative to traditional LSCs. As might be expected, to achieve very high concentration factors a PM-LSC design must also include a free energy change, analogous to the Stoke shift in traditional LSCs. Notably, unlike LSCs, the maximum concentration ratio of a PM-LSC is dependent on brightness of the incident photon field. For some brightnesses, but equivalent energy loss, the PM-LSC has a greater maximum concentration factor than that of the traditional LSC. We find that the thermodynamic requirements to achieve highly concentrating PM-LSCs differ from traditional LSCs. The new model gives insight into the limits of concentration of PM-LSCs and may be used to extract design rules for further PM-LSC design.

Towards Spectrum Control with Materials Beyond Coin-Age Metals Marina S. Leite; University of California, Davis, United States

Metallic thin films and nanostructures are vital building blocks for next generation nanophotonic devices. Nevertheless, the permittivity of pure metals frequently imposes restrictions on the materials utilized and/or on device performance. Metallic mixtures and alloys embody a promising alternative to engineer the optical response of devices, enabling extra control of the spectrum. I will present our recent advances in photonics achieved using metal alloys, comprising super-absorbers using earth-abundant Al-Cu back reflectors, Pd-Au thin films for catalysis, and photodetectors with enhanced response based on Ag-Au films. An in-depth analysis of experimental and theoretical studies of the metallic mixtures optical properties will be also provided, including their correlation with electronic band structure. In the realm of biodegradable photonics, I will share our results regarding color pixels formed by Mg and MgO. Specifically, the green chemistry reaction between these materials and water enables structural colors to disappear within a few seconds. These devices find applications in environmental science, encryption, and health care. Overall, materials beyond coin-age metals can enable a pathway for further controlling the electromagnetic spectrum.

Uncovering Polar Domains in the Rashba Semiconductor BiTeI Through Piezoresponse Force and Second Harmonic Generation Microscopy Kevin W. Kwock[1], Thomas P. Darlington[1], Kaiyuan Yao[1], Kai Du[2], Sang Wook Cheong[2], Rohit Prasankumar[3], Prashant Padmanabhan[4] and P.J. Schuck[1]; [1]Columbia University, United States; [2]Rutgers, The State University of New Jersey, United States; [3]Intellectual Ventures, United States; [4]Los Alamos National Laboratory, United States

Nonlinear optics has proven a powerful probe for understanding the intrinsic crystal structure and phase of material. Recently, it has been shown that the 2D class of vdW materials exhibit remarkable nonlinear optical properties. Among the exciting family of 2D materials that are being investigated for their nonlinear optical properties, the Rashba family of semiconductors, including BiTeI, has emerged as an excellent candidate for studying the origins of optical nonlinearities in polar semiconductors. BiTeI and related materials have a large Rashba spin-orbit coupled state, and their large polarity is expected to persist down to the monolayer limit. Here, we used second harmonic generation (SHG) microscopy to show that BiTeI is an extremely nonlinear material using layer-dependent studies and extracting its nonlinear coefficients. This then enabled us to exploit SHG microscopy to image polar domains in BiTeI and correlate it this with piezoresponse force microscopy (PFM), providing key insights into the origin of the domains.

Identifying Bacterial Pathogens in Wastewater Samples with Liquid Surface Enhanced Raman Spectroscopy Liam K. Herndon, Fareeha Safir, Baba Ogunlade, Halleh Balch, Alexandria Boehm and Jennifer A. Dionne; Stanford University, United States

The ability to accurately identify and monitor bacterial pathogens in environmental samples such as rivers, streams, and wastewater is critical to public health. Our group has recently shown that Raman spectroscopy combined with machine learning (ML) can be a powerful tool for identifying bacterial species, strain, and antibiotic susceptibility [1, 2, 3]. Gold nanorods can enhance the Raman scattering signature, owing to their ability to concentrate the incident light and selectively bind to bacteria via electrostatic interactions. In wastewater, however, anions mask the surface charges of the nanorods, disrupting interactions with bacteria and weakening the Raman enhancement.

Here, we achieve bacterial surface enhanced Raman spectroscopy (SERS) in wastewater by conjugating 12-residue gold-binding peptides (GBPs) to the bacterial surface. These peptides interact with gold through van der Waals interactions, overcoming the need for positive surface charges on the nanorods, and form bonds with gold 10 times more stable than electrostatic interactions [4]. As a proof of concept, we design a plasmid encoding a GBP conjugated to a circularly permuted outer membrane protein X (CPX) scaffold and use this plasmid to express GBPs on the *E. coli* cell surface. We describe the effects of GBP surface expression on adsorption affinity of bacteria to nanorods. Next, we use filtered wastewater samples and spike in GBP-expressing *E. coli* at a concentration of 10^7 cells/ml, a realistic total bacterial concentration for wastewater. With our surface expression of GBPs, SERS can detect *E. coli* at this concentration using only 10 second integration times in a liquid wastewater sample. Finally, to demonstrate broad application to any bacterial species, we conjugate synthetic GBPs to dibenzocyclooctyne (DBCO). These conjugates can be selectively cross-linked to azides via copper-free click chemistry, enabling GBP cross-linking to any bacteria that have been metabolically labeled with azide-conjugated cell wall and outer membrane components. Hence, by combining advances in nanophotonics, ML, and biological engineering, we demonstrate SERS can be used to detect a wide variety of bacterial species and strains in complex environmental samples, allowing rapid and label-free monitoring of a community's bacterial infections through wastewater.

Calcite Phonon Polaritons Jeff Owrutsky[1], Vanessa Breslin[1], Daniel Ratchford[1], Alexander Giles[2], Chase Ellis[1], Igor Vurgaftman[1] and Joseph Tischler[3]; [1]Naval Research Laboratory, United States; [2]Quantitative Scientific Solutions, LLC, United States; [3]The University of Oklahoma, United States

Phonon polaritons are supported within a material-specific spectral region of polar materials called the reststrahlen band, which is bounded by the transverse and longitudinal optical phonons. Surface phonon resonances (SPhPs) are widely recognized in polar semiconductor materials such as SiC and GaN, including our demonstrating active tuning of nanopillar SPhPs and Berreman modes. We have recently shown that phonon resonances are also supported by other materials, including inorganic salts and molecular crystals. Some materials have anisotropic and even hyperbolic optical properties similar to hexagonal boron nitride, in which they behave optically like a dielectric and a metal along different crystal axes. We describe IR reflection results for calcite nanopillar and nanohole arrays which support hyperbolic phonon polaritons (HPs). The HP modes observed in the nanohole arrays appear at higher frequencies than those in the nanopillar arrays. We have developed a qualitative understanding of the nature of the HP modes in the nanohole arrays, in which the modes are most likely confined to the constrictions between holes. In such a model, changing the pitch and/or the diameter of the holes will change the dimensions of the constrictions and result in changing the resonance frequency of the HP modes in a predictable way. Being able to theoretically describe HPs in calcite is a first step towards understanding the nature of these modes in a variety of materials in order to expand the range of phonon polariton materials available for mid-IR nanophotonic applications.

Emerging Materials for Plasmonics in the Visible Region—From Discovery to Application Yu-Jung Lu; Academia Sinica, Taiwan

Progress in understanding resonant subwavelength optical structures has fueled a worldwide explosion of interest in both fundamental processes and nanophotonic/plasmonic devices for imaging, sensing, solar energy conversion, and information processing. However, plasmonic platforms in the visible region with robust, high performance, thermo-stable, and low-cost remains remain unexplored. In this presentation, I will particularly discuss emerging plasmonic platforms based on transition metal nitrides. I will present an overview of my research works over the past five years on the plasmon-enhanced light-matter interactions in the visible regions and its applications [1-6], including the plasmonic nanolasers [1-2], tunable plasmonic modulators [3], plasmonic phototransistors [4], plasmon-enhanced solar energy harvesting [5], and the refractory plasmonic colors for back-light free displays [6]. My group discovered several unique working mechanisms that utilize plasmonic nanostructures to improve optoelectronic device performance. By engineering the local electromagnetic field confinement, the light-matter interaction strength can be enhanced, which results in efficient energy conversion in the designed nanosystem. The detailed mechanisms and possible applications will be discussed. These results have broad implications for the use of plasmonic crystals/metasurfaces in high-performance optoelectronic devices with efficient energy conversion.

Chiral Bio-Inorganic Hedgehogs with Birefringence Prashant Kumar[1], Emanuele Marino[2], Alexander Simon[1], Daniel Katz[1], Christopher B. Murray[2] and Nicholas A. Kotov[1]; [1]University of Michigan–Ann Arbor, United States; [2]University of Pennsylvania, United States

Spiky hedgehogs can be self-assembled from twisted ribbons formed by gold-copper-cysteine complexes.[1] Furthermore, chirality of these twisted ribbons can be controlled by the cysteine amino acid while their arrangement into supraparticles is guided by the ratio of L- vs D-form during the initial stages of self-assembly. Here we report that the spherically symmetric arrangement of twisted ribbons displays a maltese cross pattern typical of spherulites and liquid crystals under cross-polarizers.[2] This optical effect is observed at the single particle level[3] with tunable diameters of 1-10 um. We investigate the optical effects in chiral hedgehogs using single particle methodology and find that the emergence of Maltese cross pattern is dependent on the sphericity of the supraparticle and the spacing between individual spikes. We understand the interaction of light with hierarchically self-assembled structures through finite-element based electromagnetic simulations and reconstruct the distribution of electromagnetic fields around the hedgehogs in three dimensions. These hedgehogs are omnidispersible in a variety of solvents and offset the limitations of commonly observed organic molecule based spherulitic arrangement for biomolecular sensing under harsh environments.[4]

11:15 AM EQ02.06.03

Templated Dewetting of Optical Glasses—A Novel Fabrication Approach of All-Dielectric Metasurfaces Fabien Sorin[1], Pierre-Luc Piveteau[1], Tapajyoti DasGupta[2] and Louis Martin-Monier[3]; [1]Ecole Polytechnique Fédérale de Lausanne (EPFL), United States; [2]Indian Institute of Science Bangalore, India; [3]Massachusetts Institute of Technology, United States

Metasurfaces require the integration of materials with accurate control over position, size and shape for high optical efficiency. This is commonly achieved using well-established lithographic or chemical processes. Nevertheless, such processes suffer from intrinsic limitations over throughput or flexibility, and hence remain difficult to scale up and adapt to large area, flexible or stretchable substrates. Here, we present a novel fabrication approach based on controlled templated fluid instabilities of thin optical glasses, to self-organize a variety of large index contrast all-dielectric metasurfaces. Given the right annealing time-temperature settings, initial film thickness and underlying pattern, the breakup of the film can occur at prescribed locations resulting in nano-objects of tunable position, shapes and sizes. Such control paves the way towards simple fabrication route of advanced 2D and quasi-3D photonic architectures (Das Gupta, Sorin et. al. *Nature Nanotechnology*, 14 (4), 320 (2019); Martin-Monier, Sorin et. al. *Physical Review Applied* 3, 034025 (2021)). Low processing temperatures enable large-scale use of rigid but also unconventional flexible and stretchable substrates. Such structures enable strong electromagnetic field confinement, and are shown to have varieties of applications in sensing, light management and second harmonic generation. In particular, by dewetting successively increasingly thick layers, inter-particle gap down to 10 nm could be achieved. By critically coupling the in-plane diffractive mode with the radiative dipolar mode in such structures, sharp Fano-type resonances are demonstrated in the near visible region. These resonances are exploited to monitor protein monolayer concentrations down to 0.5mg/ml (Das Gupta, Sorin et. al. *Nature Nanotechnology*, 14 (4), 320 (2019)). Tailoring the underlying texture, we will also discuss recent results of chalcogenide based architectures exhibiting high second harmonic conversion efficiency of 10^{-6} in the UV region (Das Gupta, Sorin et. al., *Nanophotonics* 10, 3465 (2021)). Finally, we will further highlight the flexibility of our approach by presenting recent results on highly reflecting all-dielectric nanostructures, as well as tailored architectures for improved index sensing.

11:30 AM *EQ02.06.04
Materials for Active Photonics—Multiphysics Analysis Dmitry N. Chigrin[1,2]; [1]RWTH Aachen University, Germany; [2]DWI Leibniz Institute for Interactive Materials, Germany

The growing demand on reconfigurability in neuromorphic computing, integrated photonics and microwave photonics is attracting increasing attention towards design and optimization of active photonic components. By changing a phase of the phase change material or the state of hydrogel near a functional photonics building block, it is possible to realize (re)configurable, time dependent and (re)programmable components and materials. Phase change materials are materials in which phase transitions can be induced quickly and reversibly, resulting in pronounced changes in their physical properties. Hydrogels are macromolecular cross-linked networks swollen by the solvent in which they are dissolved. The unique property of hydrogels is their ability to dramatically change volume in response to external stimuli. Here we report on our recent developments of a multiphysics description of complex composite active photonic components incorporating phase change materials and hydrogels as their building blocks. Such a multiphysics description requires self-consistent treatment of the electromagnetic, heat transfer, mechanical deformation and phase transition models. Possible applications in the fields of integrated photonics, mid-infrared and microwave metasurfaces are discussed.

SESSION EQ02.07: Performance and Functionality II

1:30 PM EQ02.07.01
Luminescent Defects in Ion Irradiated Hexagonal Boron Nitride Giacomo Venturi[1,2], Eli Janzen[3], James H. Edgar[3], Carsten Ronning[4] and Antonio Ambrosio[1]; [1]Fondazione Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]Kansas State University, United States; [4]Friedrich-Schiller-Universität Jena, Germany

Solid-state quantum emitters represent a valuable path for quantum technologies. Engineering and control of single photon emitters (SPEs) in diamond and silicon carbide serve as a benchmark for quantum emission from crystals. However, their intrinsic 3D nature limits some of their applications. 2D materials can circumvent this issue, plus they can also be integrated with standard CMOS technology [1].
In this framework, SPEs in wide bandgap 2D hexagonal boron nitride (hBN) have many advantageous properties including high brightness, photostability, and most importantly, room-temperature operation [2]. Different forms of hBN have been studied ranging from bulk crystals epitaxial films to nanocrystals, and several techniques have been exploited to induce quantum emitting crystal imperfections.
In the present contribution, we characterize the efficacy of ion irradiation to generate emitters in hBN. We compare the throughput of different ions (Ne, Ga, C) in producing the largest number of defects within target hBN flakes. We also tune the ion energy to address a specific penetration depth inside the mechanically exfoliated hBN. Additionally, the ion fluence is also spanned across a wide range.
Irrespectively of the ionic species, a strong and broad peak in the photoluminescence spectra from irradiated hBN always appears at about 820 nm. Additionally, upon fixing the same implantation depth, gallium irradiated flakes are an order of magnitude brighter.
We conclude that the role of the impinging ions is to trigger the formation of intrinsic defects. We surmise that boron atoms are displaced from lattice sites, creating boron vacancies. These become negatively charged [3] and leads to emission in the NIR.
Such a defect, which can act as a SPE with a spin-dependent optical transition, can be employed for example in quantum communication protocols, where a spin-photon interface is highly desirable.

Massively Parallel Printing of J-Aggregate Dyes for the Formation of Optical Antennas Based on Polariton Responances Jacob LaNasa, Kyungtae Kim, Andrew C. Jones and Suryakant Mishra; Los Alamos National Laboratory, United States

The utilization of exciton-polariton resonances in dielectric materials represents a novel pathway for the realization of next generation sensors and optical

devices. Recently, the J-aggregation of cyanine dyes has been demonstrated to produce a Frenkel excitonic absorption features strong enough to enable the formation of surface exciton polariton states at room temperatures. The implementation of these optical dyes has an inherent advantage for the development of low cost, optically resonant surfaces, as they can be easily deposited from aqueous solutions to a variety of differing substrates. Here, we demonstrate the massively parallel printing of J-aggregate dyes using polymer pen lithography to fabricate large scale arrays of optical antenna nanostructures. Here, through the control of the contact parameters of the polymer pen array and annealing conditions, we demonstrate the multiplexed fabrication of dye-based optically resonant nanostructures. Reducing structure sizes into the nanoscale to reach sub-wavelength dimensions, we explore the formation of localized exciton polariton resonances in these materials. We further relate the connection between the local morphology of the J-aggregate dye nanostructures to localized optical resonances through a combination of characterization techniques including atomic force microscopy, scattering spectroscopy, and finite element method optical modeling of the near-and far- field optical response.

Active Metasurface Optics Based on Chalcogenide Phase Change Materials Juejun Hu; Massachusetts Institute of Technology, United States

Phase change materials or PCMs are truly remarkable compounds whose unique switchable properties have fueled an explosion of emerging applications in electronics and photonics. Traditional PCMs suffer from large optical losses even in their dielectric states, which fundamentally limits the performance of optical devices based on the materials. To resolve the issue, we have demonstrated a new PCM Ge-Sb-Se-Te (GSST) with broadband low loss characteristics. In this talk, we will review an array of reconfigurable photonic devices enabled by the low-loss PCM, including electrically tunable metasurfaces, beam steering optics, and parfocal zoom lenses.

Angstrom-Scale Smoothing of Aluminum Nitride Film Surfaces Using Atomic Layer Etching Haozhe Wang, Azmain Hossain, David Catherall and Austin J. Minnich; California Institute of Technology, United States

Roughness-induced light scattering is an important limitation of the performance of various on-chip optical technologies such as microresonators and quantum photonic integrated circuits. Here, we report a plasma-thermal atomic layer etching (ALE) method which enables etching and smoothing of aluminum nitride (AlN) films with Angstrom-scale precision. The ALE process employs sequential exposures of SF_6 plasma and trimethylaluminum ($Al(CH_3)_3$, TMA). In each cycle, the surface is fluorinated by flourine radicals, followed by a ligand-exchange reaction to yield etching. We observed a maximum etch rate of 1.9 Å/cycle at 300 °C as measured using ex-situ ellipsometry. After ALE, the surface roughness of AlN was measured to decrease ~35% from 4.3 Å to 2.7 Å. In addition, the etched surface was found to contain a lower concentration of oxygen compared to the original surface. We anticipate that the ALE process may be applied as a post-treatment to improve the performance of on-chip photonic devices which exploit the simultaneous second-order and cubic-order optical nonlinearities of AlN. ALE processes may be generally applicable to photonic materials to decrease losses arising from surface roughness scattering.

Spontaneous Generation of Magnetically-Active Optical Vortices in Topological Media Dongha Kim, Arthur Baucour, Yun-Seok Choi, Jonghwa Shin and Min-Kyo Seo; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Vortices, swirling textures with singularities, have been observed in various physical entities. In condensed matter, the emergence of the vortices originates from exotic physical phenomena, such as Bose-Einstein condensation and magnetic flux quantization, that provides quasi-particle nature to the textures. The optical vortex (OV) is an optical analogy to the vortices in other physical entities, exhibiting zero-intensity point with spiral phase distribution in the electromagnetic field. OVs support the orbital angular momentum of light, which provides an extra degree of freedom in fundamental studies and applications, such as optical manipulation, forbidden electronic transition, and classical/quantum information processing. However, the generation of OVs has relied on structural singularities, such as spiral phase plates and metasurfaces, rather than critical phenomena, which prevents the OVs from possessing quasiparticle-like behavior, such as dynamic and interactive characteristics.
In this study, we propose and demonstrate the spontaneous generation of real-space optical vortex and anti-vortex and their active control using an external magnetic field based on a gradient-thickness optical cavity (GTOC) [1]. The GTOC consists of a magneto-optic Ni layer, between two SiO_2 layers, on top of an Al mirror. We found singular solutions in the calculated optical reflection of GTOC depending on the Ni layer thickness (h_{Ni}) in the generalized parameter space of top and bottom SiO_2 layer thicknesses (h_1, h_2), which correspond to the OVs with winding number of $w = \pm 1$. Regarding to the emergence of the OVs, topological phase of given system can be classified as trivial ($h_{Ni} < h_{c1}$ and $h_{Ni} > h_{c2}$) and non-trivial phase ($h_{c1} < h_{Ni} < h_{c2}$), where $h_{c1} = 6.34$ nm and $h_{c2} = 13.15$ nm correspond to the critical points.
We experimentally realized the topological phases of GTOC in an actual media by the bijective projection of the generalized parameter space (h_1, h_2) into real space (x, y). The thickness changes of the top and bottom SiO_2 layers are achieved by non-uniform sputtering in the order of tens of nanometer variation in centimeter-scale distances. We fabricated GTOC samples at trivial ($h_{Ni} = 5$, 15 nm) and non-trivial ($h_{Ni} = 10$ nm) phases and characterized them using confocal reflectance scanning and off-axis holography. For the non-trivial phase, the OVs are observed in the reflection distribution as singular minima and phase singularities. For the trivial phases, weak single minimum and continuous phase distributions are observed.
The most striking point of our topological media is the magnetic field activity. The magneto-optic effect applies an effective change to the optical thickness of the Ni layer, which can perturb the topological phase of GTOC. Under the external magnetic field (B), we observed magneto-optically-driven vortex dynamics, which induce topology- and polarization-dependent movement of the OVs. From $B = -0.5$ to $+0.5$ T, the displacements showed (Δx, Δy) = (0.649 mm, -0.344 mm) and (-0.385 mm, 0.010 mm) for the optical vortex ($w = +1$) and antivortex ($w = -1$), respectively, under the right circularly polarized incidence. The displacement directions were reversed when the incidence polarization changed into left circular. Finally, we demonstrated the magnetic-field-induced generation of the optical vortex-antivortex pair at the critical point ($h_{Ni} \sim h_{c2}$) of the topological phase. This is the first observation of field-induced topological phase transition in photonic media. We believe that our findings will pave a way to study topological photonic interactions and

inspire the exploration of quasiparticle-like nature in various topological photonic textures, such as toroidal vortices, polarization/vortex knots, and optical skyrmions.

Engineering the Spectral and Spatial Dispersion of Thermal Emission Using Phonon Polaritons Guanyu Lu[1], Christopher R. Gubbin[2], J. R. Nolen[1], Thomas G. Folland[3], Katja Diaz-Granados[1], Ivan Kravchenko[4], Joseph A. Spencer[5], Marko Tadjer[5], Don G. Walker[1], Orest J. Glembocki[1], Simone D. Liberato[2] and Joshua D. Caldwell[1]; [1]Vanderbilt University, United States; [2]University of Southampton, United Kingdom; [3]The University of Iowa, United States; [4]Oak Ridge National Laboratory, United States; [5]US Naval Research Laboratory, United States

Every object has a temperature greater than zero Kelvin can emit thermal emission according to the fundamental principles of statistical mechanics. Thermal emission, especially in the long-wave infrared region (LWIR), is of great importance in a variety of fields, including spectroscopy, imaging, communication, and energy management. Recently, the possibility of controlling thermal emission based on nanophotonic structures has been intensively investigated with a view towards a new generation of far-field thermal emitters. Such control is demonstrated in the aspects of engineering narrowband, polarized, and spatial coherent (directional) thermal emission. While narrow-band thermal emitters that provide IR LED-like performance have been demonstrated in photonic crystals, perfect absorber geometries, metallic bullseye structures, and periodic arrays of nanoantennas, spectral tunability and control of the spatial coherence within a given platform is challenging.
We present phonon-polaritonic thermal emitter designs to control the spectral and spatial dispersion of thermal emission. Surface phonon polaritons (SPhPs) are quasiparticles comprising a photon and a coherently oscillating charge on a polar lattice. Localized SPhPs (LSPhPs) can be supported by periodic SiC nanopillars, offering exceptionally high Purcell enhancements that are in excess of plasmonic counterparts, which result from the narrow resonance line widths. We demonstrate that such large-scale narrowband thermal emitters, featuring near-unity absorption, can serve as LWIR sources with effectively no net power consumption, enabling their operation entirely by waste heat from conventional electronics [1]. Furthermore, increasing the complexity of the LSPhPs unit cell can serve to modify the resonant near-field and intra- and inter-unit-cell coupling as well as to dictate spectral tuning in the far-field. We also exploit more complicated unit-cell structures to realize new LSPhPs modes with additional degrees of design freedom [2]. Unlike LSPhPs, which offer no spatial coherence, spatially coherent thermal emission can be induced by a one-dimensional grating with propagating SPhPs. However, only a single spatially coherent mode is supported by purely periodic grating structures. We explore superstructure gratings to enable polaritons with different frequencies/wavevectors in a single grating, manifesting as additional spatial modes in the thermal emission profile [3]. By combining the corresponding virtues of both localized and propagating SPhPs through the introduction of strong coupling, we demonstrate a new hybrid mode with narrowband, spatially coherent thermal emission signature. Additionally, through coupling to a third zone-folded longitudinal optic phonon (ZFLO) mode, the realization of electrically driven emitters is possible [4]. Thus, our results show that phonon polaritons and strong coupling phenomenon enable thermal emitters, which meet the requirements for a host of LWIR applications in a simple, lightweight, and intense emitter.

Applications of Epsilon-Near-Zero (ENZ) Materials to Quantum Systems Jeremy N. Munday; University of California, Davis, United States

The application of epsilon-near-zero (ENZ) materials to photonic devices has resulted in a wealth of fascinating phenomena such as electromagnetic supercoupling, resonance pinning, perfect optical absorption, and ultrafast optical switching. However, the effect of ENZ materials on quantum fluctuations is much less developed. Here, we will present out recent work on use of epsilon-near-zero (ENZ) materials to engineer quantum effects and discuss how they can be applied to various technologies. Specifically, we show how ENZ materials can be used to control the spontaneous emission rate of quantum emitters and present the concept of electromagnetic bandgaps for nanoparticles comprising an ENZ material. Further, we will show how tunable ENZ materials can be used to convert electrical bias into mechanical motion through the modification of the allowed modes within a cavity composed of an ENZ material. Finally, we will discuss the outlook for using the concepts in future device architectures.

Polaritonic Metasurfaces Andrea Alu; City University of New York, United States

In this talk, I will discuss our recent progress in the area of polaritonics and its role in advancing the field of metamaterials and metasurfaces. Tailored material resonances, based on excitons, phonons, or electronic transitions, can be strongly coupled to light in natural or engineered metasurfaces, unveiling new degrees of freedom for the control of light-matter interactions with light-based quasi-particles. I will discuss how, as the degree of lattice symmetries in the involved materials and in optically engineered structures is reduced, new opportunities emerge in manipulating light and matter at the nanoscale, unveiling giant nonlinearities and topological phenomena in real and reciprocal space.

SESSION EQ02.09: Emergent Phenomena and Light-Based Quasiparticles II

9:00 AM EQ02.09.01
Photoinduced Excited-State Dynamics in Co-Doped $BaFe_2As_2$ Superconducting Films Roman Kolodka[1], Alexander Bartenev[1], Ki-Tae Eom[2], Jong-Hoon Kang[2], Eric E. Hellstrom[3], Chang-Beom Eom[2], Armando Rua[1] and Sergiy Lysenko[1]; [1]University of Puerto Rico at Mayagüez, United States; [2]University of Wisconsin-Madison, United States; [3]Florida State University, United States

We report on nonlinear optical dynamics and structural reconstruction of Co-doped $BaFe_2As_2$ single-crystal superconducting films within a broad range of temperatures. Films were grown by pulsed laser deposition on (La,Sr)(Al,Ta)O3 [LSAT] and $LaAlO_3$ [LAO] crystalline substrates with epitaxial $SrTiO_3$ [STO] template buffer layer used for higher epitaxial bonding of $BaFe_2As_2$. Samples show superconducting transition with T_c~15.5-20 K. Temperature-

dependent optical transmittance measurements in the range from 290 K down to 10 K were conducted using a supercontinuum laser source, revealing a distinct increase of the transmittance within the wavelengths range from λ=400 nm to λ=1.6 μm, as the sample temperature drops below T_c. Reflectivity measurements at λ=800 nm also show an abrupt decrease of the reflectance below T_c. Drude-Lorentz model was applied to fit the optical transmittance spectra in order to demonstrate the contribution of a free-carriers component in the optical signal. The noticeable change of both, carrier scattering rate and plasma frequency near ~150 K is associated with the spin density wave (SDW) transition in $BaFe_2As_2$. The angle-resolved hemispherical elastic light scattering surface metrology measurements performed with a light scatterometer at cryogenic temperatures indicate that this transition is accompanied by surface reconstruction. High-resolution angle-resolved hemispherical scattering imaging of multi-scale nonequilibrium processes in $BaFe_2As_2$ reveals that the small change in the elastic energy upon SDW formation results in the splitting of the film into domains due to the same or different structural phases since this process is accompanied by tetragonal-to-orthorhombic phase transition. Several competitive transition processes at ~150 K alter the correlation length of the surface and optical properties. In the region of superconducting transition, $BaFe_2As_2$ films demonstrate abrupt changes in surface morphology (surface autocorrelation length, optical isotropy, and root-mean-square roughness). A strong correlation between the observed temperature dependence of the surface statistics and quasiparticle dynamics near T_c was found. Time-resolved measurements of transient reflectivity performed in a relatively high-fluence regime, of several mJ/cm^2, reveal a strong dependence of the excited-states-dynamics on sample temperature, morphology, and laser excitation energy. Femtosecond photoexcitation demonstrates complex reflectance traces attributed to two distinct ultrafast processes: (i) instantaneous formation of the nonequilibrium state of quasiparticles with its subsequent thermalization within ~3 ps with characteristic time τ_1, and (ii) slower few-picoseconds phonon-phonon scattering. Temperature-dependence of τ_1 shows its noticeable drop as the temperature rises above Tc. Observed nonlinear optical dynamics correlate with the temperature dependence of the surface morphology near T_c and provide a new understanding of light-induced processes in the superconducting state of $BaFe_2As_2$.

Efficient Modulation of Two-Dimensional Excitons via Subwavelength Mie Resonators Jie Fang and Yuebing Zheng; The University of Texas at Austin, United States

Two-dimensional (2D) semiconducting transition metal dichalcogenides (TMDs) have attracted great interests because of their novel excitonic properties, providing new opportunities in nanophotonic devices, excitonic physics, and polaritonic systems. Efficient modulation of the 2D excitons in TMDs is attractive yet challenging. Coupling TMDs with single Mie resonators at the subwavelength scale can be a promising strategy.
Here, playing with the electric (ED) and magnetic dipole (MD) modes, we apply single hydrogenated amorphous Silicon nanospheres (a-SiNS:Hs) to facilitate favorable far-field or near-field light manipulations for effective control of TMD excitonic properties. The a-SiNS:H Mie resonators are designed via bandgap engineering to support near-zero losses at full visible wavelengths and tunable refractive index based on hydrogen dopants (*Nature Communications* **2020**, *11*, 5055). Different from the high index in typical Mie resonators, a unique moderate refractive index of ~2.1 is proposed for broadband and highly interacted ED and MD. The size dependence of Mie resonances is also utilized and sphere diameters from 400 down to 200 nm are chosen for various modulation functions.
(1) Targeting at the directional modulation of far-field excitonic radiation patterns, we control the a-SiNS:H sizes between 300 and 400 nm with partially overlapped ED and MD. The a-SiNS:H Mie resonator is proposed as a highly miniaturized platform for controlling exciton emission through both the excitation and emission processes. Based on the mutual interference of Mie resonances, efficient modulation of directional excitation and exciton emission have been achieved in different TMD materials. A modified Mie theory for dipole-sphere hybrid systems is derived to instruct the optimal design for desirable modulation, leading to the potential of multifunctional integrated photonics. (*Advanced Materials* **2021**, *33*, 2007236)
(2) By coupling single a-SiNS:Hs of 250 to 290 nm in diameters with monolayer WS_2 in water, we successfully tune the WS_2 homogeneous exciton linewidth between 35 and 7 meV at room temperature (RT), providing a practical method to modulate exciton quantum dynamics at the subwavelength scale. Impressively, with an optimal sphere size of 268 nm, we achieve near-intrinsic exciton linewidth at RT, approaching the theoretical limit at 0 Kelvin. The linewidth-narrowing mechanism manifests the dynamic competition between exciton and trion decay channels. Specifically, the a-SiNS:H Mie resonator is designed to selectively boost the trion radiative decay, which breaks the charge balancing in inherently n-doped WS_2 and rebuilds the excitonic relaxation processes with suppressed exciton nonradiative decays. (*Advanced Materials* **2022**, *34*, 2108721)
(3) For a sphere diameter of 240 nm, ED and MD are found to be perfectly overlapped among the whole visible wavelengths. We employ this unique a-SiNS:H Mie resonator for broadband ultra-strong light-matter interactions with 2D excitonic materials. By coupling it with monolayer TMDs, we have achieved multi-Rabi splittings and robust exciton-polariton emission at RT.
In conclusion, by using a moderate-refractive-index a-SiNS:H Mie resonator, we have shown the efficient modulation of 2D TMD excitons in multiple dimensions. The subwavelength nature of the proposed Mie resonator ensures the good coupling efficiency with 2D excitons and practically enables the miniaturization of functional photonic devices.

9:30 AM *EQ02.09.03
Active Epsilon-Near-Zero Optical Materials Aleksei Anopchenko, Sudip Gurung, Christopher M. Gonzalez, David Dang, Leon Zhang, Kent Nguyen, Quynh Dang, Alexander Galkin, Tingwei Liu, Meena Salib and Ho Wai Howard Lee; University of California, Irvine, United States

Epsilon-near-zero materials have been shown to be as one of the most promising optical materials in the recent years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties. I will review our recent studies on the active linear, nonlinear, and emission properties of conducting oxide and metallic nitride epsilon-near-zero materials. Discovery of novel active materials is fundamental for photonic applications. The epsilon-near-zero (ENZ) materials have been shown to be as one of the most promising optical materials in the recent years as the electromagnetic field inside media with near-zero permittivity has been shown to exhibit unique optical properties, including strong electromagnetic wave confinement, enhanced quantum emission near ENZ media, non-reciprocal magneto-optical effects, unique topological properties, and abnormally large optical nonlinearity. While ENZ optics have been investigated extensively in the last few years, the current commonly used ENZ materials suffer from limited optical enhancement because of the lack of precise control of ENZ frequency, loss, and thickness for efficient ENZ mode excitation. In addition, the active tunability and enhanced nonlinearity and emission properties in ENZ materials have yet been fully experimentally explored. This talk will review our recent studies on the active linear, nonlinear, and emission properties of conducting oxide and metallic nitride epsilon-near-zero materials in planar and optical fiber platforms [1-7]. I will present a method to engineer the field intensity enhancement of the Al-doped zinc oxide (AZO) ENZ thin films synthesized by atomic layer deposition (ALD) technique. I will then discuss the observation of abnormal nonlinear temporal dynamic of hot electrons and enhanced optical nonlinearity in AZO and ITO ENZ thin films under different pump fluences and excitation angles using a degenerate pump-probe spectroscopy technique. I will present the first comprehensive study of photoluminescence from a 2D material placed near ENZ films and its dependence on the losses of materials, as well as the spectral response of such emitters with excitation wavelengths across the ENZ regime. Finally, I will also discuss the first experimental demonstration of optically confined ENZ resonance excitation in an optical fiber waveguide uniformly coated with AZO nanolayer. These studies enrich the fundamental understanding of emission and nonlinear properties on ENZ thin films and the integration of ENZ materials and optical fiber will open the path to revolutionary ultracompact in-fiber optical devices for optical communication, imaging, sensing/laser applications. This work was supported in part by the National Science Foundation (grant number: 2113010), and Air Force Office of Scientific Research (FA9550-21-1-02204) (AFOSR-AOARD, FA2386-21-1-4057)

Control of Nonreciprocal Surface Plasmon Polariton Transport in Weyl Semimetals via Optical Pumping and Strain Engineering Morgan Blevins and Svetlana V. Boriskina; Massachusetts Institute of Technology, United States

Weyl semimetals (WSMs) are a material of emerging interest due to their distinct electronic band structure, which supports pairs of chiral Weyl nodes formed from intersecting, linearly dispersing bands. The Weyl nodes in a pair each act as a source and a sink of Berry curvature respectively, resulting in a net flux of Berry curvature between them and zero Berry flux outside of them in momentum space. The flux of Berry curvature between the Weyl nodes gives rise to the unique, conductive Fermi arc surface states of WSMs.
Either time-reversal symmetry or inversion symmetry breaking is required for the existence of a WSM. Time-reversal symmetry breaking gives rise to the anomalous Hall effect in WSMs. On the other hand, inversion symmetry breaking WSMs have exhibited an exceptionally large bulk photogalvanic effect (PGE) under illumination from linearly polarized infrared (IR) light. This linear bulk PGE results in part from the Berry curvature induced shirt current, in which an electron excited by linearly polarized light experiences a spatial shift upon transition from the valence to the conduction band, resulting in a photocurrent without the need for a p-n junction or external field. The detection of mid-IR light with conventional noncentrosymmetric semconductors is limited by a lack low energy bandgap materials but is enabled in a WSM by the gapless nature of its bandstructure. The use of the bulk PGE in WSMs has great potential for IR imaging and energy harvesting applications and for surpassing the efficiency limits inherent to p-n junction type detectors [1,2].
In addition to exploiting the bulk PGE, WSM surfaces can be engineered to control the *surface* photogalvanic effects, which opens the door to manipulating both bulk and surface photocurrents in WSMs for enhanced IR detection and devices. Surfaces of WSMs with broken time-reversal symmetry also support non-reciprocal surface plasmon-polariton modes (SPP) propagation, that enable directional energy transfer, Kirchhoff's law violation, and tunable near-field radiative heat transfer [3].
A key step in the development of WSM SPP engineering is to establish means to control them by external stimuli, especially optical stimuli. In this work, we model the impact of the bulk and surface photogalvanic effects as well as material strain on the WSMs surface states. Recent works have shown the Lorentz reciprocity of materials is broken by applying dc currents which produce a Doppler frequency shift of the electron plasma (Fizeau drag) [4]. Here, we exploit the fact that spontaneous photocurrent in WSMs acts as a dc current in the illuminated sample and imparts Fizeau drag on the electron plasma, providing an additional mechanism to control the nonreciprocal behavior of WSM SPPs by optical means. We also compare the impact of the PGE-induced Fizeau drag to the impacts of strain [5] on the SPP modes. A combination of these two mechanisms enables effective means for both static and dynamic control of nonreciprocal SPP propagation.

Nonlinear Optical Response of Two-Dimensional Materials Giulio Cerullo[1], Chiara Trovatello[1,2] and P.J. Schuck[2]; [1]Politecnico di Milano, Italy; [2]Columbia University, United States

Two-dimensional materials such as graphene and transition metal dichalcogenides (TMDs) show extraordinarily strong second- and third-order nonlinear optical responses which, thanks to their unique electronic properties and despite their atomic thickness, allow a wide range of fundamental studies and technological applications. In this presentation we will discuss some of our recent results on the study of the nonlinear optical properties of two-dimensional materials.
We show that the third-harmonic generation efficiency in graphene can be increased by almost two orders of magnitude by controlling the Fermi energy and the incident photon energy [1]. This enhancement is due to logarithmic resonances in the imaginary part of the nonlinear conductivity arising from resonant multiphoton transitions. Thanks to the linear dispersion of the massless Dirac fermions, gate controllable third-harmonic enhancement can be achieved over an ultrabroad bandwidth, paving the way for electrically tunable broadband frequency converters.
Using semiconducting TMDs, we demonstrate single-pass optical parametric amplification at the ultimate thickness limit, down to a single atomic layer [2]. Second-order nonlinear interaction at the two-dimensional limit bypasses phase-matching requirements and achieves ultrabroad amplification bandwidths. In agreement with first-principle calculations, we observe that the amplification process is independent of the in-plane polarization of signal and pump fields.
We investigate 3R-stacked TMD crystals which combine broken inversion symmetry and aligned layering. By measuring second harmonic generation (SHG) of 3R-MoS_2 with various thickness, from monolayer (0.65 nm) to bulk (»1 µm), we present the first measurement of the SHG coherence length (» 530 nm) at 1520nm and achieve record nonlinear optical enhancement from a van der Waals material, > 10^4 stronger than a monolayer. We find that 3R-

MoS_2 exhibits similar conversion efficiency as lithium niobate, but with more than 100-fold shorter propagation lengths [3].
Finally, we demonstrate a novel approach for the all-optical control of SHG polarization in MoS_2 and show that this can be used for all-optical modulation of the SHG efficiency with modulation depth close to 100% and speed limited only by the fundamental frequency pulse duration [4].

Emergent Properties of Noble-Transition Metal Alloys—Near-Infrared Interband Hot-Carrier Generation for Ultrafast Optoelectronic Devices
Orhan Kizilkaya[1], Gregory Manoukian[2], Sergi Lendinez[1], Luis Manuel[1], Karunya Shirali[1], Tiago R. Leite[1], William Shelton[1], Phillip Sprunger[1], Jason Baxter[2] and Kevin M. McPeak[1]; [1]Louisiana State University, United States; [2]Drexel University, United States

Noble-transition metal alloys are a promising class of materials for interband-driven hot hole generation with NIR light.[1] NIR hot-carrier generation in pure, noble metals suffers from insufficient energy to exceed the interband energy threshold (IET) (e.g.,> 2 eV), and in pure transition metals, rapid hot-carrier thermalization. Band hybridization in select noble-transition metal alloys can overcome these issues, yielding emergent properties that facilitate tuning the hot-carrier distribution and lifetime.

We deposit disordered Cu_xPd_{1-x} alloy thin films under non-equilibrium conditions and investigate their stoichiometry-dependent optical, structural, electronic, and transient near-infrared absorption properties.[2] We show experimentally through ultraviolet photoelectron spectroscopy and computationally through the projected density of states calculations that strong hybridization between the Cu 3d and Pd 4d bands exists in the alloy films. Unlike the Au 5d band, the Cu 3d band does not exhibit strong spin-orbit coupling. Therefore, we observe the formation of a common band between the full Cu 3d and Pd 4d bands. This strong d-band hybridization in the alloy films drives emergent behavior across various measurement techniques.

Time-resolved terahertz spectroscopy with near-infrared (e.g., 1550 nm) excitation displays composition tunable electron dynamics. We posit that the negative peak in $\Delta T/T$ below 2 ps from dilute Pd alloys is due to non-thermalized hot-carrier generation and field-driven electron emission. On the other hand, Pd-rich alloys exhibit an increase in $\Delta T/T$ due to thermalization effects upon ultrafast NIR photoexcitation. Cu_xPd_{1-x} alloys in the dilute Pd regime may be a promising material for future ultrafast NIR optoelectronic devices.

Nonequilibrium Carrier Dynamics in $FeSe_{0.8}Te_{0.2}$ Roman Kolodka, Alexander Bartenev, Camilo Verbel, Manuel Lozano, Felix Fernandez, Armando Rua and Sergiy Lysenko; University of Puerto Rico, United States

We report on the nonequilibrium dynamics of photoinduced collective excitations in $FeSe_{0.8}Te_{0.2}$ films in a superconducting (SC) state. Epitaxial films were grown on CaF_2 single-crystal substrates by pulsed laser deposition. The SC properties were tuned by varying the strain level by altering the film thickness of the epitaxial film. It was found that increased strain in film can depress SC when the film thickness riches a threshold minimum, while the increased thickness can result in static domain structure via generation of the dislocation network, but with the introduction of new grain boundaries or microcracks. This fact was observed in angle-resolved light scattering measurements of the surface morphology within a broad temperature range, down to 7 K. It was also found that the surface domains undergo temperature-dependent reorganization when $FeSe_{0.8}Te_{0.2}$ film undergoes a solid-to-solid structural phase transition. Ultrafast time-resolved measurements of reflectivity were performed with 35-fs laser pulse excitation, 1 kHz repetition rate, the central wavelength of 800 nm, and orthogonal polarization for pump and probe pulses. The $FeSe_{0.8}Te_{0.2}$ film was maintained in its SC state at 7.5 K, while excitation fluence was tuned from up to ~10 mJ/cm^2, sufficiently below the damage threshold. The obtained reflectance traces show three distinct regions attributed to different dynamical processes in the material within the 50 ps time scale: (i) drop of the reflectivity signal within 200 fs, (ii) its subsequent rise within 1 ps, and (iii) much longer process of tens picoseconds. First two processes are associated with collective excitations and photoexcitation of quasi-particles (QP) in $FeSe_{0.8}Te_{0.2}$. A gradual increase of the excitation energy results in a gradual growth of QP density. Moreover, the QPs decay rate slows down as excitation fluence increases. The transient measurements manifest a gradual time-shift of the specific signal minimum on the reflectivity diagram, since the QPs decay rate slows down as excitation fluence increases. The characteristic time of the process (ii) shows a linear increase with excitation fluence, while the process (i) is more complex. The process (iii) is associated with phonon-phonon scattering demonstrating a decrease of its characteristic time as excitation increasing. This could be a signature of photoinduced structural transformation or a hidden phase in the film. A strong acoustic phonon generation starts at ~ 100 ps, right after the process (iii) completes. This reveals new features of photoinduced dynamics of superconducting $FeSe_{0.8}Te_{0.2}$ in high excitation regime.

Tunable Strong Light-Matter Coupling in Colloidal Transition Metal Dichalcogenide Nanowires Jingang Li[1,2], Kan Yao[2], Yun Huang[2], Donglei

(Emma) Fan[2] and Yuebing Zheng[2]; [1]University of California, Berkeley, United States; [2]The University of Texas at Austin, United States

Transition metal dichalcogenides (TMDCs) are an emerging class of materials with extraordinary physical properties, which are investigated for a wide range of electronic, photonic, and optoelectronic applications. While TMDCs have been extensively explored as an excitonic platform with novel optical and electronic functionalities, it is less appreciated that TMDCs also have a high refractive index. The presence of excitons in high-index TMDC nanoresonators enables the formation of unique self-hybridized exciton polaritons, which remarkably enrich the capabilities of nanophotonic systems.

Here, we present strong coupling between excitons and Mie resonances in individual colloidal TMDC nanowires. Molybdenum disulfide (MoS_2) nanowires are chemically synthesized with tailorable dimensions to support tunable Mie-exciton polaritons in visible wavelengths. Compared to previously reported TMDC nanoresonators that are fabricated by lithographical methods (e.g., electron beam lithography), colloidal MoS_2 nanowires provide additional possibilities in the design and fabrication of nanophotonic devices. Specifically, the chemical synthesis approach permits the scalable and high-throughput production of TMDC nanoresonators with tunable optical responses, which can be easily integrated with other techniques for on-demand dispersion, transfer, manipulation, and assembly. Moreover, we show that the MoS_2 excitonic properties and spectral splittings can be optothermally modulated under light illumination, which offers a promising platform for the development of active photonic devices, such as all-optical switches and sensors.

Towards a First-Principles Description of Real Systems in Realistic Cavities with MQED and QEDFT Mark Kamper Svendsen[1], Kristian S. Thygesen[1] and Johannes Flick[2]; [1]Technical University of Denmark, Denmark; [2]Flatiron Institute, United States

Quantum Electrodynamic Density Functional Theory (QEDFT) is a generalization of time-dependent DFT in the presence of quantized modes of the electromagnetic field. QEDFT presents a good compromise between accuracy and computational effort that makes it possible to treat quantum light-matter interactions even for large electronic systems and many modes of the electromagnetic field. At present, however, the light-matter coupling strengths are essentially free parameters and it is unclear how to relate them to a real cavity setup.
In this talk, I will discuss how we can formulate the length-gauge light-matter Hamiltonian in terms of the quantized fields from Macroscopic QED and the extent to which it can be solved using QEDFT. This formulation lets us relate all cavity coupling parameters to the classic Green's function of the electromagnetic field and eliminates all free parameters related to the light-matter coupling strength. Our approach provides a step towards a parameter-free, quantitative description of light-matter interactions in arbitrary electromagnetic environments.

4:00 PM EQ02.12.03
Time-Modulated Conducting Oxide-Based Nanoantennas for Shared-Aperture Multi-Frequency Metasurfaces Raana Sabri and Hossein Mosallaei; Northeastern University, United States

Actively tunable optical nanoantennas are of great importance for dynamic control over the wavefront of light, where real-time and reprogrammable functions are required. Electro-optical tuning mechanisms based on electro-refraction effects induced by the free carriers in doped semiconductors are of growing interest for the realization of active metasurfaces. In particular, indium tin oxide (ITO) is a degenerately doped semiconductor, whose incorporation into the subwavelength unit cells of the geometrically-fixed metasurfaces enables post-fabrication electrical tuning of the optical response at near-infrared frequencies. The epsilon-near-zero transition in the ITO as well as novel design paradigms leveraging high-Q resonant modes allow for extreme light-matter interactions for enhancing the tunability of optical response. Despite the fruitful progress, the operating principle of ITO-integrated quasi-static metasurfaces relies on the modulation of resonant modes between the over- and under-coupled regimes. This limits the performance of such quasi-static metasurfaces to negligibly narrowband regime due to the strong resonant dispersion. Introducing time-modulation into the nanoantennas as an additional degree of freedom, renders a four-dimensional design space and surmounts the limitations of the quasi-static metasurfaces by converting the incident signal at the fundamental frequency to the higher-order sidebands. The phase of higher-order sidebands generated by a time-modulated metasurface can be tuned with uniform amplitude via a non-resonant dispersionless geometric phase shift induced by the modulation phase delay. This dispersionless phase elevates time-modulated metasurfaces beyond their quasi-static counterparts in that it increases the functionality bandwidth, expands the angle-of-view, and minimizes the power coupled into undesired sidelobes by providing access to the full phase span (2π) with uniform amplitude. The current architecture of deep space and local area networks calls for high capacity and high-speed platforms that can simultaneously address multiple users with minimal crosstalk. Time-modulated nanoantennas are promising candidates for multi-frequency functioning as they feature all-angle and all-wavelength optical response due to the access to dispersionless phase span at the sidebands. To demonstrate the adaptive multi-frequency multi-beam steering by the time-modulated metasurface, an array of plasmonic nanostrips integrated with ITO in metal-insulator-metal configuration is considered, wherein two sets of time-varying biasing signals are independently applied to the dual-gated metasurface for modulating the permittivity of ITO in space and time. The aperture of the metasurface is then divided into several interleaved orthogonally modulated sub-array nanoantennas with distinct modulation frequencies to render a shared-aperture metasurface in space and time. The spatially interleaved sub-arrays are programmed to exploit multi-beam scanning via a pixelated control over the modulation phase delays assigned to their constituent elements. The number of sub-arrays and distinct channels can be scaled easily without suffering from crosstalk due to the orthogonality of the channels or the efficient metasurface design. The results point toward high-capacity platforms with low size, weight, and power for next-generation free-space optical (FSO) communication systems.

4:15 PM *EQ02.12.04
Refractory Plasmonics for Energy and Extreme Optics Alexandra Boltasseva; Purdue University, United States

Emerging plasmonic materials such as semimetals (transition metal nitrides and carbides), highly doped semiconductors, 2D and quasi-2D materials such as MXenes are playing an increasingly important role in emerging technologies for sustainable energy and photocatalysis [1]. For example, enhanced hot electrons generation in transition metal nitride nanoparticles compared to conventional materials such as gold enables more efficient light-to-electricity conversion [2,3]. MXenes, a class of 2D nanomaterials formed of transition metal carbides and carbon nitrides, form a promising material platform for tailorable nanophotonics. They offer a number of unusual properties and are being applied to realize novel electromagnetic shields, metal-ion batteries, super capacitors, lasers, and sensors. We utilized the plasmonic response of titanium carbide ($Ti_3C_2T_x$) MXene thin films in the near infrared spectral window to create a metamaterial for broadband absorption [4] and explore the usage of MXenes for applications in photonics, energy harvesting, and desalination. Expanding the application realm for transition metal nitrides into sustainable, scalable technologies, we also demonstrated ultra-broadband light absorbers with titanium nitride (TiN) nanoparticles obtained through fast, large-scale and environmentally-friendly processes [5]. To advance photonic applications of novel materials further, we apply machine-learning-assisted data analysis techniques coupled with topology optimization and tailorable material platforms to obtain non-intuitive photonic designs for highly efficient optical devices and energy conversion.
Support from the Air Force Office of Scientific Research (grant FA9550-17-1-0243) is acknowledged.

Germanium and Silicon Nitride Metasurfaces in Photoenergy Conversions Kuo-Ping Chen; National Yang Ming Chiao Tung University, Taiwan

Silicon photonics technology has been widely applied in communication and data centers. In this work, we experimentally demonstrate a special class of true bound state in the continuum (BIC), lattice resonance, and Kerker effect in group IV metasurface, including Si-based semiconductor and germanium (Ge). The photodetection in silicon photonics has become the very important research area. In silicon photonics, germanium (Ge) is an ideal candidate for on-chip photodetection due to the small bandgap of 0.66 eV and the compatibility with the modern CMOS technology. It has widely been used in near infrared (NIR) photodetection. However, the bulky and thick Ge film for photodetector limits the development of system minimization. By the design of metasurface, the absorption in thin Ge metasurface could have much larger absorption than the pure Ge thin-film. In addition, we also present directional emission normal to Si3N4 BIC metasurface laser with hybrid surface lattice resonances (SLRs).

Mapping $LiNbO_3$ Phonon-Polariton Nonlinearities with 2D-THz-THz-Raman (2D-TTR) Spectroscopy Haw-Wei Lin[1], Griffin Mead[2,1] and Geoffrey A. Blake[1,1]; [1]California Institute of Technology, United States; [2]National Institute of Standards and Technology, United States

Coherent control of vibrational modes is a promising route to achieving ultrafast manipulation of material properties with light. Through excitation of specific phonon modes that are strongly coupled to bulk material properties of interest, researchers have shown examples including enhancement of superconductivity and switching of the magnetic, ferroelectric, and structural phases with ultrafast optical pulses. With the development of intense terahertz (THz) sources, coherent control with THz frequency pulses, which provide phase-sensitive access to phonon modes with no parasitic electronic excitation, has gained significant attention. To achieve this future degree of control over matter, it is essential to characterize the multitude of different linear and nonlinear excitations that occur when pumped with an intense, broadband THz pulse. Lithium niobate ($LiNbO_3$) is an ideal candidate for developing techniques that can provide detailed information on the potential energy landscape due to its importance in nonlinear THz polaritonic applications. Here, we report two-dimension THz-THz-Raman (2D-TTR) measurements on x-cut $LiNbO_3$ with selective detection of the third-order nonlinear signal and significantly improved THz bandwidth (up to 9 THz). We demonstrate that 2D-TTR spectroscopy can provide insight into the excitation mechanism, nonlinear phonon-phonon couplings, and sources of anharmonicity in the system. We show that the $E(TO_1)$ and $E(TO_3)$ phonon-polaritons are excited through resonant THz one-photon absorption (1PA) as opposed to THz sum-frequency (SF) excitation. We directly observe THz and Raman nonlinear transitions between the $E(TO_1)$ and $E(TO_3)$ modes. Due to selection rules of the E-symmetry phonon modes, distinct symmetry-allowed Feynman pathways are observed for different THz polarizations. Further, our models show that the set of Feynman pathways observed are induced via mechanical anharmonicity of the phonon-polariton modes as opposed to electronic anharmonicity. Such information is traditionally only available via density functional theory (DFT) calculations. These findings provide a concrete foundation for future coherent control applications. For example, the nonlinear transitions between $E(TO_1)$ and $E(TO_3)$ may be optimized using tailored THz pulse sequences to achieve efficient population transfer between the two modes.

8:45 AM EQ02.13.03
Metasurface Enabled Polarization Sensitive Detection-Aspect Ratio and Design Tolerance for Nanofabrication for the Dielectric Metasurface Element Hosna A. Sultana; University of Alabama, United States

Using the benefit of flat optics metasurface, polarization-sensitive imaging technology has been developing in recent years with a reasonable promise to utilize it as a sensing method. Instead of imaging with light intensity, polarization-sensitive detection can take advantage of the orientation of the electric field to reveal the edge, hidden features, and many details of a target. Metasurface can serve as a stokes intensity splitter based on the incidence polarization state of light, and this utility has become a benchmark of optical sensing. This work explores high contrast dielectric metasurface design with Finite Difference Time Domain (FDTD) simulation to optimize dielectric material choice, layer combination, geometric shape, and assembly to make a total phase, transmission, and polarization control metasurface for 532 nm working wavelength. However, suitable material and design for the total phase control for this wavelength already exist, but the crucial limit of perfect nanofabrication, the design margin, needed to be relaxed. So the main focus of this research is on reducing the height of the nanoantenna and exploring the useful geometric features that can influence the mutual interaction of the metasurface element. For shape optimization, our metasurface element will go beyond the axially rotational symmetric component to affect the orthogonal phase differently. This will continue implementing anisotropic metasurface elements, which may improve the efficiency of detecting scattered light beams as expected from the diverse scattering medium.

9:00 AM EQ02.13.04
Mie Metasurfaces with Multipole Resonances in the Lattice Md Sakibul Islam, Dominic Bosomtwi and Viktoriia Babicheva; University of New Mexico, United States

Recently emerged high-index materials have been a subject of active studies in recent years. Ultra-thin optical elements can be engineered based on transdimensional photonic lattices that include 3D-designed nanoparticles supporting multipole resonances and arranged in 2D arrays to enhance collective effects in the nanostructure. Nanostructures with a high refractive index have been suggested as a promising alternative to conventional metals supporting plasmonic resonances. Here we show that the antennas made out of high-index material support several multipole resonances enabled by the supporting propagating modes with a high effective index and their reflection from the antenna boundaries. Different multipole resonances appear for the large

nanoantenna, as well as a decrease of reflection from the nanoantenna array and highly directional resonant scattering. Transdimensional lattices consisting of resonant nanoantennas in the engineered periodic arrays have great potential to serve as functional elements in flat optical components and photonic devices.
This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science by Los Alamos National Laboratory (Contract 89233218CNA000001) and Sandia National Laboratories (Contract DE-NA-0003525). The work is also supported by Contract DE-2375849.

9:15 AM EQ02.13.05
Directional Scattering and Quasi-Bound States in the Continuum in All-Dielectric Nano-Antenna Metasurfaces Dominic Bosomtwi and Viktoriia E. Babicheva; University of New Mexico, United States

Due to their capability to overcome ohmic losses, and the unique ability to manipulate, control and confine electromagnetic waves at the nanoscale dimensions, high index dielectric metastructures have become promising candidates for numerous photonic device applications such as beam steering, imaging, sensing and solar energy harvesting. We numerically study the scattering behavior of an array of silicon nanocylinders, and we show that varying the silicon nanocylinder heights results in the excitation of Fano resonance creating asymmetric scattering spectral profiles. We also demonstrate strong mode coupling behavior called quasi-bound states in the continuum where the modes are localized (trapped) in the nanostructure as a result of suppression of radiative losses leading to a high quality factor due to the disappearance of the width of the Fano lineshape. Our studies also reveal the overlap of the modes between the electric dipole and magnetic dipole moments leading to suppression of light reflectance and transmittance in the metastructure array.

9:30 AM EQ02.13.06
Infrared Plasmon and Phonon-Polaritons in Polar Semiconducting Scandium Nitride (ScN) Krishna Chand Maurya[1,1,1], Dheemahi Rao[1,1,1], Shashidhara Acharya[1], Pavithra Rao[2], Ashalatha I. Pillai[3], Shankar K. Kumar[2], Magnus Garbrecht[3] and Bivas Saha[1,1,1]; [1]Jawaharlal Nehru Centre for Advanced Scientific Research, India; [2]Indian Institute of Science, India; [3]The University of Sydney, Australia

Interaction of light with collective free electron oscillations termed plasmon-polariton and with polar lattice vibrations termed phonon-polariton, are essential to confine the light in subwavelength dimensions and for strong optical resonances. Traditionally doped-semiconductors and conducting metal oxides (CMO) are used to achieve plasmon-polaritons in the near-to-mid infrared (IR), while polar dielectrics are utilized for realizing phonon-polaritons in the long-wavelength IR (LWIR) spectral regions. However, demonstrating plasmon- and phonon-polariton in one host material with low loss is challenging due to the mutually conflicting physical property requirements.

In this work, we present high-quality plasmon- and phonon-polaritons in epitaxial polar ScN thin films deposited on (001) MgO substrates using dc-magnetron sputtering in the ultra-high vacuum (1×10^{-9} Torr). As-deposited ScN thin films exhibit an *n*-type carrier concentration of (2-4) $\times 10^{20}$ cm^{-3} primarily due to the presence of oxygen impurities. Due to such high carrier concentrations, the Fermi level in ScN resides inside the conduction band, about 0.2-0.3 eV above the band edge. Mg-hole doping is used to reduce the high carrier concentration, and *p*-type ScN is *achieved* along with high hole mobility. Scanning transmission electron microscopy (STEM) is used to characterize the microstructure of the film. Both oxygen and magnesium-doped ScN films deposited in this work on (001) MgO substrates at high-temperatures are epitaxial and nominally single-crystalline with [001](001) ScN || [001](001) MgO relationships.

Spectroscopic ellipsometry and Fourier-transform infrared spectroscopy (FTIR) analysis indicate that the highly *n*-type doped ScN thin films exhibit low-loss short-wavelength IR plasmon resonance in the 1500-2500 nm spectral range. Due to the polar semiconducting nature, Mg-doped low carrier concentration ScN also exhibits phonon-polaritons between the 340 cm^{-1} - 677 cm^{-1} spectral range. Excitation of the surface phonon-polariton modes is also demonstrated by polarization-dependent reflectivity measurement in the attenuated-total-reflection (ATR) mode using the Kretschmann configuration. A clear dip in the *p*-/*s*-polarized reflection spectrum at ~ 1.95 µm and at ~ 16 µm correspond to the surface plasmon-polariton (SPP) and surface phonon-polariton (SPhP) resonances respectively.

The plasmonic properties of ScN film are comparable to other IR plasmonic materials such as transparent conductive oxides and doped semiconductors. Also, ScN exhibit a very high figure-of-merit for SPhP propagation compared to its peer materials. Demonstration of plasmon- and phonon-polariton in one host material, ScN through carrier concentration control make it attractive for applications in epsilon-near-zero metamaterials, optical communication, solar-energy harvesting and other nanophotonic applications.

All van der Waals Nanophotonics Artur Davoyan; University of California, Los Angeles, United States

Van der Waals materials have emerged as a promising materials platform for electronics and photonics. In this talk I will overview our recent theoretical and experimental efforts on creating ultra-confined nanophotonics devices. Owing to unique and strong resonances van der Waals materials exhibit very high refractive indices and a strong anisotropy. High reflective index, in turn enables, a conceptually new set of photonic devices that outperform current semiconductor and metallic devices. I will discuss the use of high refractive index transition metal chalcogenides, such as MoS2, and hexagonal boron nitride for visible and mid-IR nanophotonics. I will show that these van der Waals materials allow extreme optical field confinement in deeply subwavelength structures. Our studies suggest that smaller and more efficient devices may be created with the use of van der Waals materials.

Active Metasurfaces in Meta-Imaging Systems Harry A. Atwater; California Institute of Technology, United States

Electro-optically tunable active metasurfaces that enable dynamic modulation of reflection amplitude, phase, and polarization using resonantly excited materials and phenomena are powerful design elements for meta-imaging and computation. We describe the role of such active metasurfaces as cascadable elements in lens-less and single-photon imaging systems. I will describe the features of a lens-less imaging system comprised of active metasurface elements as components, and compare the characteristics to conventional lens-couple image sensors.

8:30 AM EQ03.01.02
Excitonic Beam Steering in Monolayer Molybdenum Diselenide Based Active Metasurfaces Melissa Li, Claudio U. Hail, Souvik Biswas and Harry A. Atwater; California Institute of Technology, United States

We demonstrate dynamic beam steering in an active van der Waals metasurface by combining the large tunability of the complex refractive index near the excitonic resonance in monolayer molybdenum diselenide ($MoSe_2$) with an array of gold electrodes. While previous demonstrations of reconfigurable metasurfaces depend on the geometric parameters of dielectric or plasmonic Mie resonators, our design relies solely on excitonic resonances which are decoupled from geometric resonances. By varying the voltages between adjacent electrodes, we can control the phase profile of the reflected light from our $MoSe_2$ metasurface. We generate a momentum space map of the reflected beam by imaging the intensity profile at the Fourier plane with a CCD camera. Our experiments show that at 6 K, the reflected light can be steered to angles between -30° to 30° at the A exciton wavelength of 754 nm. We attribute the dynamic control to the large refractive index modulation of over 200% through tuning the carrier density in $MoSe_2$ up to 7 x $10^{12}/cm^2$. Our results suggest the potential to utilize the tunability of excitonic resonances in two-dimensional transition metal dichalcogenides for wavefront shaping in emerging photonic applications.

8:45 AM EQ03.01.04
Wavefront Manipulation Using Tunable Phase Change Metasurfaces in the Visible Spectrum Parikshit Moitra[1], Yunzheng Wang[2,3], Xinan Liang[1], Li Lu[2], Alyssa Poh[2], Tobias W. Mass[1], Robert Simpson[2], Arseniy Kuznetsov[1] and Ramon Paniagua Dominguez[1]; [1]Institute of Materials Research and Engineering, Singapore; [2]Singapore University of Technology and Design, Singapore; [3]Shandong University, China

Recent advances in wavefront shaping, by complete control of amplitude and phase of the propagating light waves, have been explored with the application of resonant all-dielectric metasurfaces, composed of high-index nano-resonators. However, there is a major limitation, in terms of lack of post-fabrication tunability of their optical responses, as these metasurfaces are commonly fabricated from passive materials. To circumvent this issue, chalcogenide phase

change materials (PCMs) have been incorporated to the design, to bestow a fast and non-volatile tunability of the optical responses. Most of these tunable metasurfaces have been demonstrated in the mid infrared spectrum using Germanium-Antimony-Telluride (GST) PCMs. To lower the absorption loss of GST in the near infrared, selenium (Se) is doped with GST to form Ge-Sb-Se-Te (GSST) to achieve lossless optical properties in the wavelength range longer than 1 μm. However, there have been no demonstrations in the visible frequencies showing complete wavefront control with high efficiency using PCMs due to the lack of lossless and high-index PCMs in the same spectral range. Antimony trisulfide (Sb_2S_3) fits the requirement very well based on its low-loss and high refractive index optical properties in the visible frequencies, along with a sharp index contrast (~0.5) between its amorphous and crystalline phases. Here, we demonstrated nanofabrication process development of this novel material using conventional methods to realize high resolution metasurfaces. Having equipped with this fabrication capability, we realized Huygens' metasurfaces with nanoholes etched on to 160 nm thick as-deposited amorphous-Sb_2S_3 film and further demonstrated tunability of transmission resonance by 60 nm and close to 2π optical phase shift upon non-volatile and reversible switching between its amorphous and crystalline phases. With the design based on phase-only manipulation, we further realized reversibly switchable beam steering, tunable holograms and bound-states-in-the-continuum (BIC). We strongly believe that these demonstrations pave the way towards future metasurface devices with dynamic wavefront control viz. high resolution spatial light modulators for AR/ VR applications, tunable flat optics, LiDAR and optical holography.

9:00 AM EQ03.01.05
Wavefront Manipulation Using Chemically and Electrically Driven Geometric Reconfiguration of Polymer Metasurfaces Siddharth Doshi[1], Anqi Ji[1], Ali Mahdi[1], Scott Keene[2], Yi-Shiou Duh[1], Skyler Selvin[1], Philippe Lalanne[3], Eric A. Appel[1], Mark Brongersma[1] and Nicholas Melosh[1]; [1]Stanford University, United States; [2]University of Cambridge, United Kingdom; [3]LP2N, Université Bordeaux, IOGS, CNRS, France

The optical transfer functions of engineered metasurfaces are defined by the geometric arrangement and material properties of their constituent meta-atoms. Optical metasurfaces have traditionally been fabricated with rigid inorganic materials and accordingly, have geometries that are fixed upon fabrication. Tuning of dynamic metasurfaces based on inorganic materials typically relies on modulation of their refractive index. While significant progress has been made in tuning with semiconductors (by free carrier generation), TMDC monolayers (by exciton generation) and phase change materials, these devices still face challenges including limited index tuning ranges and low power efficiencies.

In contrast, the geometric dimension of polymer materials can be widely reconfigured by a diverse range of stimuli, providing a powerful lever to control optical responses. For example, some thin polymer films can swell by 2-3 times their original thickness in the presence of different solvents or by electrically induced ion uptake. We leverage this property to create dynamically reconfigurable optical metasurfaces that that offer control over the intensity and phase of reflected light. Our platform consists of a spacer layer of the widely used and commercially available conducting polymer, PEDOT:PSS, situated between a metallic mirror and plasmonic nano-antennae. The degree of swelling of the PEDOT:PSS spacer is reversibly tuned through fluidic application of solvents with varying degrees of solvation energies. We thereby change the distance between the mirror and plasmonic nano-antennae and hence control the phase of light scattered from individual nano-antennae. We use this platform of "Expansion Plasmonics" to demonstrate high diffraction efficiency beam steering and continuous tuning of colour over a full gamut. Finally, we demonstrate the wider applicability of our platform by tuning our metasurface with other chemical stimuli, including electrochemical control of local ion concentrations. Our work opens the door to the broad integration of a range of polymers, engineered to respond to specific chemical stimuli, into reconfigurable optical elements with applications in bio-sensing, display, and imaging.

Optical Field and Spin Topologies in Plasmonics and Metamaterials Anatoly Zayats; King's College London, United Kingdom

The ability to engineer and manipulate the properties of optical wavefronts, such as phase, polarisation and amplitude, is very important in numerous applications including imaging, metrology, optical communications as well as biomedical and quantum technologies Metamaterials and metasurfaces provide a rich playground for both passive and active manipulation of phase and polarisation of light. Engineering spin-orbital angular momentum conversion provides practical opportunities for designing complex vector beams. In this talk, we will discuss optical vector field topologies and their transformations enabled by strongly anisotropic metamaterials and metasurfaces. Field- and spin-skyrmion and meron topologies will be discussed. An anisotropic metamaterial platform for local control of polarisation in complex vector beams, including radial and azimuthal beams, will be presented. The results enable a flexible approach for tailoring complex vector beams and achieving required polarisation patterns on demand for harvesting functionalities and applications of complex light beams with complex polarisation and phase information in numerous photonic and quantum technologies, imaging and metrology.

10:30 AM EQ03.02.02
Nanoscale Imaging of Plasmonic Coupling in Nanorod Dimers/Trimers by UEM Haihua Liu[1], Prem Singh[2], Amit Jaiswal[2], Thomas Gage[1] and Ilke Arslan[1]; [1]Argonne National Laboratory, United States; [2]Indian Institute of Technology Mandi, India

Replacing electronic signals with light pulses as information carriers is a prime motivation behind research on photonic circuits. Plasmonics based on surface plasmon polaritons, charge collectivly oscillating at the interface or surface, is attracting extensive interests because it enables concentration and manipulation of electric fields well beyond diffraction limit via nanoscale structures.[1] Therefore, direct imaging of the plasmonic field and its coupling at the nanoscale between photonics circuit components or plasmonic nanostructures is critical for nanophotonics applications, while scientists in this field mainly rely on theoretical simulation of the plasmonic field by FDTD or other programs. Noble metals such as Au or Ag are among the most popular plasmonic materials because of their strong coupling with light from visible to near-infrared (NIR) wavelengths. The anisotropic optical properties of the Au or Ag nanorods between the long and short axis provide tunable plasmonic energies and alternate ways to manipulate the plasmonic couplings between their dimer or trimer nanostructures depending on their mutual orientations and light polarizations. Photon-Induced Near Field Electron Microscopy (PINEM) developed in ultrafast electron microscopy (UEM) enables scientists to capture the evanescent electromagnetic field on its intrinsic time scale and with nanometer resolution.[2] To gain deeper insights regarding the plasmonic coupling mechanism at the nanometer scale, the dependences of the

plasmonic coupling within the dimer/trimer on laser polarizations and fluences, time, and nanorod mutual orientations were investigated at high spatiotemporal resolution on the newly established scientific UEM platform at Center for Nanoscale Materials, Argonne National Laboratory.

10:45 AM EQ03.02.03
Nanopore Arrays on Free-Standing Plasmonic Nanoassemblies for Electro-Optical Biosensing at Ultra-Low Concentrations Marzia Iarossi[1], Daniel Darvill[2,1], Aliaksandr Hubarevich[1], Jian-An Huang[3,1], Yingqi Zhao[3,1], Angela F. De Fazio[1], Devin O' Neill[1], Francesco Tantussi[1] and Francesco De Angelis[1]; [1]Italian Institute of Technology, Italy; [2]Imperial College London, United Kingdom; [3]University of Oulu, Finland

In the last two decades, nanopores have been extensively developed to detect and sequence biomolecules, providing powerful biosensing platforms. Typically, nanopore-based sensors are in contact with two compartments filled with an electrolyte solution and under an external bias a certain ionic current can be measured. When molecules are driven by electrophoresis towards the nanopore time-resolved transient fluctuations of the ionic current are observed. From an engineering point of view, solid-state nanopores are the artificial counterpart of biological nanopores and the latter have been even successfully commercialized as sensors at the single-molecule level and sequencing devices by taking advantage of the electrical detection mechanism[1]. Nevertheless, solid state nanopores still require further development to properly control the translocation events and collect as much information as possible from the passage of each molecule. For this reason, they have been integrated with plasmonic nanostructures with the aim to couple the electrical readout with an additional sensing modality based on an optical technique, such as, among others, Surface Enhanced Raman Spectroscopy[2–4]. Here, we propose an ordered array of nanopores supported on a free-standing plasmonic nanoassembly, which we use to detect DNA fragments both electrically and optically by means of SERS. We show that under resonant illumination the nanoassembly coated with a Au layer is able to highly enhance the electromagnetic field, which is highly confined at the metallic tips of the nanopores supported on the nanoassembly. This implies that the metallic nanopores can be used to detect molecules by SERS in flow-through configuration, taking advantage of the narrow sensing area generated by the plasmonic hotspots inside the nanopores. Since this platform is not based on a single nanopore but on multiple nanopores with high density, we show the detection of DNA at ultra-low concentrations in the femtomolar range. In this regard, nanopore arrays have the potential to overcome the low-throughput of single-nanopore based sensors, which are typically not able to detect molecules at concentrations lower than a few picomolars within a reasonable experimental time[5]. Furthermore, we show that our fabrication approach is based on a well-scalable method, which is based on the assembly of nanospheres, the reshaping of the interstices of the array and finally, the transfer of the nanoassembly on any holey supporting substrate. Hence, being not based on drilling techniques with electron/ion beams of expensive tools, the fabrication approach is advantageous in terms of costs and time. We believe that as a sensing platform based on arrays of nanopores our device could be interfaced with cells for biological applications, in which a significant number of molecules need to be analyzed and discriminated through SERS.

11:00 AM EQ03.02.04
Integration of Aluminum Plasmonic Nanostructures for Manipulating Organic Ultraviolet Photodetectors Qiuming Yu; Cornell University, United States

Incorporating surface plasmonics into optoelectronic devices can manipulate the performance of devices such as solar cells and photodetectors. This effect has been well-established for metals such as gold (Au), but has not been studied as extensively for metals with UV-range transitions such as aluminum (Al). UV-specific photodetectors have a wide variety of applications including environmental monitoring, scientific research, imaging, and flame and missile detection. Many of the devices currently in use are based on inorganic wide-bandgap materials such as GaN and ZnO, but organic materials offer several advantages over inorganic materials such as flexibility, tunability, and low material cost. In this work, a wide-bandgap (2.4 eV) polymer poly[(9,9-dioctylfluorenyl-2,7-diyl)-alt-co-(bithiophene)] (F8T2) was blended with a fullerene derivative [6,6]-phenyl-C71-butyric acid methyl ester ($PC_{71}BM$) for device active layers. We integrated Al plasmonic nanostructures into the organic UV photodetectors with the photodiode structures either as a transparent electrode or at the top metal electrode. For the devices with the Al plasmonic nanostructures as the transparent conducting electrodes, we replaced the indium tin oxide (ITO) with Al plasmonic nanohole arrays (Al-NHAs) with the device structure of glass/Al-NHA/PEDOT:PSS/F8T2:$PC_{71}BM$/LiF/Al, where PEDOT:PSS and LiF were used as hole and electron transport layers, respectively. We applied 3-dimensional finite-difference time-domain (3D-FDTD) electromagnetic simulations to design the Al-NHA to produce strong UV absorption in the active layer and enhanced internal electric field intensity. We successfully fabricated the Al-NHA electrodes using nanosphere lithography and incorporated into photodetectors, which produced two narrow photoresponse peaks with specific detectivity (D*) values of 4.0×10^9 and 4.6×10^9 jones under 340 and 515 nm illumination, respectively, and −2 V bias and one broad photoresponse peak with a peak D* of 8.8×10^9 jones under 450 nm illumination and 2 V bias. For the devices with the Al plasmonic nanostructures at the top metal electrodes, we imprinted nanohemisphere arrays (NHSAs) into the top surface of the active layer (F8T2:$PC_{71}BM$) in conventional organic UV photodetectors with the structure of glass/ITO/PEDOT:PSS/F8T2:$PC_{71}BM$/LiF/Al. NHSAs were transferred to the top Al cathode in the following thermal deposition of LiF and Al to generate plasmonic Al nanostructures. 3D-FDTD simulations revealed that the devices with plasmonic NHSA top electrodes exhibit stronger UV absorption in the active layer and enhanced electric fields at the interface of the top of the active layer and the Al electrode, especially for devices with thinner active layers. The inclusion of a NHSA was found to improve the photoresponse strength, sensitivity and speed through increased UV absorption and enhanced electric fields resulting from angular reflection of light in the active layer and the plasmonic effects of the Al NHSA electrode. The novel bias dependent response switching improves the applicability of UV photodetectors through the cost-effective, flexible, and performance-enhancing plasmonic Al-NHA transparent conducting electrodes. Our work also demonstrates that imprinting an NHSA into the top of the active layer, thus structuring the top metal electrode, is an effective approach for incorporating performance-enhancing plasmonic nanostructures into organic UV photodetectors.

11:15 AM EQ03.02.05
Enhancing the Broadband Photoresponse of Superconducting Microwire Single Photon Detectors Based on Ag Plasmonic Crystals Jingwei Yang[1], Tzu-Yu Peng[2,1], Jia-Wern Chen[1], Li-Chung Yang[1,2] and Yu-Jung Lu[1,2,2]; [1]Research Center for Applied Sciences, Taiwan; [2]National Taiwan University,

Taiwan

Superconducting photon detectors (SPDs) have many advantages like low dark noise, low time jitter, and broad detection range. However, there are some trade-offs that should be taken into account during fabricating the device. For example, a superconducting wire with narrower width performs a higher detection efficiency than a wider wire, but its detection area becomes smaller and its critical temperature is suppressed at the same time. On the other hand, a typical nano-meander shows high polarization sensitivity, which is inconvenient in many applications, e.g., quantum communication using MMF coupled systems. To overcome this predicament, we design a superconducting NbN microwire photon detector with gap plasmon enhancement. The gap plasmon resonance in an Al_2O_3 layer between Ag nanostructure and NbN microwire confines a strong electrical field, which destroys the Cooper pairs and further promotes the detection efficiency. For instance, we discovered a localized plasmonic resonance, which resonated at 532 nm wavelength, at the edge of Ag nanocube with 40 nm long and 30 nm thick. Hence, we can enhance the photon response of the detector to the visible range which can attribute to the gap plasmon resonance and the minimum detectable power of light is 4.4 nW. We design 9 different sizes of Ag nanocubes with side lengths of 30 nm to 70 nm (thickness of 30 nm) as a unit cell that resonate at different wavelengths to demonstrate a broadband photon detector with high detection efficiency from visible to NIR. In addition, though the choice of nanocube and microwire makes polarization sensitivity of the device lower, we still can make an SPD with polarization-dependent gap plasmon resonance by the different length-wide ratios of Ag nanoantenna. In the end, we discuss the potential for superconducting microwire photon detector applications, such as large active area, tunable polarization sensitivity, and low time jitter, etc.

11:30 AM EQ03.02.06
Temperature Non-Uniformities in Plasmonic Catalyst Beds: Measuring, Modeling and Implications for Catalysis Man Xu[1,2], Lun Cheng[1], Tim den Hartog[1], Roberto Habets[1], Jonathan van den Ham[1], Nicole Meulendijks[1], Francesc Sastre Calabuig[1] and Pascal Buskens[1]; [1]TNO, Netherlands; [2]Delft University of Technology, Netherlands

Distinguishing between photothermal and non-thermal contributions is essential in plasmon catalysis. Use of a tailored optical temperature sensor based on fiber Bragg gratings enabled us to obtain an accurate temperature map of an illuminated plasmonic catalyst bed with high spatiotemporal resolution.[1] We demonstrate that this fiber optical sensor (FOS) enables accurate temperature measurements at multiple positions inside an illuminated plasmonic catalyst bed realizing monitoring of local temperatures and temperature profiles and gradients. We validate the performance of this FOS sensor using spherical and rod-like alumina-supported Ru nanocatalysts recently developed by our research group for sunlight-powered conversion of CO_2 and H_2 to CH_4.[<!--[endif]----->[2-4] Using the FOS, we measured temperature differences exceeding 50 °C in the top 0.5 mm of the catalyst bed. Furthermore, we discovered differences between the surface temperature and the temperature obtained via conventional thermocouple measurements underneath the catalyst bed exceeding 200 °C. When used and calibrated (emissivity) correctly an IR camera can be used to measure exclusively the surface temperature, and indicate a temperature variation in the x,y-direction. However, an IR camera is unsuited to establish temperature gradients in the z-direction. A low thermal conductivity of 0.04 – 0.08 W m-1 K-1 is found, which causes the large temperature non-uniformity in the NP catalyst bed and should be taken into account when distinguishing between thermal and non-thermal contribution to plasmon catalysis. Using the acquired information of the thermal gradient in the catalyst powders, we developed a simple empirical model to study the photothermal effect. We would also like to point out that the measured temperature gradients will lead to large local deviations in reaction rate, and possible access to additional reaction pathways and mixed reaction mechanisms. Latter may explain differences in selectivity between illuminated reactions and their counterparts in dark. <!--![endif]----> <!--[endif]---->

11:45 AM EQ03.02.07
Thin-Film Exsolution of Metal Nanoparticles and Their Galvanic Restructuring for Plasmonically Enhanced Photocatalytic Activity Kevin Gregor Both[1,1], Vilde M. Reinertsen[1,1], Xiaolan Kang[1,1], Dragos Neagu[2], Øystein Prytz[1,1], Truls Norby[1,1] and Athanasios Chatzitakis[1,1]; [1]University of Oslo, Norway; [2]University of Strathclyde, United Kingdom

The exsolution and precipitation of metal nanoparticles (MNPs) from the bulk of a host material have been studied extensively due to their ability to create well-socketed particles on the host material's surface. This method is particularly useful in catalysis, as these supported catalysts generally have a longer lifetime due to the better adhesion with the substrate. This has been extensively applied to the field of solid oxide fuel cells for electrochemical energy conversion. But, could we apply it to semiconducting materials and improve their photoelectrocatalytic properties?

Most metals considered for exsolution (e.g., Ni, Fe, Co) do not possess notable plasmonic properties, rendering the possibility of increasing the efficiency of wide band gap semiconductors, such as strontium titanate (STO) through the surface plasmon resonance of socketed and plasmonically active nanoparticles. However, silver (Ag) and copper (Cu) can be substituted into STO and forced to exsolve by introducing a reducing environment at elevated temperatures. Moreover, utilizing the principle of galvanic replacement/deposition reaction allows the introduction of other plasmonically active elements, such as gold (Au), despite their inability to be exsolved. We have recently demonstrated this principle by exsolving nickel (Ni) and replacing it with the plasmonically active Au [1].

The direct exsolution or exsolution with subsequent galvanic replacement offer not only the ability to create well-socketed particles, but the latter also ensures that the precious metals are only present on the surface, reducing the amount of precious metals significantly. Moreover, the combination of exsolution and galvanic replacement allows the synthesis of materials with two different MNPs, one located in bulk and one sticking out of the surface. The combination of two plasmonically active elements enables an additional degree of freedom to adjust the absorption spectrum of the final device. In this work, Ag-doped thin films and Cu-doped thin films have been exsolved. Additionally, Ni MNPs created by exsolution have been galvanically replaced by Ag and Au. The samples were characterized by X-Ray Diffraction and electron microscopy (both scanning electron microscopy and scanning transmission electron microscopy), including energy-dispersive X-ray spectroscopy and electron energy loss spectroscopy. These techniques allowed the study of thin films on the nanometer scale. Additionally, the photoelectrochemical performance was determined, and a clear improvement was found between a sample with Au MNPs, and samples without MNPs.

Moreover, the shape, geometry, and the STO-matrix in proximity influence the peak position drastically. Combined with Finite Difference Time Domain

(FDTD) calculations, the results indicate that hot charge carriers are mainly responsible for enhancing photocatalytic properties. Recently, we considered MNPs of two elements close to each other, where one is plasmonically active and the other inactive (i.e., Au and Ni). The plasmonically inactive MNPs showed enhanced absorption while near the plasmonically active MNPs [1]. This configuration is evidence of a reactor-antenna formation, further increasing the possible structures obtained by our proposed methodology.

In brief, thin films with well socketed MNPs were created by exsolution and galvanic replacement. The particles were well dispersed and plasmonically active. The photoelectrochemical response was enhanced in comparison to thin films without MNPs.

1:30 PM *EQ03.03.01
Strong Light-Matter Interactions in Low-Dimensional Excitonic Semiconductors Deep M. Jariwala; University of Pennsylvania, United States

The isolation of stable atomically-thin two-dimensional (2D) crystals has led to a revolution in solid state physics and semiconductor device research over the past decade. A variety of other 2D materials (including semiconductors) with varying properties have been isolated raising the prospects for devices assembled by van der Waals forces.[1] Particularly, these van der Waals bonded semiconductors exhibit strong excitonic resonances and large optical dielectric constants as compared to bulk 3D semiconductors.
I will focus this talk on our recent works in strong light-matter coupling in excitonic 2D semiconductors, namely chalcogenides of Mo and W. Visible spectrum band-gaps with strong excitonic absorption makes transition metal dichalcogenides (TMDCs) of molybdenum and tungsten as attractive candidates for investigating strong light-matter interaction formation of hybrid states.[2-4] We will present our recent work on the fundamental physics of light trapping in multi-layer TMDCs when coupled to plasmonic substrates.[5]
Then, I will show the extension of these results to superlattices of excitonic chalcogenides. These hybrid multilayers offer a unique opportunity to tailor the light-dispersion in the strong-coupling regime.[6] We will discuss the physics of strong light-matter coupling and applications of these multilayers. If time permits, I will also present our recent work on scalable, localized quantum emitters from strained 2D semiconductors.[7]
Our results highlight the vast opportunities available to tailor light-matter interactions[8] and building practical devices with 2D semiconductors. I will conclude with a broad vision and prospects for 2D materials in the future of semiconductor electronics and opto-electronics

Room Temperature Mie-Polaritons in a Monolayer WSe_2 Coupled to van der Waals Nanophotonic Structures Yadong Wang[1], Sam Randerson[1], Panaiot Zotev[1], Xuerong Hu[1], Yue Wang[2], Charalambos Louca[1], Thomas F. Krauss[2] and Alexander Tartakovskii[1]; [1]The University Of Sheffield, United Kingdom; [2]University of York, United Kingdom

Dielectric nanostructures exhibit low optical losses and a wealth of distinct Mie resonances in contrast to their plasmonic counterparts(*1, 2*). Meanwhile, the strong light−matter coupling has attracted long-standing interest due to its fundamental importance in Bose-Einstein condensation, polariton lasing, and potential in quantum optics applications(*3*). However, strong coupling with relatively broad Mie resonances has been rarely observed. Here, we employ relatively narrow Mie resonances in high-refractive-index WS_2 nanoantennas placed on gold, and demonstrate strong exciton-photon coupling (Mie-polaritons) in monolayer WSe_2 exhibiting room temperature stable excitons with a large oscillator strength.
To achieve the Mie-polaritons, we fabricate nanoantennas by etching thin film WS_2 (30-nm thickness) that is exfoliated on a gold substrate, and then stack a monolayer WSe_2 onto them by using a dry transfer method. We use nanoantennas with radii (r) from 83 to 155 nm, which allows gradual tuning of the Mie resonance through the WSe_2 exciton energy. Thanks to the high refractive index of WS_2 and the gold substrate, Mie resonances with a narrow bandwidth of $\Gamma_M \approx$ 105 meV are achieved in WS_2 nanoantennas, suitable for observation of the strong coupling with WSe_2 excitons. The Mie resonances in the hybrid monolayer WSe_2/nanoantenna structures undergo significant changes compared with bare WS_2 structures. Typical anti-crossing behaviour is observed using dark-field scattering spectroscopy. The energy splitting between the upper (UBP) and low (LPB) polariton branches is fitted as $\Gamma_p \sim$86 meV, which is higher than the value reported in plasmonic systems (~50 meV)(*4*). Considering the linewidth of Mie resonance and neutral exciton ($\Gamma_0 \approx$ 38 meV), the strong coupling condition is thus satisfied at room temperature. Our results provide a promising platform for the realisation of the strong coupling in nanophotonic structures and controlled light emission in nanophotonics(*5-7*). Furthermore, one of the keys to our results is the use of hybrid dielectric/metal structures, achievable in a straightforward fashion with layered van der Waals materials.

Graphene-Based Mid-Infrared Emitters Geoff Nash, Prarthana Gowda, Dean Patient and Simon Horsley; University of Exeter, United Kingdom

Cost-effective and sustainable mid-infrared light sources are required for applications such as gas sensing and infrared beacons. Semiconductor LEDs are a natural replacement for the conventional incandescent sources still widely used in many applications, but to achieve emission at long wavelengths requires the realization of devices with narrow effective bandgaps, inherently leading to relatively poor internal and external quantum efficiencies. Recently, the technological potential of graphene-based incandescent emitters has been recognized, in part due to the ability of graphene to sustain extremely large current densities. Mid-infrared sources based on such emitters potentially offer an alternative, less complicated, approach to mid-infrared semiconductor LEDs [1], where the low thermal mass of graphene offers the potential for high frequency modulation [2]. Encapsulation of the emitting layer with hexagonal boron nitride allowed devices to run continuously in air for over 1000 hours [3], with the emission spectrum covering the absorption bands of many important gases. The h-BN encapsulation also allows the incorporation of a frequency selective surface metamaterial layer and we have previously shown that a metasurface consisting of ring resonators acts to tailor the broadband thermal emission into a dual band radiation, with measurements of both reflection and emission spectra agreeing well with simulations [4]. Here we describe a simple architecture, consisting of a back-reflector behind a multilayer graphene filament, which we use to produce emitters with wall-plug-efficiencies comparable to state-of-the art semiconductor cascade LEDs. Such high relative efficiencies demonstrate the feasibility of developing a graphene based mid-infrared light emitting device, which could be more cost effective and sustainable to manufacture than either silicon MEMs or compound semiconductor based alternatives. We show that the spectral characteristics of the emission could also be tailored for specific applications, such as gas sensing, through the incorporation of a metasurface.

Charge Transfer Between Infrared Plasmonic Nanocrystals and Two-Dimensional Semiconductor Michele Guizzardi[1], Michele Ghini[2], Ilka Kriegel[2], Giulio Cerullo[1] and Francesco Scotognella[1]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy

Infrared carrier transfer processes are a key technology to harvest energy from light. The standard photovoltaic materials work only in the visible range, but 45% of the emitted light from the sun is in the near-infrared region (NIR).
Indium Tin Oxide (ITO) has a localized surface plasmon resonance (LSPR) in the infrared region tunable between 1.5 um to 4um [1], and it has a bandgap of 3.6 eV ITO is a transparent material in the visible range. This makes it one of the key materials for the development of infrared plasmonic devices.
Charge transfer between infrared plasmonic nanocrystal that absorb in the IR and Two-dimensional semiconductor enables the extraction of charges excited with low-energy photons.
Ultrafast pump-probe spectroscopy has proven to be a powerful technique to study out-of-equilibrium phenomena, being applicable over a broad range of photon energies from THz to x-rays. In pump-probe, a medium is first excited with a short pump pulse and the photoinduced dynamics are probed by a time-delayed broad-band probe pulse.
Here, we used a broadband ultrafast optical spectroscopy to investigate the charge transfer between Indium tin Oxide nanocrystals and a large area Molybdenum disulfide (MoS_2) single layer.
After the excitation of the plasmon, in an ultrafast time scale of around 20fs, we have the plasmon dephasing due to electron-electron scattering, this leads to the generation of the so-called “Drude” electrons around the Fermi level, these carriers are not in equilibrium and they will reach it through e-e scattering. After ~100fs we have generated a hot FD distribution, that will relax by electron-phonon scattering, this process has a different timescale in different materials, however in plasmonic nanocrystal we are in the order of few ps.
When we generate the hot FD, the higher energy electron has enough energy to overcome the Schottky barrier and be transferred into the MoS2.
To study this we tuned our Noncollinear optical parametric amplifier to 0.7 eV (1750nm) to be resonant with the infrared plasmon of the ITO and the probe is in the visible region to keep track of the change in the transmitted probe resonant with the MoS2 excitons, while the ITO have a small negative signal in the visible coming from the ultrafast change in the refractive index.
We were able to see the feature of the A and B exciton of the MoS2 even if the energy is not enough to excite the exciton of the material, this is a clear sign of plasmon-induced charge transfer from the ITO to the MoS2.
We moreover compare the dynamics of directly excited MoS2 and the one induced by the plasmon to see the difference time constant of the exciton in both cases, when directly and indirectly excited.

Vortex Beams for Photonic Metasails and Optomechanical Rotation Mohammadrasoul Taghavi, Mohammadmojtaba Sadafi and Hossein Mosallaei; Northeastern University, United States

It has been proven experimentally that light can generate optical forces while interacting with nano-objects, resulting in various interesting applications such as optical trapping. Inspired by that, lightsailing has been introduced recently as a novel concept, exploiting the radiation pressure of light to reach the relativistic velocities with the hope of exploring the undiscovered universe. Metasurfaces, due to the taking advantage of the generalized Snell's law, can offer the possibility of controlling the wavefront of the reflected/transmitted light to engineer the amplitude and direction of the optical forces to obtain the desired goals. Lightsailing technology seems to be an ideal platform for probing the nearest inhabitable exoplanet within the human lifetime thanks to the exclusive functionalities that the photonic metasurfaces offer. Light tends to carry both the linear and angular momenta while propagating, where the exchange of the former one with the matter can result in linear acceleration, having been the subject of numerous studies so far. The linear momentum exchange between the light and the object exerts an optical force, which can be exploited for accelerating gram-scale space probes. Nevertheless, the transfer of angular momentum to an object will potentially impose a rotational motion, being desirable in a variety of applications. Here, we put our major focus on the study of the rotational behavior of our designed metasail while it exchanges the orbital angular momentum (OAM) with light. The rotational motion of the lightsail will be advantageous in various scenarios, including stability improvement. Moreover, enabling the self-stabilizing mechanism while minimizing the acceleration time in the propulsion stage is one of the key elements to realizing such nanocrafts. Conventional designs of metasails require a parachute configuration with a detached payload for enabling the passive self-stabilizing mechanism. Therefore, spinning the lightsail at high speeds can be introduced as a beneficial tool to provide a new degree of freedom in the stability criteria of the lightsails, which can be exploited to further widen the stability margins. In our study, we design an all-dielectric photonic metasail using multi-objective optimization, which consists of both the reflective and transmissive elements that can provide the required optomechanical performance for reaching the relativistic velocities in an acceptable period of time. Also, we carefully design each unitcell of the metasurface, considering the delicate trade-off between the linear acceleration and rotational motion of the sail. We illustrate the interaction between the vortex beam associated with different OAM states and photonic metasails for achieving desired propulsion performance. Generally, the rotational force would be expected if the incident light is carrying an orbital angular momentum or if the metasail imparts an orbital angular momentum to the incident beam. In the latter case, the propulsion beam upon reflection from a metasail with a broken azimuthal symmetry contains an orbital angular momentum (OAM) which seems to be a viable solution for generating large in-plane rotational torque. Our work addresses in detail the relation between the amount of OAM accompanied by the reflected beam and rotational speed of the sail as well as the linear acceleration. It is shown that a careful design can result in a metasail, having both the desirable linear acceleration and rotational motion, providing the self-stability feature to the sail, simultaneously. We believe that the studies in our work can be used to open a new perspective on the lightsailing field as our results show the impacts of both the linear and rotational motions on the functionality of the metasail.

Expanding the Materials Palette for Nanophotonics with Super-Mossian and Quantum Materials Guru V. Naik; Rice University, United States

Emerging meta-devices need novel optical materials, both metals and dielectrics, for high performance, flexibility, and large-scale integration. Novel metallic materials or plasmonic materials such as transparent conducting oxides and transition metal nitrides have significantly expanded the scope of nanophotonics in the past. Further improvements are required in dielectrics and tunable dielectrics. Here, I will describe how super-Mossian dielectrics enable high performance and quantum materials enable MHz-fast ultralow-power tunability.
Super-Mossian dielectrics are very high index dielectrics that significantly beat the predictions of Moss' rule. The commonly-known form of Moss' rule states that the fourth power of the refractive index of a dielectric inversely scales with its direct bandgap or absorption edge. Thus, the refractive index of dielectrics has an upper limit for a given operating wavelength. However, there are certain materials with special energy band features that can significantly beat Moss' predictions. Here, I will describe how to identify such super-Mossian dielectrics. Also, I will show high-Q dielectric resonances enabled by one such outstanding super-Mossian dielectric, iron pyrite.
While a high refractive index is needed for high-quality factor resonators, tunable optical properties are required for reconfigurable and non-linear devices. Low-power tunability is desired in many such devices because of their applications on mobile platforms. Here, I will show how quantum materials offer a paradigm shift in optical tunability. I will describe ultralow-power MHz-fast optical tunability in 1T-TaS_2, a charge-ordered material at room temperature. Finally, I will demonstrate tunable and color-changing metasurfaces built on 1T-TaS_2.

Large Area Periodically Modulated 2D Transition Metal Dichalcogenide Layers Featuring Flat-Optics Light Harvesting Matteo Gardella, Giulio Ferrando, Giorgio Zambito, Maria Caterina Giordano and Francesco Buatier de Mongeot; Università di Genova, Italy

Transition Metal Dichalcogenides (TMDs) are two-dimensional semiconductors featuring high optical absorption coefficient combined with good transport and mechanical properties. Although mechanically exfoliated TMD flakes ensure the best opto-electronic properties, homogeneous large area growth techniques are mandatory for real world applications [1,2]. At the same time, in view of light conversion applications in the extreme thickness regime of 2D-TMDs it is essential to develop effective photon harvesting strategies.
Here we demonstrate that periodic modulation of MoS_2 layers on large area nanostructured samples (either MoS_2 nanostripes arrays or conformal MoS_2 layers grown on top of nanogrooved silica templates) efficiently steers light parallel to the 2D material, exploiting photonic anomalies in the flat-optics regime [3,4].
As a case study, we demonstrate that flat-optics light harvesting in periodically corrugated MoS_2 layers employed as photocatalysts boosts photodissociation of Methylene Blue (MB), a polluting dye molecule commonly used in the textile industry. When illumination occurs at the optimized angles which couple light to the photonic anomalies a two-fold faster photodissociation rate is observed with respect to planar MoS_2 films [6].
In a recent development of our TMD platform, we demonstrated the possibility to stack different 2D-TMDs layers forming large area arrays of van der Waals heterostructures. For this purpose, we developed a custom prototype setup which allows sequential deposition of different TMD layers, MoS_2 and WS_2, by Ion Beam Sputtering. Physical deposition of WS_2 at glancing angles on the nanogrooved silica templates leads to the formation of laterally confined nanostripes which are subsequently coated by a MoS_2 layer, thus achieving maskless deposition of large area arrays of TMD heterostructures. Our preliminary results demonstrate the higher light trapping potential of the TMD heterostructures with respect to single component MoS_2 layers, to be employed as optical sensitizers in water remediation and photocatalytic applications [7].

Optical Customization of Two-Dimensional Exciton Decay Dynamics with Plasmonic Metasurface Sanghyeok Park, Dongha Kim and Min-Kyo Seo; Korea Advanced Institute of Science and Technology(KAIST), Korea (the Republic of)

Excitons in transition metal dichalcogenides (TMDCs) monolayers have been focused on owing to their fascinating physical characteristics such as large binding energy, valley property, and high quantum efficiency. The decay dynamics control of excitons in TMDC monolayer becomes a key issue in various research areas: quantum many-body physics, optoelectronics, valleytronics, and excitonics. The conventional methods applying mechanical strain or electrostatic biasing and implementing defects efficiently control the decay dynamics of excitons. But, those methods accompany the generation of undesired exciton complexes, formation of non-radiative decay channels, and significant changes in the electronic band structure and exciton binding energy. As an alternative method, radiative decay control via optical vacuum field engineering has been suggested. However, the use of typical planar mirrors strictly limits the possibilities of applying further characteristics, such as spectral dispersion, spatial distribution, polarization dependency, and so on, to the dynamics of two-dimensional excitons.
Here, we present the optical customization of the decay dynamics of exciton in $MoSe_2$ monolayer using plasmonic metasurfaces. The plasmonic metasurface, a square array of Au disks on SiO_2/Au/Si substrate, is covered with hydrogen silsesquioxane (HSQ) to avoid the undesired strain on the $MoSe_2$ monolayer. The hexagonal boron nitride (hBN) encapsulated $MoSe_2$ monolayer is transferred on the metasurfaces. The engineered reflection phase shift of the metasurface provides the on-demand vacuum field distribution at the $MoSe_2$ monolayer depending on the position and frequency. We designed and fabricated three different metasurfaces (A, B, and C) that excite the neutral excitons in the $MoSe_2$ monolayer at almost the same conditions but make them decay at different rates. With the holography setup, it was experimentally confirmed that the metasurfaces A, B, and C have the same reflection amplitude and reflection phase at the pumping frequency (2.33 eV). On the other hand, the reflection phase changes from destructive interference condition to moderate condition at emission frequency (1.64 eV) depending on the metasurfaces. The metasurface platform controls the radiative decay rate of the neutral exciton in the $MoSe_2$ monolayer by two orders of magnitude depending on the vacuum field interference. Arranging different metasurfaces in two dimensions enables us to tailor the spatial landscape of exciton radiative decay in a single TMDC flake.
We measured the photoluminescence (PL) spectrum of the neutral exciton in the $MoSe_2$ monolayer on the metasurfaces, employing a confocal microscope setup. The metasurfaces A, B, and C placed end-to-end resulted in a precise step-wise distribution in the PL intensity. The linewidth and intensity from the Lorentzian fitting of the PL spectra clearly show a positive correlation. The median linewidths at the metasurface A, B, and C are extracted as 2.24, 1.56, and 1.28 meV, respectively. The total decay rate in a two-level system, like excitons, corresponds to the linewidth of the PL spectrum. Employing the coherent optical feedback model, we extract the radiative decay rate from the measured linewidth and reflection phase. We then reveal that the radiative lifetime of the exciton in the TMDC monolayer is successfully controlled by the metasurfaces as desired. We also demonstrated the polarization-dependent radiative decay control of excitons employing an anisotropic metasurface of Au nanorods.
We expect that tailoring the artificial landscape of exciton lifetime by our platform will serve as a building block for the demonstration of advanced exciton transport devices. Also, employing the state-of-the-art metasurfaces will provide more ingredients, such as spectral dispersion, in-plane momentum, and spin/orbital angular momentum, for two-dimensional exciton's decay dynamics.

4:30 PM EQ03.04.05
Atomic Scale van der Waals Nonlinear Optical Metamaterials Bumho Kim[1], Jicheng Jin[1], Zhi Wang[1], Li He[1], Thomas Christensen[2], Eugene Mele[1] and Bo Zhen[1]; [1]University of Pennsylvania, United States; [2]Massachusetts Institute of Technology, United States

Material's responses to light are governed by symmetry. For example, the nonvanishing second-order susceptibilities of materials in the 32 point groups have been tabulated and experimentally confirmed. Methods breaking symmetries at interfaces of bulk crystals introduce new electric-dipolar second-order susceptibilities that do not exist in the natural bulk materials, enabling nonlinear metamaterials composed of centrosymmetric dielectrics (Si and Al_2O_3 *etc*.) and metals (Au, Ag and Al *etc*.). However, the interfacial nonlinear responses of bulk crystals are inefficient due to the inherently low interface area-to-volume ratio and prevent further miniaturization. The advent of twisted bilayers has provided a new way to create a pristine crystalline interface between two monolayers with an exceptionally low volume fraction. Reconfigured electronic potential in twisted structures enables non-localized nonlinear responses on an atomic scale, promising atomic scale nonlinear optical metamaterials. Most current research focuses on nonlinear responses caused by a superposition of constituent monolayers upon adjusting twist angle or stacking more layers while neglecting interfacial nonlinear responses. Exploring emerging interfacial second-order susceptibilities of van der Waals lattices can bring a new degree of freedom in nonlinear optics, which can be applied to a broad range of nonlinear nanophotonic applications.

In this work, second-harmonic generation (SHG) measurements on ±30° twisted bilayer WS_2 unveil the effect of an interfacial second-order sheet susceptibility ($\chi^{(2)}_{s,\,xyz}$) that does not exist in natural WS_2. In these samples, the interfacial second-harmonic (SH) polarization orientation is solely determined by an interfacial twist orientation. Thus, controlling the twist orientation of trilayer WS_2 enables enhancing and suppressing the interfacial nonlinear response. Furthermore, we devised and demonstrated a twisted quadruple WS_2 with a dominant interfacial nonlinear response ($\chi^{(2)}_{s,\,xyz} \neq 0$ and $\Sigma\chi^{(2)}_{s,\,yyy} \approx 0$), which is significantly modified from monolayer WS_2 ($\chi^{(2)}_{s,\,xyz} = 0$ and $\Sigma\chi^{(2)}_{s,\,yyy} \neq 0$). The suppression of $\Sigma\chi^{(2)}_{s,\,yyy}$ in the quad-WS_2 is attributed to a screw axis symmetry. As stacking two quad-WS_2 vertically (octa-WS_2), we observe the interfacial sheet susceptibility increases linearly with the sample thickness, indicating a coherent interference in the thin material. Remarkably, our results demonstrate a new avenue to engineer each component of second-order susceptibilities by twisting and stacking WS_2 layers.

High-Performance Flat Optics—From Metasurfaces to High-Volume Manufacturing for Consumer Electronics and Communications Federico Capasso; Harvard University, United States

Since the demonstration of the generalized laws of refraction for metasurfaces[1] and the first high performance metalenses[2], metaoptics has rapidly progressed from the laboratory to manufacturing, propelled by the vision that the foundries that manufacture ICs will manufacture CMOS compatible flat optics using the same semiconductor technology based on deep-UV lithography.[3,4]This will impact the consumer electronics market in areas such as smart phones and wearable displays for AR/VR. Metasurfaces are now on the market through its partnership with STMicroelectronics, marking the introduction

of this revolutionary optical technology in real-world devices.[5] I will present recent major advances in cm scale achromatic RGB metalenses for VR by inverse design[6] and 10 cm metalenses for space optics consisting of 20 billion metatoms.[7] A compact and highly integrated metasurface-based inverse designed mode multiplexer that takes three single-mode fiber inputs and converts them into the first three linearly polarized spatial modes of a few-mode fiber with high fidelity the C-band (1530−1565 nm) of fiber optics will be presented.[8] I will conclude with the report of hybrid silicon-organic electrooptic metasurface modulators that use Mie resonances for efficient electro-optic modulation at GHz speeds for free-space communications. Multi-channel Approach for Secure Metasurface-Based Image Encryption Romil Audhkhasi and Michelle Povinelli; University of Southern California, United States

Recent advances in two disparate but complementary research fields: *metasurfaces* and *hyper-spectral imaging*, suggest exciting new possibilities for the development of secure communication schemes. Metasurfaces can encode information in optical waves by manipulating them in the spatial and spectral domain. On the other hand, hyperspectral imagers can record optical information as a function of both position and wavelength, providing an ideal, complimentary receiver for the transmitted light. Here we introduce a novel, secure communication scheme that takes advantage of the unique opportunities provided by such spatially- and spectrally- multiplexed communication channels. While conventional image encryption approaches perform a 1-to-1 transformation on a plain image to form a cipher image, we propose a 1-to-*n* transformation scheme. Plain image data is dispersed across *n* seemingly random cipher images, each transmitted on a separate wavelength channel. The intended recipient converts the cipher images into meaningful information by using a decryption key. We show that the size of our key space grows double-exponentially with the number of channels, providing strong security against both brute force attacks and more advanced attacks based on statistical sampling of the key space. Moreover, our multi-wavelength encryption scheme can be cascaded with traditional 1-to-1 methods, effectively *squaring* the size of the key space. Our results suggest exciting new opportunities for secure transmission in multi0wavelength imaging channels.

11:15 AM EQ03.05.03
Shining Light on the Deep—High Quality Factor Metasurfaces for Real-Time Ocean Observation Halleh Balch[1], Jack Hu[1], Sahil Dagli[1], Varun Dolia[1], Kai Chang[1], Fareeha Safir[1], Greg Doucette[2], William Ussler[2], Chris Scholin[2] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]Monterey Bay Aquarium Research Institute, United States

Phytoplankton are microscopic photosynthetic organisms responsible for half of the global photosynthetic carbon fixation and are an essential part of the earth's carbon cycle. But, under certain conditions, phytoplankton can undergo explosive growth forming dense blooms that can cover hundreds of square kilometers and can release powerful biotoxins (phycotoxins) that contaminate drinking water sources, harming humans and wildlife. Understanding how environmental drivers impact phycotoxin production is key to advancing climate resilience but remains an outstanding challenge due to the difficulty of measuring toxin prevalence and persistence in situ. Predominant methods of studying phycotoxins are based on mass spectroscopy, polymerase chain reaction, and DNA/RNA sequencing. These lab-based methods are costly, require sophisticated infrastructure, and lack remote in situ detection capabilities. Current in situ approaches, such as surface plasmon resonance (SPR), are limited by low sensitivity, poor quantification range, and are challenging to scale.

Here, I will describe the development of a nanophotonic sensor for in situ aquatic toxin detection using surface-functionalized high quality factor (high-Q) silicon metasurfaces. Our metasurfaces are composed of sub-wavelength silicon nanobars with dimensions 500 nm x 600 nm x 160 nm on sapphire substrates. First, we show that by introducing small biperiodic perturbations to the lateral block dimension, free space radiation can be coupled into guided mode resonances to produce high-Q resonances with Q factors exceeding 1,000 in aquatic environments. We demonstrate in simulation and experiment that by varying the biperiodic perturbation from 10 nm to 50 nm, the quality factor can be modulated from a few hundred to nearly 10,000 and that the local electric field can be driven to the silicon surface, increasing the overlap between the probe field and the binding surface by nearly four-fold. We show that long resonance lifetimes together with the increased field penetration at the binding surface results in strong spectral shifts of the resonance mode due to small perturbations to the local dielectric environment. We fabricate our metasurfaces by e-beam lithography and demonstrate that the optical responses of individual resonators can be spatially resolved as individually addressable 'pixels' and simultaneously read out as a change in resonance wavelength or as a change to the scattering intensity on a 2D InGaAs CCD array using a home-built infrared optical reflection microscope in a cross-polarized reflection configuration.

We then apply this platform to the detection of two aquatic phytotoxins: domoic acid, a neurotoxin responsible for human and wildlife mortalities, and microcystin, a liver toxin produced by cyanobacteria that poses a threat to drinking and agricultural water supplies. We selectively target domoic acid and microcystin using tailored surface functionalization of self-assembled monolayers (SAM) and a competitive antibody binding assay. We show that domoic acid and microcystin can be directly crosslinked to the metasurface through a step-wise covalent silanization. We observe in both calculations and experiment that consecutive molecular layers generate 0.5 nm - 4 nm shifts to the resonant wavelengths as sequential layers bind to the resonator surface. We then describe selective and quantitative toxin detection using a competitive antibody binding assay, where the metasurface optical signal is inversely proportional to the toxin concentration. Finally, I will discuss the integration of our high-Q metasurfaces with the Environmental Sample Processor (ESP), an autonomous robotic water sampler developed at the Monterey Bay Aquarium Research Institute (MBARI), that offers a pathway for in situ phycotoxin detection, processing, and analysis.

11:30 AM *EQ03.05.04
Lighting Up the Oceans—Real-Time, Multi-Omic Ocean Observation with High-Quality-Factor Metasurfaces Jennifer A. Dionne[1], Halleh Balch[1], Varun Dolia[1], Greg Doucette[2], William Ussler[3] and Chris Scholin[3]; [1]Stanford University, United States; [2]National Oceanic and Atmospheric Administration, United States; [3]Monterey Bay Aquarium Research Institute, United States

Phytoplankton are microscopic organisms responsible for half of the global photosynthetic carbon fixation and at least half of the world's oxygen production. The changing climate is driving fundamental shifts in phytoplankton nutrient cycling, with profound impact on marine and freshwater ecosystems. For example, certain phytoplankton taxa can produce powerful biotoxins that harm humans and wildlife, contaminate water sources, and

damage local economies, leading the National Academies to call for the development of *in situ* sensors of phytoplankton nutrient cycling as critical infrastructure needed to advance climate resilience. Predominant methods of studying phytoplankton toxins and their genes are based on tandem mass spectrometry (LC/MS-MS), the polymerase chain reaction (PCR), and DNA/RNA sequencing. These methods are costly, require sophisticated infrastructure, and lack remote, autonomous, real-time detection capabilities that are central to time-series measurements necessary to understand coupled hydrography and climate/ecosystem dynamics.

Here, we present a metasurface-based technology to simultaneously and rapidly measure multiple 'omic' signatures of phytoplankton from aquatic samples. Our high-quality-factor ("high-Q") dielectric metasurfaces produce a large amplification of the electromagnetic field intensity, increasing the response to minute refractive index changes from target binding; simultaneously, the light is beam-steered to particular detector pixels. By combining metasurface design with acoustic bioprinting of samples, we produce microarrays of densely packed sensing pixels, each functionalized with distinct molecular recognition elements. On the same metasurface, we demonstrate specific detection of gene fragments, proteins, and small molecule toxins across hundreds of individual resonators simultaneously. We describe application of this quantitative assay to in-situ molecular analysis of environmental DNA, domoic acid, and microcystin. Finally, we discuss integration of our high-Q metasurfaces with the Environmental Sample Processor, an autonomous robotic water sampler developed at the Monterey Bay Aquarium Research Institute (MBARI), that offers a pathway for in situ phycotoxin detection, processing, and analysis.

Approaches to Violation of Kirchoff's Law without a Magnetic Field Michelle Povinelli[1], Alok Ghanekar[1], Jiahui Wang[2] and Shanhui Fan[2]; [1]University of Southern California, United States; [2]Stanford University, United States

Kirchoff's Law of thermal radiation states that for any given angle and wavelength, the absorptivity and emissivity of are equal in steady state. Previous work has achieved violations of Kirchoff's Law only through the use of magneto-optical materials and require the use of an external magnet. Here we introduce an approach to Kirchoff's Law violation using spatiotemporal modulation of the material refractive index. We first introduce a theoretical formalism for calculating absorptivity and emissivity suitable for modulated systems, which fully incorporates the effect of frequency-conversion processes within the material. We show that for nonreciprocal systems with nonzero absorption, Kirchoff's Law may be violated. We introduce a metallodielectric grating design amenable to spatiotemporal modulation through carrier modulation effects and directly calculate the absorptivity and emissivity numerically using finite-element simulations. We show that in addition to nonreciprocal effects in reflection, the absorptivity at fixed angle and wavelength differ. For stronger modulation, we observe directional Rabi splitting, giving rise to even stronger violations of Kirchoff's Law. The results illustrate a potential pathway to achieving non-reciprocal thermal emission without the use of magneto-optical materials.

2:00 PM EQ03.06.02
Tailoring Thermal Emission with Ultrathin Films Jeremy N. Munday; University of California, Davis, United States

The thermal spectrum of hot bodies is well-known and described by Planck's law for blackbody emission. However, for many modern technologies, it is desirably to have significant deviations from this law to achieve directional or wavelength-controlled emission. Many approaches exist, yet difficulties arise due to thermal compatibility of materials at high temperatures, as well as stability of nanostructures when metasurfaces are employed. Here we present an alternative route involving single-layer, ultrathin films. We explored >100 materials that are stable above 2000°C and found combinations that allow for significant tunability of thermal emission throughout the near-infrared frequency range. We have fabricated and tested several material combinations at high temperature and show that the spectrum can be significantly modified using this simple configuration. Using these structures, we optimize the emission spectra of such emitters to match five common thermophotovoltaic cells and show that efficiencies in excess of 45% are achievable at moderate temperatures.

2:15 PM EQ03.06.03
Three-Dimensionally Printable Ultrawhite Radiative Cooler Using Hollow Structured Nanoparticles Seok-Beom Seo, Su-Jin Park, Sunho Jeong and Sun-Kyung Kim; Kyung Hee University, Korea (the Republic of)

Owing to the global consensus on energy-saving, radiative cooling has attracted much interest as a passive thermal management technology. Technically, to cool down objects below ambient temperature, radiative coolers must exhibit low absorption under solar illumination (e.g. l = 0.3 – 2.5 mm) and high emission in the mid-infrared spectral range (e.g. l = 8 – 13 mm). It can be achieved by stacking several materials or using a nanoscale photonic structure, which bring an increase in cost and fabrication difficulty.
We use dielectric nanoparticles as an alternative while maintaining the optical properties for sub-ambient radiative cooling. We demonstrated near-perfect reflectance in ultraviolet to near-infrared spectral range using hollow structured silica nanoparticles (HSNPs), owing to the enhanced scattering characteristics of the hollow structure. Note that low absorption and strong reflection in ultraviolet and near-infrared wavelengths are difficult to achieve with conventional silica nanoparticles. HSNPs coated Si shows an average of 0.96 reflectance in the solar spectral range and an average of 0.95 emissivity in the mid-infrared spectral range. We conducted an outdoor cooling experiment on Si wafers. The HSNPs coated Si, covered 8.89% of surface area of full Si wafer, show 4.4°C temperature drop in comparison to bare one.
But one critical issue remains for printability; hollow structured nanoparticles aggregate each other during the solvent evaporation (the final step of printing sequences) and leads to a crack on its surface that diminishes the overall reflectance and durability. We used PVP (Polyvinylpyrrolidone) to prevent aggregation. The PVP molecules are attached to the surface of the HSNPs and impede free motion to fix their coordinates rigidly. The crack-resistant property of the PVP assisted HSNPs paste holds the promise of implementing three-dimensionally printed devices with high precision, such as serpentine-shaped electrodes. In addition, spray coater also can be used to sprinkle HSNPs on a large area due to its great uniformity. We believe that the printable HSNPs developed herein can be extended to a variety of components on arbitrarily designable platforms such as curved or flexible optoelectronic devices.

2:30 PM EQ03.06.04
Electrochemical Dynamic Solar and Mid-Infrared Synergistic Radiative Thermoregulation Chenxi Sui and Po-Chun Hsu; Duke University, United States

The coldness of the deep universe and the hotness of the sun have been considered renewable thermodynamic resources for sustainable thermoregulation. How to utilize both resources showed drastic improvement in the past decade, enabled by the plasmonic and nanophotonic research. Remarkably, the rational photonic and thermal design has pushed forward the power and efficiency of daytime radiative cooling. In this presentation, we will introduce our recent research progress on electrochemical devices that can dynamically switch between solar heating and radiative cooling states, by tuning their optical properties. Such a non-trivial and opposite spectral tuning requires the fabrication of the ultra-wideband transparent conductive electrode, which is transparent in both solar and mid-IR regimes, and the precise control of the plasmonic nanoparticles' morphology during the reversible metal electrodeposition. With the optimization of every device component, this device can maximize its solar reflectivity at the cooling state and minimize its thermal emissivity at the heating state, and thus can serve as the smart building envelope for year-round HVAC energy saving. Ideally, the device can help buildings save 19.2% of HVAC energy across the United States, based on the building energy simulation results. The durable electrodeposition and the broad-band optical spectral tuning ability are confirmed by the DFT simulations and effective medium theory. In addition to the synergistic solar and mid-IR dual-band tuning, our electrochromic device can tune the thermal emissivity with 0.85 contrast based on non-volatile and reversible metal electrodeposition, bringing vast opportunities for applications in space heat management, and thermal camouflage.

Scalable Temperature-Adaptive Radiative Cooler for Thermal Regulation Jiachen Li[1,2], Kechao Tang[3,2,1], Kaichen Dong[2,1] and Junqiao Wu[1,2,2]; [1]Lawrence Berkeley National Laboratory, United States; [2]University of California, Berkeley, United States; [3]Peking University, China

The wavelength range of the mid-infrared atmospheric window matches that of thermal radiation near room temperature, thus the sky is used as a natural heat sink for passive radiative cooling of houses. For decades, experiment works in the field have focused on using static, cooling-optimized material properties to maximize the radiative cooling power of roof coating. However, in cold nights or winter times, especially in climates where heating dominates house energy consumption, the resultant overcooling exacerbates the heating cost and causes more energy consumption over the year. Here we present a different approach to thermal regulation by developing a mechanically flexible and energy-free temperature-adaptive radiative coating (TARC) to minimize the total energy consumption throughout the year, rather than only on hot days. The TARC is a metasurface that optimally absorbs solar energy and automatically adapts its thermal emittance to different ambient temperatures, driven by a photonically amplified metal-insulator transition. We demonstrate its performance in thermal regulation for energy-saving through simulation, lab characterization, and field tests.
Simulations based on real climate data show that TARC outperforms existing roof coatings in yearly energy saving in most climates, especially those with substantial seasonal variations. We also develop a scalable process to print TARC in large sizes and at low cost. The scalable fabrication makes TARC a promising product for thermal regulation in other systems such as spacecraft and tents.

Probing ND7/23 Neuronal Cells Before and After Differentiation with SERS Using Sharp-Tipped Au Nanopyramid Arrays Marzia Iarossi[1], Aliaksandr Hubarevich[1], Giuseppina Iachetta[1], Michele Dipalo[1], Jian-An Huang[2,1], Daniel D. Price[3,1] and Francesco De Angelis[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of Oulu, Finland; [3]Imperial College London, United Kingdom

The development of local plasmonic nanosensors which can investigate cellular processes, whilst remaining non-invasive, with high sensitivity is still challenging but of great interest in the field of sensing.[1,2] The use of plasmonic nanostructures for Surface-enhanced Raman spectroscopy (SERS) measurements is one promising route for diagnostics and the measurement of cell activity and cell constituents. SERS allows for highly specific optical data in much shorter acquisition windows for the detection of molecules and markers of interest.
In this work we show the development of a SERS based sensor, which was conceived with the aim of monitoring cell activity and to discriminate cells before and after differentiation.[3] The SERS sensor is composed of a platform of label-free sharp-tipped Au nanopyramids. To create the array we demonstrate a fabrication technique based on colloidal lithography. We have however altered the technique by using surface charged PS spheres and controlling the pH of the water. This allows us to tune the size of the nanoparticle interstices with sharp definition before metal depositions and achieve tip curvatures of 10nm without the use/cost of mask etching (i.e., reactive ion or plasma etching) or other expensive fabrication routes. Characterisation of the array shows a good matching of both the experimental and simulated optical data, with a plasmonic hotspot confined at the tip of the structure.
The focus of this study was ND7/23 neuronal cells where we performed SERS measurements of the cells both before and after differentiation. We found good success in discriminating the two groups' data by multivariate analysis. From the SERS data we were able to identify fingerprints of both the cell membrane, such as lipids and proteins, and intracellular components, such as RNA/DNA. This shows that the sharp tips of our structure are also able to penetrate the cell membrane and spontaneous poration occurs. A viability test of the cells showed high viability on the sensor and the cells were still found to be in good condition after hours of measurements.
This plasmonic array shows the realisation of a sensing platform which greatly enhances the SERS, with a high signal to noise ratio and reproducibility. This is a structure of interest as we show the development of an efficient SERS sensor based upon a novel facile low-cost fabrication route. The structure is also found to be a good bio-interface with high cell viability and the ability to spontaneously porate the cell. Taking in mind the potential of nanostructured colloidal templates, our fabrication technique is compatible for use with other substrates of interest, including flexible substrates for in-vivo studies. Moreover, the fabrication is very controllable and can be easily tuned to produce NPs with resonances in other wavelength windows of interest.

Direct Imaging of Light-Matter Interaction of Localized Excitonic Emitters Using Tip-Enhanced Scanning Probe Technique Kiyoung Jo[1], Emanuele Marino[1], Jason Lynch[1], Zhiqiao Jiang[1], Natalie Gogotsi[1], Thomas P. Darlington[2], Mohammad Soroush[3], P.J. Schuck[2], Nicholas Borys[3],

Christopher B. Murray[1] and Deep M. Jariwala[1]; [1]University of Pennsylvania, United States; [2]Columbia University, United States; [3]Montana State University, United States

Strong light-matter interaction in nanoscale emitters at optical frequencies using far-field spectroscopic analysis has been a subject of sustained research activity. Yet, direct visualization of the interaction in real space has been restricted by diffraction-limited measurement systems. Here, we perform near-field hyperspectral analysis using scanning probe techniques to image strong light-matter interactions of quasi 2-dimensional emitters on plasmonic Au substrates. We find exciton-polariton formation induced by strong coupling between an excitonic dipole in CdSe/CdS nanoplatelets and a gap mode plasmon in the Au tip under contact mode. Moreover, with the aid of tapping mode measurements, we observe that surface plasmon polaritons launched by excitonic emission from the nanoplatelets propagate in directional and radiative fringe patterns with periods of 317 nm. Extensive optical simulations offer proof that the fringes are the result of a standing wave formed between the tip and the nanoplatelets. Additionally, we find that the fringe shape and its period can be engineered by controlling the exciton dipole orientation of the nanoplatelets, as well as the permittivity (ε = 3-15) and thickness (0.7 - 5 nm) of dielectric capping layer on the Au. The fringe patterns are also observed in WSe_2 nano-bubbles and CdSe/CdS nanoplatelets deposited on SiO_2/Si substrate, which implies that phenomenon is universal to localized emitters on various substrates. Our results enable deeper understanding of in-plane, near-field electromagentic energy transduction from nanoscale emitters with wide implications in nano and quantum photonics.

4:00 PM EQ03.07.03
Ultracompact Imaging Devices by Deep Diffractive Neural Networks Yilin Zhu and Luca Dal Negro; Boston University, United States

Deep diffractive neural networks (D2NNs) that combine optical diffraction physics and deep learning capabilities have recently been utilized for the inverse design of multi-layered diffractive devices that include pulse shaping elements, broadband filters, and ultracompact dual band lenses with designed spectral and spatial responses. D2NNs are directly trained using error backpropagation within the diffractive layers without the need of training datasets. Moreover, when combined with adaptive loss weight algorithms, these networks achieve a more efficient inverse design of complex phase devices compared with purely data-driven neural network approaches.
In this talk, we present our work on the design, development, and experimental characterization of novel ultracompact diffractive devices based on adaptive-weight D2NN (a-D2NN). Specifically, based on the highly transparent hydrogenated amorphous silicon platform, we will introduce two-layer diffractive devices that operate over multiple visible and infrared spectral bands with designed point-spread functions (PSFs) and optimal focusing efficiency beyond the theoretical limit of single-lens devices. Moreover, we will discuss ultracompact focusing spectrometers (100μm-footprint) that achieve <10nm spectral resolution and >50% diffraction efficiency across the visible spectrum. Finally, we will introduce a-D2NN for the inverse design of hyperuniform phase plates (HPPs) and experimentally demonstrate high-fidelity image reconstruction based on fabricated 4-level diffractive devices in silicon. The flexible a-D2NN approach discussed here enables the engineering of multi-layer diffractive optical devices with targeted spectral and spatial responses for advanced multiband imaging and microscopy applications.

A New Option for Efficient Up-Conversion—Crown-Ether-Coordination Compounds Claus Feldmann; Karlsruhe Institute of Technology, Germany

Despite of a rich coordination chemistry, fluorescence is not a salient property of crown-ether coordination compounds until now. Recently, we obtained novel crown-ether coordination compounds such as EuX_2(18-crown-6), Mn_3X_6(18-crown-6)$_2$ (*X*: Cl, Br, I), and Mn_2I_4(18-crown-6), which exhibit unprecedented luminescence properties.[1] Thus, they show extremely intense emission, ranging from blue to red light, with outstanding quantum yields of 85-100%. Due to their specific structural features, some crown-ether coordination compounds exhibit intense second-harmonic generation (SHG), where the SHG-generated lines can be used for intrinsic excitation themselves.[1,2]

Mn_2I_4(18-crown-6), for instance, is able to convert infrared photons (1160-1280 nm) via SHG to green photons (580-640 nm), which are converted to orange photons (605 nm) via photoluminescence.[1] Due to the strong SHG effect and the outstanding quantum yield of the luminescence process, in sum, very efficient up-conversion from infrared light to visible light is possible. With these features, crown-ether coordination compounds can become a new and extremely promising class of compounds for up-conversion and non-linear optics (NLO).

We discuss the promising optical properties – including emission, up-conversion, and NLO effects – of the novel crown-ether coordination compounds and the theoretical and structural background of these unique compounds.

Gap-Controlled Core-Satellite Assembly Nanostructures for Efficient Broadband Photocatalytic Hydrogen Evolution Yonghyeon Kim and Sang Woo Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

The development of photocatalysts highly active in the visible-to-near-infrared light region is desired work for efficient solar energy conversion. Here, we introduce a newly designed plasmonic metal-semiconductor hybrid photocatalyst consisting of an Au core-satellite assembly and a crystalline TiO_2 shell. TiO_2 was used as a spacer to control the interparticle gaps between the Au nanocrystals to obtain the core-satellite assemblies. Following the additional growth of TiO_2 and calcination, the Au core-satellite assembly@TiO_2 core-shell nanostructures were successfully synthesized. Depending on the thickness of TiO_2, the gap distance between the core and satellite Au NCs was readily regulated in the same morphological unit. Thanks to this structural controllability, gap distance-dependent plasmonic and photocatalytic properties of Au nanocrystal assembly@TiO_2 structures were clearly elucidated.

Nanostructures possessing the smallest interparticle distances between the core and satellite Au nanocrystals showed superb photocatalytic performance under the visible-to-near-infrared light irradiation attributed to the strong plasmon coupling between the Au nanocrystals and efficient hot electron transfer from the plasmon coupling site to TiO_2.

EQ03.08.02
Spatially Resolved Dynamics of Cobalt Color Centers in ZnO Nanowires by Nanoscale X-Ray Analysis Christian T. Plass[1], Valentina Bonino[2], Maurizio Ritzer[1], Lukas R. Jäger[1], Vicente Rey Bakaikoa[2], Martin Hafermann[1], Jaime Segura Ruiz[2], Gema Martinez Criado[2,3] and Carsten Ronning[1]; [1]Friedrich-Schiller-Universität Jena, Germany; [2]European Synchrotron Radiation Facility, France; [3]Instituto de Ciencia de Materiales de Madrid, Spain

Color centers in semiconductors provide properties of great importance for quantum technologies. Their most prominent characteristics are the capability to act as qubits and to offer high quality single photon sources. A promising wide-bandgap semiconductor material for defect-related emission in the visible range is zinc oxide. Creation of color centers in zinc oxide can be achieved by doping it with rare earth elements or transition metals, such as coper, nickel, iron or cobalt. The transition metals provide particularly fast decay times and therefore fast responses. The potential of a coupling platform between single photon emitters and photonic circuits can additionally be gained by embedding such color centers into nanowires, because they provide waveguiding and a cavity for the emitted photons. Investigating the photocarrier dynamics, with respect to the local environment, in such a system is thus of great importance. We apply high spatial resolution synchrotron-based methods to evaluate how the carrier dynamics and the luminescence is influenced by the elemental composition and the local environment of cobalt centers in zinc oxide nanowires. Such systems were previously investigated by different techniques such as photo- or cathodoluminescence measurements. However, these techniques lack crucial complementary information, e.g. spatial or compositional variations of the system, respectively. Simultaneous spatially resolved measurements of the X-ray fluorescence and the X-ray excited optical luminescence provide both information at once. Our findings show an anti-correlation between the band edge emission of the zinc oxide host and the intra-3d cobalt luminescence indicating two competing recombination paths. The luminescence dynamics are temporally resolved with a streak camera providing unique insights into the different decay paths of the intra-shell luminescence of the cobalt atoms incorporated into the lattice of zinc oxide nanowires. Two different exponential decays of the cobalt-related emission are revealed. A fast and newly observed decay is attributed to a recombination cascade within the cobalt atom, resulting from direct excitation.

EQ03.08.06
Photonic Properties of Metal-Dielectric Photonic Crystal OLEDs David Allemeier, Matthew S. White, Khadga Thakuri and Thomas Cleary; University of Vermont, United States

Metal-dielectric photonic crystals (MDPCs) represent a unique class of photonic structures realized through vertically-stacked metallic OLED microcavities. The coupling of multiple microcavities results in hybridization of the cavity modes to form a band of narrow linewidth, tunable emission peaks, expressed directly though the electroluminescence spectrum of the OLEDs. The properties of the photonic band depend sensitively on the resonance states of the underlying unit cells and lie outside the effective medium regime. We discuss the photonic band structure observed in binary (two-cavity) and mono-cell MDPCs and explore the role of the metallic layers in determining the device performance. We examine trends in the state positioning, modal quality factor, and spontaneous emission enhancement as functions of the number of cavities, unit cell geometry, and material properties. The analysis is extended outside the light cone using transfer matrix simulations to discern the waveguided mode structure.

EQ03.08.10
Hydrogenated Zinc Oxide as an Alternative Low-Loss Plasmonic Material with Fano Resonance in Near-IR Samar Fawzy and Nageh K. Allam; American University in Cairo, Egypt

Low-loss plasmonic materials are of great importance due to their use in many photonic and optoelectronic devices. Doped transparent conducting oxides (TCOs) are potential alternatives to metallic plasmonic materials owing to their reduced losses and the tunability of their complex dielectric function. In this work, first-principles calculations were employed to reveal the role of interstitial hydrogen (H_i) doping in zinc oxide (ZnO) to achieve low losses and excite surface plasmon polaritons (SPPs). Three different concentrations of H_i doping (4.16, 6.25, 8.33%) were investigated. The results show that an H_i concentration as low as 4.16% achieves excellent low-loss plasmonic behavior. The fitted Drude damping parameter at 4.16% H_i doping was found to be lower than that reported for the same aluminum (Al) concentration. Finally, we numerically show that Fano resonance can be excited in near-infrared (IR) using a simple symmetric cylinder with an air hole made of hydrogen-doped ZnO placed on a pure ZnO substrate, revealing its potential use in numerous applications.

EQ03.08.12
Optimizing Up-Conversion Single-Photon Detector for Measurements of Femtosecond Time-Bin Pulse and Photon Echo Yuta Kochi[1], Yutaro Kinoshita[1], Sunao Kurimura[2], Kouichi Akahane[3] and Junko Ishi-Hayase[1]; [1]Keio University, Japan; [2]NIMS, Japan; [3]NICT, Japan

In a wide range of fields including quantum technology and quantum optics, it is important to measure single-photon-level ultraweak light in the ultrafast range. For measurements with a high signal-to-noise ratio, it is necessary to separate signals from noise in the frequency and/or time domains. However, in conventional electronic single-photon detectors (SPD) such as Si avalanche photodiode (APD) and superconducting nanowire SPD (SNSPD), the dead time and the temporal resolution were limited to 10 ns and 50 ps, respectively. Pulse-pumped frequency up-conversion single-photon detector (UCSPD) is one of the promising candidates to solve these problems. In this method, the signal and pump pulse is incident on a nonlinear crystal, and only the sum-frequency light is extracted by a bandpass filter and detected by a Si APD. By using femtosecond pulses as the pump light, the UCSPD enables dead-time-free measurements with the femtosecond-order temporal resolution. In previous UCSPD research in the ultrafast regime, however, the performance of UCSPD has not been quantitatively evaluated so far [1, 2]. Moreover, ultraweak light measurements from materials using UCSPD have also not been reported so far.
In this study, we developed a UCSPD using commercial PPMgSLT bulk crystals and optimized the experimental conditions such as the crystal length and pump power for measurements of femtosecond single-photon pulses [3]. In addition, we demonstrated the measurements of temporal waveforms of time-bin pulses and photon echo from quantum dots using UCSPD in the femtosecond range.
First, we optimized the performance of the UCSPD. Owing to the group velocity dispersion of the nonlinear crystal, the time delay between the pump and signal pulses is changed as propagating in the PPMgSLT crystal. Therefore, the temporal resolution and up-conversion efficiency strongly depend on the crystal length L. In this study, we estimated the temporal resolution to be 255, 415, 591 fs and the up-conversion efficiencies to be 6.1, 10.1, 10.2 % (the pump power of 300 mW) for L = 1, 2, 3 mm, respectively. By calculating the convolution of the pump and signal waveforms by taking into account the group velocity dispersion, we find that the experimental results of the waveforms and the crystal length dependence of the conversion efficiency can be well explained.
Next, we investigated the dependence of the pump power on the average number of photons at the detection limit. Consequently, the detection limit did not change significantly above 200 mW for any L and reached a minimum value at 300 mW. In this situation, the average number of photons at the detection

limit was 8.6, 3.3, 3.1 × 10^{-5} /pulse (L = 1, 2, 3 mm, respectively). These results indicate that L = 2 mm and a pump power of 300 mW are the optimal conditions for UCSPD. These results should be important because they provide guidelines for setting conditions for single-photon-level weak light measurements using UCSPD in the femtosecond range.
Finally, as a demonstration for the measurement of emitted light from materials, we measured photon echo light from broadband quantum memory using quantum dots. The stored light was a femtosecond time-bin signal with a pulse interval of 1 ps, which is the shortest time-bin signal measurement ever reported. This technology is expected to enable quantum communication in the femtosecond range, making possible communications that are 1,000 times faster than previous.

Acknowledgments
This work was supported by MEXT Q-LEAP (No. J PMXS0118067395), and CSRN, Keio University. The quantum dot samples were fabricated with the support of the NICT Advanced ICT Device LABO. The authors would like to thank Prof. R. Shimizu from the University of Electro-Communications for the useful discussion.

EQ03.08.14
Integration of a Superconducting Nanowire Detector into a Confocal Microscope for TRPL-Mapping: Sensitivity and Time Resolution Volker Buschmann[1], Eugeny Ermilov[1], Christian Oelsner[1], Felix Koberling[1], Jan van Willigen[2], Guy Brammertz[3,4,5] and Rainer Erdmann[1]; [1]PicoQuant GmbH, Germany; [2]Single Quantum, Netherlands; [3]Hasselt University, Belgium; [4]imec, Belgium; [5]EnergyVille, Belgium

Superconducting Nanowire Single Photon Detectors (SNSPDs) were introduced to the market in 2003 and since then have found a niche in multiple quantum optics applications, due to their outstanding properties such as fast instrument response and high quantum efficiency.[1] The high quantum efficiency is especially important for material science applications in the IR-range beyond 1000 nm, where other available single photon detectors have a low sensitivity, high dark noise, and slow time response.
We have integrated a SNSPD (Single Quantum) into a standard MicroTime 100 confocal photoluminescence lifetime microscope (PicoQuant) in order to compare the performance of different SNSPD designs with a standard IR-PMT for time-resolved photoluminescence (TRPL) measurements and imaging of a CIGS ($Cu(InGa)Se_2$) device.
While one of the used SNSPDs had a classical single mode fiber coupling to guide the light onto the sensor, the other detector was coupled by an internal multimode fiber instead[2].
We detected a significant increase in photoluminescence sensitivity of both designs compared to a standard IR-PMT, as well as a several times higher sensitivity of the multimode-fiber coupled nanowire compared to the singe-mode fiber one, in spite of comparable photon quantum efficiencies in this wavelength range for the sensor only. The increased sensitivity combined with the lower dark count rate resulted in an increase of the signal-to-noise ratio by more than 2 orders of magnitude compared to the IR-PMT.
The high sensitivity of SNSPDs combined with high temporal resolution (instrument response function of the overall system was below 100 ps) allows to identify and investigate highly quenched micrometer-sized defect sides of the thin-layer CIGS sample even at low illumination levels.

EQ03.08.15
A Near-Perfect Transmissive Metamaterial Heater for Radar Applications Young-Bin Kim, Eun-Joo Lee, Jun-Young Kim and Sun-Kyung Kim; Kyung Hee University, Korea (the Republic of)

Microwaves are used in a variety of industries including mobile communication, satellite broadcasting, aviation altitude meter, and radar sensor, depending on the bandwidth of interest. Specifically, W-band microwaves (a frequency band of 76 to 81 GHz) are used for accurate real-time obstacle detection in radar sensors of smart mobility such as autonomous vehicles and drones. A typical radar module is equipped with a protective cover and an electrical heater, which enables an automobile to navigate even in harsh environments (i.e., icy and frost conditions). However, conventional grid-shaped heaters have a trade-off relationship between microwave attenuation and temperature uniformity because these two features heavily rely on the inherent metallic characteristics of electrodes. To address this issue, we propose a metamaterial-based transparent heater as an effective route to simultaneously achieve both high microwave transmittance and temperature uniformity/electrical conductivity.
We experimentally demonstrated an electrically and thermally interconnected metamaterial-based electrical heater. A properly designed heating electrode induced artificial electromagnetic resonances and it behaves as a low-permittivity dielectric material at W-band frequencies. This enables remarkably high microwave transmission while preserving the electrical conductivity of bulk metal. We also conducted electromagnetic simulations to predict the properties of developed metamaterials and compared their simulated and measured transmission spectra in the f = 50–110 GHz range. The measured spectra were well-matched with the simulated ones; the maximum transmittance was over 90 % near 80 GHz despite the metal filling ratio exceeding 70 %, which was readily tuned by changes in structural variables. Developed metamaterial-based heaters were fabricated based on the standard semiconductor manufacturing process but can be manufactured by other scable techniques such as three-dimensional printing.

EQ03.08.17
Electro-Optical Chromophores and Polymers for Short-Wavelength NIR Applications Florens R. Kurth[1,2], Li Zhao[1,2], Tasja Schwenke[1,2], Ons Amira[1], Gao Yuqing[1], Emil Agocs[1,2], Hans-Hermann Johannes[1,2], Henning Menzel[1,2] and Wolfgang Kowalsky[1,2]; [1]Technische Universität Braunschweig, Germany; [2]Cluster of Excellence PhoenixD, Germany

With the increasing influence of photonics in communication and sensing, especially in integrated circuits, functional optical materials are at the center of this development. The ability to translate an external impulse into an optical signal and vice versa as exhibited by piezo- and elasto-optic, magneto-optic, acousto-optic and electro-optic materials is utilized in modulators, sensing resonators and beam steering devices. In the field of electro-optics (EO), which has long been dominated by periodically poled $LiNbO_3$, a shift towards specialized applications has driven demand for alternatives with differing properties. Organic electro-optic chromophores exhibit a Pockels effect through the intramolecular movement of electrons along the molecular axis in a donor-acceptor structure upon external stimuli in an electric field. As a part of composite polymer materials, they are compatible with common spin-coating and molding methods and can be integrated into waveguides. This ease of fabrication and the high electro-optical activity r_{33} when compared to $LiNbO_3$, at specific wavelengths lead to an accessible and low-voltage alternative.

Electro-optic polymer materials are developed to operate at 850 nm (shortwave infrared window) and 980 nm (Nd/YAG) which are two significant wavelengths at the shorter end of the NIR spectrum. The active component of such materials are electro optical (EO) chromophores, which are integrated in a suitable host polymer, mostly amorphous polycarbonate (APC) and poly (methyl methacrylate) (PMMA) and electro-poled to achieve parallel

orientation. A range of molecular parameters such as the dipole moment μ, hyperpolarizability β, the optical absorption and miscibility with the host polymer need to be taken into account. Due to this, the synthesis of EO chromophores is accompanied by DFT calculations which guide the main scaffold and the attachment of side groups. Chromophores with structural variations and their effect on absorption, miscibility and EO activity are shown. Through the utilization of bulky side groups, intermolecular interactions are reduced for more efficient external electro-poling. A copolymer of bulky isobornyl methacrylate and methyl methacrylate has been found to give significantly higher glass transition temperatures and temperature stabilities of the poled state alongside good miscibility. A lower refractive index compared with the more common polycarbonates opens up broader applications in waveguide cladding.

Chromophores with anchor groups have also been synthesized for covalent integration of the chromophores into polymethacrylate and polycarbonate chains. This allows for significantly more stable orientations and prevents agglomeration as the chromophores are held in place by their connection to the main chain.

EQ03.08.18
Enantiomer-Selective Molecular Sensing via Upconverted Chiral Metamaterials Byunghoon Kim[1], Kyu-Tae Lee[2], Doo-Hyun Ko[3] and Wenshan Cai[2]; [1]Princeton University, United States; [2]Georgia Institute of Technology, United States; [3]Sungkyunkwan University, Korea (the Republic of)

Chirality in Nature is a physical property that cannot be superimposable on each other. At the molecular scale, the spatial asymmetry of atomic configuration contributes to a fascinating yet dramatic difference in chemical and physical characteristics. Discriminating enantiomers via optical techniques has been primarily employed since it enables nondestructive characterization; however, enantiomers show these signatures in the ultraviolet region, which limits the versatile application for biochemical species. Here, we proposed a simple but effective method to discriminate chiral molecules via asymmetric behavior of plasmonic metamaterial, leading to the selective optical response in a nonlinear regime. The enantiomers dissimilarly interact with the plasmonic chiral metamaterial, which gives rise to a change in the circular dichroism of chiral metamaterial in the near-infrared region by chirality transfer effect. The distinction of the circular dichroism is clarified by the upconverted photoluminescence in the visible region.

EQ03.08.19
Unidirectionally Aligned Single Bottom Faceted Nanoparticle-Based Plasmonic Nanogap Structures—Design Idea, Fabrication Methods and Applications to Surface-Enhanced Raman Scattering Platform Jong-Min Lee[1], Minjun Kim[2] and Donghan Lee[2]; [1]Hallym University, Korea (the Republic of); [2]Chungnam National University, Korea (the Republic of)

The significant advantage of utilizing plasmonic nanostructures is strong light–matter interaction on the subwavelength scale. The plausibility of achieving such extreme nano-optical properties can be realized with the help of a nanoparticle-on-mirror (NPOM) system [1]. NPOMs provide highly efficient platforms in the field of nano-plasmonic sensors or energy devices, and they have emerged as strong candidate building blocks. NPOMs were optimized with gaps between nanoparticle and mirror less than 1 nm, which can yield extremely high plasmonic properties. To achieve strong plasmonic properties, the size of the active material to be coupled with the NPOMs platforms is limited to less than 1 nm. As with the simple electromagnetism example problem, the gap size and plasmonic enhancement of NPOMs are inversely proportional to each other. Due to this limitation, the use of large active materials (10 nm or larger, ex: biomolecule, quantum dots) in NPOMs resulted in low plasmonic enhancement.
Herein, we propose an unidirectionally aligned single bottom faceted NPOMs (FNPOM) nanostructure with enhanced plasmonic enhancement, even in the presence of a large gap size exceeding 20 nm. The design started with the simple idea that the relation of the distance between two parallel plane charges and the electric field strength are more gently decrease compared to point charges. Nanoparticle fabrication was performed with vacuum furnace system. Single bottom faceted sphere shape nanoparticles are fabricated under conditions where the surface tension between the substrate and the molten metal is properly balanced. The diameter of the gold nanoparticles formed is about 100 nm, and the plasmonic resonance wavelength is in visible light. FNPOM was successfully fabricated on a 4-inch substrate, and the statistical uniformity based on optical properties is within 10%. The successful demonstration of FNPOM is meaningful in confirming the critical correlation between nanoparticle micromorphology and optical properties.

Towards Integrated Barium Titanate Electro-Optic Modulators Through Epitaxial Film Growth Larissa Little, David R. Barton, Matthew Yeh, Lorena Britton, Charles Brooks, Marko Loncar and Julia Mundy; Harvard University, United States

Electro-optic modulators are a backbone of the efficient data transfer necessary for modern optical communications. These modulators directly connect a driving electric field with optical properties of a material, and allow for transforming an electrical signal to an optical signal. Modern data centers and high speed internet, as well as sensing systems, heavily rely on these devices. The electro-optic modulators are often bulk crystals with proton-exchanged or titanium-indiffused waveguides, limiting their size, speed, and efficiency. Modern developments in integrated lithium niobate on insulator enables photonic device integration akin to the integrated circuit. In this work, we explore expanding the materials palette for integrated photonic devices with thin film materials such as barium titanate.
The current industry standard for integrated electro-optic modulators are typically Silicon or indium phosphide. Here, carrier injection and dynamics of the modulation mechanism limit performance through optical absorption, operating speed, or half-wave voltage. Bulk lithium niobate devices are also used (electro-optic coefficient r33 ~ 30 pm/V), but cannot be scaled in the same manner.
We use oxide molecular beam epitaxy to grow high quality, single crystal thin film of non-centrosymmetric materials that have superior electro-optic properties. For example, barium titanate (BaTiO3) exhibits an extremely high electro-optic coefficient (r42 ~ 900 pm/V), a reasonably high band gap (> 3eV), and relatively high refractive index (n = 2.4). Additionally, previous work has shown that the ferroelectric properties of BaTiO3 vary significantly in epitaxially strained thin films. Since ferroelectric and electro-optic properties are both rooted in the crystal structure of these materials, we expect that the electro-optic properties will be equally affected by epitaxial strain.
Here we grow BaTiO3 on strontium titanate substrates, as well as on a variety of scandate substrates, to understand and characterize the impact of epitaxial stran on the electro-optic tensor of BaTiO3. Furthermore, in order to facilitate scalability and creation of devices with BaTiO3, we show our progress in transferring our thin films onto silicon substrates. This is accomplished through growth of a dissolvable interlayer between the growth substrate and the BaTiO3 that can be used to easily separate the two.

Beyond Band-Edge Lasing: Plasmonic Lattices with High-Gain Materials Teri W. Odom; Northwestern University, United States

This talk will describe access to new classes of optical modes that can provide feedback for plasmonic nanoscale lasing. We will discuss how quasi-propagating modes supported by plasmonic lattices can be used to facilitate lasing over a continuous range of discrete angles and wavelengths if the modal gain of the material is high enough. Aluminum nanoparticle lattices combined with halide perovskite nanocrystals can exhibit lasing emission from a single device with multiple beams at angles and wavelengths that depend on the gain bandwidth and lattice characteristics.

Towards Tunable Lasing in Thin-Film Lithium Niobate/III-V Cavities David R. Barton[1], Rebecca Cheng[1], Mengjie Yu[1,2], Linbo Shao[1,3], Hannah Grant[4], Leif Johansson[4], Amirhassan Shams-Ansari[1], Dylan Renaud[1] and Marko Loncar[1]; [1]Harvard University, United States; [2]University of Southern California, United States; [3]Virginia Tech, United States; [4]Freedom Photonics, United States

Thin-film lithium niobate (LN) is a promising platform for high performance chip-scale optical systems, owing to its large electro-optic effect, low-loss waveguides, and wafer scalability. An outstanding challenge for thin-film LN photonics, and many photonic platforms in general, is integration of tunable high-power, low-noise, and narrow-linewidth lasers. Integrated lasers have previously been demonstrated on LN through butt-coupling of high performance DFB lasers and heterogeneous integration of III-V gain material. Further improvements can be made through injection locking with high-*Q* rings and external cavity laser development.
Here, we demonstrate lasing action from a InP reflective semiconductor optical amplifier (RSOA) using thin-film LN as a wavelength-selective reflector. Our scheme is composed of several integrated components on 600 nm thick x-cut LN. First, we designed low-loss horn couplers to efficiency collect light from the RSOA to the LN chip. Next, we use two cascaded ring resonators with different free spectral ranges and integrated heaters to act as an active thermal filter. We purposefully overcoupled the rings (Q factors ~50,000) to reduce on-chip losses. Finally, we included a narrow-band photonic crystal to act as a partial reflector in the spectral region with the largest optical gain. Our RSOA (Freedom Photonics) emits maximum spontaneous emission at 1590 nm and small-signal gain of 25 dB. The nanofin photonic crystal has a period of 410 nm to match the stop band bandwidth with the maximum gain of the amplifier. We make the mirror partially reflective (R = 70%) by using 150 unit cells.
Our initial demonstration of lasing relies on tunability of the Vernier filter using thermo-optic shifting. We chose ring radii of 120 and 130 microns to set the Vernier FSR similar to the bandwidth of the DBR mirror. After aligning the ring resonances, we estimate the roundtrip reflection to be -17.5 dB, substantially lower than the gain provided by the amplifier. We couple the amplifier to the LN chip, forming a cavity with high reflection only at the optical mode filtered by the Vernier filters within the band gap of the DBR. With proper thermal tuning to manage the mode profiles, we find single-mode lasing over a range of RSOA injection currents from 0.1 A to 0.4 A. We measured both the LI curve and laser linewidth to demonstrate the lasing action of our device. The LI curve shows the clear onset of lasing around 0.1A and saturation above 0.3A. The maximum lasing power we achieved is -9.5 dBm, limited by the distance between the RSOA and input facet of the LN chip. Finally, we measured single mode lasing with sideband suppression ratios greater than 40 dB, and linewidths as low as 250 kHz. Finally, we will discuss progress towards active control and high power, narrow-linewidth lasing using the electro-optic effect in LN. Our results represent progress towards a tunable, robust, and low-cost integrated light source with narrow linewidth and high power, amenable for long haul telecommunication networks, data center optical interconnects, and microwave photonic systems.

8:45 AM EQ03.09.03
M-Point Lasing in Plasmonic Honeycomb Lattices Xitlali G. Juarez[1], Ran Li[1], Jun Guan[1], Thaddeus Reese[1], Richard Schaller[1,2] and Teri W. Odom[1,1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Honeycomb lattices can be defined as hexagonal lattices with a two-nanoparticle (NP) unit cell or considered as a superposition of two identical, but inequivalent hexagonal sublattices. Due to their non-Bravais nature, honeycomb NP lattices exhibit unique optical properties. For instance, honeycomb lattices have received attention for their ability to host topological edge states at the Γ and K points of photonic crystals. When the unit cell is redefined to consist of six NPs, edge states can be accessed at the Γ point of the lattice by deforming the unit cell while preserving its C_{6v} symmetry. If a honeycomb lattice is designed with a unit cell consisting of two NPs with inequivalent radii, the mirror and inversion symmetry of the lattice is broken, allowing edge states to emerge at the K points of photonic crystals. To assess the prospects of experimentally realizing topological states in plasmonic honeycomb NP lattices, a deeper understanding of their off-normal, high symmetry points is necessary. This presentation discusses the observation of band-edge states at the M point of Ag NP honeycomb lattices. Honeycomb lattices support the emergence of two surface lattice resonances (SLRs) at the M point: (1) a blue-shifted SLR_{M1} due to coupling of two distinct out-of-plane dipole resonances; and (2) a red-shifted SLR_{M2} resulting from in-plane dipole-dipole coupling. Although honeycomb lattices support two M-point SLR modes, only one mode supported lasing when organic dye solution was used as gain with the Ag NP lattices. This study demonstrates the unique coupling interactions at high symmetry points of non-Bravais plasmonic lattices.[1]

Engineering Strong Coupling in a Nano-Plasmonic Cavity Using Transition Metal Dichalcogenide Nanobubbles Thomas P. Darlington[1], Emanuil Yanev[1], Ravindra Saxena[2], Vishal Venkatesh[2], Andrey Krayev[3], Deep M. Jariwala[2] and P.J. Schuck[1]; [1]Columbia University, United States; [2]University of Pennsylvania, United States; [3]Horiba Scientific, United States

In the interaction of light and matter, strong coupling occurs when exchange between a photon and electronic transitions exceeds the relative loss rate leading to hybridization of the optical and electronic states. The behavior is well known in cavity quantum electrodynamics (QED), and is a fundamental ingredient in single photon quantum logic gates [1]. In solid-state systems, many strong coupling phenomena have been explored between different material excitations. Plasmons in particular have attracted great interest owing to their small mode volumes [2], allowing for strong coupling of a plasmon and single quasi-particles excitations such as excitons, potentially recreating in the solid-state, at the nanoscale, and at elevated temperatures many of the phenomena previously studied in traditional trapped atom QED.

Strong coupling between plasmons and excitons has been observed in excitons systems: e.g., J-aggregates [3], and colloidal quantum-dots [4-5]. While these systems offer large coupling strengths, the exciton transition energies are largely fixed, and vary randomly depend on variations in growth conditions. By contrast, transition metal dichalcogenides offer strong exciton and large tunability of exciton energy by applied strain. However, to date strong coupling between plasmons in the excitons in transition metal dichalcogenides has only been achieved in multilayer stacks[6], which have significantly weaker light emission compared to monolayers.

Building off our previous work observing quantum-dot like exciton states in nanobubbles [7], here we show signatures of strong coupling between nanobubble-localized excitons and a gap-mode plasmon mode formed between a scanning near-field optical probe and substrate. By adjusting the gap mode distance, the coupling strength and plasmon energy can be dynamically tuned. Further, by applying pressure with the nano-optical probe the emission energies of localized excitons can be adjusted. When approaching the tip to the nanobubble surface, we observed striking emission peak splitting. Comparing the energy dependence with a coupled oscillator model, we see qualitative agreement of the gap size dependence of the coupled exciton emission. Our results show the promise of engineering room-temperature strong coupling of plasmons with excitons in monolayer semiconductors for use as a model system and for building compact quantum plasmonic-photonic devices.

On-Chip Optical Dispersion Management for Femtosecond Pulse Generation David R. Barton[1], Mengjie Yu[1,2], Rebecca Cheng[1] and Marko Loncar[1]; [1]Harvard University, United States; [2]University of Southern California, United States

Dispersive materials properties are a fundamental part of any optical system, and needs to be carefully managed or compensated for in applications spanning spectroscopy, sensing, and communications. Optical pulses in particular are necessarily composed of multiple frequency components, meaning that dispersion management is vital to maintaining high peak power pulses with short time durations. Carefully engineering the dispersive properties of a nanostructured material is one way to manage dispersion in a controllable manner, and can make dispersive elements orders of magnitude smaller than using bulk materials. This offers the ability to sculpt the temporal profile of light with unprecedented control on a chip.
The ability to generate ultrashort, broadband and high-peak-power optical pulses on-chip has been a long-sought-after goal. However, all demonstrations to date rely on a table-top pulse laser source which increases the system complexity, size, and cost, and thus hinders practical applications. In addition, optical pulses can be generated via microresonator frequency comb sources through coupling a continuous-wave laser into a high-quality-factor microresonator. These devices are limited by their low efficiencies (usually <2%), comb-line power and high repetition rates. Therefore, high-power and controllable integrated pulse sources are still missing, a major roadblock for fully integrated nonlinear photonic circuits.
Here we generate femtosecond laser pulses using an integrated electro-optic time lens. Whereas a spatial lens system can focus a collimated laser beam to a spot at its focal plane, a time lens system can compress CW light to a short pulse at a proper dispersive focal length. The key components to build such a spatial/temporal lens system are an aperture, a lens which induces a quadratic phase in space/time, and a diffraction/dispersion medium representing the focal length of the imaging system. In our EO time lens, these roles are played by a single amplitude modulator, one phase modulator, and a dispersive medium (chirped Bragg grating). In the frequency domain, we generate an optical comb spectrum with a flat-top envelope. Without the dispersive medium, the pulse is 16.6 ps long.
To integrate dispersion management on-chip, we designed a chirped Bragg grating based on a nanofin photonic crystal in LN. By linearly chirping the Bragg period from 406.5 nm to 414.5 nm over a length L, we generate the desired group delay dispersion by modifying to total grating length. On a second chip with the chirped grating, we compress the pulse to its bandwidth limit. Fabry-Perot fringes in reflection show spectrally-varying FSR, which we use to compute the group delay. By varying the length of the grating we determine the optimal length for the desired GDD. The generated frequency comb still shows high power and a flat-top spectrum after compression owing to the low loss nature of the grating. Finally, the autocorrelator trace demonstrates a pulse width is 545 fs using a Bragg grating length of 2.25 mm, near the transform limited value. This represents a 25,000 times reduction in the required path length. The loss of our Bragg grating is estimated to be 0.033 dB/mm. Our results represent a tunable, robust and low-cost integrated pulsed light source with CW-to-pulse conversion efficiencies an order of magnitude higher than achieved with previous integrated sources. The novel pulse generator can find applications from ultrafast optical measurement to networks of distributed quantum computers.

Nanophotonic Approaches to Controlling Spectral and Directional Thermal Emission Aaswath P. Raman; University of California, Los Angeles, United States

Nanophotonic structures have shown great promise in controlling the spectral and directional nature of thermal emission. Yet thermal emission's intrinsically broadband and omnidirectional nature have posed a fundamental challenge in simultaneously controlling these characteristics. In this talk, we will present our theoretical, computational and experimental approaches to engineering the spectral and directional emissivity in fruitful ways. We will introduce a coupled-mode theory capable of describing highly complex emissivity from multi-resonant systems. We will also describe a tandem ResNet-based inverse design technique that allows for the design of highly complex supercell metasurfaces which exhibit tailored, multispectral emissivity responses. As an example of a system that can benefit from multiple spectral peaks, we will also describe a multi-scale Mie resonant architecture that is simultaneously ultralight and also has enhanced emissivity for novel aerospace applications. Beyond spectral control, we will next discuss our work on enabling anomalous directional control of emissivity over broad spectral bandwidths. In particular we will describe how gradient Epsilon-near-zero (ENZ) photonic structure can enable broadband directional thermal emission. We will also show experimental results on how gradient ENZ thermal emitters can be fabricated from both oxides as well as graded-doped III-V films, enabling new capabilities in the control of thermal emission.

10:30 AM *EQ03.10.02
3D Optical Metamaterials from Colloidal Nanocrystal Assemblies Cherie R. Kagan; University of Pennsylvania, United States

Colloidal nanocrystals (NCs) have inorganic cores and are commonly synthesized with organic shells. Chemical exchange of the long ligands used in NC synthesis with more compact ligand chemistries reduces the interparticle distance (*d*) and increases interparticle coupling [1, 2]. Similarly, thermal annealing can decompose ligands, reduced *d*, and drive NC fusion. We pattern 2D structures using one large-area imprint lithography step. Then, we exploit the different chemical and physical properties of NC assemblies from bulk thin films, to construct NC/bulk bilayer heterostructures that fold into three-dimensional structures upon ligand exchange and/or mild thermal annealing [3-5]. Using this simple fabrication route, we demonstrate 3D chiral metamaterials with configurable bandwidth and reconfigurable optical responses in the infrared.

Bilayer and Multilayer Moiré Plasmonic Lattices Jun Guan[1,2], Jingtian Hu[1], George C. Schatz[1] and Teri W. Odom[1]; [1]Northwestern University, United States; [2]Massachusetts Institute of Technology, United States

Plasmonic nanoparticle lattices can provide a platform for both deep-subwavelength light confinement and strong far-field scattering. However, previous studies mostly focused on how a single layer of a lattice can control the flow of light. This talk describes how bilayer and multilayer plasmonic lattices enable unique optical properties. Superimposing two or more periodic structures resulted in moiré superlattice patterns. We demonstrated that bilayer superlattices combined with dipole emitters can facilitate the engineering of light-emitting characteristics. In addition, we revealed the coupling mechanism in three-layer moiré structures.

11:15 AM EQ03.10.04
Developing Highly Nonlinear Materials and Nanostructures on the Largely Tunable ITO/TiN Platform Tornike Shubitidze, Wesley Britton and Luca Dal Negro; Boston University, United States

The engineering of the optical dispersion of thin-film transparent conductive indium tin oxide (ITO) and titanium nitride (TiN) has enabled novel nanostructured materials with largely tunable epsilon-near-zero (ENZ) behavior from the visible to the mid-infrared spectral range as well as optical nonlinearities dramatically enhanced by small refractive index values. Combined with their CMOS compatibility, these materials have been integrated into compact photonic devices and nanostructures that perform efficient nonlinear operations such as sub-picosecond all optical modulation, ultra-fast pulse shaping through frequency translation, and optical time reversal. However, the fundamental mechanisms governing their nonlinear responses remain unclear. In this talk, we use the Z-scan nonlinear optical characterization technique to systematically investigate the complex nonlinear susceptibility $c^{(3)}$ and the intensity-dependent refractive index change D*n* of ITO samples grown by RF reactive magnetron sputtering followed by post-deposition annealing. Specifically, we study polycrystalline thin films with different microstructural and crystallographic orientations and we demonstrate that post-deposition conditions can modify the crystallographic texture of ITO and further enhance the nonlinear optical properties resulting in a 30X enhancement compared to commercial ITO thin films with similar thickness and optical dispersion. Finally, we discuss opportunities to further control and enhance the optical nonlinearity of ITO using ITO/TiN multilayer stacks with controlled volume fractions, providing large tunability of both ENZ wavelengths and nonlinear responses in the 680nm-1200nm spectral range.

11:30 AM EQ03.10.05
Processing-Dependant Optical and Electrical Properties of Indium Tin Oxide Nanocrystals Thin Films Fabio Marangi; Politecnico di Milano, Italy

Transparent conducting oxides play a significant role in nowadays electronic devices. Among those, indium tin oxide (ITO) is one of the most relevant materials used for transparent electrodes. Even if the fabrication of ITO-based electronic devices in the form of thin films is mainly carried out by means of sputtering, electrically conductive films may be obtained by the deposition of thin layers of ITO Nanocrystals (NCs) through spin coating and other related wet chemistry techniques. ITO NCs films show interesting properties deriving from the plasmonic behaviour of ITO in the form of small nanoparticles. Localized plasma frequency, which occurs in the infrared, can be tuned by playing around the shape and size of the nanocrystals but also strongly depends on the percentage of doping. Electrical properties of the films are strongly influenced by the properties of the single nanocrystals and morphology of the whole film. Processing conditions during the fabrication of the devices also affect the final conductivity of the films. Electrical conductivity of a number of ITO NCs thin films has been measured as a function of thickness of the films and processingtime and temperature, both in controlled atmosphere and in presence of air. Both optical and electrical properties of the films showed to be strongly affected by annealing temperature, regardless of being processed in air or in a controlled environment leading to different outcomes. In particular, films annealed at higher temperature showed greater electrical conductivity but poor optical response in the region of interest. The opposite was observed for lower annealing temperatures. The combination of all those tests allowed the definition of a recipe for the fabrication of ITO Nanocrystals with desired electrical properties and optical response. The plasmonic response of the films can be tuned after deposition, without acting at the single nanocrystal level in terms of doping, size and shape. Even if microscopically influenced by the single nanocrystal, the properties of the system as a film show a macroscopic behaviour deriving from the nanocrystals acting as a whole.

11:45 AM EQ03.10.06
Lateral Permittivity Patterning by Ion Irradiation in CdO Thin Films for Mid-IR Plasmonics Angela Cleri[1], Mingze He[2], Joshua Nordlander[1], Joshua D. Caldwell[2] and Jon-Paul Maria[1]; [1]The Pennsylvania State University, United States; [2]Vanderbilt University, United States

Donor doped cadmium oxide (CdO) thin films demonstrate excellent optoelectronic properties, further enabled by advanced synthesis techniques such as high-power impulse magnetron sputtering (HiPIMS), which yields high quality films with easily controllable transport properties. Tunable carrier concentrations between 10^{19}-10^{21} cm^{-3} while maintaining mobilities between 300-500 cm^2/V-s facilitate low-loss plasmon polaritons spanning the mid-wave infrared (IR). Further, fabricating layered CdO structures with varying thickness and carrier density between each layer has given way to interesting nanophotonic phenomena such as multiple epsilon-near-zero (ENZ) resonances in a single structure, strong coupling between ENZ and surface plasmon polariton modes, and hyperbolic behavior in homoepitaxial structures. By controlling donor dopant levels in individual CdO layers, one controls optical

interfaces in the out-of-plane dimension. Here, we extend this principle to the in-plane dimensions by ion irradiation patterning to locally induce donor defects and achieve lateral permittivity control over relatively large areas. This method creates lateral patterns which exhibit minimal physical interfaces, yet sharp permittivity contrast. In this presentation, we will explore methods for ion irradiation and patterned masks and demonstrate lateral control of optical properties through both near-field and far-field measurements.

Properties and Control of Excitons in 2D Semiconductor Heterostructures Tony F. Heinz[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

: In this paper we will describe some of our recent progress in understanding fundamental aspects of excitons in 2D heterostructures in the transition metal dichalcogenide (TMDC) family. For many of these systems, type II band alignment is obtained in stacked layers, causing the lowest-lying optical excited state to be an interlayer exciton. Because of the static dipole moment of these charge-separated states, they are highly tunable by external electric fields, making them interesting sources with readily tunable photon energy by gating available in the visible and infrared spectral ranges. In addition, for crystallographically aligned samples, the moiré potential leads to distinctive exciton localization effects. We will present recent advances in characterizing these states, both through direct optical absorption measurements and through the use of time-resolved, angle-resolve photoemission spectroscopy (tr-ARPES). These methods give us new insight into the radiative lifetime of these states and the degree and nature of exciton localization in moiré structures. In addition to their intrinsic interest, the ability to transfer these materials and to tune them renders them attractive building blocks for integration into photonic devices using meta-materials.

2:00 PM *EQ03.11.02
Image Polaritons in van der Waals Crystals Min Seok Jang and Sergey Menabde; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Polaritons in two-dimensional materials have been attracting enormous research interest due to their deep-subwavelength field confinement enabling strong light-matter interactions. In this presentation, I introduce a new class of polaritonic modes – image polaritons - that appear when a polaritonic material is in close proximity to a highly conductive metal so that the polaritonic mode couples with its mirror image. The image polaritons constitute an appealing nanophotonic platform, providing an unparalleled degree of optical field compression into nanometric volumes while exhibiting lower normalized propagation loss compared to conventional van der Waals polaritons on nonmetallic substrates. I will cover three different mid-infrared image polaritons in van der Waals Crystals: image plasmons in graphene and image phonon polaritons in h-BN and α-MoO3.

2:30 PM EQ03.11.03
Measurement of Plasmonic Enhancement of Photoluminescence in Monolayer WSe_2 Stanislav Tsoi, Kathleen McCreary, Marc Christophersen, Hsun-Jen Chuang and Igor Vurgaftman; U.S. Naval Research Laboratory, United States

Recent experimental studies have demonstrated that coupling monolayer transition metal dichalcogenides to plasmonic cavities can significantly enhance their photoluminescence (PL). The present work aims to determine experimentally the magnitude of the plasmonic enhancement in WSe_2. Periodic arrays of gold nanodisks are fabricated using electron beam lithography on Si substrates. The localized plasmon resonance of the nanodisks is characterized using reflectivity measurements. Monolayer flakes of WSe_2 with a lateral size over 30 μm, grown by chemical vapor deposition on separate Si substrates, are transferred on top of the gold nanodisk arrays. Stretching of the flexible monolayer over individual nanodisks creates localized nanoscale regions of WSe_2 under tensile strain, separated by fully relaxed WSe_2 regions between the nanodisks. Accordingly, room-temperature PL recorded from the WSe_2 contains an emission band at 1.65 eV, characteristic of exciton recombination in the fully relaxed monolayer, as well as additional low-energy bands assigned to the strained nano-regions. The strained PL is strongly enhanced when the excitation wavelength approaches the plasmon resonance, consistent with the spatial co-location of the strained nano-regions and the localized plasmonic field. Comparison of the strained PL intensity under the excitation on and off the plasmonic resonance allows us to assess the magnitude of the plasmonic enhancement. The results obtained are in quantitative agreement with numerical simulations.

2:45 PM EQ03.11.04
Van der Waals Nanophotonics Panaiot Zotev[1], Yue Wang[2], Toby Severs Millard[3], Daniel Andres-Penares[4], Luca Sortino[5], Nic Mullin[1], Donato Conteduca[2], Mauro Brotons-Gisbert[4], Sam Randerson[1], Jamie Hobbs[1], Brian Gerardot[4], Thomas F. Krauss[2] and Alexander Tartakovskii[1]; [1]University of Sheffield, United Kingdom; [2]University of York, United Kingdom; [3]Imperial College London, United Kingdom; [4]Heriot-Watt University, United Kingdom; [5]Ludwig-Maximilians-Universität München, Germany

Nanophotonic structures enable a range of applications including optical waveguiding, Purcell enhancement of emission, low-threshold lasing and higher harmonic generation enhancement. Many research fields and technologies have benefited from nano-scale resonators and waveguides previously fabricated from high refractive index dielectrics such as silicon [1] and III-V materials [2] or noble metals [3]. While these offer a large range of opportunities for both research and technology, van der Waals materials can expand the possibilities of nanophotonics in the visible and near-infrared part of the spectrum due to high refractive indices (n>4) [4], a large range of transparency windows, nonlinear optical properties, and new fabrication possibilities exploiting intrinsic van der Waals forces enabling adhesion to any substrate or between different nanophotonic structures. In order to realize this potential, we extract the dielectric constants of a diverse set of materials including transition metal dichalcogenides (TMDs), III-VI semiconductors, and magnetic layered materials. Employing well established techniques, we fabricate nanoantennas with a range of geometries from these materials and observe Mie resonances as well as strong coupling between the excitonic features of TMDs and anapole modes with Rabi splittings up to 140 meV. After the transfer of a monolayer of WSe2 onto WS2 nanoantennas, we observe room temperature Purcell enhancement of emission [5] as well as low temperature formation of single photon emitters with enhanced quantum efficiencies within a system fabricated entirely of layered materials. Due to the weak van der Waals interactions of the nanoresonators and the substrate, we were able to employ an atomic force microscopy cantilever in the repositioning of double-pillar nanoantennas to form ultra-small optical mode hotspots as a result of the small gaps achieved (10 nm) [5]. This post-fabrication technique enables applications such as stable, low-power optical trapping of quantum emitters with Purcell enhancement factors above 150.

Dispersion-Engineered Metasurfaces and RGB-Achromatic Metalens Yao-Wei Huang[1,2], Zaoyi Li[2], Raphaël Pestourie[3], Peng Lin[4], Joon-Suh Park[2], Cheng-Wei Qiu[5], Ji-Xin Cheng[4], Steven G. Johnson[3] and Federico Capasso[2]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]Harvard University, United States; [3]Massachusetts Institute of Technology, United States; [4]Boston University, United States; [5]National University of Singapore, Singapore

In this talk, I will report our recent developments and applications of dispersion-engineered metasurfaces in millimeter-scale diameter RGB-achromatic metalens and potential for future virtual-reality platforms. We demonstrate millimeter-scale diameter, high-NA, submicron-thin, metalenses that achieve diffraction-limited achromatic focusing of the primary colors by exploiting constructive interference of light from multiple zones and dispersion engineering. We also utilize inverse-design framework for aperiodic large-scale complex meta-optics in three dimensions, which alleviates computational cost for both simulation and optimization via a fast-approximate solver and an adjoint method, respectively. To illustrate the potential of this approach, we demonstrate a future virtual-reality platforms by using our meta-eyepieces with a home-built fiber scanning near-eye display or a laser back-illuminated micro liquid crystal display.

4:00 PM EQ03.12.02
Triplet Fusion Upconversion Nanocapsules for Volumetric 3D Printing Tracy H. Schloemer[1,2], Samuel Sanders[2], Mahesh Gangishetty[2], Daniel Anderson[2], Michael Seitz[1,2], Arynn O. Gallegos[1], Christopher Stokes[2] and Daniel Congreve[1,2]; [1]Stanford University, United States; [2]Rowland Institute at Harvard, United States

Three-dimensional (3D) printing has revolutionized additive manufacturing, but the layer-by-layer process of traditional stereolithography can limit resin selection, shape selection, and material quality. One way to achieve volumetric 3D printing, where a vat of polymerizable resin is patterned by light in three dimensions, is to use triplet fusion upconversion (UC). Triplet fusion UC occurs when a sensitizer molecule absorbs low energy light and generates triplet states, which transfer to the annihilator molecules to ultimately generate an excited singlet state that emits higher energy light to initiate polymerization. To ensure excellent light penetration through the vat of resin and maintain the high sensitizer/annihilator concentrations required, the UC materials are encased in silica to generate robust nanocapsules for suspension in the resin. Fundamental nanocapsule design criteria demonstrates tunable optoelectronic and mechanical properties. By pairing upconverting nanocapsules and photoinitiators tailored to the upconverted light to commercially available printing resins, we generate prints on the centimeter scale with fine details in multiple resins. Importantly, this method uses low energy light to print, as compared to high energy lasers that directly initiate polymerization, which allows for deep light penetration into the vat of resin for volumetric 3D printing.

4:15 PM EQ03.12.03
A General Framework for Scintillation in Nanophotonics Charles Roques-Carmes[1], Nicholas Rivera[1], Ali Ghorashi[1], Steven E. Kooi[1], Yi Yang[1], Zin Lin[1], Justin Beroz[1], Aviram Massuda[1], Jamison Sloan[1], Nicolas Romeo[1], Yang Yu[2], John Joannopoulos[1], Steven Johnson[1], Ido Kaminer[3] and Marin Soljačić[1]; [1]Massachusetts Institute of Technology, United States; [2]Raith America, United States; [3]Technion–Israel Institute of Technology, Israel

Bombardment of materials by high-energy particles (e.g., electrons, nuclei, x-ray and gamma-ray photons) often leads to light emission, known generally as scintillation. Scintillation is ubiquitous and enjoys widespread applications in many areas such as medical imaging, x-ray non-destructive inspection, night vision, electron microscopy, and high-energy particle detectors. A large body of research focuses on finding new materials optimized for brighter, faster, and more controlled scintillation. Recent results have proposed scintillation enhancement relying on photonic effects, either by enhancing the rate of spontaneous emission [1], or through improved light extraction [2].

Here, we develop a general theoretical and experimental framework based on integrating nanophotonic structures into scintillators to enhance their emission, which we coin “nanophotonic scintillators” [3]. To start, we develop a unified and *ab initio* theory of nanophotonic scintillators that accounts for the key aspects of scintillation: the energy loss by high-energy particles, as well as the light emission by non-equilibrium electrons in arbitrary nanostructured optical systems and arbitrary material systems. This theoretical framework allows us, for the first time, to experimentally demonstrate nearly an order-of magnitude enhancement of scintillation, in both electron-induced scintillation (via direct enhancement of the rate of spontaneous emission by shaping the local density of states), and X-ray-induced scintillation (through improved light extraction from bulk scintillators. Beyond enhancement of the scintillator brightness, which is important from the perspective of many of the above applications, we also show how it is possible to strongly shape the spectral content of the scintillation: showing how the peak wavelength in a broadband scintillator can be changed (e.g., from green to red, for the case of self-trapped holes in silica, using high-Q resonances in photonic crystal slabs). Additionally, we show how our full framework enables us to infer the level diagram of complex defects, based on the dependence of the observed scintillation signal on the energy and flux of impinging high energy particles.

Our theory also allows the discovery of structures that could eventually achieve several orders-of-magnitude scintillation enhancement and shaping of scintillation’s optical properties (e.g. angular, spectral, polarization). The framework and results shown here should enable the development of a new class of brighter, faster, and higher-resolution scintillators with tailored and optimized performances – with many potential applications where scintillators are used.

4:30 PM EQ03.12.04
Low-Loss, Geometry-Invariant Optical Waveguides with Zero-Index Materials Danqing Wang[1,2], Kaichen Dong[1], Jie Yao[1], Jin Hong[3] and Junqiao Wu[1]; [1]University of California, Berkeley, United States; [2]Miller Institute for Basic Research in Science, United States; [3]To be updated, United States

Compared to electronic circuits, photonic chips that communicate using light offer a solution to faster computing with the potential for larger bandwidth, faster modulation speed, and lower power consumption. Miniaturization of optical elements is essential in increasing the device density for future photonic circuits, but small-scale optical waveguides based on traditional dielectrics exhibit large radiative loss to the free space when the device size approaches the diffraction limit. In addition, light scattering at the bends and crossings of curved waveguides in Si photonics leads to significant optical loss. In contrast, materials with nearly-zero refractive indices show exotic optical behavior at their interface with conventional dielectrics, which has driven applications ranging from geometry-invariant optical tunneling, nonlinear optics, optical cloaking to thermal emission manipulation.
This presentation will focus on zero-index materials as a cladding layer for low-loss and geometry-invariant optical waveguides, where electromagnetic modes are tightly confined within the dielectric core region. Unlike photonic waveguides based on conventional dielectrics, waveguides with a zero-index cladding layer show the advantage of maintaining a high mode-filling factor for small device sizes close to the diffraction limit. Such tight mode confinement is also tolerant to small permittivity variation in the zero-index materials. Because of a greater numerical aperture for waveguides based on zero-index materials, we found that light propagation is robust to bends in a small radius (~μm) and geometry variation in the cross section. We also investigated hollow zero-index waveguides that further support low-loss light propagation, where materials absorption is minimized because of the air core. Our work offers critical insights into future designs of low-loss and miniaturized photonic devices.

4:45 PM EQ03.12.05
Photonic Band Gaps in Colloidal Crystals of Chiral Hedgehogs Prashant Kumar, Alain Kadar, Kody Whisnant, Michael Veksler, Sharon Glotzer and Nicholas A. Kotov; University of Michigan–Ann Arbor, United States

Colloidal crystals are desirable for photonic bandgaps, that can be tuned by the change in periodic arrangement of particles. While spherical particles are a trivial shape to crystallize, their monodispersity determines the long-range order that is achievable [1]. Here we report the formation of colloidal crystals from spherically shaped chiral microparticles of gold-cysteine complexes [2]. These microparticles are self-assembled from twisted spikes whose length, width and twist angle can be controlled by physical-chemical parameters such as enantiomeric excess, temperature, and charge screening. Using a mixture of L- and D-cysteine we self-assemble chiral hedgehogs of diameters 1-10 μm, at temperatures of 30-90^{o} C. Machine vision algorithms reveal that 1 μm diameter hedgehogs show higher hexatic order parameter [3] as compared to larger sized hedgehogs. Using two-phase self-assembly we deposit these crystals over 1 cm x 1 cm region through controlled evaporation and study their photonic properties. Inherent chirality of hedgehogs imparts an added dimension to photonic bandgaps by their differential interaction with left- vs right-polarized electromagnetic wave. We evaluate these differences through finite element modeling and generate a band diagram for chiral colloidal crystals.

Dynamic Reflective Structural Color Pixels that Are Color Tunable and On/off Switchable via Electrochemical Metal Deposition Youngji Kim, Cheon Woo Moon and Jerome K. Hyun; Ewha Womans University, Korea (the Republic of)

For reflective color displays (e.g., colored e-reader and e-paper), the ability to tune the color within a single pixel is important for maintaining high brightness. To this end, advances in this direction have been made with dynamic structural colors. However, many designs that actively tune the pixel color across the gamut cannot produce a black color, representing the ‘off’ mode. In a few cases, the black color is produced only when the color is shifted, indicating that the color shift and intensity are coupled. This is due to the fact that the real and imaginary part of refractive index are coupled through the Kramers-Kronig relation. In this work, we demonstrate how color tuning across a wide gamut and on/off switching with high contrast can be achieved in a single reflective pixel. Our pixel consists of 1D TiO_x grating on a Pt working electrode (and reflector) within an electrochemical cell with electrolyte containing Cu ions and an ITO counter electrode. By electrodepositing Cu inside the dielectric gratings, modal interference between the primary waveguide-array modes changes to produce resonance shifts, appearing as color shifts, when viewed through a cross-polarized configuration. Different colors from resonance wavelength shifts up to ~200 nm were observed with a cathodic bias (-1.7V). Black colors were produced during electrodissolution as the Cu becomes disordered and porous by applying an anodic bias (0.7V). This results in plasmonic absorption and depolarization of the reflected light, making the pixel turn “off” with switching contrasts up to ~ 97 %. Based on these results, we demonstrate an actively tunable and on/off switchable image and 3x5 pixel array, showcasing the potential of our approach in dynamic reflective displays.

EQ03.13.03
Effect of The Temperature-Dependent Anisotropic Refractive Index on The Spectral Resonances of β-Ga_2O_3:Cr Nanowire-Based Optical Microcavities Daniel Carrasco[1], Manuel Alonso-Orts[1,2], Eva Nieto[3], Jani Jesenovec[4], Jose Maria San Juan[5], Maria Luisa Nó[5], John S. McCloy[4], Rosalia Serna[3], Emilio Nogales[1] and Bianchi Mendez[1]; [1]Facultad Ciencias Físicas de la Universidad Complutense de Madrid, Spain; [2]University of Bremen, Germany; [3]Instituto de óptica, CSIC, Spain; [4]University of Washington, United States; [5]Facultad de Ciencias y Tecnología, Universidad del País Vasco, Spain

A field of great interest for photonic applications is semiconductor micro and nanowires, since thanks to the modification of the composition of the material or the creation of artificial optical structures it is possible to control its optical properties.

A key photonic structure is the set of optical micro- and nanocavities based on distributed Bragg reflectors (DBR), obtained by periodic modulations of the refractive index in dielectric media. The creation of this type of structures in semiconductor micro- and nanowires broadens their potential applications as micro and nanoscale light sources.
Among the materials of great interest for this type of applications is gallium oxide in its monoclinic phase (β-Ga_2O_3), a transparent conductive oxide (TCO) that presents a high thermal and chemical stability and high resistance to radiation, key properties for use under extreme conditions. Its bandgap of 4.8 eV results in a transparency range from infrared to deep UV. Among the optically active dopants that efficiently emit light along this transparency range, Cr^{3+} results in an intense photoluminescence (PL) yield in the red-near-infrared (NIR) range due to its intra-ionic transitions. DBR-based optical microcavities made of Ga_2O_3:Cr micro- and nanowires show very interesting applications [1].
An analysis of the thermal dependence of the spectral resonances in such optical cavities was recently reported and applied to develop a new wide-range thermometer [1]. Spatial confinement of light within the cavity results in Fabry-Perot-type NIR-red spectral resonances, whose positions depend on temperature. This effect is mainly due to a change in the refractive index and, to a lesser extent, to a change in the length of the optical cavity. The monoclinic crystal structure results in an anisotropic refractive index, thus being necessary a detailed analysis to fully understand the optical behaviour. However, only a few previous works have been devoted to this topic in β-Ga_2O_3, therefore being still only partially understood [2,3].
In this work, the temperature-dependent refractive indices along the main axes have been obtained experimentally by ellipsometry in bulk monocrystalline β-Ga_2O_3. These results have been implemented in analytical and finite-difference time-domain simulation models of the resonances in the nanowires to further evaluate their spectral behaviour with temperature.

EQ03.13.04
Investigation of Optical Coupling in ZnO Nanowires by µ-PL Measurements Lukas R. Jäger, Francesco Vitale, Christian T. Plass, Edwin Eobaldt and Carsten Ronning; Friedrich-Schiller-Universität Jena, Germany

Semiconductor nanowires are a keystone in the miniturization of optoelectronic devices, because they bring the potential to realize compact and low power consumption nanolasers. This is due to their good waveguiding properties, high optical gain and low power consumption.
For many nanoscale applications, the evanescent coupling between two adjacent nanowires may yield interesting consequences, such as frequency selection of the Fabry-Perot modes.
In recent years the optical resonances in nanowire pairs have been investigated for Silicon nanowires, GaN nanowires and CdS nanowires for various arrangements and with disparate measurement techniques.
It is possible to set the nanowire spacing and angle, using nanomanipulation to precisely position ZnO nanowires. In this study, we used this to examine the effect of a varying overlap of the evanescent fields for a chosen nanowire pair. Performing µ- photo luminescence measurements with a pulsed 355nm laser offers three approaches: Emission spectra provide insights into mode selection, a Fourier back focal plane setup may reveal lasing coherence and intensity measurements could show changes in the lasing threshold.

EQ03.13.05
Vertically Stacked Split-Ring Resonators Derived from Block Copolymer Self-Assembly for Polarization-Sensitive Dichroic Responses Sanghoon Kim, Chunghwan Jung, Jungho Mun, Junsuk Rho and Jin Kon Kim; Pohang University of Science and Technology, Korea (the Republic of)

We realized stacked split-ring resonators (SSRRs) arrays from “pagoda-like” nanorods over a large area (~cm^2) exhibiting polarization differences in visible and near-infrared (NIR) wavelengths. The lamellar-forming polystyrene-block-poly (methyl methacrylate) copolymer (PS-*b*-PMMA) was confined in cylindrical pores of aluminum oxide (AAO) template grafted by thin neutral brush layers to create this array of "pagoda-like" nanorods. Along the nanorod direction, PS and PMMA lamellae nanodomains with 25 nm were alternately stacked. After the AAO template was removed, “pagoda-like” nanorods were generated by O_2 reactive ion etching. Silver SSRRs formed from the “pagoda-like” nanorods via oblique angle deposition (OAD) exhibit optical polarization differences due to asymmetric architectures. This method of constructing complex nanoscale architectures using block copolymer self-assembly and tilt deposited plasmonic metal could be applied to optical anti-counterfeiting, structural color, and commercial optical components in a large area.

EQ03.13.06
Towards to Fabrication of Plasmonic Conductive Nitrides by Pulsed Laser Ablation for Biomedical Applications Nikolaos Pliatsikas, Spyridon Kassavetis, Aphrodite Koutsogianni, Ilias Fekas, Stavros Panos, Tamara Odutola, Christos Kapnopoulos, Maria Gioti and Panos Patsalas; Aristotle University of Thessaloniki, Greece

Plasmonics is one of the most dynamic and fast-developing scientific and technological fields nowadays. Metal nanoparticles (NPs) with plasmonic response in the Near-Infrared (NIR) spectral range can be applied for biological applications due to the efficient absorption and heating at extremely confined volume in the vicinity of the NPs. “Traditional” plasmonic metal NPs, such as Au and Ag, fail to endure high temperatures and/or the high electric fields of NIR concentrated light, required for biological applications. We could pave the way to emerging plasmonic bio-applications by the fabrication of refractory transition metal nitrides NPs, such as TiN, whose plasmonic performance can extent into the NIR spectral range by varying their stoichiometry or via alloying to form ternary systems. The most promising route to fabricate plasmonic TiN NPs, in terms of reproducibility and ease process upscaling, is by pulsed laser ablation in solvents (LA). As the NIR plasmonics are extremely sensitive to the stoichiometry and/or doping of TiN, LA emerges as the undisputed method of choice, because the ablated NPs retain in the elemental composition of the solid target.
In this work, we present the controlled fabrication of functional refractory and stable plasmonic TiN NPs with absorption in the NIR biological window by LA. The initial targets have been developed by reactive Magnetron Sputtering at room temperature while the final shaping of the colloidal NPs was performed through a laser ablation process by the 532 nm beam of a picosecond laser system and/or by 1064, 532, and 355 nm beam of a nanosecond Nd:YAG pulsed laser system. TiN NPs structure and morphology as well as the quality of the materials have been analyzed by XRD, SEM, EDX, AFM, and XPS. The optical properties of the TiN target materials have been evaluated by NIR-Vis-UV Spectroscopic Ellipsometry, while an optical absorbance characterization was performed on the colloidal TiN NPs. The photothermal properties of these colloidal NPs have also been investigated, and preliminary biocompatibility tests have been carried out using proteins such as albumin and fibrinogen in PBS solvent.

EQ03.13.07

Lithography-Free Fabrications of Chiral Metamaterials with Twisted Micro and Nanowrinkle Patterns Based on Asymmetric Buckling Processes
Myonghoo Hwang and Bongjun Yeom; Hanyang University, Korea (the Republic of)

Chiral metamaterials can interact differently with circularly polarized lights, that is determined by their mirror-symmetric structures in three-dimension. Fabrications of the chiral structures in nano and microscales were mostly accomplished by advanced lithography techniques and wet chemical synthesis methods with bio derivatives containing innate molecular chirality. These previous fabrication methods limit wide applications of chiral metamaterials because of high cost in mass production and narrow windows for material selections. Herein, we suggest a facile and general fabrication method based on step-wise buckling processes with biaxial and asymmetric strains for twisted wrinkled patterns in chiral geometry. Soft polydimethylsiloxane substrates were utilized to be biaxially stretched in asymmetric directions. Then, the PDMS surfaces were oxidized by ozone treatment or oxygen plasma to produce hard oxide layers with different moduli from the substrates. By removing in-plane strains in stepwise manner with additional surface treatments, fusilli pasta-shaped twisted wrinkle patterns were produced on top of the substrates. Based on asymmetric angle, degree of strains and the surface treatments, the mirror-symmetric geometries of the twisted wrinkle patterns were controlled, which further utilized for fabrications of various 3D chiral metamaterials. Layer-by-Layer assembly methods for depositions of plasmonic nanoparticles and selective areal depositions over the pattern surfaces were introduced. Optical activity in wide ranges of optical frequencies from visible to THz were realized based on these chiral twisted metapatterns. It is noted that preparations of these materials do not necessitate any lithography or bio-additives, which will be advantageous for facile fabrications of chiral structures for various applications, such as advanced optoelectronic devices, bio sensors and pharmaceutical applications.

EQ03.13.08
Reflection-Enhanced Raman Detection of Single Bacterial Cells Patterned Using Capillary Assembly Joong Bum Lee[1], Minjoon Kim[1], Stefan A. Maier[2,3,4], Emiliano Cortés[4], Yeon Sik Jung[1] and Yoon Sung Nam[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Monash University, Australia; [3]Imperial College London, United Kingdom; [4]Ludwig-Maximilians-Universität München, Germany

The worldwide prevalence of bacterial infections calls for early diagnostic tools based on rapid, reliable, and accurate identification of pathogenic bacteria. Raman spectroscopy has emerged as an attractive alternative to existing detection techniques to this end, as it offers fast and direct output of molecular fingerprint information. However, an open challenge still remains for Raman detection of bacteria in terms of effectively locating and obtaining reproducible signals from single cells. Herein, we utilize capillary-assisted particle assembly (CAPA) to pattern single bacterial cells into a topographical template which provides a regular alignment of the most Raman active region of the cells as per the geometry of the patterned traps. The supporting template is composed of a highly reflective Ag/SiO_2 film which enhances the inherently weak Raman signals by reflecting the laser for re-excitation of the cells and by reflecting the downward scattered photons towards the detector. The detection platform is simple and provides highly reproducible signature spectra for different bacteria such as *Staphylococcus aureus*, *Salmonella gallinarum*, and *Escherichia coli*. Finally, CAPA is used to directly separate single cells from a suspension of biologically relevant media namely artificial urine, which helps discard additional processes required to isolate the bacteria such as centrifugation. The proposed system can potentially offer new opportunities in clinical settings that require reproducible, simple, and accurate identification of single bacterial cells.

EQ03.13.09
Graphene-Based Antenna Coupled Terahertz Detector Francisco Javier Gonzalez[1], Robert Peale[1], Michael Lodge[2], Richard Klemm[2], Masahiro Ishigami[2], Chris Fredricksen[1] and Ami Rathod[2]; [1]Truventic-University of Central Florida, United States; [2]University of Central Florida, United States

Graphene-based optoelectronic devices has drawn great interest due to its atractive electromagnetic, mechanical, electrical, and thermal properties. Unlike semiconductors graphene has no band gap, therefore can absorb photons from a wide frequency bandwidth efficiently by impedance matching. In graphene photon energy can increase its temperature significantly and due to the very stiff carbon lattice the electron-phonon interaction is weak, making cooling contribution by phonon emission very small. All these characteristics make graphene a good candidate for thermal based photon detectors. Antennas are elements that can be used either to receive or to transmit electromagnetic waves, when used in reception mode electromagnetic waves induce currents in the antenna elements that can be later detected and used for various applications. Antennas have several unique advantages such as polarization sensitivity, directivity, small footprint, tunability and the possibility of integration into electronic and photonic circuits. Antennas have been coupled to thermal detectors, such as bolometers, to increase its frequency response and incorporate some desirable characteristics of the antenna into the antenna-coupled detector, such as a specific bandwidth or polarization dependence. In this work different types of antennas coupled to graphene nanostructures will be evaluated numerically using COMSOL Multiphysics. Results will show the bandwidth, polarization dependence and responsivity of square-spiral, log-periodic and Archymedean spiral antennas coupled to graphene nanostructures, and the advantages of using each one of those antennas in terahertz detection applications.

EQ03.13.10
Laser-Induced Forward Transfer of Silk Fibroin Periodic Structure—Controlling Mid-Infrared Reflectivity Cleber Mendonca[1], Filipe Couto[1], Kelly Tasso[1], Moliria Santos[1] and Sidney Ribeiro[2]; [1]University of Sao Paulo, Brazil; [2]University of São Paulo State–UNESP, Brazil

Periodic dielectric structures offer an efficient way to control light propagation at micro- and nanoscale. Among many techniques that can produce such types of structures, femtosecond Laser-Induced Forward Transfer (fs-LIFT) is a promising one due to its ability to process different kinds of materials, preserving their integrity. In particular, Silk fibroin (SF), a natural biopolymer, can be processed by fs-LIFT to print well-ordered periodic arrays of microstructures. Due to its high transparency, biocompatibility, and possibilities of functionalization, SF is a suitable material for photonics. In this work, a 2D lattice of hemi-elliptical SF microdroplets was fabricated via fs-LIFT, and finite-element (FEM) simulations were carried out to study their response to electromagnetic radiation in the near to mid-infrared spectral region, considering the influence of the substrate. The simulation results indicated a decrease in reflectivity, which was corroborated by experimental results. In addition, coating the fabricated structures with a higher index dielectric material was shown to enhance the reduction in reflectivity in the mid-infrared spectral region. These results demonstrate a straightforward way to print ordered arrays of SF microstructures in a relatively large area, with potential application as controllable reflectivity coating for the near to mid-infrared spectral region.

EQ03.13.11
Cavity Quantum Electrodynamics on a Single Gold Nanoprobe for Biological Application Kyungwha Chung[1,2], Subin Yu[3,2] and Luke P. Lee[2,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Brigham and Women's Hospital, Harvard Medical School, United States; [3]Ewha Womans University, Korea (the Republic of)

Cavity quantum electrodynamics (CQED) is an interesting phenomena but difficult to realize. Here, we report the probe that allows strong coupling with biological molecules within a single particle. We accomplish CQED structure in a single gold double nanoring with an intrinsic nanogap of 4-8 nm. We observe topological CQED characteristics in dark-field microscopy measurements.
This CQED probe can be applied to the living cells, showing extraordinary ability to amplify biomolecular signal through strong coupling between the CQED probe and biomolecules. We believe that this 3D CQED nanocavity is a promising nanoprobe for detection of small molecules in the cells and a

platform for breakthrough biomolecular studies.

EQ03.13.13
High-Quality-Factor Dielectric Metasurfaces for Rapid Identification and Classification of Mycobacterium Tuberculosis Using Surface-Enhanced Raman Spectroscopy Baba Ogunlade[1], Loza Tadesse[2], Jack Hu[1], Sahil Dagli[1], Amy Barczak[3] and Jennifer A. Dionne[1]; [1]Stanford University, United States; [2]Massachusetts Institute of Technology, United States; [3]Ragon Institute, United States

Rapid identification of mycobacterium tuberculosis (MTB) infection and antibiotic susceptibility testing (AST) is essential for effective patient treatment, prevention of community spread, and combating antimicrobial resistance. To date, culture-based techniques remain the gold standard for the identification of TB strains and determination of their antibiotic susceptibility. Unfortunately, such identification and AST can take several days to multiple weeks in well-equipped labs, due to the slow growth rate of MTB. One promising alternative to culture-based cellular fingerprinting is Raman spectroscopy, an optical characterization technique which probes vibrational modes of a sample. It relies upon the inelastic scattering of photons incident on a sample and measures their wavelength shift after interacting with a sample. Raman scattering offers three key advantages over alternative cellular fingerprinting approaches. First, it is label-free and generalizable to all kinds of cells; the intrinsic vibrations of the cells serve as native labels. Second, Raman can be fast, with sub-second acquisition times, and accurately measured with minimal sample preparation. Lastly, because peaks in a Raman spectrum are unique to the vibrational modes of particular biomolecules, Raman cell signatures can be used to assess and monitor the composition, structure, and vitality of that cell and uniquely differentiate it from another cell. Despite these advantages, obtaining and utilizing Raman spectra from cells presents a challenge due to (1) Raman's inherently weak scattering efficiency and low signal-to-noise ratio and (2) its complexity in spectral interpretation.
To address these two issues, we present a combined nanophotonic-machine learning platform that uses resonant nanophotonic surfaces, known as high-quality factor (high-Q) dielectric metasurfaces, to provide critical Raman signal enhancement. Using FDTD simulations, we demonstrate a metasurface of subwavelength silicon nanoblocks that are biperiodic in length to generate a high Q resonance. These nanoblocks have a width of 120 nm, a biperiodic length of 430 and 400 nm, and a height of 500 nm. By tuning the nanoblocks' dimensions, we place a high-Q resonance at the Raman excitation wavelength that will be used to enhance the local electric field amplitude as well as a broad magnetic dipole Mie resonance at the MTB's Stokes-shifted Raman region to provide strong, broadband Raman signal enhancement . Collectively, these two resonances provide a maximum Raman signal enhancement of over 105 over a wide spectral range of 1500 cm-1
We fabricate these metasurfaces using electron beam lithography and experimentally verify this enhancement by placing dried MTB bacterial samples on the metasurfaces and measuring their Raman spectra. We use four unique strains of antibiotic-resistant Bacillus Calmette-Guérin (BCG), an attenuated form of Mycobacterium Bovis, as a model for Mycobacterium tuberculosis, as well as a control strain. We classify the antibiotic resistant BCG strains according to their Raman spectra using logistic regression. Specifically, we use a 80/20 train-test split, in which 80% of the data is used to train the model and the remaining 20% is held out and tested on the model in order to evaluate the accuracy of the model. Through this machine learning model, we are able to identify and differentiate the 5 BCG strains with ~98% accuracy. Through this combined nanophotonic-machine learning platform, we have demonstrated a rapid and accurate platform for bacterial identification and classification using Raman spectroscopy.

EQ03.13.14
Light Localization in Multifractal Dielectric Environments Yilin Zhu, Tornike Shubitidze and Luca Dal Negro; Boston University, United States

Multifractals are heterogeneous structures with multi-scale properties described by a continuous spectrum of fractal dimensions, i.e., the so-called multifractal singularity spectrum. In contrast to traditional fractals, or monofractals, which possess only one global scaling exponent corresponding to the fractal dimension, multifractals have a broad distribution of generalized fractal dimensions and their structural properties exhibit extreme (heavy-tailed) non-Gaussian fluctuations. While the optical properties of fractal structures are well-understood, multiple scattering, light localization and emission phenomena in multifractal dielectric environments remain to be explored. Using rigorous Green's matrix and multi-particle Mie scattering theory, in this talk we systematically investigate light-matter interactions in engineered photonic multifractal media. Specifically, we generate multifractal point patterns from random multiplicative processes with different correlation properties that interpolate in a tunable fashion between random structures, monofractals, and strongly inhomogeneous multifractals. We study photonic structures with different values of dielectric constants and analyze their spectral statistics, optical Thouless conductance, and local density of states. Our findings demonstrate that tailored multifractal dielectrics support scattering resonances with a stronger localization (i.e., smaller localization length) compared to both uniform random and monofractal systems across a broad spectrum extending from visible to infrared wavelengths. Device applications of multifractal media for the demonstration of ultracompact spectrometers and novel broadband lasers will also be presented.

Low Loss Mid-Infrared Plasmonic Waveguides—Extending the Limits of Noble Metals Mauro David, Elena Arigliani, Alicja Dabrowska, Anna Lardschneider, Masiar Sistani, Daniele Nazzari, Davide Disnan, Ismael C. Doganlar, Hanh T. Hoang, Georg Marschick, Hermann Detz, Ulrich Schmid, Bernhard Lendl, Walter M. Weber, Gottfried Strasser and Borislav Hinkov; TU Wien, Austria

Surface plasmon polaritons (SPPs) combine the high-speed capabilities of photonic circuits with the ability of plasmonic confinement below the diffraction limit. In particular, modes supported at (noble) metal/dielectric interfaces in various configurations have gained great attention owing to their prospects for attractive applications. However, considering such plasmonics as an established technology in the visible (VIS) and near-IR spectral range, plasmonic concepts in the mid-IR spectral range are still in their infancy. This significantly hampers addressing emerging mid-IR applications by chip-scale devices, e.g. in real-time liquid sensing experiments or optical free-space communication. Thus, realizing novel device concepts and introducing new materials aims at mimicking VIS/near-IR properties such as wavelength-scale mode confinement and guiding. Succeeding will enable a novel class of photonic integrated circuits (PICs) with breakthrough performance characteristics like compact chip-scale Mach-Zehnder interferometers, monolithic heterodyne detectors or on-chip logic networks. They all strongly benefit from miniaturization and the use of mid-IR wavelengths.
In this work, we surpass the limitations of traditional noble metal-based plasmonics by exploiting the approach of surface-loading using two different highly transparent mid-IR materials leading to different characteristics. In the first part of this work, we introduce, supported by finite element (FEM) simulations, a new concept of semiconductor-loaded SPPs (SLSPPs), resulting in experimental low-loss, ultra-broadband waveguides covering a full octave between 5.6 µm and 11.2 µm. This is obtained by depositing thin Ge-slabs on a gold layer supported by a Si substrate, allowing to couple and confine mid-IR photons on the wavelength-scale to the chip-surface and efficiently guide them for a few millimetres. Germanium combines multiple advantages including broadband transparency, i.e. low loss, characteristics throughout the mid-IR spectral range, well-known interface characteristics and fabrication protocols from its decades of use in micro- and nano-electronics as well as CMOS compatibility. Its refractive index profile allows the realization of Ge/Au SLSPP waveguides, where >95% of the mode are guided in the surrounding medium, making it highly suitable for monolithic chip-scale liquid spectrometers. Moreover, we exploited previous work on combining high-k dielectrics like HfO_2, Al_2O_3 and ZrO_2 with Ge for stabilizing its surface-oxides GeO_x. We demonstrate that 10 nm of atomic layer dielectric deposition protects our Ge/Au SLSPP waveguides from being etched in normal water. This opens the pathway towards bio-sensing applications, where water is the most relevant background matrix.

In the second part, we show a novel fabrication technique for spin-coating high-quality polyethylene (PE) films as well as their processing into micrometre-

thick ridges to efficiently confine and guide mid-IR plasmons along the chip surface. In this way, we find a new path to extend the concept of so-called dielectric-loaded SPP (DLSPP) structures to the mid-IR and beyond, based on the broad transparency window (2-200 µm) of this material. Therefore, PE can play a similarly important enabling role in the mid-IR as PMMA does at shorter wavelengths.

We show the design (including FEM-simulations), fabrication, and optical characterization of such PE-based DLSPP waveguides. This includes the first experimental demonstration of SPPs in PE-based mid-IR plasmonic waveguides. They show capabilities in directing the mode along the chip surface in low-loss straight waveguides and very importantly also adiabatic S-shaped bends (50 µm bending offset along 120 µm waveguide length) with extracted bending losses of <2.5 dB per bend.
Overall, we show for both types of presented waveguides (SLSPP & DLSPP) total losses of significantly below 20 dB/mm together with their broadband mid-IR plasmonic operation.

EQ03.13.17
Tilt-Rotate Evaporation Colloidal Lithography for Large-Area Nearly-Monodisperse Metasurfaces MaCayla Caso, Michael G. Benton and Kevin M. McPeak; Louisiana State University, United States

Colloidal lithography (CL) has become a key fabrication technique for metasurfaces due to the method's low cost and scalability. Multiple types of structures are fabricated from CL, such as nanohole and nanodot arrays. Controllability of shape, pitch, and size of the features is necessary to tune the optical response of the metasurface. CL allows this control by utilizing assembled colloids as an ordered mask that can be plasma etched to achieve the desired features. Although CL allows for large-scale fabrication the resulting structures are limited in their minimal feature size and uniformity. Reducing the diameter of the polystyrene sphere mask by plasma etching unavoidably increases their coefficient of variation (CV) and deforms their shape, thereby limiting the pitch-to-hole-diameter ratio of the resulting nanohole array (NHA) to less than 3:1 and the minimum hole size to 200 nm with a 10% or better CV. While there has been extensive research on improving the average diameter and defect density in CL derived NHAs, little work has been done in reducing the polydispersity of the hole diameters in the NHAs, especially in the sub-200 nm diameter range.
We show that a modified CL method, tilt-rotate evaporation colloidal lithography (TRE-CL), breaks the trade-off between hole diameter and polydispersity by leveraging glancing angle evaporation, not plasma etching, to adjust the hole size. [1] TRE-CL allows pitch-to-hole-diameter ratios as high as 7:1 and nanohole diameters down to 60 nm while maintaining a nearly constant CV below 10% and hole circularity above 91%. Furthermore, we transfer these hole arrays into ultrathin Si_3N_4 films to fabricate adhesion-layer-free plasmonic Au nanodot arrays down to 70 nm in diameter with 10% CV embedded in Si_3N_4. TRE-CL allows for large-scale fabrication of uniform metasurfaces quickly and at a low cost while achieving periodic features in the critical 50 – 200 nm regime.

Large Area Flexible Terahertz Textile Metamaterial Ruben Del Rio Ruiz[1], Aydin Sadeqi[2] and Sameer R. Sonkusale[1]; [1]Tufts University, United States; [2]Georgia Institute of Technology, United States

The terahertz and millimeter wave band of the electromagnetic spectrum has been underdeveloped due to the lack of naturally occurring materials that respond at these frequencies. Artificially designed metamaterials offer to fill this terahertz gap by engineering constituent resonant unit cells in large periodic or quasi-periodic arrays. In fact terahertz metamaterials have been developed to demonstrate quite unique properties, such as perfect absorption, amplitude modulation, imager, spatial light modulation, beam steering etc.[1-6] However, current approaches to realizing metamaterials is limited in size to few centimeters and are always rigid due to reliance on expensive cleanroom fabrication process. To truly revolutionize the field of devices that exploit terahertz-matter interaction, we need approaches that allow for large area (meters) metamaterials with arbitrary flexibility and stretchability. Towards that goal, the utilization of common fabrics and advanced textile processing such as stitching or embroidering to design flexible stretchable metamaterial devices on them adds a new dimension enabling terahertz applications. This work presents a millimeter wave and terahertz metamaterial fabrication process on a textile substrate. The fabrication process employs commonly available materials such as pure copper polyester taffeta fabric (PCPTF), thermally activated adhesive mesh, paper adhesive sheets and polyester cotton-based fabric processed using modified textile processing. The material options can be easily expanded to other textile materials in the future. The fabrication process is based on a combination of thermally adhering different materials, laser cutting the metamaterial pattern and peeling the fiducial conductive layer from the final design. A fabrication accuracy down to 0.7mm was easily achieved. It was reproduced eleven times to validate the proposed construction process. The measured average values of the transmission coefficient, and resonance frequency of the designed metamaterial absorbers were 0.09 and 88GHz, respectively. Moreover, the standard deviations of measured transmission coefficient, and resonance frequency equal 0.05 and 0.9GHz, respectively. Interestingly, we realized large area patterns exceeding 10s of centimeters easily, achieved for the first time in literature at these frequencies. These results confirm that novel process flow employing a combination of laser processing, screen printing and textile processing allows realization of large area textile terahertz metamaterials. This will open up new avenues for applications of terahertz metamaterials for the first time.

EQ03.13.20
Filterless Infrared Chemical Sensing with Narrowband Thermal Emitters Thiago S. Arnaud[1,2], Guanyu Lu[2], Mingze He[2], Ryan Spangler[3], Joshua

Nordlander[3], Jon-Paul Maria[3] and Joshua D. Caldwell[2,4]; [1]University of Florida, United States; [2]Vanderbilt University, United States; [3]The Pennsylvania State University, United States; [4]Sensorium Technological Labratories, United States

A plasmon polariton is a quasiparticle made from the coupling of a photon with coherently oscillating free charge carriers. A TAMM plasmon mode couples a surface plasmon polariton (SPP) with a distributed Bragg reflector (DBR) that provides a significant reduction in the spectral linewidth of the resonant absorption/emissivity. While this had been demonstrated for thermal emitters and absorbers previously, the periodic nature of the DBR restricted the passbands to a single frequency, while the noble metals employed as the SPP material limited the tunability of the design. Building on prior efforts from our group where we illustrated that an aperiodic DBR with frequency tunable cadmium oxide as our SPP layer can provide a multifrequency, broadly tunable emitter, here, we employ such structures for demonstrating novel gas sensing modalities. We implement a machine-learning algorithm to inversely design the structure of the aperiodic DBR and the carrier concentration of the doped CdO, an n-type semiconductor that we use as the conductive layer to support the TAMM plasmon to optimize the structure for a given spectrum. Due to the tunability of these structures, they can be designed for narrow absorption and thus, thermal emission peaks at an arbitrary spectral position, linewidth and amplitude. This attribute allows for the design of selective infrared sources for chemical sensing, which targets the emission to match the vibrational mode of a desired molecule. Commercially, chemical sensing techniques are typically limited to one target molecule per device due to the dependence of a bandpass filter that is required to eliminate other frequencies where molecular absorption would limit the chemical specificity of the device. Currently, there has not been any successful efforts in discriminating between molecules of nearby vibrational modes without the use of a bandpass filter. By implementing a TAMM-emitter-based sensor, we demonstrate its viability for filterless non-dispersive infrared sensing, while maintaining the ability to also discriminate the response from other molecules. Here the target molecule was CO_2. The vibrational mode of CO_2 however spectrally overlaps with the absorption of CO, making discrimination between the gases challenging in non-spectroscopic methods (e.g. NDIR). A TAMM emitter was designed, fabricated, and tested to achieve CO_2 sensing, with ppm sensitivity, while maintaining its capability to successfully discriminate from the presence of CO gas without the need for an additional bandpass filter. From plotting the ratio of power decrease due to gas absorption as a function of concentration, the TAMM demonstrated higher sensitivity for concentrations of CO_2 than a blackbody with a bandpass filter, while providing the potential for new functionality, such as the ability to incorporate multiple gas sensors within a single platform.

Advancing Photonic Design and Quantum Photonics with Machine Learning Alexandra Boltasseva; Purdue University, United States

Discovering unconventional optical designs via machine-learning promises to advance on-chip circuitry, imaging, sensing, energy, and quantum information technology. In this talk, we discuss photonic design approaches and emerging material platforms for showcasing machine-learning-assisted topology optimization for optical metasurface designs with applications in thermophotovoltaics, reflective optics, and lightsail technology. We demonstrate the effectiveness of autoencoders for compressing the vast design space of metasurfaces into a smaller search space. By employing global optimization via adjoint methods or quantum annealing, one can find the optimal metasurface designs within the smaller space constructed by the autoencoder. The quantum-assisted machine learning framework, named bVAE-QUBO, presented in this work is the first demonstration of a generic machine learning framework that compresses an arbitrary continuous optimization problem into an Ising-model formalism for quantum sampling. When compared to other global optimization techniques, bVAE-QUBO has the potential for quantum speedups and achieving higher quality designs than traditional adjoint optimization methods. The techniques employed in this work extend well beyond the metasurface optimization space and into many inverse design problems for engineering and physics.

9:00 AM EQ03.14.03
Highly Uniform and Indistinguishable Scalable Single Photon Source Arrays—Towards Quantum Optical Circuits Qi Huang[1], Jiefei Zhang[1], Swarnabha Chattaraj[1], Lucas Jordao[1], Siyuan Lu[2] and Anupam Madhukar[1,1,1]; [1]University of Southern California, United States; [2]IBM Thomas J. Watson Research Center, United States

In the field of quantum information processing, realization of integrated quantum optical circuits towards quantum communication, quantum sensing, quantum cryptography, and quantum computation has been a long-sought goal. The biggest obstacle towards achieving such a goal is the lack of an ordered scalable array of on demand single photon sources (SPSs) having sufficient spectral uniformity, near unity brightness, single photon purity and indistinguishability meeting functional requirement for specific applications.
In this talk, I will present our continued study of a unique class of mesa top single quantum dot (MTSQD) in an ordered array[1-3], which is grown using the substrate-encoded size reducing epitaxy (SESRE) approach where surface curvature induced surface stress gradient is exploited as the driving force to have adatoms preferentially migrate from mesa side wall towards pre-patterned nanomesa top. The planarized GaAs/$In_{0.5}Ga_{0.5}As$ MTSQDs grown in a 5x8 array is shown to have high spectral uniformity with standard deviation σ_λ~2.8nm, within the local wavelength tunning range to bring different MTSQDs into resonance with each other. The highly spectrally uniform MTSQDs show near unity internal quantum efficiency, high single photon purity >99% ($g^{(2)}(0)$~0.015), and high two-photon interference (TPI) visibility of 0.83±0.03 (measured at 11.5K without Purcell enhancement) [4]. The TPI visibility is limited by phonon induced dephasing and can reach ~0.92 at 4K. The TPI visibility can be further improved to approach unity with MTSQDs integrated with appropriate photonic structure to provide Purcell enhancement. The reported TPI visibility is one of the best reported amongst various site-controlled QDs [4]. The MTSQDs also show highly uniform behavior in single photon emission purity and TPI visibility. Statistics on these will be discussed. Further work on establishing MTSQDs uniformity across larger arrays, i.e 10x10 and 50x50 is underway.
Such planarized MTSQDs in an ordered array with near unity quantum efficiency, single photon purity, and indistinguishability, provide a highly promising platform towards realizing quantum optical circuits in a horizontal architecture using well established monolithic or hybrid integration approach that enable on-chip multiphoton interference and entanglement towards various quantum information applications. Work on the integration of MTSQDs to light manipulation units using waveguide and 2D photonic crystal approach is underway.

Exciton-Polaritons in Two-Dimensional Ruddlesden–Popper Perovskites Strongly Coupled with Plasmonic Lattices Jeong-Eun Park[1,2] and Teri W. Odom[2]; [1]GIST, Korea (the Republic of); [2]Northwestern University, United States

Strong coupling between light and matter can produce hybrid eigenstates known as exciton-polaritons. Although polariton dynamics are important photophysical properties, the relaxation pathways of polaritons in different coupling regimes have seen limited attention. This paper reports the dynamics of hybridized states from 2D Ruddlesden-Popper perovskites coupled to plasmonic nanoparticle lattices. The open cavity architecture of Al lattices enables the coupling strength to be modulated by varying either the lead halide perovskite film thickness or the superstrate refractive index. Both experiments and finite-difference time-domain simulations of the optical dispersion diagrams showed avoided crossings that are a signature of strong coupling. Our analytical model also elucidated the correlation between the exciton/plasmon mixing ratio and polariton coupling strength. Using fs-transient absorption spectroscopy, we found that both the upper and lower polaritons have shorter lifetimes than the excitons and that polaritons can show faster excited state dynamics when they have access to additional energy transfer channels.

10:45 AM EQ03.15.03
Plasmon-Exciton-Polaritons from Nanoparticle Lattices Strongly Coupled to Metal–Organic Framework Ligands Alexander D. Sample, Jun Guan, Jingtian Hu, Thaddeus Reese, Charles Cherqui, Jeong-Eun Park, Francisco Freire Fernandez, Richard Schaller, George C. Schatz and Teri W. Odom; Northwestern University, United States

Strong coupling between light and matter has received significant attention for its interesting fundamental properties and diverse applications. Despite the breadth of work done in this field, the systems capable of achieving strong coupling are still relatively limited. To continue to diversify polariton work, new excitonic materials and cavities must be developed. Surface-mounted metal-organic frameworks (MOF) with a porphyrin-based ligand were synthesized on top of Ag nanoparticle lattices. Angle-resolved transmission measurements of the coupled system reveal a lower energy polariton mode with signature avoided crossing at the exciton energy. With modeling, the upper polariton was predicted and estimated to have a Rabi splitting of 110 meV. By changing the refractive index of the solvent in the MOF, the plasmon energy could be tuned and thus the coupling strength could be controlled from the strong to weak regime. Transient absorption spectroscopy showed that the lower polariton decays rapidly at <500 ps scales, but at later times scales, the decay is slowed by energy transfer from the upper polariton. This work highlights MOFs as an effective molecular exciton and plasmonic lattices as an accessible open cavity for strong light-matter coupling.

11:00 AM EQ03.15.04
Nanostructured Isolation Layer for Enhanced III-Nitride Photonics Performance Ganapathi Subramania[1], Nicholas Karl[1], Keshab Sapkota[1], Zachary Meinelt[1], George Wang[1], Igal Brener[1], Elizabeth Delong[2] and Daniel Feezell[2]; [1]Sandia National Laboratories, United States; [2]The University of New Mexico, United States

Operation in the visible and ultraviolet frequencies are enabled by III-nitride based nanophotonics that are important for many applications like solid-state lighting, lasers, flat optics and quantum information science. A low refractive index interface cladding region between the high refractive index substrate GaN and the active layer enables the confinement of electromagnetic field in the active layer leading to superior performance. While there are some examples in III-nitrides of low threshold lasing in nanowire array geometry photonic crystals [Sci. Rep. **2013**, 3, 2982] achieving simple optical isolation for membrane PhCs, metasurfaces, and VCSEL structures has been a challenge. In silicon photonics, natural oxide (SiO_2) provides such isolation from the substrate and similarly in III-V semiconductors active GaAs region can be isolated from the substrate by oxidizing an $Al_xGa_{1-x}As$ buffer layer with high Al content. The oxidized $Al_xGa_{1-x}As$ has lower refractive index (~ 1.7) than GaAs (3.5). Since GaN and other III-nitrides do not possess naturally low refractive index oxide other approaches are required to address this challenge. A nanoporous layer with an effective low refractive index formed by electrochemical etching in a highly doped layer of GaN shows to be a promising approach [App. Phys. Lett. **2018**, 112, 041109]. Here we will discuss achieving optical substrate isolation in III-nitride nanowire array-based resonators using electrochemically etched nanoporous layer as well as creating an undercut layer below the active layer. Optical reflectance characterization of the nanowire resonators exhibits the emergence of distinct magnetic and electric dipole resonances depending upon the refractive index of the isolation layer which can be used to characterize the refractive index of the isolation layer.
Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

11:15 AM EQ03.15.05
Can Organic Conjugated Polymers, Despite Their Broad Excitonic Linewidth, Serve as Materials for Strong Plasmon-Exciton Coupling? Christopher E. Petoukhoff and Deirdre M. O'Carroll; King Abdullah University of Science & Technology (KAUST), Saudi Arabia

Conjugated polymers are organic molecular semiconductors that are unique materials for next-generation thin-film optoelectronic devices. Because of their low dielectric constant, conjugated polymers support highly localized Frenkel excitons, which have binding energies of over a few hundred meV. These Frenkel excitons are particularly interesting for coupling with light because of their stability at room-temperature, imbuing the polymers with large absorption and emission cross-sections. This makes conjugated polymers particularly suitable for flexible photovoltaic and light-emitting devices, and have

potential for exotic physics such as Bose-Einstein condensation and low-threshold lasing of exciton-polaritons.

When considering plasmon-exciton interactions, the strong coupling regime can be achieved when the rate of energy exchange between the plasmon and exciton exceeds the decay rates of the individual oscillators. When this occurs, the two oscillators hybridize to form new light-matter quasiparticles, called plasmon-exciton polaritons, which have two distinct energies separate from the initial oscillators. This is typically observed when the splitting energy between the two polariton modes exceeds the linewidth of the individual oscillators. Therefore, conventionally, it has been assumed that to achieve strong plasmon-exciton coupling, it is necessary to have narrow plasmon and exciton linewidths.

Plasmonic nanostructures have been employed as an architecture for enhancing light-trapping in conjugated polymer-based solar cells, leading to up to 2-fold enhancement in device efficiencies [1]. When incorporating plasmonic nanostructures into conjugated polymer devices, there have previously been signatures of strong light-matter interactions observed, such as strong splitting in the scattered-light spectra [2,3] and enhanced absorption at the red-edge of the polymer's absorption band. But, is it possible for conjugated polymers, with their broad excitonic linewidths, to serve as materials for strong plasmon-exciton coupling?

Here, we explore two systems to investigate the nature of light-matter interactions between surface plasmons and excitons in conjugated polymers: 1) conjugated polymer-coated Ag plasmonic metasurfaces [2,3] and 2) Ag-conjugated polymer core-shell nanoparticles [4]. We employ dark-field scattered light spectroscopy, finite-difference time-domain simulations, and analytical Mie theory calculations to evaluate the spectroscopic nature of plasmon-exciton coupling. We investigate a range of different conjugated polymers, including P3HT, PCDTBT, and PTB7, as well as model conjugated polymer systems based on vibrationally-dressed Lorentzian oscillators, modified by Frank-Condon factors. We show that conjugated polymer-coated Ag plasmonic metasurfaces exhibited a splitting energy of >1700 meV, far exceeding the linewidths of either the plasmonic metasurface or the conjugated polymer. We predict that for Ag-conjugated polymer core-shell nanoparticles, there exist many conditions to achieve strong coupling by varying different parameters of the Lorentzian oscillators. Finally, we demonstrate the application of these strongly coupled plasmon-exciton polaritons to improve the absorption and carrier generation in hybrid organic-2D mixed-dimensional photovoltaics [5].

Understanding the Confinement Factor—Shaping Light to Optimize Optical Gain Marianne Aellen and David J. Norris; ETH Zurich, Switzerland

Photonic integrated circuits utilize waveguides to route electromagnetic signals. To amplify these signals, a gain material must be included. In this case, design optimization requires the relationship between amplification and waveguide geometry to be understood. The confinement factor links the gain experienced by the guided mode to the geometry-independent amplification strength of the gain material. Several expressions for the confinement factor have appeared in the literature. Unfortunately, not all of these expressions apply to strongly confined waveguide modes, which are desired in miniaturized optical components. Here, we elucidate the most general description of the confinement factor. Further, we clarify which simplifications have led to other formulations. While related to confinement, these are not generally applicable to the determination of the amplification of a guided mode. Using two numerical examples, we demonstrate the validity and limitation of various expressions of the confinement factor. In high-index-contrast or metallic waveguides, it is typically found that the confinement factor exceeds unity. This counter-intuitive result can be explained by a slowdown of the guided light. Only the general expression of the confinement factor can capture this behavior. Our discussion here provides the necessary understanding to correctly employ the confinement factor for optimization of designs in nanophotonics and plasmonics.

Ultrafast Magnetism Enabled by Nanoplasmonics Alexandre Dmitriev; University of Gothenburg, Sweden

The quest to improve the density, speed and energy efficiency of magnetic memory storage has led to the exploration of new ways of optically manipulating magnetism at the ultrafast time scale, in particular in ferrimagnetic alloys. While all-optical magnetization switching is well-established on the femtosecond timescale, lateral nanoscale confinement and thus the potential significant reduction of the size of the magnetic element remains an outstanding challenge. Thus magnetic memory combining plasmonics and magnetism is poised to dramatically increase the bit density and energy

efficiency of light-assisted ultrafast magnetic storage, thanks to nanoplasmon-driven enhancement and confinement of light [1]. I highlight several recent examples from our work, were we employ plasmon nanoantennas to either funnel electromagnetic energy into ferrimagnetic films assisting the demagnetization at the nanoscale [2], or to build hybrid plasmon-ferrimagnet nanoantennas forming magnetophotonic surface crystals [3,4]. The produced robust magnetophotonic architectures could serve as the building blocks for plasmon-assisted all-optical magnetization switching technology in ferrimagnetic rare earth – transition metal alloys that are the prime candidates to realize in practice femtomagnetic memory storage. In addition, the produced platforms could help realizing the conceptually new high-resolution light incidence direction sensors or systems with multistate ultrafast demagnetization states, potentially opening up for so-far-unforeseen nanomagnetic neuromorphic-like devices operating at femtosecond timescales controlled by light.

Synthesis of Chiral Plasmonic Gold Nanoplates with Broad Chiroptical Activity Eunjeong Jo, Sang Won Im and Ki Tae Nam; Seoul National University, Korea (the Republic of)

Plasmonic chiral nanostructure provides a novel route for extraordinary optical properties such as negative refractive index and light polarization control, and has drawn significant attention in various fields. The symmetry of chiral nanostructures such as helix, gyroid, and the irregular tetrahedron is deeply correlated to chiroptical responses and thus represents an important design parameter. Recently, we demonstrated a new pathway for facile synthesis of the chiral plasmonic nanoparticle by controlling the symmetry of gold nanoparticles utilizing enantioselective interactions on surface kink sites. Particularly, 432 symmetric helicoid nanoparticles were synthesized by breaking the mirror symmetry in single crystalline gold nanoparticles with 4/m 3 2/m symmetry. Here, we aimed to extend further the chiral symmetry of gold nanoparticles and their chiroptical properties. The symmetry of gold nanoparticles can be modulated from that of crystal lattice by inducing single or multiple twin planes in seed nanoparticles. We successfully synthesized chiral gold nanoplates with 3-fold symmetry by using triangular and hexagonal seed nanoplates with 3 2/m symmetry. Chiral gold nanoplates have great significance as they show optical activity in a wide range, from vis to NIR region. This approach provides insight into the changes in optical properties of the gold particles depending on symmetry and can be extended to a material platform for developing next-generation telecommunications and optical devices such as sensors and lidars.

Scalable, Angle-Insensitive Structural Color Printing Using Refractory Metals for High-Temperature Applications Margaret A. Duncan[1], Landin Barney[2], Mariama Rebello Sousa Dias[2] and Marina S. Leite[1]; [1]University of California, Davis, United States; [2]University of Richmond, United States

Structural color systems are growing in popularity due to their myriad of applications ranging from sensing to selective absorption. However, typical structural color devices require nanopatterning, which is difficult to scale up and can have negative environmental effects, or complicated many-layer geometries, which require multiple fabrication steps to achieve their vivid coloration. We utilize the oxidation of several sputtered refractory metal thin films at high temperatures (600°C) to produce four unique three-layer Fabry-Perot-type resonators which each offer vibrant colors with only two fabrication steps: MoO_3/Mo/Si (Purple), RuO_2/Ru/Si (Pink), Ta_2O_5/Ta/Si (Yellow), and WO_3/W/Si (Teal). These optical devices have the added benefit of being thermodynamically stable up to 700°C in an inert environment, making them ideal for high-temperature structural color applications. We heat these samples utilizing *in situ* ellipsometry, allowing very precise control over the thickness of the oxide layers *via* real-time sample characterization during high-temperature oxidation. In addition, we simulate the expected absorption spectra for different thicknesses of the two thin-film layers to determine the full range of colors each material combination can produce, showing that a wide area of the color gamut is accessible for these samples utilizing layer thicknesses of 10 – 100 nm. A detailed and quantitative analysis of the optical response of all refractory metals and their respective oxides will be presented. Our approach of using metals and dielectrics based on refractory metals offers a promising new avenue for structural color fabrication, requiring a single sputtering fabrication step that enable vibrant colors across a large portion of the color gamut.

K-Space Hyperspectral Imaging of Photonic Devices and Metasurfaces by a Birefringent Common-Path Interferometer Armando Genco[1], Cristina Cruciano[1], Matteo Corti[1], Kirsty McGhee[2], Benedetto Ardini[1], Luca Sortino[3], Ludwig Hüttenhofer[3], tersilla virgili[1,4], David Lidzey[2], Stefan A. Maier[3,5,6], Andrea Bassi[1], Gianluca Valentini[1], Giulio Cerullo[1] and Cristian Manzoni[1,4]; [1]Politecnico di Milano, Italy; [2]The University of Sheffield, United Kingdom; [3]Ludwig-Maximilians-Universität München, Germany; [4]CNR, Istituto di Fotonica e Nanotecnologie, Italy; [5]Monash University, Australia; [6]Imperial College London, United Kingdom

Optical microcavities and metasurfaces feature distinctive polarization-dependent energy-momentum dispersions, whose determination is crucial for a broad range of fundamental studies and applications. Planar microcavities confine photons in resonant optical modes, created as a consequence of the out-of-plane constructive interference condition for electromagnetic (EM) waves travelling through the cavity, with a resonant wavelength strictly dependent on the viewing angle. More recently, high refractive index semiconductor nanoresonators have shown optical Mie-resonances in the form of interference of electric and magnetic multipoles, such as the non-radiative anapole excitation, which can also lead to high light confinement within the resonator. Fourier-plane microscopy is a powerful tool for measuring the angular optical response of such devices. The information about the energy-momentum dispersion of such samples can be accessed by exploiting the propagation properties of the EM field through a lens. In fact, when an object is placed in the focus of a lens, the spatial Fourier transform of its field is formed at the lens back focal plane. The momentum space (or k-space) intensity profile can therefore be obtained by imaging a microscope objective back-focal plane on a two-dimensional detector, instead of the object plane. This imaging technique is able to

provide good angular resolution over a wide field of view, but typically losing the spectral information, since it integrates the light intensity over a broad wavelength range. The measurement of the spectrum for each point of the k-space can be then carried out upon insertion of a dispersive spectrometer in the imaging system and using a scanning lens, spanning through the angular field-of-view. However, the intrinsically high losses introduced by the spatial filtering and the dispersive elements impose tedious and alignment-sensitive scans.
In this work, we combine the concept of Fourier-transform hyperspectral imaging, which provides simultaneously a spectrum of the transmitted/reflected/emitted light for each pixel of the image, with k-space microscopy. To this aim, we exploit a common-path birefringent interferometer, placed in the detection path of our microscope, which generates two delayed replicas, whose interference pattern is measured as a function of their delay. The Fourier Transform of the resulting interferogram yields the intensity spectrum as a function of the wavelength for each point of a wide angular field-of-view. Using our technique, we obtain a complete angle- and wavelength-resolved analysis of the samples in just one measurement, with a high throughput. We optimized the technique to get an angular resolution of 0.3°, while ensuring a spectral resolution of less than 0.1 nm in terms of peak shift and 3 THz (4 nm at lambda=635nm) in terms of peak broadening. In order to demonstrate the capabilities of our technique, we measured the energy-momentum dispersion of complex nanostructured devices. We reconstructed a full 3D map of the dispersion of an organic planar microcavity in the energy-momenta space, clearly evidencing also the polarization dependent behaviour of the resonant cavity modes, owing to the polarizing elements present in the interferometer. Furthermore, we apply our technique for the characterization of a dielectric nanostructured metasurface consisting of an array of GaP nanodisks, revealing an anapole mode with unusual polarization-dependent angular and spectral behaviour. The angular dependence observed for different polarizations is in very good agreement with the results of finite differences time domain simulations. Our approach provides a complete optical characterization of materials and devices with complex angle/wavelength-dependent properties, fundamental for future developments in the fields of topological photonics and optical metamaterials.

Rapid Bacterial Identification and Antibiotic Susceptibility Testing Using Raman Spectroscopy and Machine Learning Loza Tadesse[1,2,3], Chi-Sing Ho[3], Baba Ogunlade[3], Chris Cundy[3], Ahmed Shuaibi[4,3], Fareeha Safir[3], Pierre Khuri-Yakub[3], Stefanie S. Jeffrey[3], Stefano Ermon[3], Amr Essawi[5,3] and Jennifer A. Dionne[3]; [1]UC Berkeley, United States; [2]Massachusetts Institute of Technology, United States; [3]Stanford University, United States; [4]Princeton University, United States; [5]Cairo University, Egypt

Bacterial bloodstream infections account for over 40% of death in hospitals and are one of the most expensive medical conditions in the US. Current diagnostic methods are slow and costly, due to the long bacterial culturing step. Our work utilized Raman spectroscopy for rapid culture-free, sensitive, and specific bacterial identification and antibiotic susceptibility testing. Here, I will present three major milestones that bring Raman closer to clinical application by using machine learning and nanophotonics. First, we achieve high (>99%) species level classification accuracies across 30 major disease-causing bacterial species. Second, we showcase the first of its kind demonstration of a versatile and antibiotic co-incubation free susceptibility testing. Third, we develop a simple liquid well setup for clinical sample handling with uniform Raman spectral enhancement using gold nanorods. Overall, our work opens the door for clinical translation of novel spectroscopy based diagnostic tools for identifying bacterial infections, viral infections such as COVID-19 virus, early cancer detection and drug susceptibility testing by merging machine learning and nanophotonics.

Suppressing Charge Recombination in Photoelectrochemical Cells from Plasmon-Induced Resonance Energy Transfer Young Moon Choi and Jong Hyeok Park; Yonsei University, Korea (the Republic of)

The application of n-type metal-oxide based photoelectrode, such as hematite (α-Fe_2O_3) and bismuth vanadate ($BiVO_4$), for the photoelectrochemical (PEC) water splitting has been regarded as a promising approach for clean H_2 production because of their earth abundance and high stability in an aqueous electrolyte. However, their too short hole diffusion length, poor electrical conductance, and inferior oxygen evolution reaction (OER) kinetics deteriorate the PEC response, which limits to reach the theoretical maximum PEC water splitting performance.
In this work, we introduced a 2D nanoamplifier metal film composed of an assembled globular Au nanosphere (AuNS) array with a highly ordered hexagonal pattern (hereafter, Au array) onto the surface of α-Fe_2O_3 film to enhance the PEC water oxidation through the plasmon-induced resonance energy transfer (PIRET). The Au array is self-assembled on the hexagonally patterned polyurethaneacrylate (PUA) pillar molds and transfer-printed on the surface of the photoanode. The Au array induced the near-field coupling interaction and amplified the electromagnetic field, thus promoting plasmonic energy transfer into the underneath film, resulting in efficient light harvesting in a broadband light spectrum and suppression of charge recombination, which increases the carrier lifetime. The long-lived photogenerated holes at the surface of photoanode were demonstrated from the transient absorption (TA) decay profile. Enhanced charge transfer efficiency was also investigated. Furthermore, the Au array was introduced on the surface of molybdenum-doped $BiVO_4$ film to demonstrate the high versatility of facile transfer printing Au arrays. Consequently, the transfer-printed Au array resulted in an efficient PIRET effect on both α-Fe_2O_3 and $BiVO_4$ films. An over 3.3-fold higher photocurrent density at 1.23 V versus reversible hydrogen electrode (RHE) was achieved for the Au array-incorporated α-Fe_2O_3 film. As for $BiVO_4$, Au array improved the photocurrent density by 1.5-fold more than bare photoanode.
In conclusion, we introduced a 2D arranged Au array in a highly ordered hexagonal pattern onto the surface of α-Fe_2O_3 and $BiVO_4$ films via a facile transfer printing process and confirmed the enhanced PEC response through the PIRET effect. The rationally designed Au array film can provide a potential strategy for the versatile application in various light-mediated energy conversion and optoelectronic devices.

EQ03.18.02
Performance Analysis of Materials for Plasmonic Computing Samantha Lubaba Noor[1], Dennis Lin[2], Pol Van Dorpe[2], Francky Catthoor[2] and Azad Naeemi[1]; [1]Georgia Institute of Technology, United States; [2]imec, Belgium

Plasmonic metal-insulator-metal (MIM) slot waveguide (WG), a promising building block of the plasmonic integrated circuits, has been heavily utilized to explore and demonstrate devices like logic gates, modulators, power splitters, frequency filters, and multiplexers. For the MIM slot WG, the choice of material is critical since it primarily controls the degree of signal attenuation and the extent of confinement of the supported modes. A trade-off always exists between the signal attenuation and mode confinement in plasmonic WGs that define the energy consumption and integration density of the

components, respectively. Therefore, a systematic analysis of the possible material combinations is essential for the MIM WG to optimize the performance of the plasmonic devices. This work presents a comprehensive numerical analysis of the possible material combinations of the plasmonic MIM WG for computation purpose. To demonstrate the material effect on computing related context, the analysis incorporates plasmonic MIM interconnect and MIM majority logic gate as use cases. The potential material combinations are initially selected from material quality factor and CMOS compatibility. For each selected material combinations, the confinement factor, propagation length, and coupling length are calculated for the WG. Also, using the coupling length and power transfer data between two nearby WGs, the WG pitch is optimized considering the trade-off between crosstalk and footprint/integration density of the devices. The manipulated plasmon signal in the MIM WG needs to be converted into current/voltage using a detector for readout purposes. Therefore, the effect of material selection on plasmon detection efficiency is next studied by introducing a Ge-based plasmonic metal-semiconductor-metal (MSM) WG as a plasmon detector. For each material case, the MIM WG width is optimized to match the characteristics impedance of the two WG sections resulting in maximum power transmission. Based on various trade-offs, a system-level holistic performance metric, Emin/bit or minimum required energy to detect a single bit sent from the MIM interconnect/logic gate, is introduced, and compared for all the material combinations. This holistic metric encompasses the effect of signal attenuation, mode confinement, WG coupling efficiency, plasmon detection efficiency, and detection bandwidth. Moreover, signal to noise ratio (SNR) and footprint of the devices are calculated. Lastly, considering the trade-off between Emin/bit, SNR and footprint, the optimized material combination is identified. The study shows that Al and Cu are promising metals for MIM WGs for computing. Regarding dielectrics, SiO2 offers a low Emin/bit value and large device area, whereas a high-k dielectric material like Si offers a more compact layout at the cost of a higher energy per bit. It is found that Cu-TiO2-Cu and Al-Al2O3-Al are the two optimum material combinations for MIM WG for plasmonic computing circuits.

A Facile Method for Selective Deposition of Metal Nanoparticles into Nanohole Arrays for Recyclable Plasmonic Sensors Pooria Golvari[1], Stephen M. Kuebler[1,1,1] and Jimmy Touma[2]; [1]University of Central Florida, United States; [2]AFRL/Munitions Eglin AFB, United States

Plasmonic nano-arrays are extensively studied as ultrasensitive vapor sensors [1, 2]. Tunable processes for selective deposition of plasmonic nanoparticles in arrays of host nanoholes are desired for fabrication of next-generation plasmonic devices and sensors. Reported techniques [3, 4] for deposition of gold nanoparticles (AuNPs) into prepatterned nanoholes yield low filling density and are limited to holes created in polymeric substrates which are known to be labile and subject to swelling. We report a method for selective deposition of gold nanoparticles (AuNPs) into nanoholes fabricated in fused silica (FS). Arrays of nanoholes with variable hole size and density are created in the positive resist PMMA by e-beam lithography and transferred into fused silica using cyclic reactive ion etching. The nanoholes are filled with AuNPs using evaporative deposition followed by mechanical rubbing. This simple yet effective approach yields highly selective deposition of AuNPs in nanoholes as small as 150 nm. The effect of the chemical termination of the substrate, the concentration of the AuNPs suspension, and the size and the pitch distance of the nanoholes on the density of AuNPs in the holes was investigated. This approach is being extended to other plasmonic nanoparticles and a variety of substrates. We also demonstrate that the AuNPs can be etched away to reproduce the nanohole array in FS, which can be refilled with fresh nanoparticles. Hence, this method paves the way for recyclable plasmonic sensors that can be regenerated after exposure to analyte.

Gold-Copper Oxide Core-Shell Plasmonic Nanoparticles Rosemary L. Calabro[1,2], Stephen F. Bartolucci[2], John Burpo[1,1] and Joshua A. Maurer[2]; [1]United States Military Academy, United States; [2]U.S. Army DEVCOM Armaments Center, United States

Noble metal nanoparticles exhibit localized surface plasmon resonance (LSPR) when interacting with light. This property has led to the study of these particles for numerous applications, such as catalysis, energy, biosensing, gas detection, and chemical sensing. One commonly used material in hydrogen sensing is palladium, which can dissociate hydrogen gas and form a hydride, resulting in a shift of the LSPR absorption. Core-shell nanoparticles consisting of a noble metal core and a shell material, such as a transition metal oxide, could provide a material system for hydrogen detection with a more permanent plasmonic shift during exposure to hydrogen compared to palladium. In this work, we show the synthesis of various noble metal core-shell nanoparticles, including gold-copper (I) oxide with spherical, rod, spiked, and bipyramid structures and evaluate their plasmonic behavior and ability to detect hydrogen in colloidal suspensions. In addition, we will discuss the plasmonic properties of these particles and hydrogen sensing ability on various substrates, such as metals.

EQ03.18.08

Seed Mediated Growth of Oxidation Resistant Copper Nanoparticles with Optical Properties Rosemary L. Calabro[1,2], John Burpo[1,1], Stephen F. Bartolucci[2] and Joshua A. Maurer[2]; [1]United States Military Academy, United States; [2]U.S. Army DEVCOM Armaments Center, United States

Metal nanoparticles (NPs) exhibit localized surface plasmonic resonance (LSPR) allowing them to span broad applications including energy, catalysis, biomedicine and sensing, and their optical properties can be tuned by changing the size, shape and surrounding environment of the nanoparticles to achieve a LSPR suitable for the desired application. Copper has a low cost, high conductivity, tunable optical properties, and reported LSPR which make copper nanoparticles (CuNPs) an interesting alternative over other noble metal plasmonics. However, the extinction properties of copper nanostructures can be influenced by both interband and intraband transitions, so a deep understanding of the optical properties is required. Copper also suffers drawbacks such as instability and susceptibility to surface oxidation which can further impact the optical properties of the CuNPs. Copper nanoparticles ranging in size from 20-60 nm were synthesized through a seed mediated growth in tetrahydrofuran using polyvinylpyrrolidone (PVP) as a stabilizing agent. Various average molecular weights of PVP were explored and showed influence on both the optical properties and overall shape and size of the resultant NPs where lower molecular weights of PVP resulted in broader spectra and polydisperse particles while higher molecular weights presented narrower spectra with lower polydispersity. The size of the particles could be tuned by changing the PVP amount and by adding acetic acid to the reaction media. Wide angle x-ray scattering measurements show that the particles consist of Cu metal and that no oxide species were present. The particles remained stable in solution for over a month with no shift to the optical properties over time and were resistant to oxidation after addition of water or hydrogen peroxide, or after heating in air. By examining the extinction and true absorbance measurements we determined that all samples had a true absorption peak due to interband transitions at around 590 nm and peaks observed at longer wavelengths were due to scattering effects. The crystallinity and size of these CuNPs was further studied by transmission electron microscopy (TEM) and small angle x-ray scattering (SAXS). Future work will expand on the synthesis strategy to better tune the shape of the copper NPs and we aim to apply this synthesis strategy to prepare other plasmonic metal nanostructures with controlled sizes and optical properties.

EQ03.18.09
Non-Polar GaN Micro-Crystal Array for High-Efficiency Light-Emitting Diodes Minjoo Kim and Won Il Park; Hanyang University, Korea (the Republic of)

GaN-based micro light-emitting diodes (μ-LEDs) have been considered next-generation displays, given the stable operation for a long time and red, green, and blue light emissions through control of the GaN/InGaN structure and composition. However, GaN nano/micro rod crystals grown in the c-axis ([0001]) direction have physical limitations in luminous efficiency due to spontaneous and piezoelectric polarizations. In this work, we employed the epitaxial growth of non-polar GaN nano/micro crystals in the m-axis ([1-100]) direction. The key to the vertically exposed m-axis GaN relies on the precise rearrangement of the ZnO crystals via shear force. We confirmed that most ZnO crystals over a cm-scale wafer were uniformly re-aligned along the shearing direction. Then, the growth of non-polar GaN crystals and subsequent epi-growth (InGaN/GaN MQW, p-type GaN) were performed in turn. Optical and electroluminescence characterizations showed the enhanced luminous efficiency compared with polar crystals, suggesting that our approach can overcome the performance limitations of c-GaN crystals.

EQ03.18.10
Preparation of Metallic Tungsten Oxide Nanoparticles for Visible Upconversion Emission Enhancement Yuta Osa, Mahito Yamamoto and Mitsuru Inada; Kansai University, Japan

It is well known that localized surface plasmon resonance (LSPR) enhances fluorescence from adjacent luminescent materials. This LSPR effect is also effective for infrared (IR) to visible light upconversion emission. Gold and silver nanoparticles are typical nanoparticles with LSPR, but they are not the suitable materials for visible upconversion emission because they absorb visible light. Transition metal oxides are usually transparent in the visible light region but they are insulators. However, they can form metallic phases due to the presence of oxygen defects. In fact, tungsten oxide WO_{3-x} is known to form a metallic phase at x=0.3. Therefore, metallic tungsten oxide nanoparticles are one of the candidates for materials to gain upconversion luminescence in the visible range.

In this study, we have prepared metal tungsten oxide nanoparticles with LSPR in the infrared region by sputtering method. Atomic force microscopy revealed that the diameter of these nanoparticles was approximately 50 nm. Hall measurements showed that the nanoparticles were metallic with a carrier density of $5.9\times10^{22}cm^{-3}$ at room temperature. X-ray diffraction measurements showed that the nanoparticles were crystalline. The nanoparticles had a peak in optical absorption by LSPR at around 960 nm. These results indicate that metallic tungsten oxide nanoparticles have the potential to enhance the upconversion emission from IR to visible light in Er^{3+} doped glass ceramics. Details of upconversion enhancement using LSPR of metal tungsten oxide nanoparticles will be presented and discussed at the meeting.

EQ03.18.12
Efficient and Selective Photocatalytic Conversion of Methanol Using Porous Au-WO_3 and Visible Light Robert B. Tracy and Christopher C. Landry; University of Vermont, United States

Volatile organic compounds (VOCs) are common pollutants found in indoor and outdoor air. An efficient removal process for high-concentration VOCs can be a challenging task, having a new elimination process would a crucial development. In the past, we have a developed a continuous flow gas-phase reactor to monitor the visible light photocatalytic oxidation of methanol with porous WO_3 and Au loaded WO_3. Porous WO_3 had a much higher activity than commercial WO_3 and doping with Au improved upon that activity in both samples. In the present studies, we focus on changing the reaction conditions, specifically the concentration of methanol and oxygen to improve upon the visible light photoactivity of porous WO_3 based materials. The change in conditions also have shown to have a major impact on the reaction intermediates and photooxidation pathways on the photocatalytic oxidation of methanol. The continuous flow gas phase reactor was hooked up to a GC-MS which used to monitor the photooxidation process of methanol. EPR and XRD was used to determine the phase of WO_3. The Lewis acidity of the materials were monitored with the use of TPD. Finally, Nitrogen physisorption was used to monitor the porosity of the materials.

EQ03.18.13
A Surface-Plasmon Enhanced Mid-Infrared Lab-on-a-Chip for Real-Time Reaction Monitoring of Liquids Borislav Hinkov[1], Florian Pilat[1], Mauro David[1], Andreas Schwaighofer[1], Patricia L. Souza[1,2], Benedikt Schwarz[1], Daniela Ristanic[1], Elena Arigliani[1], Laurin Lux[1], Dominik Wacht[1], Felix Frank[1], Hermann Detz[1,3], Aaron M. Andrews[1], Bernhard Lendl[1] and Gottfried Strasser[1]; [1]TU Wien, Austria; [2]Pontificia Universidade Católica do Rio des Janeiro, Brazil; [3]Brno University of Technology, Czechia

The mid-infrared (mid-IR) spectral range is highly suitable for selective and sensitive probing of molecules by addressing their fundamental fingerprint absorptions. While high performance gas sensing has already been demonstrated in many different experiments including frequency-comb based techniques and exploiting concepts from direct absorption spectroscopy to photo-acoustics and dispersion spectroscopy, the mid-IR analysis of liquids is still in its infancy. Though recently gaining particular interest, it is still in main parts limited to bulky detection systems like Fourier-Transform Interferometer (FTIR-)based sensors, demanding for liquid films on the order of a few micrometers only. This often results in time-consuming offline analytics, preventing real-time analysis of rapidly changing liquid systems like when undergoing chemical reactions or conformational changes of molecules in the sample.
For enabling the next generation of liquid sensing by going beyond such limitations, we present in this work a novel high-performance monolithic mid-IR sensor. It relies on pioneering quantum cascade (QC) technology by merging a similar wavelength QC laser (QCL) and QC detector (QCD) into one active region and combining it with a novel mid-IR plasmonic concept. Using a surface-sensitive dielectric-loaded surface plasmon polariton (DLSPP) structure, which consists of a SiN-slab on a gold layer, results in a fingertip-sized optical sensor, highly suitable for the monitoring of liquids. In contrast to state-of-the-art systems, its robustness and compactness allow the real-time analysis of dynamical processes in liquids including inline and in-situ measurements by direct exposure to the liquid. In our DLSPP approach, the plasmonic mode propagates along the sample surface, being efficiently guided by more than 95% in the surrounding medium. Our presented FEM-based simulations confirm the preservation of the plasmonic capabilities also in a liquid matrix.
We demonstrate the breakthrough performance of the plasmonic concept implemented into the sensor in an analytical chemistry experiment. We measure the time-dependent conformational changes of the model-protein bovine serum albumin (BSA) with our compact on-chip sensor. Time-resolved measurements are performed by combination of the device with a custom-made 60-μl flow cell for inline measurements at $\lambda = 1620\ cm^{-1}$. We use a D_2O matrix for reduced background absorption, while maintaining comparable protein unfolding results as in biophysical buffer, i.e. H_2O. BSA unfolds irreversibly from α-helix to antiparallel β-sheets when heated from 20°C to 90°C. In our experiments we obtain the typical protein denaturation curves, following a sigmoidal Boltzmann equation (”s-shaped”) with increasing temperature. In good agreement with literature, we observe a decreasing transition temperature with increasing BSA-concentration, confirming the proper operation of our compact sensor. By additionally directly submerging the sensor into a beaker with the protein-analyte and monitoring its absorbance vs concentration curve (calibration line) for increasing BSA concentrations, we can extract the important figures-of-merit of our on-chip device. A comparison with a state-of-the-art attenuated total reflection (ATR-)FTIR reference system reveals the superior performance of our ultra-compact sensor with: 55-times higher absorbance, 120 times lower LOD (LOD_{QCLD} ~75 ppm) and coverage

of more than three order of concentrations of 0.0075 % to 9.23 %.
In the second part of this paper, we will show how the plasmonic surface of our sensor can be further enhanced through functionalization. By depositing compatible mesoporous membranes based on ZrO_2 or TiO_2, molecules can be trapped close to the sample surface. This yields a significant increase in sensitivity by molecule enrichment factors well above 100 (e.g. 162 in a typical setting using a ZrO_2 membrane).

EQ03.18.14
Nickel-Infused Nanoporous Alumina as Tunable Solar Absorber for Desalination Xuanjie Wang and Shankar Narayan; Rensselaer Polytechnic Institute, United States

Solar energy can alleviate our dependence on traditional energy sources like coal and petroleum. In this regard, the design and performance of solar absorbers are crucial for capturing energy from sunlight. Specifically, for applications relying on solar-thermal energy conversion, it is desirable to construct solar absorbers using scalable techniques that also allow a variation in optical properties. In this study, we demonstrate the ability to tune the spectral absorptance of nickel-infused nanoporous alumina using a scalable and inexpensive fabrication procedure. With simple variations in the geometry of the nanostructures, we enable broadband absorption with a net solar absorptance of 0.96 and thermal emittance of 0.98 and spectrally-selective absorption with a net solar absorptance of 0.83 and thermal emittance of 0.22. We demonstrate a scalable approach involving the use of wicking materials interfaced with the spectrally-selective absorber for the desalination of saline water to get 73% of overall efficiency using a solar flux of one sun. This demonstration of an inexpensive strategy for producing clean water can potentially transform the field of solar-thermal desalination to address the rising demand for water. The simple manufacturing techniques presented in this study to generate nanoengineered surfaces can lead to further advancements in solar absorbers with well-controlled and application-specific optical properties.

EQ03.18.15
Excitonic Properties of *sp3*-Doped (6,5) Single-Walled Carbon Nanotubes as a Single Photon Emitter Kasidet Jing Trerayapiwat[1], Diego Barrutia[2], Xuedan Ma[3,4] and Sahar Sharifzadeh[1,1]; [1]Boston University, United States; [2]Dartmouth College, United States; [3]Argonne National Laboratory, United States; [4]The University of Chicago, United States

Single-walled carbon nanotubes (SWCNTs) doped with *sp3* defects are a promising class of optoelectronic materials with bright tunable photoluminescence and demonstrated single-photon emission (SPE). Experimental and theoretical studies on *sp3*-defective (6,5) SWCNT performed by us suggest that the introduction of the defect leads to presence of a localized unpaired electron around the *sp3* defect site and an in-gap dispersionless state. Here, we study the low-energy excitations associated with this defect state in order to better understand the role of *sp3* defects in SPE. Many-body perturbation theory within the GW/BSE approximation predicts strong excitonic effects with an exciton binding energy of ~ 1 eV for both the pristine and defective (6,5) SWCNT. Additionally, GW/BSE, as well as hybrid time-dependent density functional theory, indicate that the exciton in the enhanced photoluminescence state is a linear combination of the pristine-like transition and that involving the in-gap defect state. Lastly, we present studies of carrier-phonon scattering as a cause of exciton dephasing in *sp3*-defective (6,5) SWCNT by considering electron-phonon and hole-phonon interactions using the independent boson model.

Bright and Highly Uniform, Pure, Indistinguishable, Spatially-Ordered Single Quantum Dot Emitters—Molecular Beam Epitaxial Growth and Structural Characterization Lucas Jordao[1], Jiefei Zhang[1], Qi Huang[1], Swarnabha Chattaraj[1], Siyuan Lu[2] and Anupam Madhukar[1]; [1]University of Southern California, United States; [2]IBM T.J. Watson Research Center, United States

A significant step forward in the long-sought goal of on-chip quantum optical circuits is the development of spatially-ordered and spectrally highly uniform and pure single photon emitters provided by a unique class of shape and size controlled single quantum dots, dubbed mesa-top single quantum dots (MTSQDs [1,2]). Quantum dots are the only known solid-state on-demand single photon emitters that have been shown to intrinsically exceed all required quantitative figures-of-merit known for realizing on-chip networks aimed at linear optical quantum computing (LOQC), secure high-capacity quantum communication, and multi-photon entangled states as a basic quantum resource for quantum information processing. The realization of spatially-ordered scalable arrays of MTSQDs while maintaining individual QD characteristics above the threshold [1,4] has thus paved the way for the fabrication and study of quantum optical networks. In this talk we report on (i) the molecular beam epitaxial growth of these remarkable MTSQDs based on the underlying physics of the substrate-encoded size-reducing epitaxy (SESRE) on patterned substrates with judiciously chosen scalable nanomesa arrays, and (ii) their structural and compositional character as determined by scanning transmission electron microscopy (STEM) [4]. The demonstrated uniformity and reproducibility of the SPS characteristics is, for the first time, shown to arise from the unprecedented control on shape, size, and composition of the individual quantum dots across the arrays. Equally significant, such quality is controlled from run-to-run when guided by RHEED-based machine condition transfer function as we demonstrate here.
The SESRE approach enables the formation of single quantum dots of controlled shape and size on mesa-tops for both lattice matched (GaAs/AlGaAs) and lattice mismatched (InGaAs/AlGaAs) material systems. Results of STEM studies provide (i) evolution of the growth front profile through the stages of as-patterned nanomesa size-reduction, deposition of the SQD, and continued growth of the morphology planarizing overlayer; (ii) evidence for the unprecedented control over size and shape uniformity of epitaxial QDs underpinning the spectral uniformity emission (<3nm) across the arrays [1,4]; (iii) control of SQD lateral positions to an accuracy of <10nm. The planarization of the MTSQDs [3] makes them naturally suitable for horizontal on-chip integration with light manipulating units (cavity, waveguide, directional coupler) using either standard monolithic integration or hybrid integration with silicon photonics. The MTSQD arrays thus pave the way as a unique platform of quantum emitters for realizing the long-sought on-chip QOCs.

Study of Far-Field Radiation Pattern in Nano-Photonic Devices and Its Application in Single Small Particle Detection Abbas Ghaffariesfehani and Robert Riehn; North Carolina State University, United States

The optical properties of zero-mode waveguides (ZMW) in metal films has been studied extensively. Here, we investigate the far-field radiation pattern of two zero-mode wavegiudes surrounded by circular corrugations. We monitor the direction and intensity variation of the transmitted light of the sub-wavelength apertures in the back-focal plane of the microscope objective. Any phase contrast between two holes results in a deflection in the direction or

intensity distribution of light in far-field pattern. We introduce a refractive index contrast between two ZMWs by anchoring a quantum dot within of one of them, which results in a phase difference between holes. Introduction of a phase difference can also be achieved by fabricating two asymmetric ZMWs. We show that in both cases the induced phase variation between two holes lead to a deflection in the far-field diffraction pattern. We find that the complex pattern of the transmitted light can be quantified through a scalar measure of asymmetry along the symmetry axis of the aperture pair. We also demonstrate that asymmetry parameters increase can be controlled by the number of circular rings surrounding ZMWs. Finally, we perform a series of Finite-Difference Time-Domain (FDTD) computational study to propose a new design of double-ZMWs sensors that can be used for small particle detection with higher sensitivity and also applicable to control the direction of the light.

Hybrid Fabrication of High Quality Titanium Nitride Nanostructures for Plasmonic Applications Spyridon Kassavetis, Stavros Panos, Despina Tselekidou, Evi Rabota, Nikolaos Pliatsikas and Panos Patsalas; Aristotle University of Thessaloniki, Greece

Nanomaterials for plasmonic devices have attracted enormous and multidisciplinary interest and efforts over the last decade. However there are few examples of plasmonic devices mainly due to materials issues, since gold and silver, the “traditional” plasmonic materials, show limited tunability of their plasmonic response across the spectra and low melting point, which makes them incompatible with CMOS technology.
Transition metals nitrides (TMN) emerge as alternative plasmonic nanomaterials suitable for a wide range of applications from microelectronics to photonics and medicine. The TMN are conductive ceramics with exceptional properties such as substantial electronic conductivity, high melting point (>3000 K), tunable work function, while the TMNs are particularly stable in hostile chemical environments, high temperature, and strong electric fields, such as in lasers. Among them, titanium nitride (TiN) is recently emerging as significant candidate material for plasmonic applications (biosensors, catalysis and photochemistry, solar energy harvesting, photo-detection, and optical storage of information).
In this work, we focus on the hybrid fabrication of TiN nanostructures with controlled spacing and tunable dimensions (thickness and lateral dimensions) using a combination of Nanosphere Lithography (NSL) and reactive magnetron sputtering (MS). Several MS techniques such as DC, Closed-Field Unbalanced MS and Highly Power Impulse MS were used with the target to succeed high quality materials. NSL appears as a very promising approach, due to its rapid implementation and compatibility with wafer-scale processes, combines the advantages of both top-down and bottom-up approaches and includes: (a) preparation of the nanospheres colloidal mask, (b) deposition of the desired material in the empty space between the nanospheres and (c) removal/lift-off of the nanosphere colloidal mask to “reveal” the deposited material that keeps the ordered patterning of the mask interstices. Specifically, a suspension of monodisperse polystyrene nanospheres (diameter, d=552 nm or d=175 nm) was spin coated on a substrate (several substrates were used such as Si (001), glass, and flexible PET to target applications in flexible printed photovoltaics) to form the colloidal mask. A UV ozone process was used to confine the triple-junction vias of the polystyrene mask. Subsequently, the selective growth of TiN was made by the above mentioned MS in Ar/N atmosphere by varying the TiN thickness from 10 to 30 nm, while the MS process parameters were also fine-tuned to increase the directionality of deposited species, TiN crystal quality (low concentration of point defects). In particular, the substrate-to-target distance was maximized to improve geometrical directionality, and a negative bias voltage was used to “guide” the ionic species deep into the vias between the nanospheres. The arrays of ordered TiN nanostructures appear after the lift-off of the mask. The proposed process produces well-defined TiN triangular nanoislands with low concentration of point defects, similar structure with the continuous TiN films of high electrical conductivity and plasmonic performance, and durability at least up to 400^{o} C. Finally it should be noted that TiN is used as a case study as very good representative of other refractory TMNs, such as ZrN, HfN, NbN, and TaN.

Reversible Photochemical Switching via Plasmonically Enhanced Photoluminescence in a Quasi-Periodic Metallic Nanostructure Byunghoon Kim[1], Kyu-Tae Lee[2], Wenshan Cai[2], M. Zahid Hasan[1] and Doo-Hyun Ko[3]; [1]Princeton University, United States; [2]Georgia Institute of Technology, United States; [3]Sungkyunkwan University, Korea (the Republic of)

Incorporating metallic nanostructure with fluorophore has offered desirable properties, such as plasmonically enhanced photoluminescence and ultra-sensitive optoelectronic response. The physics behind these improvements is controlling the near-field characteristics as well as finely tuning the wavelength of cavity mode corresponding to the photophysical energy gap of the activator. It leads to achieving a remarkable enhancement of photoluminescence intensity and sensitivity; however, inherent limitations (e.g., the narrowband resonance and restricted wavelength) prevent feasible applications in photochemistry. Here, we’ve achieved broadband photoluminescence enhancement by breaking the symmetry of the periodic metal nanostructure. The proposed quasi-periodic plasmonic platform allows strong electric field localization and intensity enhancement, which leads to the improvement of photoluminescence of photoswitching upconverting nanoparticles while conserving the spectral orthogonality. The accelerated reversible-photoisomerization kinetics is experimentally validated with the amplification of the photoluminescence intensities of the photochromic disulfonyldiarylethene derivatives.

SESSION EQ03.19: Metasurfaces and Metamaterials II

Meta-Optics for Image Processing and Object Classification Hanyu Zheng[1], Quan Liu[1], You Zhou[1], Ivan Kravchenko[2], Yuankai Huo[1] and Jason G. Valentine[1]; [1]Vanderbilt University, United States; [2]Oak Ridge National Laboratory, United States

Image processing has become a critical technology in a variety of science and engineering disciplines. While most image processing is performed digitally, optical analog processing has the advantages of being low-power and high-speed though it requires a large volume. Meta-optics provide the advantage of thin form factor optics while also allowing complex transfer functions to be employed. In this talk, I will discuss the use of meta-optics for applications in image processing as well as object classification. Specifically, I will discuss the use of meta-optics as optical front-ends that perform edge filtering as well as identification of higher level spatial features for object classifiers. The meta-optics are designed using end-to-end optimization so that the optical front-end and digital back-end work in harmony. This architecture allows for multiple metasurfaces to be optimized while also allowing us to incorporate noise in the design loop, resulting in robust experimental systems. The meta-optics processors are designed for both coherent and incoherent illumination,

enabling a wide range of use cases that take advantage of both a reduction in processing time and power consumption.

Self-Assembled Plasmonic Metasurfaces Using DNA Origami with Dynamic Optical Response Mihir Dass, Lena Raab, Chris Pauer, Gregor Posnjak and Tim Liedl; Ludwig Maximilians University Munich, Germany

Plasmonic nanoparticles interact strongly with light, concentrating far-field radiation into sub-wavelength volumes, producing effects like near-field coupling. We combine nanosphere lithography and DNA origami placement developed by Gopinath et al.[1,2] with plasmonic particles and chiral plasmonic metamolecules assembled using gold nanorods and DNA origami to explore the possibility of creating patterned metasurfaces with a dynamic optical response. Since we can fabricate these surfaces on glass, they are compatible with optical techniques like Dark Field and TIRF microscopy. This method enables the creation of optical metasurfaces on the wafer scale and the pursuit of new applications on solid substrates usually incompatible with liquid phase colloidal suspensions.

9:00 AM EQ03.19.04
Metasurface-Enhanced Full-Space Structured Light for Depth Sensing Gyeongtae Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Laser-based imaging technology is regarded to be one of the most promising and accurate three-dimensional (3D) depth sensing technologies when combined alongside the rapid advances in computer science. To image 3D objects over a wide field of view (FOV), the laser beams illuminate the objects, and backscattered light is monitored through detectors. Structured light (SL)-based imaging system splits the light into an array of dots or lines over the FOV, enabling imaging of multiple objects simultaneously. So far, diffractive optical elements (DOEs) or spatial light modulators (SLMs) have been used to form the laser spot arrays. However, such architectures suffer from small FOVs, low efficiency, and bulkiness resulting from the large micron-scale pixel size. Here, we propose a metasurface-based SL imaging platform, allowing for subwavelength scale manipulation of incident light. The scattered light from the metasurface covers the full 180° FOV, with a high-density ~10K dot array. The metasurface is composed of a periodic supercell, and the properties of diffraction patterns are analyzed by convolution theorem considering the supercell as a kernel function. As a proof-of-concept, we place face masks one on the laser beam axis and the other 50° apart from axis within distance of 1 m and estimate the depth information from the backscattered light using a stereo matching algorithm. Furthermore, we demonstrate the replication of our metasurface on a glass surface using the nanoimprinting of a nanoparticle-embedded-resin (nano-PER) for high-throughput fabrication.

9:15 AM EQ03.19.05
Terahertz Metamaterial Absorber in Pesticide/Herbicide Detection Khwanchai Tantiwanichapan[1] and Habibe Durmaz[2]; [1]National Electronics and Computer Technology Center, Thailand; [2]Karamanoglu Mehmetbey University, Turkey

Terahertz (THz) technology has been attracted great interest in many research areas, especially THz plasmonics for sensing applications since intra- and inter-molecular vibrations are within the THz range. The sensitivity of free-space THz detection can be boosted up by use of metamaterials. Here, metamaterial absorber (MA) which are artificial structures in subwavelength scale of the incident light is introduced as a sensing device in THz regime. The operational principle of the MA sensor system is based on trapping the incident electromagnetic field at the interface of metallic antennas and the dielectric layer. These sensors are very sensitive to the change in their surrounding medium; therefore, highly sensitive, label-free, real-time sensing, and non-invasive detection are possible.
This work focuses on the detection of paraquat [(C6H7N)2Cl2 and glyphosate [N-(phosphonomethly)glycine] herbicide/pesticide based on the polarization-insensitive THz MA. The MA sensor consisting of a metal-dielectric-metal structure is numerically designed by a commercial electromagnetic solver (CST microwave studio, 2018) software. The spectral response of the MA sensor with different geometrical parameters, such as metallic antenna structure and dielectric thickness is analyzed to optimize the resonance frequency and absorption efficiency. In the sensor fabrication process, general C-MOS technology is applied and characterized. Subsequently, the sensing capacity of the THz MA systems is analyzed numerically and measured experimentally for different concentrations of paraquat and glyphosate (5 ppM to 500 ppM). The Fourier Transform Infrared Spectroscopy (FT-IR) is used for measurement from the chip surface with/without paraquat and glyphosate. The experimental results show that the presence of paraquat and glyphosate with concentrations ranging from 5 ppM to 500 ppM in the THz MA sensor surface shifts the spectral position of the absorption peak to the lower frequency. The numerical and experimental results are in good agreement for different concentrations of pesticide molecules. The experimental sensitivity of this THz MA sensor is around 52 GHz/ppM and 89 GHz/ppM for paraquat and glyphosate, respectively These results indicate that the proposed MA sensor platform has potential use for highly sensitive THz applications in food quality and safety control [1].

9:30 AM BREAK

10:00 AM *EQ03.19.06
Full-Color Non-Dispersive Visible Metalens by Sequentially Stacked Bilayers of HAR SiN Mold and TiO_2 Pillars Seunghoon Han, Hyun Sung Park, Hyeonsoo Park, Hae-Sung Kim, Ki-Deok Bae, Woong Ko, Eun-Hyoung Cho, Jeong Yub Lee and Hyuck Choo; Samsung Electronics, Korea (the Republic of)

We present a new visible metalens, which works as an ideal non-dispersive diffractive lens by providing equal transmission phase profiles over the full-color broadband of light (wavelengths from 400 to 700nm). To implement such engineered dispersion, we sequentially stacked bilayers of meta-structures, i.e., high-index TiO_2 pillars in SiO_2 mold and low-index air holes in SiN mold of high-aspect-ratio (HAR, ~30). When the metalens phase profile is slowly-varying across the device (i.e., low numerical aperture), the dispersion at each location of the metalens through which light propagates can be designed by optimizing the bilayers’ structural and material dispersions. As a result, the metalens has polarization independence and high focusing efficiencies (~83%, experiment, improving), which overcomes the limitations of the previous metalens approaches. The high-aspect ratio structuring of ~2um thick SiN layer is

a key new material opportunity for visible meta-optics. This is an important advancement of the diffractive lens for many emerging applications; Fresnel lenses that have been used for DSLR cameras with refractive lenses are bulky, expensive and suffer various diffractive artifacts, whereas this metalens is thin, mass-producible and suppresses the artifacts significantly. The non-dispersive nature of the metalens allows it to be a basic building block for more complicated dispersion engineered optical systems. Furthermore, the sequentially stacked bilayers will enable new functional metasurfaces at visible frequencies by harnessing its structural and material compositions.

10:30 AM *EQ03.19.07
Advances on Nonlocal Metasurfaces Andrea Alu; City University of New York, United States

In this talk, I will present and discuss our recent advances on metasurfaces based on highly delocalized modes, stemming from long-range resonant interactions and lattice phenomena. Different from conventional metasurface approaches, engineered nonlocality offers tailored spectral control, and at the same time can be tailored in space with large resolution using geometric phase concepts. Their response is ideal for imaging and signal processing applications, and to enhance light-matter interactions. We achieve these features by combining quasi-bound states in the continuum with geometric phase variations in engineered metasurfaces, tailoring at will the supported eigenwaves. The resulting metasurfaces support ultrasharp responses selective to the impinging wave properties, effectively realizing ultrathin transparent films that highly reflect light only when illuminated by selected polarization, frequency and wavefront spatial distribution of choice. The demonstrated wavefront selectivity of nonlocal metasurfaces opens exciting opportunities for augmented reality, secure communications, thermal emission management, optical modulators and enhanced light-matter interactions for nonlinear and quantum optics. In particular, in the talk we demonstrate our recent experimental demonstrations on highly efficient signal processing metasurfaces for polarization imaging, thermal metasurfaces, and other applications of these phenomena.

11:00 AM EQ03.19.08
High Quality Factor Dielectric Metasurfaces for Two-Dimensional Wavefront Manipulation in Transmission Claudio U. Hail, Morgan Foley, Ruzan Sokhoyan and Harry A. Atwater; California Institute of Technology, United States

The strong interaction of light with optical nanostructures plays a critical role in optical sensing, nonlinear optics, and active optical devices. However, for wavefront shaping, the required local, sub-wavelength control over the phase of light limits this interaction, leading to low-quality-factor optical devices. Here, we report on high quality factor dielectric metasurfaces for complete, local wavefront manipulation of near infrared light in transmission mode, and in two dimensions. Our structure consists of high-index dielectric nanoparticles exhibiting strong, lattice-coupled Mie resonances with high quality factors. The local control of these resonances enables setting the phase of transmitted light over a range of 0-2π with experimentally measured quality factors of up to 295 at a wavelength of $\lambda = 1290$ nm. By appropriately tailoring the dimensions of these dielectric building blocks to attain the desired phase distribution, we experimentally realize wavelength-selective beam deflectors and radial metalenses with a bandwidth of only a few nanometers. Furthermore, we demonstrate the operation under finite illumination apertures (< 50 μm) and oblique incident illumination. This contrasts with other mechanisms for high-quality-factor optical metasurfaces which rely on inherently non-local principles, such as guided mode resonances or symmetry-breaking bound states in the continuum, limiting their application to one-dimensional wavefront shaping or geometric phase tuning, respectively. Our findings demonstrate that local control over the wavefront is successfully attained with high quality factor, opening doors to new applications in active metasurfaces and sensitive, free-space-coupled optical sensing.

11:15 AM EQ03.19.09
Experimental Demonstration of Space-Time Modulated Metasurfaces Jared Sisler, Prachi Thureja, Meir Y. Grajower, Ruzan Sokhoyan and Harry A. Atwater; California Instiute of Technology, United States

We experimentally demonstrate operation of a space-time modulated metasurface at 1550 nm in a switchable diffraction experiment. Space-time metasurfaces are a class of tunable metasurfaces that simultaneously impart a spatial and temporal phase gradient to incoming light [1]. Experimentally, this is realized by first modulating all metasurface elements with a high-frequency voltage signal to generate harmonic sidebands of the incident light wavelength. Then, by introducing a time delay to the driving waveform between adjacent metasurface elements, a spatial phase-gradient is created. The phase shift imparted by introducing a time delay to the electrical signal is nonresonant and covers a full 360° range without an associated covariation of amplitude: an issue that has previously limited the performance of tunable metasurfaces. There is currently a surge of interest in the photonics community to produce a space-time optical metasurface because of their potential to enable full 360° phase shift with constant amplitude, multi-channel communication in a single aperture, and nonreciprocal behavior [2,3].

By using a reflective gate-tunable indium-tin-oxide (ITO) based metasurface operating at 1550 nm integrated into an electrical circuit [4], we first demonstrate the generation of multiple harmonics as a function of modulating waveform for frequencies up to 5 MHz. Our device consists of an array of interdigitated plasmonic nanoantennas with two electrical contacts that are initially modulated in-phase such that all harmonics are normally reflected. Next, we offset the electrical waveforms by half a period between the two electrodes such that a spatial binary phase grating is achieved. By doing this, we measured an increase in the intensity of the +/- 1st diffraction orders, enabling a switchable diffraction functionality. Due to the nonideal properties of our metasurface (i.e., a covarying and nonlinear amplitude and phase response), the efficiency of our device is limited. This can be increased by optimizing the driving waveform to improve the frequency conversion efficiency to a single harmonic using a genetic algorithm and arbitrary waveform generator. Future experiments will use a more complex metasurface design with 32 individually addressable electrodes. This metasurface will operate under the same principle as our current two-electrode device but will be able to demonstrate more complex functionalities such as dynamic steering and focusing. We are further exploring new device architectures and driving schemes that will enable multi-frequency, multi-beam steering as well as the breaking of reciprocity.

11:30 AM EQ03.19.10
Tailoring the Spectral Characteristics of Multilayered Chiral Mid-Infrared Metamaterials Hannah Barnard and Geoff Nash; University of Exeter, United Kingdom

Metamaterials, in particular chiral metamaterials, are of great interest in recent years as they offer potential for application in enhanced sensing techniques [1]–[3]. This is because the structures absorb incident radiation, and confine it to nanoscale regions, which can then be used to probe some analyte. Of particular interest are those materials which absorb mid-infrared (mid-IR) radiation, as the confined fields can then be used to probe the molecular

vibrational frequencies of molecules, which also fall in this spectral region. Here, we present a simulation and experimental study into a particular class of chiral metamaterial, made up of twisted U-shape resonator elements [4]–[6], forming a multi-layered stack. First we scale the dimensions of the structures using simulations, to ensure the resonances fall in the important mid-IR region of the spectrum. Then, the structure is fabricated using standard lithographic techniques to produce gold resonators on an Si/SiO_2 substrate. By measuring the structure in an FTIR spectrometer we demonstrate high levels of circular dichroism (CD), a consequence of the chirality of the structure, in the mid-IR region, for three different configurations [7]. The three configurations discussed include a double layer structure, and two 4-layer structures. Finally, we demonstrate that the spectral position of the metamaterial resonances, and subsequent CD, can be tailored simply by changing the stacking configuration of the layers [7]. We explain this behaviour using a model of the induced magnetic dipoles at each resonance, caused by the coupling of adjacent twisted resonators, when the structure is excited.
This study provides an important insight into the mechanisms of optical activity in an important class of metamaterial, particularly, how to tailor its spectral response. Demonstrating high levels of CD indicates that this structure is strongly optically active in the important mid-IR region, making it a possible candidate for enhanced spectroscopy applications in the future. Further work is underway to investigate the nature of the confined fields produced, how chiral they are, and how accessible they might be to a molecular analyte on the structures surface.

11:45 AM EQ03.19.11
Mass-Production of Visible Metalenses via Wafer-Scale Printing Joohoon Kim and Junsuk Rho; Pohang University of Science and Technology, Korea (the Republic of)

Currently, metasurface-based flat optics is going from science to technology transition. A representative example includes a flat and ultra-thin metalens, which has potential to overcome the limitations of conventional optical lenses, such as bulky system, heavy weight, shadowing effect, and chromatic aberration. As an example, typical digital single-lens reflex (DSLR) camera which have a length of over 30 cm and a weight of over 4 kg. On the other side, metalens has near-zero weight and nm-scale thickness. However, their inherent fabrication limitations such as high manufacturing cost, low throughput, and small patterning areas hindered their widespread use. In this abstract, we introduce a new fabrication method for the mass production of visible metalenses. The proposed fabrication method includes an argon fluoride immersion scanner, wafer-scale nanoimprint lithography, and atomic layer deposition. The argon fluoride immersion scanner is used to fabricate a 12-inch master stamp. Once a 12-inch master stamp is imprinted, hundreds of 1-centimeter metalenses can be transferred to the substrate. Since nanoimprint lithography features low cost and high throughput, metalenses can be fabricated with extremely low cost and high throughput. However, a low refractive index of printed resin causes low efficiency. To increase the effective refractive index of printed resin, the printed resin is thinly coated with a high-index film. As a result, the conversion efficiency of the designed meta-atom is drastically increased. In this method, we mass-produced 1-centimeter metalenses on a wafer-scale, even in a laboratory environment. As a proof of concept, a VR device integrated with mass-produced metalens was demonstrated. Moreover, the proposed method can also be applied to various metasurfaces such as holograms, color filters, and biosensors.

Ultra-Narrowband Mid-Infrared Thermal Emitters Based on Phononic Metasurfaces Soheil Farazi and Srinivas Tadigadapa; Northeastern University, United States

In this work, we demonstrate a new class of ultra-narrowband coherent emitters in the mid-IR range using bound states in the continuum (BICs) [1]. Most of the existing sources in the mid-IR range are thermal emitters and consequently spontaneous, incoherent, and broadband. Manufacturing a narrowband coherent source is vital in many applications including sensing, lasing, and optical communications. In addition, the ultra-narrowband emitter investigated in this work can pave the way to design and fabricate Vertical Cavity Surface Emitting Lasers (VCSELs) in the 10-12 um wavelength range.

Although several works have been done to design and fabricate narrowband emitters at visible and near-IR regimes, this goal is still challenging in mid-IR wavelengths. By utilizing polar materials like silicon carbide (SiC) supporting surface phonon polaritons (SPhPs) one can achieve partially coherent emitters with near-unity emissivity [2]. Indeed, the surface waves excited by SPhPs generate thermal radiation with enhanced intensity beyond blackbody radiation; however, the quality factor of the emission peak has thus far been limited due to the intrinsic losses of plasmonic and phononic materials. We have shown by utilizing Friedrich-Wintgen BICs [3], we can establish a high *Q*-factor coherent source with a near-unity emissivity For both TE and TM polarization. The emission peak of the phononic metasurface has a *Q*-factor as high as 3,400 which is two orders of magnitude higher than any plasmonic or photonic structure in this wavelength range. Moreover, our simulated results show that the proposed structure has a reasonable fabrication tolerance meaning that any small deviations from the desired construction parameters may not affect the amplitude and Q-factore of the emission peak drastically.

Dynamically Regulated Radiative Cooling with Continuously Variable Emission Xiaojie Liu[1], Yanpei Tian[1], Fangqi Chen[1], Alok Ghanekar[2], Mauro Antezza[3] and Yi Zheng[1]; [1]Northeastern University, United States; [2]University of Southern California, United States; [3]Institut Universitaire de France, France

Passive radiative cooling drawing the heat energy of objects to the cold outer space through the atmospheric transparent window (8 μm ~ 13 μm) is significant for reducing the energy consumption of buildings. Daytime and nighttime radiative cooling have been extensively investigated in the past. However, radiative cooling which can continuously regulate its cooling temperature, like a valve, according to human need is rarely reported. In this study, we present a concept of reconfigurable photonic structure for the adaptive radiative cooling by continuously varying the emission spectra in the atmospheric window region. This is realized by the deformation of the one-dimensional Polydimethylsiloxane (PDMS) grating and the nanoparticles embedded PDMS thin film when subjected to mechanical stress/strain. The proposed structure reaches different stagnation temperatures under certain strains. A dynamic tuning in emissivity under different strains results in a continuously variable "ON"/"OFF" mode in a particular atmospheric window that corresponds to the mechanical deformation induced fluctuation of the operating temperatures of the reconfigurable nanophotonic structure.

Directly Violating the Kirchhoff Thermal Law Komron J. Shayegan[1], Souvik Biswas[1], Bo Zhao[2], Shanhui Fan[3] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]University of Houston, United States; [3]Stanford University, United States

The Kirchhoff thermal radiation law provides an inherent constraint on the ability to harness thermal radiation, requiring that the spectral emissivity and absorptivity are equal and exhibit identical angular distributions for a given polarization. This equality is built on the fundamental assumption that all materials obey Lorentz reciprocity. One class of materials that does not satisfy Lorentz reciprocity, and thus can violate the Kirchhoff thermal law, is magneto-optically-active materials. In this work, we experimentally demonstrate a direct inequality between the absorptivity and emissivity in the mid-infrared of a guided-mode-resonant (GMR) structure with a magneto-optical InAs underlayer that breaks time-reversal symmetry, and thus reciprocity, in a moderate external magnetic field. We demonstrate the angular and spectral distribution changes of both the emissivity and the absorptivity in magnetic fields. Furthermore, we use the symmetry of the GMR structure to tune the Kirchhoff violating emission's dispersion and magnetic field dependence. We conclude with an outlook on the dynamic tunability of such structures and their practical implications.

2:30 PM EQ03.20.05
Cooler-free operation (up to 120ºC) of microbolometers based on amorphous VO_x thermistor deposited at different growth temperatures Dasom Wang[1,2], Ho Won Jang[2], Dong Hee Park[1] and Won Jun Choi[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

The recent growth of the autonomous driving market increased demands for IR image sensors due to the detection capability in the absence of visible light, e.g., night, rainy, or foggy conditions. Since the cost-effectiveness is essential for commercialization of autonomous vehicles, cooler-free operations of IR detectors at high ambient temperature for autonomous vehicles is in high demand. Microbolometers are the most widely used thermal detector in commercial thermal cameras because of its advantages like portability and low cost. However, the upper limit of conventional microbolometers is approximately 70ºC since the temperature coefficient of resistance (TCR) is lower than 1 %/K of TCR value that is required for ROICs in microbolometers. Thus, high temperature coefficient of resistance (TCR) value and low resistance is required.

In this work, we report on the amorphous vanadium oxide thin films as thermistor materials for microbolometers. Vanadium oxide thin films were deposited using pulsed DC sputtering processes under different growth temperatures from 160ºC to 230ºC. We also studied their electrical properties and effects on the performances of fabricated microbolometers. These processes were carried out under 350ºC which is suitable for ROIC integration without any doping or annealing process. XRD analysis was carried out to identify the structural properties of thin films and the results show that thin films grown at different temperatures were amorphous phases. The sheet resistances of thin films decrease from 330 to 70 kΩ/sq with increasing growth temperature. XPS analysis confirms that it is due to the increase of oxygen vacancies at higher growth temperature. Amorphous VO_x thin films show non-hysteresis behavior up to 120ºC, which in turn shows clear activation energies. The TCR values at room temperature and activation energies of the films increased from 2.44 to 2.8 (-%/K) and from 0.145 eV to 0.190 eV by decreasing growth temperature. These thin films also showed higher than 1 %/K of TCR value even at 120ºC. Amorphous VO_x based microbolometers have been fabricated using electron-beam lithography and lift-off techniques. Characterizations of fabricated microbolometers were carried out under various ambient temperatures from room temperature to 120ºC. Responsivities of fabricated microbolometers based on the amorphous VO_x thermistors change from 1.14×10^3 V/W to 3.04×10^3 V/W at room temperature and from 3.02×10^2 V/W to 9.54×10^2 V/W at 120ºC. The fabricated microbolometers showed high frequency operation properties as well. Thermal time constants were from 1.38 to 0.95 ms at room temperature and from 1.77 to 1.22 ms at 120ºC which show that the microbolometers are suitable for high-speed camera applications such as autonomous vehicles.

This work reveals the correlations between growth temperatures of vanadium oxide thin films and their electrical properties. Amorphous VO_x based microbolometers showed good performance not only at room temperature but also at high ambient temperature up to 120ºC without any cooling device. The results of this work will be highly encouraging for the development of IR detector for autonomous vehicle.

Electrochemically Dynamic Materials for Solar and Radiative Thermoregulation Po-Chun Hsu; University of Chicago, United States

The solar energy has been the cleanest renewable heat sources for humankind. On the other hand, the rest of sky provides the clean cold source via radiative cooling, mitigating the energy consumption for refrigeration and space cooling. While both technologies have been significantly advanced by recent research in photonics and thermal science, there will be a shift of paradigm to combine and dynamically utilize both of them to broaden the

applicability and efficiency for all seasons and climate zones. In this talk, I will summarize recent research progress in this field and introduce our works that use reversible metal electrodeposition to dynamically switch between a plasmonic selective solar absorber and a mid-IR-emitting solar mirror, which can provide year-round HVAC energy saving. Furthermore, the electrochemically variable emittance concept is also applied to ultralow-energy personal thermoregulation, bringing new opportunities in the human-building-energy nexus.

3:45 PM EQ03.21.02
Semiconductor-Based Hyperbolic Metamaterials Dongxia Wei, Patrick Sohr and Stephanie Law; University of Delaware, United States

Traditional metals are good plasmonic materials in the visible spectral range, but do not work well in the infrared (IR). Small gap heavily-doped semiconductors like InAs, InGaAs, and InSb have been shown to be good plasmonic materials in the IR. The carrier density can easily be controlled in these materials, leading to tunable optical properties across wide bandwidths. III-V semiconductors can be grown by molecular beam epitaxy (MBE), an ultra-high vacuum technique in which the materials are grown one atomic layer at a time. This also enables these plasmonic materials to be epitaxially integrated with existing semiconductor-based optoelectronic devices.

MBE is also an excellent technique for the growth of superlattices. A superlattice comprising alternating metal (doped) and dielectric (undoped) layers of subwavelength thickness can act as a hyperbolic metamaterial (HMM). HMMs have an anisotropic dielectric tensor which results in an open, hyperbolic isofrequency surface. The open nature of the isofrequency surface enables HMMs to support the propagation of light with large wavevectors limited only by the subwavelength feature size. In an HMM composed of subwavelength metal and dielectric layers, the modes that support the large wavevector light are called volume plasmon polaritons (VPPs). VPPs are bulk cavity modes that arise from the coupling of surface plasmon polaritons (SPPs) located at the interfaces of the metal and dielectric layers. These features have made HMMs important for studying a variety of light-matter interactions, including negative refraction, subwavelength focusing, subwavelength imaging, modified spontaneous emission, and slow light.

In this presentation, I will describe our results on synthesizing and characterizing semiconductor-based HMMs in the infrared spectral range, explaining how material choice impacts HMM performance, showing far-field thermal emission properties, and demonstrating strong coupling between the HMM VPP modes and epitaxially embedded quantum wells. This work lays the foundation for the creation of new types of IR optoelectronic devices that take advantage of these unusual materials.

4:00 PM EQ03.21.03
A Scalable Metasurface Based Platform for Compact Optical Atomic Clocks Amit Agrawal, Wenqi Zhu, Junyeob Song, Chad Ropp, Vladimir Aksyuk, Andrew Ferdinand, Sindhu Jammi, Grisha Spektor, Scott Papp and Lu Chen; National Institute of Standards and Technology, United States

Over the last decade, flat optical elements composed of an array of deep-subwavelength dielectric or metallic nanostructures of nanoscale thicknesses – referred to as metasurfaces – have revolutionized the field of optics. Because of their ability to impart an arbitrary phase, polarization or amplitude modulation to an optical wavefront as well as perform multiple optical transformations simultaneously on the incoming light, they promise to replace traditional bulk optics in applications requiring compactness, integration and/or multiplexing. Recent demonstrations including imaging, full-Stokes polarimetry, quantum-light generation and LIDAR demonstrate the range of technologies where metasurfaces have already had a significant impact.

In this work, we demonstrate the versatility of wavefront shaping metasurfaces as a compact, efficient and multifunctional interface to: (a) trap single neutral atoms of ^{87}Rb in an optical tweezer trap for application in quantum information science, and (b) trap ensemble of Sr atoms in a magneto-optical-trap (MOT) for realization of a compact optical lattice clock. We further establish a scalable infrastructure for strontium optical-atomic clocks, leveraging advances in visible integrated and metasurface photonics along with a compact, commercially available Sr source and vacuum chamber to reduce the overall SWaP of the physics package. We present experiments with laser cooling and trapping Sr atoms in a metasurface MOT with our compact vacuum chamber and atom source, demonstrating a path toward scalable, compact optical clocks that is completely alignment-free and does not utilize any free-space optics.

In another integration step, combining metasurfaces directly with integrated photonic circuits, replacing bulk optical elements, promises increased complexity and functionality in a batch-fabricated optical microsystem ultimately capable of fully replacing the laboratory optical table. With this goal in mind, we leverage integrated photonic and metasurface optics that interface directly with light from single-mode fibers; and how integration of many such structures on a single chip in a CMOS foundry manufacturable platform enable new capabilities for cold atom atomic clocks and other quantum sensors.

4:15 PM EQ03.21.04
Double Negative Acoustic Metamaterial Reaching Operating at 300 kHz in Water Based on Silicon Microfabricated Unit-Cells Jiaying Wang[1], Florian Allein[2], Cecile Floer[3], Nicholas Boechler[1], James Friend[1] and Oscar Vazquez Mena[1]; [1]UC San Diego, United States; [2]Le Mans Université, France; [3]Université de Lorraine, France

Negative acoustic metamaterials have shown extraordinary novel capabilities such as enhancement of evanescent waves with subwavelength components, negative refractive angle, opposite phase and group velocities, and enhancement of transmission through high-contrast acoustic barriers. This shows enormous promise for medical ultrasound applications. However, a major challenge is increasing their frequency operations. Double negative metamaterials have been demonstrated at 300 Hz(1) and 30 KHz(2), which falls below medical ultrasound range that covers a broad range from 200 kHz to 50 MHz. Herein, we demonstrate a double negative acoustic metamaterial operating at 300 kHz using robust silicon microfabrication technology. The main fabrication novelty is the fabrication of silicon chips as individual unit-cells. Each chip contains sub-100 micron Helmholtz resonators and silicon nitride membranes, which produce negative modulus and negative density behavior, respectively. Then, the silicon chip unit-cells are assembled in water, forming a periodic structure integrating the Helmholtz resonators and silicon nitride membrane that result in a double negative acoustic metamaterial operating at 300 kHz. Our metamaterial consists of an acoustic waveguide 60 um wide, silicon nitride membranes 200 nm thick, and Helmholtz resonators (500x500x10 um^3) with a neck with a cross section of (20x10um) and a length of 50 um connecting the Helmholtz resonator to the acoustic waveguide. Our key fabrication strategy is that instead of forming a monoblock structure, we fabricate individual chips, allowing the fabrication of high-resolution micromechanical components, which are then assembled to form the metamaterial. The assembling is done with mechanical screws and using a laser to verify alignment. Silicon and silicon nitride are chemically stable in water and their mechanical properties allows for operation >100 kHz. We present analytical models, finite element method simulations, and laser-doppler vibrometry experimental results that indicate double negative behavior and negative-index propagation in the 0.25-0.35 MHz range. At 300 kHz, Our metamaterial shows a positive group velocity (wave packets carrying information propagate forward) of 200 m/s, but with a negative phase velocity (valleys and peaks moving backwards) of -1750 m/s. The opposite propagation between wave packets and peaks/valleys, together with a close agreement between analytical, simulations and experimental results, provides strong evidence for the negative-index behavior of our metamaterial. We estimate an effective density near -2000 kg/m^3 and a modulus of -9 GPa at 300 kHz. The acoustic index with respect to water covers a range from -5 at 0.25 MHz to -1 at 0.35 MHz. Our technology has several advantages: 1) the use of microfabrication tools allows for further reduction in size and increase in frequency operation; 2) the long-term mechanical and chemical stability of silicon

nitride and silicon that open possibilities for using different propagation media besides water; 3) the design flexibility to modify each acoustic component to target specific density/modulus/index value; 4) the fabrication in individual cells also facilitate the integration of membranes and Helmholtz resonators in different 1-D, 2-D and 3-D arrangements. There are also several challenges ahead, such as improving assembling and alignment precision, as well as studying the role of viscosity and damping as sound propagates in structures below 100 um in size.

Stain-Free Tissue Imaging with Scalable Plasmonic Metasurfaces Doeun Kim, Juhwan Kim, Soeun Ko, Jin Kyeong Lee, Jang-Hwan Han and Hyeon-Ho Jeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Label-free tissue diagnostics using plasmonics, a.k.a. histoplasmonics, enables morphological analysis of cells with colorful contrast in the refractive indices between cells and surroundings (Ref. Nature 598, 65, (2021)). However, this method still requires not only cell staining with molecular dyes (hematoxylin and eosin, H&E) for enhanced contrast, but also a regular array of plasmonic nanopatterns via nanolithography, limiting mass-production. We here describe a 'lithography-free' scalable fabrication of plasmonic metasurfaces using a rapid electrostatic coating of nanoparticles and their use for 'stain-free' colorful refractive index imaging of cells. The colloidal solution of negatively-charged plasmonic nanoparticles is casted onto a positively-charged metallic mirror, enabling the rapid (but massive) nanoparticle coating in a random fashion (> 10% surface coverage for 10 seconds) and thus formulating well-defined solid nanogaps between the nanoparticles and the mirror underneath through the centimeter scale film. Such plasmonic metasurfaces defined with a solid nanogap not only provides the uniform, vivid colors through the entire surface, but are also sensitive to the change in the surrounding refractive index so readily visualize its variation in the extremely localized area (ideally single nanoparticle level) in colors from red to green under an ambient light. More crucially, this metasurface offers the distinct color of the cultured animal cells (3t3-L1, adipose cell, n= 1.358-1.374) against the water environment (n = 1.33), otherwise impossible to be seen with standard optical microscopy.
In this presentation, the fabrication method of the plasmonic metasurfaces and their theoretical and experimental optical features will be discussed. Furthermore, we will show how to qualitatively model the resonant plasmonic spectra as a function of the refractive index spectroscopically for in-situ colourful imaging of the cultured animal cells.

SESSION EQ03.22: Advanced Nanophotonic Design III

Friday Morning, December 2, 2022
Hynes, Level 2, Room 202

8:30 AM *EQ03.22.01
High-Index Metastructures with Lattice Multipole Resonances Viktoriia Babicheva; University of New Mexico, United States

Nanoparticle clusters, such as oligomers, support modes with different symmetries resulting in Fano resonances. Moreover, periodic nanoparticle arrays give rise to lattice resonances at the wavelength close to the Rayleigh anomaly, i.e., effective wavelength in the medium is equal to the array period. Compared to a single nanoscatterer, drastic changes in the metastructure resonances can be induced by arranging nanoparticles into a periodic array. This often facilitates the excitation of additional resonances known as lattice resonances.

In this work, we aim to design efficient directional scatterers and their arrays for metasurfaces and transdimensional metastructures. The combination of different materials in the nanoparticle allows the tune of electric and magnetic resonances of the nanoparticles and achieving broadband overlap. The nanofabrication and characterization include sample preparation, deposition of metals and oxides, as well as optical measurements of reflection and transmission spectra. One or multiple nanoparticles (or scattering elements, or scatterers) are considered in the unit cell of the lattice unit. We introduce mismatched resonances excited in the array and show that the dimensions of scatterers define the type and character of excitations.

This work was performed, in part, at the Center for Integrated Nanotechnologies, an Office of Science User Facility operated for the U.S. Department of Energy (DOE) Office of Science by Los Alamos National Laboratory (Contract 89233218CNA000001) and Sandia National Laboratories (Contract DE-NA-0003525). The work is also supported by Contract DE-2375849.

9:00 AM EQ03.22.02
Pico-Photonics in Silicon Sathwik Bharadwaj, Todd Van Mechelen and Zubin Jacob; Purdue University, United States

The concept of frequency (ω) - momentum (q) dispersion has been extensively studied in artificial dielectric structures such as photonic crystals and metamaterials. However, the ω − q dispersion of electrodynamic waves hosted in natural materials at the atomistic level is far less explored. Here, we develop a Maxwell Hamiltonian theory of matter combined with the quantum theory of atomistic polarization to obtain the electrodynamic dispersion of natural materials interacting with the photon field. We apply this theory to silicon and discover the existence of anomalous atomistic waves. These waves occur in the spectral region where propagating waves are conventionally forbidden in macroscopic theory. Our findings demonstrate that natural media can host a variety of yet to be discovered waves with sub-nanometer effective wavelengths in the pico-photonics regime. This study bridges the fields of optics and condensed matter physics, spawning a new area of research in material science and engineering.

9:15 AM EQ03.22.03
Single-Shot Microfabrication of Complex 3D Structures by Volumetric Multiphoton Lithography He Cheng[1], Pooria Golvari[1], Chun Xia[1], Mingman Sun[2], Meng Zhang[2], Stephen M. Kuebler[1,1,1] and Xiaoming Yu[1]; [1]University of Central Florida, United States; [2]Kansas State University, United States

Multi-photon lithography (MPL) is a technique for fabricating three-dimensional (3D) microstructures with submicron resolution. Arbitrarily complex forms are created by scanning a focal spot in a photoresist using a galvo scanner or a piezoelectric stage to locally induce multi-photon polymerization. The

requirement for point-by-point scanning severely limits the throughput of MPL and hinders its industrial use. Methods for parallel exposure have been explored for improving the fabrication speed in MPL. Various approaches for 2D beam shaping have been used to pattern layers in parallel, but little is known of ways to achieve volumetric exposure, in which whole 3D sub-parts or complete 3D structures are patterned in a single exposure. We recently reported a method for high-throughput fabrication of complex 3D volumes using normal and superposed Bessel beams [1-7]. Complex structures were created in a single static exposure using one or a few laser pulses, including cylinders, needles, and spirals with tunable pitch. Importantly, the pitch distance can be designed to vary along the optical axis, creating "accelerating" or "decelerating" spirals with desired handedness. With complementary horizontal beam scanning, self-supporting matrices of spirals were fabricated in the photoresist SU-8 demonstrating the feasibility of large-scale fabrication. Volumetric exposure increases fabrication throughput by at least two orders of magnitude. This method paves the way for mass production of functional devices using MPL having applications in photonics, microfluidics, bioscaffolds, medicine, and more.

9:30 AM EQ03.22.04
Optical Microcavities in Luminescent Beta-Ga2O3 Nanowires—Tunability from Near-UV to Near-IR and Wide Range Temperature Sensors
Manuel Alonso-Orts[1,2], Daniel Carrasco[2], Gerwin Chilla[1], Rudolfo Hötzel[1], Jose Maria San Juan[3], Maria Luisa Nó[3], Martin Eickhoff[1], Alicia de Andrés[4], Emilio Nogales[2] and Bianchi Mendez[2]; [1]University of Bremen, Germany; [2]University of Complutense-Madrid, Spain; [3]Universidad del País Vasco, Spain; [4]Instituto de Ciencia de Materiales de Madrid (CSIC), Spain

Semiconductor nanostructures-based optical microcavities have attracted much attention for decades. Gallium oxide, an ultra-wide bandgap semiconductor, is currently attracting great interest, especially for its applications in high power electronics [1]. Photonics applications are being parallelly explored, particularly solar-blind UV photodetectors and tunable emitters that take advantage of its 4.8 eV bandgap, allowing wide tunability from the UV to the IR [1]. Indeed, this oxide has shown highly interesting properties as a light emitter in this photonic range.
In this work, we show the use of beta-Ga2O3 nanowire-based photonic structures that result in optical microcavities to be used as resonant, tunable emitters and as thermal sensors. To this aim, microcavities with pairs of distributed Bragg reflectors (DBRs) were created in nanowires by drilling holes with a focused ion beam (FIB) [2] to yield carefully tuned stop bands, i.e. to strongly enhance the reflectivity for specific wavelength ranges. Widely tunable Fabry-Perot (FP) optical resonances are observed in the micro-photoluminescence (PL) spectra obtained from the cavities, which were thoroughly analyzed both experimentally, analytically and through finite-difference time-domain (FDTD) simulations. The results show nice agreement and allow to design and optimize their performance, as demonstrated in two different regions of the spectrum: the blue-NUV [3] and the red-NIR [2].
Finally, a novel design of thermal sensor based on these microcavities is presented [4]. Two different PL features – the R-lines of Cr3+ ions and the FP resonances created within the cavity – are monitored, observing a temperature-dependent spectral shift for both of them. Each feature is optimum for a different range, allowing to sense at least from 150 K up to 550 K. Temperature precision is around 1 K and the full width at half maximum of the FP peaks is nearly unchanged in the whole temperature range. These thermometers present a wide dynamic range, high spatial resolution - in the range of microns - , very high thermal and chemical stability and can be used in harsh environments, ideal for high electronic/optical power devices, among other applications.

9:45 AM EQ03.22.05
A System for Measuring Deep Ultraviolet Cathodoluminescence
Simo Pajovic[1], Charles Roques-Carmes[1], Steven E. Kooi[1], Nicholas Rivera[1], Ali Ghorashi[1], Yang Yu[2], Ido Kaminer[3] and Marin Soljačić[1,1]; [1]Massachusetts Institute of Technology, United States; [2]Raith America, Inc., United States; [3]Technion–Israel Institute of Technology, Israel

Deep ultraviolet (DUV) radiation plays an essential role in several important technologies, including fluorescence, photolithography, and water purification. However, existing methods of producing DUV radiation have limitations: nonlinear processes (such as those used in Nd:YAG lasers) have limited efficiencies because of phase matching requirements and absorption; the efficiencies of state-of-the-art DUV LEDs (typically based on AlGaN) are limited by defects and electron leakage [1]; and mercury-vapor lamps are plagued with health and safety concerns. Scintillation—light emission from transparent materials due to the passage of high-energy particles—could be a viable alternative, particularly if the high-energy particles are electrons (also known as incoherent cathodoluminescence, or ICL). In this case, it has been predicted that direct bandgap emission could be highly efficient compared to the state of the art [2]. Additionally, the emission spectra of scintillators can be tailored by patterning their surfaces with photonic crystals [3], meaning that ICL-based DUV sources could be tunable in ways conventional ones are not. We have built an experimental setup based on a modified scanning electron microscope capable of measuring both ICL and coherent CL in the DUV (> 130 nm). In our setup, the electron beam impinges on the sample at grazing incidence, causing it to emit light. Emission is collected by a DUV coated reflective objective and sent to a UV monochromator and CCD camera, which finally measures the emission spectrum. Our setup has enabled us to measure DUV emission from wide bandgap materials such as diamond and h-BN and can be used to probe samples with patterned surfaces. We anticipate patterning will lead to spectral shaping and enhancement of DUV ICL based on our simulations of an h-BN nanophotonic scintillator, which showed a wavelength-dependent enhancement of the emitted power by nearly three orders of magnitude [3]. Our work enables the advancement of DUV scintillators and highlights the potential of electron beam pumping to lead to more efficient DUV sources, which would be desirable for all the aforementioned applications. This material is based upon work supported by the US Army Research Laboratory and the US Army Research Office through the Institute for Soldier Nanotechnologies under contract W911NF-18-2-0048.

Selective Capture of Hot Electrons/Holes for Plasmon Decay at an Atomically Sharp Metal-Semiconductor Interface Zehao Song and Alois Lugstein; Technical University of Vienna, Austria

Surface plasmon polaritons (SPPs), enabling to operate electro-magnetic waves at nanometer dimension and femtosecond time scale, provide a favouable bridge of combining the compactness of an electronic circuit with the bandwidth of a photonic network. However, this will require the exploration of effective photon to electron and electron to photon converters. Selectively collecting the non-equilibrium hot electrons/holes generated from SPPs decay at Schottky contacts is a promising approach to achieve on-chip hot-carrier photodetectors. Although there are already many studies on hot electron capturing and a few on hot holes, the mechanism is still under debate. This is mainly because the effect is difficult to study separately from common photo-generation and certain metal-smiconductor combinations can only selectively capture either holes or electrons. In this work, we report a gated Schottky diode device with a plasmonic nano-antenna coupled to the monolithic and atomically sharp aluminum-silicon (Al-Si) heterojunction enabling to capture selectively hot holes and/or electrons. Compared to the noble metals gold or silver, Al features an approximately uniform energy distribution, almost the same lifetime and mean free path for hot electrons and holes. The clear geometric separation of the SPPs source and the energy filtering Schottky diode allow precise investigation of the decay of SPPs and the capture of hot charge carriers. Using scanning photocurrent microscopy analysis, we elucidated the electrostatic potential in the ultrascaled Si channel and the tunable Schottky barrier. Using a sophistically split gate configuration, hot electrons or hot holes can be selectively captured with similar external quantum efficiency, demonstrating experimentally the uniform energy distribution of hot electrons/holes energy for SPPs in Al.

10:45 AM EQ03.23.02
Spectral Emissivity Prediction in Multi-Resonator Metamaterials Using Temporal Coupled-Mode Theory Romil Audhkhasi and Michelle Povinelli; University of Southern California, United States

The ability to design thermal emitters with a multi-resonant spectral response is essential for advancement of a wide variety of applications such as thermal management and sensing. To this end, several numerical methods for predicting the spectral response of complex, multi-resonator systems have been investigated. In this work, we propose an alternative semi-analytical approach to spectral prediction based on temporal coupled-mode theory. In our approach, a complex thermal emitter is fully described by a set of coupled-mode parameters, which can be straightforwardly calculated from simulations of single and double resonators. We demonstrate the accuracy of our method by predicting and optimizing spectral response in a coupled, multi-resonator system based on hBN ribbons. Our approach greatly reduces the computational overhead associated with spectral design tasks in coupled, multi-resonator systems. In addition, it provides valuable insights into the relationship between structural parameters and spectral response that is not always possible with purely numerical methods.

11:00 AM EQ03.23.03
Nonreciprocal Photonics Using Surface Waves in the Magnetic Weyl Semimetal $Co_3Sn_2S_2$ Arun Nagpal[1], Christopher Ciccarino[2], Chandra Shekhar[3], Claudia Felser[3], Prineha Narang[4] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]Stanford University, United States; [3]Max Planck Institute for Chemical Physics of Solids, Germany; [4]University of California, Los Angeles, United States

The demonstrations of a large intrinsic anomalous Hall effect and large nonlinear optical response in Weyl semimetals is attributable to the presence of nontrivial Berry curvature in regions of reciprocal space between recombinant Weyl points. We explore the properties of single crystals of the magnetic Weyl semimetal $Co_3Sn_2S_2$ for non-reciprocal photonics and polaritonic devices. Using Fourier transform infrared spectroscopy and ellipsometry, we characterize the material Mueller matrix at 80K in the MIR range we extract a Kramers Kronig consistent permittivity tensor. With [110]-oriented single crystals, we demonstrate the manifestation of non-equivalent reflection coefficients at +/- 70°, induced through the generation of plasmons with a non-reciprocal dispersion. We find for our sample, the non-reciprocity is maximized at 0.17 eV, where the ratio of diagonal and off-diagonal components of the permittivity diverge. We discuss device designs that exploit these relations for use in magnet-less magneto-optical systems.

11:15 AM EQ03.23.04
Arbitrary Space-Time Wave Packet Synthesis Lu Chen[1,2], Wenqi Zhu[1,2], Pengcheng Huo[3], Junyeob Song[1], Henri J. Lezec[1], Ting Xu[3] and Amit Agrawal[1]; [1]National Institute of Standards and Technology, United States; [2]University of Maryland, United States; [3]Nanjing University, China

Dielectric metasurfaces, composed of deep-subwavelength nanostructures, can sculpt the phase, amplitude, and polarization of light at the nanoscale. Their multifunctional response at the single-pixel level, combined with compact form-factor and integrability with other CMOS compatible devices make them key components for miniaturized photonic platforms, leading to numerous applications in spatial domain wavefront manipulation of light [1]. Recently, temporal-domain shaping of scalar waveforms of a linearly polarized ultrafast pulse has been demonstrated using dielectric metasurfaces [2, 3]. Here, we show, both theoretically and experimentally, that a single-layer transmission-mode dielectric metasurface can be leveraged to simultaneously and independently tailor the complete spatiotemporal properties of a near-infrared femtosecond pulse. This approach offers the most complete and general control of light field across an ultrabroad bandwidth, enabling synthesis of arbitrary space-time wave packets.
The spatiotemporal profile of a *p*-polarized femtosecond pulse of ≈10 fs duration (full-width at tenth-maximum bandwidth of ≈ 80 THz, centered at 800 nm) is tailored by manipulating the constituting discrete frequency lines. A 4-*f* Fourier-transform pulse shaper spatially disperses and focuses the frequency lines at the Fourier plane, where a metasurface is positioned to implement a complex masking function sampled by 200 super-pixels. Each super-pixel contains a two-dimensional (2D) array of rectangular silicon nanopillars orientated at 45° with respect to the horizontal direction, providing parallel phase

modulation along the two birefringent axes. In this way, each super-pixel can independently impart a 2D spatial phase function as well as an overall phase-shift to the two orthogonal polarization components of frequency lines that reside within the super-pixel. The shaped frequency lines are then subsequently recombined into a spatiotemporally engineered femtosecond pulse.
This approach, leveraging ultra-high spectral resolution of a Fourier-transform pulse shaper and multifunctional responses at the nanoscale provided by the dielectric metasurface, offers ready design flexibility that can enable the synthesis of a vast variety of complex ultrafast spatiotemporal wave packets. To demonstrate the versatility of this approach, exotic femtosecond pulses, exhibiting a rich set of time-varying instantaneous polarization states and structured wavefronts within a single pulse, are designed and experimentally demonstrated. Comprehensive analysis, including numerical simulations and analytical modeling, are also performed to explain their spatiotemporal evolution.
In conclusion, we have demonstrated tailoring of both the temporal and spatial degrees of freedom of an ultra-broad bandwidth, near-infrared femtosecond pulse using a single-layer transmission-mode dielectric metasurface. Such an approach further promotes the already intriguing applications of metasurfaces, revealing new possibilities in the field of ultrafast science and technology.

11:30 AM EQ03.23.05
Tailoring the Optical Properties of Zinc Oxide via Bismuth Doping and Co-Doping Strategies—From Birefringence to Metallicity Samar Fawzy, Yehea Ismail and Nageh K. Allam; American University in Cairo, Egypt

We make use of density functional theory to explore the effect of Bi as a high-index dopant on the optical properties of 3 metal-oxide structures: Titanium dioxide (TiO_2), Zirconium dioxide (ZrO_2) and Zinc Oxide (ZnO). It was found that Bi_{Metal} substitutional doping results in reducing the bandgap (E_g) by creating new defect states in the 3 oxides. In case of ZnO, the in-plane refractive index ($n_{x,y}$) is doubled (>3) over a wide band in mid and far IR, and huge birefringence is obtained compared to other materials in literature. The presence of Oxygen vacancies (O_v) in the structure was found to lower the losses, which was elaborated by the decreased absorption cross section of a sphere of 250 nm radius, using FDTD. At 12% Bi doping, metallicity is obtained with losses lower than Silver, Gold, and Nitrides. Co-doping of Bi with interstitial Hydrogen doping (H_i) or substitutional Aluminium (Al_{Zn}) doping give the same effect, which is increasing both the in-plane and out of plane indices even higher, but on the expense of increasing optical losses.

SESSION EQ03.24: Active Plasmonics
Session Chairs: Claudio Hail and Yu-Jung Lu
Friday Afternoon, December 2, 2022
Hynes, Level 2, Room 202

1:30 PM EQ03.24.01
Tunable Electrical and Optical Properties of Photonic and Plasmonic Multilayer Metastructures Based on Alternative Plasmonic Materials Cristina Mancarella[1], Liliana Moscardi[1], Lorenzo Stasi[1], Ludovica Tovaglieri[1], Gianluigi Baiardi[1], Giacarlo Terraneo[1,2], Vincenzo Caligiuri[3,4], Antonio De Luca[3,4], Francesco Scotognella[1,2] and Andrea Li Bassi[1,2]; [1]Politecnico di Milano, Italy; [2]CNST - Italian Institute of Technology, Italy; [3]Università della Calabria, Italy; [4]CNR - Nanotec, Italy

The current research in plasmonic nanotechnologies is focusing on nano-systems with intrinsic multifunctionalities, aimed at reaching large tunability of properties to fulfill at once multiple needs, spanning different applications (optoelectronics, biosensing, solar-energy harvesting). The archetypal plasmonic materials, i.e. noble metals, show limited modulation outside the visible spectrum due to the fixed charge carrier density [1]. This justifies the spreading interest for alternatives (transparent conductive oxides TCOs, transition metal nitrides or oxynitrides) and periodically-arranged multi-phase nanostructures, where the high level of control in carrier concentration is achievable directly at synthesis or with an “active” approach (e.g. external bias). Indeed, several nanoarchitectures have been investigated to modulate optical characteristics of plasmonic metals outside the visible, enhance performances, and eventually activate novel functionalities. Hyperbolic metamaterials especially sustain unique “high-k modes” activated by the periodic alternation of conductors (e.g. noble metals) and dielectrics (e.g oxides) of subwavelength thicknesses [2]. Besides, when increasing the characteristic dimension of layers, Bragg’s reflections start to appear and one-dimensional (1D) photonic crystals can be achieved straightforward [3].
Here, a variety of novel multifunctional nano-structures have been developed, involving alternative materials (TCOs, nitrides and oxynitrides) and original design routes (via pulsed laser deposition PLD) with the aim to explore, from a material science perspective, electrical/optical responses resulting from unusual combinations of materials and properties (transparency, conductivity, tunable VIS-IR plasmonics, active modulation).
For instance, novel TiN-TiO_2 plasmonic multilayers have been realized as hyperbolic metamaterial in the visible, with added advantages determined by the good material affinity and the versatility of TiO_2 as a wide-band gap semiconductor. In addition, the resulting features can benefit from the refractory nature and CMOS compatibility of TiN, along with the possibility to modify the plasmonic response through stoichiometry. Then, original transparent conducting multilayers based on the less-explored Tantalum-doped TiO_2 (Ta:TiO_2) TCO have been obtained directly in a simple one-step synthesis, by alternating conductive (compact) and dielectric (nanoporous) layers of the same TCO achieved by varying the deposition pressure (1-6 Pa O_2). Structural and electrical properties have been optimized to control optical/plasmonic outputs as a function of deposition conditions, doping content and geometrical parameters. Future applications are foreseen as hyperbolic platforms or biosensing devices in the IR, while 1D photonic crystals can be accomplished by customizing compact/porous fraction and dimension of the layers. The proper optimization of material properties leads to an intense photonic band gap, spanning from green to red wavelengths in the visible, which in turn can be actively modulated with an external bias. Finally, the investigation of TiON films as tailorable oxynitrides with expected epsilon-near-zero behaviour, has been started by finely controlling the oxygen content directly during PLD synthesis.
Concluding, these multifunctional meta-devices are application-oriented and possess a cross-disciplinary attitude. Current challenges are related to mastering the material properties and designing devices to prove the real applicability of such meta-structures. Hence, the list of practical applications includes, but is not limited to, VIS or mid-IR biosensors, surface enhanced infrared Raman spectroscopy, optoelectronic elements for color manipulation and thermophotovoltaic emitters.

Helicity-Driven Spin Currents and Magnetization Dynamics in Au-Based Structures Chuangtang Wang and Yongmin Liu; Northeastern University,

United States

Ultrafast helicity-dependent all-optical switching of magnetization by a femtosecond laser pulse has attracted extensive interest, because it holds the promise for future high-rate magnetic storage. Controlling the spin angular momentum transfer from light to magnetic materials is the key to achieve the helicity-dependent switching of a single layer's magnetization. Researchers have found that a capping layer made of heavy metal with large spin-orbital coupling strength, such as Pt, Ta, and W, could enhance the spin momentum transfer, namely optical spin-transfer torque, compared to the direct interaction between the light and magnetic materials. In this work, we will discuss the potential of Au as a better choice for the capping material, because it supports plasmonic resonances which enable both enhanced spin-momentum transfer and nanoscale plasmonic integration. We have studied the magnetization dynamics of Au/Co structures with a time-resolved magnetic-optical Kerr effect spectroscopy. The existence of large spin-transfer torque is observed in the system. The overall efficiency is as high as that in Pt/Co. The mechanism is revealed by the detailed thickness- and wavelength-dependent measurements of magnetization dynamics. Our findings will stimulate future research using Au plasmonic structures to achieve more efficient and denser magnetic storage.

2:00 PM DISCUSSION TIME

2:15 PM EQ03.24.04
Electrically-Switchable Angle-Dependent Plasmonic Coloration Gyurin Kim, Jang-Hwan Han, Hyun Min Kim, Juhwan Kim and Hyeon-Ho Jeong; Gwangju Institute of Science and Technology, Korea (the Republic of)

Optical encryption using plasmonics is a superior concept for security as it offers fade-free rich colorations with viewing-angle and/or polarization dependency.[1] However, such plasmonic coloration typically not only necessitates complex nano-lithographic patterning for multilayered plasmonic systems with their precise nanoscale dimension, but also remains in the production of static image planes.
We here present a 'lithography-free' method to fabricate wafer-scale multi-layered 'active' plasmonic metasurfaces, which show angle-dependent as well as electrically switchable coloration across the whole visible spectra. The physical vacuum growth with substrate cooling allows us to grow a wafer-scale array of dense plasmonic nanoaggregates on a metallic mirror coated with a conductive polymer layer (here polyaniline). Such nanoparticle-on-mirror constructs filled with polyaniline intrinsically possess two dominant gap plasmonic modes, i.e. (i) in-plane coupling between densely-positioned nanoparticles and (ii) out-of-plane coupling between the nanoparticles and the mirror underneath. These two coupling modes can be excited selectively depending on an incident angle of the light and thus reveal a vivid color transition. More crucially, such colors can now be further electrically tunable in response to an external voltage applied (< 1V), thanks to the change in the redox states of the polyaniline within the nanojuctions and thus associated refractive indices.[2] With the combinatorial control in the light angle and the electrical input, the single plasmonic metasurface gives rise to rich colorations across the whole visible spectra, potentially useful for 'active' optical information storage and encryption.
In this presentation, the structural design, numerical simulation, fabrication method, optical feature and analysis of the electrically switchable plasmonic metasurfaces will be discussed.

2:30 PM EQ03.24.05
Microporous Multiresonant Plasmonic Meshes by Hierarchical Micro–Nanoimprinting for Bio-Interfaced SERS Imaging and Nonlinear Nano-Optics Aditya Garg, Elieser Mejia, Wonil Nam, Meitong Nie, Wei Wang, Peter Vikesland and Wei Zhou; Virginia Tech, United States

Due to their low elastic moduli and high permeability to nutrients and oxygen, mesh-like flexible microporous devices confer significant biocompatibility advantages to interface with cell networks and tissues for biomedical sensing or actuation applications. Microporous mesh plasmonic devices have the potential to combine the biocompatibility of microporous polymeric meshes with the capabilities of plasmonic nanostructures to enhance nanoscale light-matter interactions for bio-interfaced optical sensing and actuation. However, scalable integration of dense and uniformly structured plasmonic hotspot arrays with microporous polymeric meshes remains challenging due to the processing incompatibility of conventional nanofabrication methods with flexible microporous substrates. For the first time, we have created microporous multiresonant plasmonic mesh (MMPM) devices via a dissolvable template-based hierarchical micro-/nanoimprinting approach. The MMPMs carry 2-tier nanolaminate plasmonic crystals (NLPCs) consisting of two optically coupled nanodome and nanohole multiresonant sub-systems. The NLPCs can support many hybridized plasmonic modes with spatial overlap and can allow for multiresonant nanoscale light concentration across a wide wavelength range between 400 and 1400 nm. We demonstrate that MMPMs can serve as broadband nonlinear nanoplasmonic devices to generate second-harmonic generation (SHG), third-harmonic generation (THG), and upconversion photoluminescence (UCPL) signals with multiresonant plasmonic enhancement under fs pulse excitation. Moreover, we demonstrate that MMPMs can function as bio-interfaced surface-enhanced Raman spectroscopy (SERS) mesh sensors that enable in-situ spatiotemporal molecular profiling of bacterial biofilm activity. We envision that microporous mesh plasmonic devices can open exciting avenues for bio-interfaced optical sensing and actuation applications, such as inflammation-free epidermal sensors in conformal contact with skin, combined tissue-engineering and biosensing scaffolds for in vitro 3D cell culture models, and minimally invasive implantable probes for long-term disease diagnostics and therapeutics.

Discovery of New Plasmonic Metals Using First-Principles Simulations and Machine Learning Ethan Shapera, Andre Schleife and Erick I. Hernandez Alvarez; University of Illinois at Urbana-Champaign, United States

Discovering new materials with low-loss response to an applied optical field while exhibiting collective oscillations due to intraband transitions is an outstanding challenge for the field of plasmonics. While nanoscale structuring also affects practical applications in this context, here we view this as a materials selection problem: In particular, we aim to address the gap between the large number of a priori candidate materials and high computational cost

to accurately compute optical properties from first principles. We combine the Materials Project database with first-principles simulations and the Drude model. Using density functional theory we compute a training set of geometry-dependent plasmonic quality factors for almost 1,000 materials and train random-forest regressors on this data. Our descriptors ignore crystal structure and are limited to symmetry, quantities obtained using the chemical formula, and the Mendeleev database. Using the trained model we rapidly screen 7,445 candidates and subsequently use density functional theory to compute quality factors for the 233 most promising materials. From this, we identify $AlCu_3$, ZnCu, and $ZnGa_3$ as excellent potential new plasmonic metals and substantiate these results by analyzing their electronic structure and interband optical properties in detail.

3:45 PM EQ03.25.03
Mechanical Deformation Induced Tunable Mid-Infrared Optical Properties Fangqi Chen, Xiaojie Liu, Yanpei Tian and Yi Zheng; Northeastern University, United States

Over the past decade, tremendous efforts have been devoted to the design of metamaterials with ultrahigh absorption. These perfect absorbers can realize the annihilation of incident electromagnetic waves by eliminating reflection and transmission of microwaves, infrared, visible, and ultraviolet. However, the optical properties are usually unchanged due to a rigid structure. In this work, we propose a mechanically stretchable metamaterial composed of polydimethylsiloxane and gold with tunable optical properties in the mid-infrared region. A large variation of absorptances with different gold filling ratios is demonstrated as well as the corresponding electric field distributions. Under moderate uniaxial and biaxial tensions, the proposed two-dimensional grating structure has achieved a dynamic tuning of infrared thermal properties, including a sharp reflectance-absorptance switch. This mechanically stretchable metamaterial can serve different optical and sensing functions due to its facile tunability.

4:00 PM EQ03.25.04
Ultrathin Perfect Absorbing Metamaterial Stacked with Solid and Inverse Antenna Above Metal Ground Minji Kim[1], Kyungmin Jung[1], Youmee Choi[2], Seung Sang Hwang[2] and Jerome K. Hyun[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Metamaterials have proven to be effective electromagnetic (EM) wave absorbers with unprecedented control over the properties of the wave.(*1-3*) To achieve ultracompact, flexible, and lightweight EM absorbers, the ability to perfectly absorb an EM wave with a material much thinner than the wavelength is required. Herein, we demonstrate a metamaterial with extreme subwavelength thickness by introducing a cross-shaped aperture into the bottom metal plane of a conventional three-layer metal patch/dielectric/metal stack.(*4*) With the stack placed above a metal ground for perfect absorption, a total thickness of only 1/1250 of the working wavelength is achieved. The aperture increases the resonance wavelengths by up to 10-folds by enlarging the inductance of the stack. More specifically, the induced current in the aperture plane must flow around the aperture, creating a magnetic flux that increases with aperture area. Using this approach, we experimentally demonstrate perfect absorption using the appropriate dielectric thickness and loss tangent needed to achieve critical coupling. To the best of our knowledge, our EM absorbers provide the largest wavelength-to-thickness ratios to date. The principles outlined here are general and can be extended to other frequencies.

4:15 PM EQ03.25.05
Compound Meta-Optic for Lossless Complete Field Manipulation Hanyu Zheng[1], Mingze He[1], You Zhou[1], Ivan Kravchenko[2], Joshua D. Caldwell[1] and Jason G. Valentine[1]; [1]Vanderbilt University, United States; [2]Oak Ridge National Laboratory, United States

The ability to independently control the amplitude, phase, and polarization state of light is needed for a wide variety of scientific and industrial applications and generally requires multiple conventional optical elements such as lenses, polarizers, and amplitude masks. The need for multiple elements results in large systems that can be difficult to integrate into compact optical packages. Optical metasurfaces, comprising sub-wavelength scale meta-atoms, provide a versatile platform for manipulating optical waves in a compact form factor, and have been used to create a wide variety of optical elements such as lenses, beam splitters, and waveplates. Metasurfaces, moreover, can go beyond simple replacement of conventional optics by providing novel functionalities including multi-functional imaging, phase-mining, image processing, polarimetry, augment reality, holography.
Although metasurface-based wavefront control has been demonstrated in the past, independent control of phase and amplitude using a single metasurface comes at the expense of a polarization-dependent response. The involvement of polarizer components introduces loss that can be as high as 90% in some circumstances. Moreover, the symmetric Jones matrix that dictates the transmission of each meta-atom prevents independent control over polarization conversion for orthogonal axis. Spatial multiplexing, on the other hand, can provide independent polarization manipulation over orthogonal states by using interference between the neighboring meta-atoms. However, this method leads to higher diffraction orders due to the use of a larger supercell, limiting the diffraction efficiency in the target order. An alternative approach is the use of multi-layer, compound meta-optics, which harness independent design degrees of freedom in each layer and allow for light redistribution during propagation for realizing near loss-less amplitude and phase functions.
In this work, we expand on the multi-layer meta-optic platform to include polarization by employing end-to-end design optimization. In this platform, birefringent meta-atoms are used for both metasurfaces, enabling independent control over orthogonal polarization states as well as polarization conversion between those states. Redistribution of the wavefront between metasurface layers allows for loss-less, complex-valued wavefront and polarization control, that is not limited by the symmetric Jones matrix. As a proof of concept, we experimentally demonstrate a meta-optic for optical mode manipulation, including a spatial division multiplexer (SDM), an optical mode converter, and a vectorial hologram.
All the demonstrated devices are optimized by an end-to-end inverse design algorithm, which is a stochastic gradient descent (SGD)-based platform, a common approach in machine learning applications. The use of multiple loss functions as well as *k*-space constraints during optimization avoids overfitting and scattering phase morphology for metasurfaces, allowing for highly improved device performance. In our case, all the devices achieve diffraction efficiency above 80% in experimental measurements. Meanwhile, the meta-optic platform that combines birefringence with the ability to redistribute the wavefront across the aperture, also demonstrates independent and decent control over the amplitude, phase and polarization state. We believe that the increased engineering freedom provided by compound meta-optics will open new avenues for the development of compact optical systems with novel functionalities and applications in quantum entanglement, optical encryption, and optical communications.

4:30 PM EQ03.25.06
Polarization-Selective Non-Volatile Switching in Hybrid Phase-Change Nanowires June Sang Lee[1], Nikolaos Farmakidis[1], C. David Wright[2] and

Harish Bhaskaran[1]; [1]University of Oxford, United Kingdom; [2]University of Exeter, United Kingdom

Polarization, one of the fundamental properties of electromagnetic waves, provides extra physical dimensions for multiplexing optical information and has been essential for applications in optical communication, storage, and encryption. However, such multiplexing properties have been mostly passive thus far, and have not been employed as a tunable factor in optical systems.

Reconfigurable photonics on the other hand, has been rapidly growing. The use of phase change material is established as a functional block for non-volatile photonic and mixed-mode memories with prospective applications in neuromorphic and in-memory computing paradigms. These devices incorporate phase change materials as the reconfigurable elements and have been shown to achieve nanosecond switching performance with large optical modulation over a broad bandwidth. Reconfiguration in phase-change photonic devices is commonly achieved by controlling the intensity or pulse shape of an incident light wave while resonant structures are broadly employed to achieve wavelength-selective operation and enhanced modulation depths. The equivalent functionality in polarization-space is however absent. This significantly limits the addressability of distinct elements in cascaded systems without harnessing full advantages of photonic bandwidths.

Here, we demonstrate for the first time polarization-selective switching in hybrid phase-change nanowires,[1] wherein the optical absorption in the nanowires is modulated by polarization of incoming light. In doing so, the transient temperature profile is controlled to induce reversible switching of the hybridized phase-change element. Our hybrid nanowire consists of a two-layered system of $Si/Ge_2Sb_2Te_5$ (GST) where dielectric resonance of Si leads the GST to be switched in a polarization-selective manner. Such switching operation is finely modulated by changing the polarization directions, and therefore provides an important degree of freedom for control over the multilevel device states. Using this concept, we demonstrate the polarization-decoupled but electrically-interfaced multi-nanowire system to achieve polarization-selective demultiplexing at highly-confined spatial scales. We further show the use of this system to carry out matrix-vector multiplications with using polarization as a tunable variable. This leads to a huge enhancement of computing density, exceeding that of conventional electronic chips by several orders of magnitude. Our work provides the first such pathway for exploiting polarization to actively modulate device-states with applications ranging from optical encryption/storage to computing.

Structures and Materials for Highly Efficient Non-Linear Optics at the Nanoscale Stefan A. Maier[1,2]; [1]Monash University, Australia; [2]Imperial College London, United Kingdom

Nanophotonic resonators combined with two-dimensional materials are a fertile environment for the development of new approaches for highly efficient non-linear optical devices. Here we will survey our recent work in this regard, focusing on plasmonic or dielectric nanoresonators coupled to a variety of two-dimensional materials. One example is a ring-like resonator sturcture supporting bound states in the continuum, which due to its compact size is ideal for interfacing with flakes of 2D materials.
We will further present a highly promising class of materials with an extraordinarily high second-order non-linear response, two-dimensional ferroelectric materials.

8:30 AM EQ03.26.03

Characterization of Optical/Electrical Properties and Application of High Crystalline Titanium Nitride Ultrathin Films I-Hung Ho[1], Ching-Wen Chang[2], Yu-Jung Lu[3], Shangjr Gwo[2] and Hyeyoung Ahn[1]; [1]National Yang Ming Chiao Tung University, Taiwan; [2]National Tsing Hua University, Taiwan; [3]Academia Sinica, Taiwan

Recently, titanium nitride (TiN) attracts a great attention as a refractory plasmonic material owing to its superior optical properties in the visible and near-infrared spectral regions, high melting temperature, low extinction loss, and excellent mechanical and chemical stabilities. TiN also possesses the epsilon-near-zero (ENZ) point in the shorter end of visible spectrum than gold. One of the many exciting significances of ENZ materials is the strong enhancement of nonlinear optical processes and even higher nonlinear optical effect can be obtained for ultrathin ENZ films or metamaterials, in sharp contrast to conventional high nonlinear response for thick or bulk materials.
In order to realize these excellent performances of TiN, the growth of high quality TiN particularly in the form of ultrathin film is requisite; however, most of previous works on TiN have been reported for the films grown via reactive sputtering, pulsed laser deposition, or atomic layer deposition techniques. Only recently, single-crystalline, stoichiometric TiN films could be realized by the molecular-beam epitaxy (MBE) under the ultrahigh vacuum (UHV) environment. In this work, we will present the growth of TiN ultrathin films with 2−10 nm in thickness and the characterization of optical and electrical properties. Owing to UHV growth, the influence of oxygen-related defects which causes critical degradation of performance is greatly reduced in our MBE-grown TiN epilayers. Formation of continuous and smooth ultrathin TiN films is realized by X-ray diffraction (XRD) and the surface morphology is measured by atomic force microscopy (AFM) and scanning electron microscopy (SEM). The cross-section transmission electron microscope (TEM) image of the 2.4 nm TiN film shows a clear atomic alignment, confirming the growth of high crystalline quality epitaxial film with thickness even down to 2.4 nm.
The optical and dielectric properties of ultrathin TiN epilayers are determined by the reflection/transmittance/absorption measurement and spectroscopic ellipsometry. As the film thickness decreases below 10 nm, the ENZ point of ultrathin TiN epilayers shifts from 480 nm to 550 nm, enabling the realization of tunable plasmonic material. The optical loss also decreases with reduction of film thickness and the optical transmittance increases up to >75% for the 2.4 nm film over the whole visible regime. Electrical properties of the ultrathin TiN films are explored by employing the THz time-domain spectroscopy (THz-TDS) as well as the Hall effect measurement technique. THz-TDS is an optical and non-contact method to characterize the electrical properties of various materials including nanostructured metals, whereas the Hall effect technique is a direct electrical measurement method. THz spectroscopy reveals that the percolation thickness of the MBE-grown TiN epitaxial film is less than 2.4 nm, which is much thinner than the percolation thickness (6 – 10 nm) of noble metals. More importantly, the conductivities measured by THz-TDS are in excellent agreement with those measured by the Hall effect method. This

is in sharp contrast to previous reports showing a large discrepancy between optically and electrically measured conductivities for ultrathin TiN films fabricated by other techniques in atmospheric environments. The excellent electrical properties of MBE-grown ultrathin TiN films are attributed to their high crystalline quality with the low density of oxygen-related and structural defects. Our results demonstrate the wide potential applications of ultrathin TiN epilayer films as refractory plasmonic material.
Additionally, high optical transmittance and electrical conductivity of MBE-grown ultrathin films demonstrate that combined with its high mechanical, thermal, and chemical stabilities, they can serve as a high performance and robust transparent and conductive metal electrode compatible to complementary metal–oxide–semiconductor (CMOS) fabrication technology.

Magnetically Tunable 1D Plasmonic Photonic Crystals Chaolumen Wu, Qingsong Fan and Yadong Yin; University of California Riverside, United States

Structurally colored materials have been attractive for many years due to their vivid colors, long stability, and easy tunability, and within them, plasmonic and photonic nanostructures are two powerful systems to generate structure colors with easy control of the photonic colors. Although promising, the combination of plasmonic resonance and photonic bandgap within a single system is challenging. In this work, 1D plasmonic photonic crystals with angular-dependent structural colors are fabricated by assembling magneto-plasmonic colloidal nanoparticles under an external magnetic field. Different from conventional 1D photonic crystals, the assembled 1D periodic structures show angular-dependent colors from the selective activation of photonic diffraction and plasmonic scattering. Furthermore, the magneto-plasmonic nanoparticle chains can be fixed in an elastic polymer matrix to produce photonic films with angular-dependent as well as mechanically tunable optical properties. Thanks to the easy and precise modulation of magnetic assembly, the orientation of the nanochains within the polymer matrix can be precisely controlled to produce photonic films with desired patterns, showing versatile colors from the backward photonic diffraction and forward plasmonic scattering. This work demonstrates an easy way to combine plasmonic and photonic properties within a single system, showing synergetic optical properties and indicating the potential for the development of programmable optical functions for the applications in color display, optical devices, and information encryption.

Understanding Photovoltage Response of Hexagonal Boron Nitride (hBN)-Graphene-Silver Based 2D van der Waals Heterostructures Towards the Realization of UV-Visible Photodetectors Debaleena Majumder; Indian Institute of Science (IISc), India

Various Graphene-plasmonic nanoparticle hybrid devices have paved a way for sensitive photodetection of UV signal leading to multipurpose electrical as well as optoelectronic applications. A single monolayer of graphene (SLG) is sensitized with silver nanoparticles (having size distribution of 50-100nm), such that the electric field close to the nanoparticles generated due to the Localized Surface Plasmon Resonance (LSPR) results in an increased engineered photo response in the UV spectrum. Addition of an intermediate h-BN monolayer to such photodetectors aims to improve the photo response by reducing the substrate effects, interfacial resistance along with the prevention of surface oxidation. The purpose of this study is to investigate the role of 8 different 2d material based composite nanostructures fabricated using layer-by-layer build up technique, which play a determining role in controlling their optical and electronic response.
Raman Spectroscopy analyses the effect of inherent strain and local doping concentration of the graphene monolayer in presence of plasmonic structures. Full width half maxima (FWHMs) of both G and D peak are higher indicating localised strain in case of samples having Gr layer transferred on top of the Ag particles. Whereas the ID/IG ratio when much greater than 1 denotes higher defect concentration in samples due to the formation of sp3 carbon within graphene. Henceforth, significant enhancement is observed in Raman peak intensity with the introduction of HBN to the Gr-Ag composites.
The Responsivity study on such samples suggest that the position of the 2D material plays a key role in the anomalous response of these detectors. Further a correlation between optical Responsivity and Resonance plasmonic peak positions with particle distribution and shape analysis was established. Subsequently, each photo response has been deconvoluted into their characteristic rise and fall time zones using an empirical formulation, from which an idea about the effect of intermediate trapping and de-trapping states of these devices can be understood.

Topological Polarization Singular Laser Ren-Min Ma; Peking University, China

We report a new class of topological polarization singular lasers with high radiation efficiency.

11:00 AM *EQ03.27.02
Control of Nanoscale Heat Generation and Applications for Ultrafast Detectors Maiken H. Mikkelsen; Duke University, United States

Control of light-matter interactions on the deep nanoscale holds the potential to transform a wide variety of optical materials and optoelectronic devices. First, by integrating a plasmonic metasurface with an aluminium nitride pyroelectric thin film, we demonstrate spectrally selective, room-temperature pyroelectric detectors from 660–2,000 nm with an instrument-limited 1.7 ns full width at half maximum and 700 ps rise time (Stewart et al., Nature Materials 19, 158, 2020). Heat generated from light absorption diffuses through the subwavelength absorber into the pyroelectric film producing responsivities up to 0.18 V W−1 due to the temperature-dependent spontaneous polarization of the pyroelectric films. Next, we demonstrate a novel, large-area embedded metasurface architecture that is environmentally robust and capable of spectrally-selective absorption greater than 80 percent spanning from 330-2740 nm (Stewart et al., Nano Letters, in press 2022). These fully encapsulated metasurfaces leverage the capabilities of colloidal plasmonic nanoparticles with various crystallinities, materials, shapes, and sizes to access a larger spectral range and allow for control of nanoscale spatial losses and subsequent heat generation within the constituent elements of the metasurface. Through selection of material, particle size, and shape, these metasurfaces can be designed across the ultraviolet (UV) to short-wave infrared (SWIR) for various hot-electron, photodetection, photocatalysis, and photothermal processes.

11:30 AM *EQ03.27.03
Nanoengineering of Light Absorption—From Hot Carriers to Photothermal Effects Giulia Tagliabue; École Polytechnique Fédérale de Lausanne, Switzerland

In the last decade, optical nanoantennas have revolutionized light manipulation and control at the nanoscale. Light absorption was initially considered a purely detrimental process, reducing the efficiency of optoelectronic devices. Recently, however, it has attracted growing interest, enabling novel light-energy conversion pathways, such as hot carrier harnessing, but also interesting application opportunities based on nanoscale photothermal effects.
In this talk, I will first present fundamental aspects of plasmonic hot carrier generation and collection towards photoelectrochemical devices for light energy storage. In particular, I will report the construction, optoelectronic and photoelectrochemical characterization of plasmon-driven devices that operate via hot-hole injection, and I will compare them to their hot electron counterparts [1-4]. I will also show emerging opportunities for plasmonic hot carriers in redox-couple based photoelectrochemical devices and advanced optical design strategies for improving the efficiency [5]. Overall, these results demonstrate the critical role of the metal properties onto hot carrier generation and transport. Thus, I will next report on our recent effort towards the synthesis of record-high aspect ratio gold monocrystalline flakes [6]. In particular, I will discuss how we can leverage them for understanding fundamental electronic processes in metals as well as plasmonic photo-electrochemistry. Finally, I will focus on collective photothermal effects in plasmonic networks and discuss a fast computational method we developed to estimate local temperature maxima and minima. I will conclude with an outlook on applications of hot carriers and photothermal effects in nanoengineered optical antennas.

Organic Light-Emitting Diode Coupled to Photonic Bound State in the Continuum Mengfei Wu, Son Tung Ha, Ramon Paniagua Dominguez and Arseniy Kuznetsov; Institute of Materials Research and Engineering, Singapore

Lasers based on nanomaterials, such as colloidal nanocrystals, organics, and perovskites, are attractive because of their tunable lasing wavelength, feasibility on a variety of substrates, and facile fabrication. Despite significant progress in optically pumped lasers, nanomaterial-based laser diodes have remained elusive. A typical laser diode consists of a light-emitting diode (LED) integrated with a photonic cavity. Recent efforts have focused on distributed feedback (DFB) cavities, where a grating is patterned into the transparent electrode or emissive layer. Here, we employ a photonic bound state in the continuum (BIC) that arises from an array of out-of-plane dipoles oscillating in phase and has an extremely high quality (Q) factor. Specifically, we fabricate an organic LED (OLED) on a smooth substrate, in which an array of titanium dioxide cylinders is embedded to minimize effects on the electrical performance of the OLED. We demonstrate efficient coupling of the electroluminescence of the OLED to a high-Q BIC mode, paving the way for electrically-driven lasing.

12:15 PM EQ03.27.05
Ultrafast Dynamics Surface Enhanced Fluorescence Through Plasmonic Nanoclusters Belkis Gökbulut; Bogazici University, Turkey

In this work, Perovskite nanowires (NWs) are synthesized and encapsulated by gold nanoparticle clusters in polymer matrix to construct a random medium, which allows surface plasmons of the metal nanoclusters to be confined in subwavelength regions and causes an extreme electromagnetic field concentration to manipulate the fluorescence dynamics of the interacting quantum sources. The strong plasmonic field of the gold nanocluster induces a dramatic enhancement in the Purcell factor ($>10^4$). When the Purcell factor exceeds 10^4 through the intense light confinement based on plasmonic nanoclusters, the ultrafast dynamics surface enhanced fluorescence (UFDSEF) of the light emitters exists to dramatically modify the characteristic properties of the quantum sources. As the internal relaxation rate of the Perovskite quantum sources in a bare polymer is greatly faster than the total decay rate, on the excitation of the plasmonic nanocluster, which surrounds the fluorescent emitters in polymer matrix, the strong electromagnetic field enhances the population rates of the excited states; thus, electrons emit from higher vibrational excited states to the ground states. Then, the total decay rate becomes comparable to the internal relaxation rate, which results in significant changes in the spectral profiles of the quantum emitters. The fluorescence emission signal of the quantum sources surrounded by the plasmonic nanocluster seems to be shifted to the wavelength of 476 nm as the peak wavelength in photoluminescence spectrum of the semiconductor NWs in bare polymer appears at 526 nm. Thus, our photonic design proposed in this work, which consists of semiconductor nanocrystals and plasmonic nanoclusters in polymer matrix, provides a distinctive basis to explore the fluorescence dynamics of the quantum sources through UFDSEF mechanism. The first exploration of the blueshifted photoluminescence signal of the Perovskite NWs is achieved by plasmon-induced intense light−matter interaction. The concept of light concentration in deep subwavelength regions of the random medium provides a significant potential to explore light−matter interaction in photonic-plasmonic environment and to develop highly efficient light-emitting device applications.

1:00 PM EQ03.28.02
Design and Fabrication of Leaky MoS_2 Split-Nanoring Resonators for Biosensing Application Dipanjan Nandi, Andres A. Forero Pico and Manisha Gupta; University of Alberta, Canada

The emergence of novel atomically thin layered two-dimensional transition metal-dichalcogenides (TMDCs) such as MoS_2 is promising for biosensing [1,2] and optoelectronic applications [3]. In the existing literature, MoS_2 has been explored in field-effect transistor platforms for sensing protein and DNA molecules [4,5]. Recently, stacked heterostructure of MoS_2 and graphene were explored for detecting Rhodamine 6G (R6G) molecules [6] and DNA hybridization [7].
Here we propose a novel nanophotonic device platform using MoS_2 split-nanorings resonators array fabricated on SiO_2/Si substrate. We have explored MoS_2 because of its high refractive index ($n > 4$ [8]) contrast with air and low absorption ($k < 1$ [8]) both at monolayer and bulk. Also, the MoS_2 surface favors bonding with the carboxyl (-COOH) group, which makes it biocompatible. We have conducted finite difference time domain (FDTD) simulations for obtaining the best structural parameters by varying inner and outer diameter (D), periodicity (P), and height (H) of the split-nanorings array to study the resonance properties. We performed FDTD simulations by varying the number of polystyrene particles (100 nm diameter) randomly distributed on the device surface and calculated the resonance wavelength shift with the number of particles increased. Here, we have considered 100 nm-sized polystyrene particles as most of the bioanalytes have a similar refractive index to the polystyrene. One of the best-obtained design parameters is nanoring's outer diameter- 200 nm, inner diameter- 100 nm, the height of MoS_2 nanoring- 150 nm, split gap- 80 nm with unit cell periodicity- 220 nm. The split gap in each nanoring has been introduced to leak out the resonant field available on the MoS_2 surface. Attachment of target bioanalytes on the MoS_2 surface disturbs the resonance field and induces a red-shift at resonance wavelength signifies the presence of bioanalytes and detection sensitivity is obtained by calculating the slope of the resonance shift curve with respect to the bioanalytes concentrations. The large area of uniform MoS_2 thin film will be grown by pulsed laser deposition (PLD) technique on SiO_2/Si substrates and the PLD growth parameters (substrate to target distance, chamber condition, post-growth annealing temperature and duration, number of pulses, etc.) are optimized in our lab. Split-nanoring structures will be patterned by electron beam lithography (EBL) technique on the PLD grown 150 nm MoS_2 thin film and then reactive ion etching (RIE) will be performed to obtain MoS_2 nanoresonators array on SiO_2/Si substrates. Fabricated devices will be characterized by SEM, AFM, and optical reflection measurement will be carried out by our lab-made customized optical setup to get resonance conditions. We will present the design optimization and fabrication process of the MoS_2 nanoresonators array and demonstrate experimental measurements of varying concentrations of polystyrene beads of various dimensions to highlight the biosensing capability of the proposed platform.

Novel Modes of Optomechanical Manipulation by Ultrathin Dielectric Metasurfaces Yujie Luo, Avinash Kumar and Ognjen Ilic; University of Minnesota, United States

Photonic metasurfaces are attracting significant interest due to their remarkable capability to synthesize complex wavefronts, with diverse applications in beam focusing, imaging, and flat optics. In addition to these established applications, an emerging direction in the field is the use of metasurfaces to control optomechanical forces. In this work, we present the underlying principles of using the physics of metasurfaces to control the transfer of mechanical momentum from a beam to the metasurface, leading to contactless pressure that can manipulate and actuate a metasurface. This ability to use metasurfaces to shape the optical forces of light can lead to novel approaches to photonic levitation and propulsion at the macro scale, beyond the limit of current optical manipulation approaches.

We show that highly localized control of the metasurface phase can result in spatial patterns of radiation pressure that gives rise to new steering dynamics, and we present representative designs in all-dielectric and ultrathin configurations. Our analysis further elucidates design-independent limits that govern the intrinsic tradeoff between the optical (e.g., force/torque), mechanical (e.g., mass/moment of inertia) and dynamical response of a metasurface. Finally, we introduce and compare the relevant figures of merit for the interaction between a metasurface and a laser beam and point to optimal metasurface designs for contactless actuation.

1:30 PM EQ03.28.04
An Innovative PCR-Free Nanotechnology for SARS-CoV-2 Sensing Emanuele Luigi Sciuto[1], Antonio Alessio Leonardi[2], Barbara Fazio[3,4], Alessia Irrera[3,4] and Sabrina Conoci[1,5,4]; [1]University of Messina, Italy; [2]University of Catania, Italy; [3]CNR-IPCF, Institute for Chemical-Physical Processes, Italy; [4]Lab Sens Beyond NANO, Italy; [5]University of Bologna, Italy

The molecular analysis of Nucleic Acids (NA), DNA and RNA, has become nowadays crucial in many medical fields for early and accurate diagnosis, personalized therapy and preventive screening. It is particularly relevant in the field of the infectious diseases that can catastrophically affect the health of population, as it is the case of the current pandemic of SARS-CoV-2 virus that – up to now – infected up to 434 million of people causing 6 million of deaths worldwide.
In this scenario, the conventional approach for the molecular analysis of SARS-CoV-2 is based on the PCR (Polymerase Chain Reaction) reaction that, although standardized and consolidated, is quite complex and includes multiple laboratory procedures and high cost that limit, *de facto*, its massive use. These limitations make the PCR-based analysis inconsistent with the idea of an efficient patient management, in terms of fast diagnosis and prompt answer to the treatment, and viral outbreaks containment.
The PCR-free approach, that allows a fast, ultrasensitive, low cost and easy to use identification and quantification of the pathogen genome without its amplification, overcomes this issue introducing innovative methodologies suitable for the decentralised and massive infections diagnoses and prevention.
In this contribution we present an innovative PCR- and label-free technology for the SARS-CoV-2 genome photoluminescent (PL) detection based on the silicon NanoWires (Si-NWs), one of the most appealing silicon nanomaterials employed in nanodevices for biosensing applications. The strategy involves the surface capture of the whole viral genome via a cooperative hybridization with two complementary capture probes (single stranded DNA) that are

grafted on the Si-NWs surface. The hybridization is, then, optically transduced through the quenching effect of the PL signal that is intrinsically produced by the Si-NWs, due to the quantum confinement at room temperature. The occurrence of a non-radiative phenomena, introduced by the SARS-CoV-2 genome hybridization on the Si-NWs surface, determines the quenching of the PL signal and the PCR- and label-free identification and quantification of the viral RNA, with a Limit of Detection (LoD) of 4 RNA copies, below the LoD of the PCR gold standard method. Moreover, the proposed technology is suitable for Molecular "Point-of-Care" (M-PoC) applications, matching the vision of future home-made infective diagnostic microchips integrated into smart mobile devices (i.e smartphones or smart watches).

Ultrafast Dynamics of Electron Injection from Cu Embedded Nanoparticles in CeO_2 Aerogels Tara Michael, Travis G. Novak, Paul DeSario, Debra Rolison, Jeff Owrutsky, Vanessa Breslin and Adam Dunkelberger; U.S. Naval Research Laboratory, United States

Transition metal oxides such as TiO_2 and CeO_2 are wide bandgap semiconductors with photocatalytic properties used to drive electrical currents and enhance electrochemical reactions. The utility of wide bandgap semiconductors can be extended from the UV and into the visible by embedding metal nanoparticles into the semiconductor. Excitation of localized surface plasmon resonances in the metal nanoparticle generates free electrons that can be injected into the semiconductor and extend the photoactivity range using lower energy photons. In this work, ultrafast transient absorption spectroscopy is used to investigate the hot electron injection from Cu nanoparticles photodeposited onto a CeO_2 aerogel. The Cu nanoparticles are excited with a range of pulsed visible light (300 – 1000 nm) and the appearance of free electrons in the CeO_2 aerogel are detected with mid-infrared light. The transient signals are instrument limited and appear within 300 fs, indicating efficient electron transfer from the Cu nanoparticles into CeO_2. Transient signals are observed over a wide range of probe wavelengths, attributed to free or trapped electrons. Unlike other transition metal oxides, CeO_2 has an additional empty 4f state between its conduction and valence bands that can store electrons and form small polarons. The role of the 4f state in electron-phonon decay is explored by probing the 4f state directly with 266 nm light and 350 nm probe. The dynamics of this system are compared to the findings from a recent publication of TiO_2 films embedded with Au nanoparticles. The results presented here examine the utility of using Cu nanoparticles to enhance the properties of CeO_2 as a photocatalyst.

1:50 PM EQ03.28.06
Whispering Gallery Mode Microdroplet Resonators on 3D-Printed Mounts Madison S. King[1], Parker Awerkamp[2], David Hill[2], Gregory Nordin[2], Stephanie Hurst[1] and Ryan Camacho[2]; [1]Northern Arizona University, United States; [2]Brigham Young University, United States

Due to their mode stability and high quality (Q) factors; whispering gallery mode (WGM) resonators have a wide range of applications from biological sensing to lasing to quantum optical devices [1]. A variety of geometries and materials, including liquids, can be used to create WGM resonators [2]. There are several existing preparations for microdroplet resonators including suspending a drop on a glass stem [3,4] or suspending a droplet in another liquid [5,6]. These methods range in complexity, preparation time, and accessibility. The fabrication of 3D-prints is easy, quick, and accessible but their inherent surface roughness makes them less than ideal for optical applications. Due to this roughness, 3D-prints result in low-quality WGM resonators and can better serve as mounts for microdroplets. In this work a variety of different liquids, some with high dielectric constants (e.g., propylene carbonate), were characterized as WGM microdroplet resonators. Liquid-crystal WGM resonators with high dielectric constants have been shown to have a tunable geometry with an applied electric field [7]. This tunability of high dielectric materials could be advantageous for these microdroplet WGM resonators.

Tuning the Dispersion with Metal and Dielectric Layer Combination for Wavelength Multiplexing Plasmonic Metasurface Design Hosna A. Sultana; University of Alabama, United States

Thin layer plasmonic metasurfaces have offered the exciting features of guided-mode resonance, surface plasmon propagation, and converting propagating wave to surface wave. In nanophotonic devices, especially in waveguide applications, this performance can tune the propagation mode in the dielectric cavity. As the functionality of the plasmonic devices depends on the light dispersion, the wavelength-dependent dispersion engineering for the plasmonic band structure is an essential measure of proper light coupling. The main focus of this study is to select the metal-dielectric layer combination for enhancing the plasmonic mode excitation and channel as the guided mode. The plasmonic metasurface design based on this structure is investigated for their surface plasmon polariton generation. With the metasurface element phase control capability, the long-range or short-range plasmonic coupling maneuver can be utilized in the sensing application. Also, controlling the directionality of the coupled plasmonic wave depending on the incident light wavelength gives the device application in the optical coding.

2:00 PM *EQ03.28.08
Elucidating and Exploiting Hot-Carrier Dynamics in Active and Nonlinear Plasmonic Metamaterials Wenshan Cai; Georgia Institute of Technology, United States

Hybrid plasmonic metamaterials consisting of nanostructured metals and electron-accepting materials serve as an enormously fruitful arena for the investigation and utilization of optically excited energetic carriers. The coherent coupling of electromagnetic radiations to plasmons creates a nonequilibrium distribution of electrons at an elevated temperature, known as hot electrons. The dynamics of such hot carriers has been wide employed for various applications, ranging from the detection of sub-bandgap photons in semiconductors to the production of hydrogen gas via photocatalytic processes.

The generation, transfer, and relaxation of hot carriers also provide a novel route to nonlinear optical effects. For example, the optical Kerr nonlinearity of plasmonic metals provides enticing prospects for developing reconfigurable and ultracompact all-optical modulators. Although enhanced nonlinear responses of metals are known to enable the optical control of light, the intrinsically slow relaxation dynamics of photoexcited carriers, primarily governed by electron-phonon interactions, impedes sub-picosecond modulation speeds. In this talk, we present femtosecond all-optical modulation in plasmonic systems via the activation of relaxation pathways for hot-electrons at the interface of metals and electron acceptor materials. We show that the relaxation kinetics and the optical nonlinearity can be tuned by leveraging the spectral response of the plasmonic system in the linear regime. Our findings introduce a

generic scheme for achieving sub-picosecond modulation speeds in plasmonic systems, suitable for the ultrafast control of the intensity, polarization, and phase of light upon exchange of energetic hot carriers.

The dynamics of hot carriers in plasmonic system is further exploited for the creation of optically induced second-order nonlinear materials. Second-order optical processes are pivotal to the active modulation and wave mixing of light waves. The inversion symmetry in most materials, however, prevents achieving a bulk chi-2 effect, thereby limiting the portfolio of second-order nonlinear materials. We propose and demonstrate ultrafast conversion of a statically-passive dielectric to a transient second-order nonlinear medium upon the generation and transfer of plasmonically induced hot electrons. Triggered by an optical switching signal, the amorphous dielectric with vanishing intrinsic chi-2 develops dynamically tunable second-order nonlinear responses, which can be leveraged to address the critical need for all-optical control of second-order nonlinearities in nanophotonic systems.

Therefore, the consolidation of the relaxation dynamics of hot electrons with externally induced optical nonlinearity enables a unique opportunity to elucidate the generation, transport, and decay of hot carriers in hybrid plasmonic systems. Conversely, leveraging the ultrafast dynamics of plasmonically induced hot electrons allows us to achieve ultrafast all-optical control of light and realize externally triggered second-order optical nonlinearity in hybrid plasmonic metamaterials.

Passive Transmission Symmetry Breaking Without Non-Reciprocity in All-Dielectric Metagratings Stavroula Foteinopoulou; University of New Mexico, United States

While reflection symmetry can be routinely broken in a passive system by introducing loss the same is not true for transmission symmetry. Passive and linear systems exhibit transmission symmetry because of the reciprocity principle. In other words, it would appear that breaking transmission symmetry in a linear passive system would be synonymous to breaking reciprocity.

In this talk, we will present a specially designed metagrating that possesses several output channels, as a result of higher-order Bragg beams being triggered. We will discuss the transmission response of this system, exhibiting a strong asymmetry, with contrast as high as ~75% [1]. We analyze the underpinning mechanism and explain how a transmission asymmetry in this type of system remains consistent with the reciprocity principle. We further verify such transmission asymmetric behavior with an FDTD numerical experiment.

We believe this transmission asymmetry capability in these simple systems without requiring non-reciprocity can open-up new avenues for photonic components design across the EM spectrum.

White-Nanolight-Source for Background-Free Nano-Optical Investigation Prabhat Verma; Osaka University, Japan

Plasmonically enhanced spectroscopies, such as the surface-enhanced Raman spectroscopy (SERS) and the tip-enhanced Raman spectroscopy (TERS) have been well utilized for both, sensing tiny amounts of specific molecules, and imaging samples at the nanoscale [1-5]. The most important phenomenon in such measurements is the selective enhancement of Raman signal from the nanometric volume of a sample, which makes it possible to study a sample at extremely high spatial resolution and at a very low concentration. For this purpose, perfect tuning of plasmon resonance wavelength is required, which is achieved by illuminating the plasmonic antenna, such as the apex of a metallic nanotip in TERS or metallic nanoparticles in SERS, with a diffraction-limited focused laser beam. This results in the creation of a nanolight-source in the close vicinity of the antenna through the resonant oscillation of localized surface plasmons. Since the resonance condition is achieved only for a very narrow wavelength range that matches the plasmon resonance for a chosen antenna, the nanolight-source also has a narrow wavelength range. In addition to the creation of a nanolight-source in this process, one also receives an unwanted background scattering that originates from the diffraction-limited illumination of the sample. In some cases, one would like to have a fast wavelength switching or even multiple wavelengths at the nanolight-source without changing the antenna. Also, one would like to avoid unwanted background scattering.
Plasmon nanofocusing [5-7], which is not based on the plasmon resonance, is an alternative method for creating a nanolight-source. It is a phenomenon in which plasmons are excited near the broader end of a tapered metallic structure, which then propagate towards the apex and slow down by adiabatically compressing their energies and eventually stop near the apex where all energy is converted to light creating a strong light field localized at the nanometrically sharp apex of the tapered structure. Here plasmons are excited by coupling propagating photons with plasmons via a grating that works as the plasmon coupler. As the plasmon coupler and the apex of the tapered structure are physically separated by a reasonably large distance, the illuminating light does not fall on the sample, avoiding the unwanted background scattering from direct illumination of the sample. In addition, because one can create a nanolight-source through the propagation of plasmons, rather than the localized resonance, it works over an extremely wide wavelength range. However, the plasmon coupler, that is the grating, can efficiently couple only a narrow wavelength range and imposes a restriction on the wavelength range of the nanolight-source. This can be overcome, if a suitable coupler is created that couples a broad wavelength range or the white light. We found that, if properly designed, a single slit can work as an efficient plasmon coupler for white light, which ultimately results in the creation of a white-nanolight-source. We have recently proposed the generation of a white-nanolight-source through broadband plasmon nanofocusing and successfully exploited it for super-resolution spectral optical imaging, which has exhibited great potential for broadband plasmon nanofocusing not only for optical imaging but also for diverse scientific fields as a novel tiny light source. Here in this talk, we will discuss how to create a white-nanolight-source and how to utilize it in various interesting applications.

Optical Meta-Devices for Bio-Imaging Mu Ku Chen[1], Yuan Luo[2] and Din-Ping Tsai[1]; [1]City University of Hong Kong, China; [2]National Taiwan University, Taiwan

The novel property of optical meta-devices, which consist of meta-antenna made by artificial nanostructures, has attracted a lot of attention lately. Various optical devices based on the specific designs of meta-surfaces are called optical meta-devices. The great advantages of meta-devices are their new properties, lighter weight, small size, high efficiency, better performance, broadband operation, lower energy consumption, and CMOS compatibility for mass production. Given the demand for photonics, many optical meta-devices for the application and control of incident light are being quickly developed for beam deflection and reflection, polarization control and analysis, holography, second-harmonic generation, laser, tunability, imaging, absorption, color display, focusing of light, multiplex color routing, and light-field sensing. Here we demonstrated the optical meta-devices into bio-imaging. In this talk, we report 3 applications, varifocal Moiré meta-lens [1], Meta-lens based light-sheet fluorescent microscopy (MLSFM) [2], and abrupt autofocusing (AAF) meta-lens[3].

Following the Moiré technique, a variable focus dielectric meta-lens is designed and implemented for high-contrast optical sectioning fluorescence microscopy at the visible spectral region. The design principle of Moiré meta-lens and telecentric design is described in detail. We demonstrated telecentric imaging equipped with variable focus meta-lens, which performs high-contrast multi-plane fluorescence imaging for ex vivo mice intestine tissue samples. In addition, Moiré meta-lens-based fluorescence microscopy with the HiLo imaging principle provides fine optical sectioning with invariant image contrast through the entire scanning range. As a clear demonstration of imaging performance for our Moiré meta-lens-based microscope, both standard resolution target and fluorescent microspheres are imaged, with a lateral resolution of ~2 μm, as well as optical sectioning capability of ~7 μm. The varifocal Moiré meta-lens with ultra-thin size and compact design may replace its counterpart in any optical system that requires a focus-tunable lens, such as optical coherence tomography and micro-endoscopy for in vivo imaging.

We show the implementation of a metasurface optical element in LSFM for imaging lives biological samples as well. The performance of our LSFM was evaluated by utilizing standard fluorescent microspheres and in vivo imaging of fine structures associated with the developmental process in live C. elegans. Results obtained from our systems clearly show internal structures of the C. elegans up to cellular resolution for multiple wavelengths. Experimental measurements are compared with the conventional LSFM systems (i.e., without any meta-lenses), and similar image resolution is demonstrated. The results clearly illustrate the capability of the system for biomedical imaging applications. Moreover, the significance of the present techniques lies in the fact that the complexity of the instrument in the illumination is entirely reduced, from tens of centimeters to 800 nm, without affecting any imaging performance, which clearly shows great potential to utilize metasurface optics for miniaturizing microscopic imaging instruments. Applications of meta-lens can be readily extended to illumination, as well as in the detection of LSFM to include all the essential features of meta-surfaces. Metasurface optics can be utilized for many LSFM modalities to achieve novel functionalities, such as meta-lens arrays for light-sheet generation, multi-view/multi-dimensional selective plane illumination microscopy, near-infrared and multi-photon LSFM. Further, by integrating beam shaping techniques in the meta-lens design, exotic light-sheet patterns with an extended field of view and smaller thickness can be achieved. We believe this work is an advancement of the applications of meta-devices in microscopy.

9:00 AM *EQ03.29.03
Geometric Photodetectors for Mid-Infrared Light Cheng-Wei Qiu and Jingxuan Wei; National University of Singapore, Singapore

We will report zero-bias, uncooled, filterless photodetectors in mid-infrared exhibiting colossal discrimination ratio, close-to-perfect CPL-specific response, a zero-bias responsivity of 392 V/W, and a detectivity of ellipticity down to 0.03-degree Hz-1/2. Our approach employs plasmonic nanostructures array with judiciously designed symmetry, assisted by graphene ribbons to electrically read their near-field optical information. It highlights the potential of hybridizing metasurface and semimetals for miniaturized polarimetry.

9:30 AM EQ03.29.04
Plasmonic Sensing Enhancement by Dielectrophoretic Trapping of Bacteria in Total Internal Reflection Ellipsometry Soraya Zangenehzadeh[1], Fenja Schroeder[1], Annalena Eckert[1], Svenja Herdan[1], Max Schittenhelm[1], Emil Agocs[1,2], Felix Hirschberg[1], Rebekka Biedendieck[3], Hans-Hermann Johannes[1,2], Dieter Jahn[3] and Wolfgang Kowalsky[1,2]; [1]Institut für Hochfrequenztechnik, Germany; [2]Cluster of Excellence PhoenixD, Germany; [3]Institute of Microbiology and Braunschweig Integrated Centre of Systems Biology (BRICS), Germany

Bacterial infection is one of the threats for public health which causes death of millions of people every year. Detection of these microorganisms is important to prevent the prevalence of infectious diseases. There are various bacterial detection methods such as enzyme-linked immunosorbent assay (ELISA) or polymerase chain reaction (PCR) that are time consuming and expensive due to the preparation of antibodies. In recent years, optical biosensors play an important role in analysis and monitoring of binding of biological elements.
Spectroscopic ellipsometry analyzes the changes in polarization state of light after reflection or transmission from a surface and determines the optical properties and thickness of the film. These changes in polarization states are studied by the amplitude ratio (Ψ) and the phase difference (Δ) between p- and s-polarized light, respectively. Conventional spectroscopic ellipsometry is limited to monitor bacteria due to the low refractive index contrast between bacterium and its ambient. For this reason, total internal reflection ellipsometry (TIRE) consist of Kretschmann configuration is used to monitor bacterial binding to the functionalized layer. In this configuration surface plasmon polaritons (SPPs) are coupled with an incoming light beam and excited at a specific incidence angle at the metal-dielectric interface. This matching condition causes surface plasmon resonance (SPR) as a sharp dip in reflected light. SPR detects the changes in the refractive index of the sample environment which is in contact to the metal surface. This measurement technique is real-time and non-destructive which makes it reliable for precise detection of bacteria.
The aim of this research is to improve the limit of detection (LOD) of surface plasmon resonance by enhancing bacterial mass transport through the effective sensing volume of an evanescent wave in a Kretschmann flow cell. For this purpose, the effect of dielectrophoretic force on the Gram-negative bacterium *Escherichia coli* K12 (*E. coli* K12), a common well investigated apathogenic model strain, is studied in the TIRE structure. Dielectrophoresis (DEP) exerts a force on dielectric particles like bacteria when they experience an asymmetric electric field. In inhomogeneous electric fields, particles will move toward areas of maximum electric field gradient (positive-DEP) and minimum electric field gradient (negative-DEP), respectively.

9:45 AM EQ03.29.05

Self-Assembled Glass Based and Plasmonic Metasurface by Controlled Fluid Instability Tapajyoti DasGupta, Renu R. Sahu, Alwar Samy Ramasamy, Aravindkumar Yelashetty, Ajisha C, Shiju Prasad and Santosh Bhonsle; Indian Institute of Science, India

Modern devices require the tuning of the size, shape and spatial arrangement of nano- objects and their assemblies with nanometer scale precision, over large-area and sometimes soft substrates. Such stringent multi-scale and mechanical requirements are beyond the reach of conventional lithography techniques or simpler self-assembly approaches. In this talk, at first we will demonstrate an unprecedented control over the fluid instabilities of thin glass films as a simple approach for the self-assembly of advanced all-dielectric metasurfaces. We show and model the tailoring of the position, shape, size and inter-particle distance of nano-objects with feature sizes below ten nanometers [1]. This simple and versatile approach can generate optical nanostructures over tens-of-centimeters sized rigid and soft substrates, with better optical performance and a resolution on par with advanced lithography-based processes. By a programmable control of the nanoimprinting method and the initial film thickness we show that we can achieve tunable particle size and lattice using the same master Silicon mold. To underline the potential of our approach, we demonstrate various optical phenomenons like a mechanochromic sensor, second harmonic generation with conversion efficiency as high as 10^{-6}, and a Fano resonance with a highest Quality Factor ~300 in visible to date [2]. Lastly, we show by tuning just the substrate softness Gallium based liquid metals [3] for the first time could be used as a dynamic metasurface where the optical properties could be tuned in-situ by applying a simple mechanical stress.

Self-Assembled Active Deformable Liquid-Metal Based Photonic Nanostructures via Fluid Instabilities Renu R. Sahu, Alwar Samy Ramasamy, Santosh Bhonsle and Tapajyoti DasGupta; Indian Institute of Science (IISc), Bangalore, India

The use of liquid metals, particularly Gallium, and their alloys allow for the fabrication of flexible, bendable, and mechanically reconfigurable devices when deposited on an elastomeric substrate[1]. They have been the choice materials for electronic applications, particularly in the domain of soft and stretchable electronics[2]. Although an excellent optical material due to low comparative loss and UV-based plasma frequency, their applications in the photonic domain have still been limited to the THz region[3]. This is because of its inability to be scaled down to nanoscale owing to their intrinsic large surface tension, thus hindering practical use in visible, dynamic photonic systems with sub 100 nm feature dimensions. However, the possibility of exploiting fluid instabilities for nanofabrication has been well established[4].

In this talk, for the first time we will show a single-step procedure that exploits the fluid instabilities of liquid metal, tending to minimize surface energy by forming spherical droplets of sizes in sub-100nm length scales. By tuning the softness and the temperature of the substrate, the rate of deposition, and the amount of the liquid metal being deposited, we demonstrate a fabrication technique of gallium-based plasmonic thin film with tuneable structural colors for the first time, paving the way toward a novel paradigm in soft photonics and large area reflective displays. By tuning and optimizing a range of experimental parameters, and the choice of substrate material we obtain vibrant coloration encompassing a wide range of chromaticity coordinates as a result of the controlled manipulation of size distribution of Ga nanodroplets. Analysis of scanning electron microscope images for structural characterization of the samples fabricated by our methodology emphasizes the importance of liquid oligomers in the heat-cured Poly-dimethyl siloxane in the formation of non-overlapping Gallium nanodroplets, which is not the case when the oligomers are deliberately removed by toluene treatment. In the latter case, the absence of oligomers results in the formation of nanodroplets without penetration into the substrate, forming a film of nanodrops akin to a thin film over a substrate.

As a proof-of-principle, we show pallets of structural colors, whose advantages can be leveraged in in reflective display technologies. The application of the thus-fabricated device also exhibits mechanochromic sensing, which has been characterized to be of high fidelity and reliability, functionalized by exploiting the fluidic properties of Gallium. For at least 1000 cycles of uniaxial stretching and relaxing, the reflectivity spectrum of the sample for a given strain was unchanged, thus proving the reliable reconfiguration of sample response to the application and removal of mechanical strain. The reversible change in the reflectivity spectrum results in the chromaticity coordinates of the sample, hence a visible change in the sample color.
Our results have the potential to offer opportunities to dynamically reconfigure thin-film-based functional nanodevices in situ as well as process technology for high throughput fabrication to achieve the same in a single-step method.

7:00 AM *EQ03.30.02
Two UV Plasmonic Devices by High-Performance Epitaxial Al Metasurfaces—An Ultrasensitive Photodetector and a Surface-Enhanced Resonance Raman Spectroscopic (SERRS) Biosensor Abhishek Dubey[1], Ragini Mishra[1], Yu-Hung Hsieh[1,2], Chang Wei Cheng[1], Bao-Hsien Wu[1], Lih-Juann Chen[1], Shangjr Gwo[1,1,2] and Ta-Jen Yen[1]; [1]National Tsing Hua University, Taiwan; [2]Academia Sinica, Taiwan

Plasmonics-based devices have been intensively explored in visible and infrared regimes, but scarcely demonstrated in the wide UV regime, mainly because of constrained optical properties of materials. By using epitaxial Al metasurfaces, herein we report two unprecedented plasmonic applications in UV regimes- an ultrasensitive photodetector and a surface-enhanced resonance Raman spectroscopic (SERRS) biosensor. For the first UV plasmonic device, we demonstrated ultrasensitive photodetector with a maximum detectivity ($1.48\ 10^{15}$ cm $Hz^{1/2}$ W^{-1}) at the on-resonance wavelength of 355 nm. broad bandwidth photodetection through the entire UV regime, and a fast temporal response with a rise time of 51 ms and a fall time of 197 ms,

respectively. For the second UV plasmonic device, we presented an SERRS biosensor. Such a UV SERRS biosensor not only exhibited high signal to noise ratios, but also recorded an SERRS enhancement factor up to 10^6 for extremely thin layer of adenine of 1nm thick. In addition to this egregiously high EF factor, we further exhibit that our SERRS substrate is capable of detecting the single base mutation in the 12-mer ss-DNA.

Unexpected Phase-Pure Wurtzite Structure of Nitrogen Doped $ZnSe_{1-x}Te_x$ Thin Films Theodore Culman[1], Rachel Woods-Robinson[2], John Mangum[1], Rebecca Smaha[1], Chris Rom[1], Andriy Zakutayev[1] and Sage Bauers[1]; [1]National Renewable Energy Laboratory, United States; [2]Lawrence Berkeley National Laboratory, United States

Conventional II-VI and III-V compound semiconductors can be roughly split into two structural categories: zincblende and wurtzite. Both are tetrahedral systems and furthermore, their crystal structures are polytypes with only slight modification to the stacking pattern of honeycomb cation/anion planes. Controlling zincblende–wurtzite polytypism within a single material is a promising way to design semiconductor functionality. In this talk we show that nitrogen doping induces a zincblende-to-wurtzite structural transition in $ZnSe_{1-x}Te_x$ when grown as sputter deposited thin films. N-doped $ZnSe_{1-x}Te_x$ is prepared from ZnSe and ZnTe source targets with gaseous N_2 as a N source. In some doped films, there is a structural transformation from the usual zincblende to wurtzite. Depending on the temperature and N_2 flow rate during growth, wurtzite can be synthesized across most of the composition range explored, ranging from Te-rich ($x \approx 0.7$) to nearly pure ZnSe ($x \approx 0.1$). Grazing-incidence, wide-angle synchrotron x-ray scattering (GIWAXS) data show that the N-doped $ZnSe_{0.5}Te_{0.5}$ alloy forms as phase-pure wurtzite. Temperature-dependent electronic transport measurements collected from N-doped $ZnSe_{0.5}Te_{0.5}$ indicate the material is a p-type semiconductor and low-temperature resistivity data are well fit by a transport model dominated by 3D variable range hopping. Scanning electron microscopy reveals voids in the N-doped films that are not present in undoped films. We attribute these microstructural features to N_2 gas trapped during growth, which is confirmed by signals from molecular nitrogen in x-ray absorption spectroscopy data. 0 K formation enthalpy calculations do not completely describe the stability of the wurtzite phase, so we hypothesize that the open microstructure plays a role by increasing the surface energy contribution. This work highlights unexpected polytypism in one of the most studied II-VI semiconductor systems and thus motivates a closer look at other well-studied semiconductor alloys for similar structural diversity.

10:45 AM EQ04.01.02
Computational Prediction of Novel Oxy-Chalcogenides $Ln_2Ti_2O_5Ch_2$ (Ln=Y, La; Ch=S, Se) Katarina Brlec and David O. Scanlon; University College London, United Kingdom

Ruddlesden Popper (RP) phases $A_{n+1}B_nX_{3n+1}$ (n = 1, 2, 3) comprise a versatile and well-studied structural type. The variety of interesting optoelectronic and magnetic properties of RP materials allows for a wide range of applications, from photovoltaics to battery materials. While RP systems are traditionally oxides, several oxynitrides and oxysulphides have been characterised in recent years.

Cation-deficient RP phase $Y_2Ti_2O_5S_2$ has recently shown promise as an n-type thermoelectric with ZT exceeding 1 at high temperatures.[1] However, its thermoelectric performance could be further improved with cation or anion mutation as a lower lattice thermal conductivity is expected with greater variation in ion size due to enhanced phonon scattering.

In this work we use density functional theory (DFT) to predict the properties of previously unknown $La_2Ti_2O_5Ch_2$ (Ch=S, Se) and $Y_2Ti_2O_5Se_2$. In total 150 competing phases of the La-Y-Ti-O-S-Se chemical space were studied at hybrid-DFT level to determine the thermodynamic stability window of these novel chalcogenides. Furthermore, we carry out phonon calculations to confirm dynamic stability of these systems and apply hybrid-DFT methods to calculate relevant optoelectronic properties.

11:00 AM EQ04.01.03

Innovative $GeSe_{1-x}Te_x$ Chalcogenide Thin Films—From Bonding Mechanism to Phase-Change Material Applications

Martina Tomelleri[1,2], Anthony Albanese[2], Francoise Hippert[3], Jean-Yves Raty[4], Francesco D'acapito[5], Valentina Giordano[6], Daniel Benoit[1] and Pierre Noé[2]; [1]STMicroelectronics, France; [2]CEA-LETI, France; [3]Univ. Grenoble Alpes, CNRS, France; [4]Universite de Liege, Institut de Physique B5 Sart Tilman BE, Belgium; [5]CNR-IOM-OGG c/o ESRF, France; [6]ILM, UMR 5306 Univ. Lyon 1-CNRS, France

By exploiting their strong optical and resistivity contrast between the amorphous (a-) and the crystalline (c-) phase, chalcogenide phase-change materials (PCMs), such as canonical $Ge_2Sb_2Te_5$ alloy, have made possible to envisage a wide range of application in particular for data storage technology [1]. The difference in bonding mechanism between the a-phase, which is a covalent bonded (CB) structure, and the c-phase, which is governed by the recently introduced concept of "metavalent bonding" (MVB), is responsible for their large property contrast [2]. Many efforts have been devoted to shed light on this unconventional chemical bond, in order to accelerate the discovery of new PCMs with tailored properties for multiple applications. $GeSe_{1-x}Te_x$ alloys, forming a solid solution along the GeSe-GeTe pseudo-binary line, arouse particular interest since they bridge the gap between GeSe, which is a CB material in both its a- and c-phases, and GeTe that is, in its c-state, a prototypical MVB material characterized by outstanding electronic properties such as a high electronic polarizability. Indeed, despite GeTe and GeSe are both IV-VI chalcogenide compounds with an isoelectronic structure, the moderate Peierls distortion in rhombohedral (rh-) c-GeTe (characterized by 3 short and 3 long Ge-Te bonds) enables the formation of MVB, which instead collapses in orthorhombic (orth-) c-GeSe due to the too strong local distortion. In addition to being a model system for fundamental studies, the unprecedented high thermal stability of a-phase of $GeSe_{1-x}Te_x$ films, makes these materials extremely promising for embedded PCM memory applications, for which a data retention at high temperature is crucially needed [3].
A-$GeSe_{1-x}Te_x$ thin films were deposited by industrial magnetron co-sputtering on silicon and silicon oxide substrate. Their crystallization was monitored by four-point probe resistivity measurement during annealing. The crystallization temperature increases with decreasing Te content, reaching very high a-phase stability. Moreover, the resistivity contrast between a- and c-phase is extremely large for all the studied compositions, except in the case of GeSe. By means of room-temperature X-ray diffraction, Raman spectroscopy and X-ray Absorption Fine Structure on c-$GeSe_{1-x}Te_x$ films, we identified an orth-structure in GeSe and a rho-MV bonded phase, isostructural to GeTe, in the x range [0.16-1]. This is an unexpected result since, according to the GeSe-GeTe phase diagram, the domain of the rh-phase is restricted to x range [0.48-1], and a covalent-bonded hexagonal phase is stable for x ranging from 0.14 to 0.42 [4]. However, it is precisely the persistence of the rh-structure in our thin films down to x=0.16, even if metastable, that allows the formation of MVB giving to the material such unprecedented resistivity contrast upon crystallization. The replacing of a few percent of Se atoms by Te in the covalently bonded Ge-Se network transforms the latter in a MVB material with a unique portfolio of properties. The high thermal stability of GeSe is combined with the wide resistivity contrast provided by MV bonded GeTe in an alloy that remains homogenous after crystallization, thanks to the complete solubility of Te in GeSe. Besides giving the opportunity to explore the transition between CB and MVB, their exceptional combination of properties makes Se-rich $GeSe_{1-x}Te_x$ alloys an extremely promising candidate for integration in phase-change devices requiring high data retention.

Emerging Amorphous Chalcogenide Thin Films—From Bonding Mechanism to On-Chip Highly Non-Linear Photonic Devices

Anthony Albanese[1,2], Jean-Baptiste Dory[1], Jean-Yves Raty[1,3], Meryem Ibnoussina[2], Jean-Baptiste Jager[4], Anthonin Verdy[1], Francesco D'acapito[5], Magali Tessaire[1], Mathieu Bernard[1], Aurélien Coillet[2], Benoît Cluzel[2] and Pierre Noé[1]; [1]CEA-LETI, France; [2]ICB, France; [3]CESAM, Belgium; [4]CEA-IRIG, France; [5]CNR-IOM-OGG c/o ESRF, France

Chalcogenide glasses (ChGs) show a large transparency window in the infrared coupled with outstanding optical nonlinearities offering tremendous opportunities for achievement of innovative mid-infrared on-chip components. In this work, the amorphous structure and the nonlinear optical properties of As-free amorphous $GeSb_wS_xSe_yTe_z$ chalcogenide thin films are studied. The nonlinear refractive Kerr indices (n_2) of the films were evaluated through modelling of spectroscopic ellipsometry data. The method has been then validated by means of experimental characterization of Kerr indices of a set of selected glassy chalcogenide alloys and SiN_x reference material using advanced nonlinear optical characterizations of waveguides (heterodyne interferometry setup). State-of-the-art and remarkably high n_2 values were obtained for some compositions of the amorphous chalcogenide compounds. Depending on the stoichiometry of the $GeSb_wS_xSe_yTe_z$ ChGs, n_2 can vary of more than one order of magnitude. Besides, Fourier-Transform Infrared (FTIR), Raman and X-ray Absorption (XAS) spectroscopies analysis of the amorphous structure of prototypical chalcogenide alloys in relation with their nonlinear optical properties was used as a basis for *ab initio* molecular dynamics (AIMD) simulations. Thus, the intimal link between local atomic configurations recalling unique "metavalent" bonding (MVB) and optical nonlinearities is unveiled, giving unprecedented clues to control optical nonlinearities of chalcogenide materials.
In this work we evaluated first the n_2 refractive indices of a wide range of $GeSb_wS_xSe_yTe_z$ thin films by means of Sheik-Bahae model, a theoretical model already successfully applied to chalcogenide materials to predict the n_2. The amorphous as-deposited films exhibit a wide range of n_2 values that show strong dependence on the ChGs composition. The obtained results are well supported by previous study of similar $GeSb_xSe_y$ compounds in the literature. In order to relate optical nonlinearities and structure, four prototypical compositions differing by their n_2 values were selected and finely described by means of advanced optical and structural characterizations. Therefore, the experimental nonlinear coefficients γ of the prototypical Ge-Se-Sb(-N) alloys and SiN_x reference material measured in waveguides using an experimental heterodyne detection setup at 1550 nm are in good agreement with those derived from calculated n_2 Kerr indices using the Sheik-Bahae model. The obtained values are from one to two orders of magnitude higher than that of SiN reference sample. A dramatic change of Kerr index depending on the ChGs stoichiometry is observed and related to modifications of the amorphous structure. From the calculation of the bond polarizability, one could relate the origin of the local very high electronic polarizability, related to highly polarizable structural motifs in the amorphous network, to the enhanced optical nonlinearities of the material. These highly polarizable motifs are reminiscent of a unique bonding configuration that recalls the "metavalent" bonding, a unique bonding mechanism at the origin of the huge optical and electrical contrast between amorphous and crystalline state of Phase-Change Materials.
To summarize, the outstanding linear and nonlinear optical properties of selected ChGs at origin of their promising potential of applications for MIR on-

chip components is shown to result from the formation of peculiar structural motifs leading to specific bonding mechanism at the origin of their huge polarizability. In particular, some elements increase dramatically the local electronic polarizability by inducing structural motifs supporting bonds similar to the newly introduced “metavalent” bonding mechanism arising in some local crystal-like motifs. These results pave the way to control and improve further the unique optical properties of ChGs in thin films.

Ferroelectricity, Superconductivity and Non-Trivial Topology in PbSnTe Heterostructures Athby Al-Tawhid, Antonio Gonzalez, Sam Poage and Kaveh Ahadi; North Carolina State University, United States

Combination of broken inversion symmetry and spin-orbit coupling gives rise to a wide range of exotic superconducting states, such as mixed-parity superconductivity, superconducting Weyl state, and superconducting diode effect. Incipient ferroelectrics e.g., PbTe, are near a polar instability. The emergence of superconductivity has been reported in some of these incipient ferroelectrics upon doping. Many unconventional superconductors, such as the cuprates, pnictides, and heavy fermion systems, occur in close proximity to magnetic fluctuations or magnetic orders, suggesting that these are important ingredients in the superconductivity in these materials. Here, ferroelectricity and superconductivity could be connected or accidental neighbors. Furthermore, the intersection of superconductivity and topologically nontrivial states is a fertile landscape for exciting quantum phenomena, including non-abelian excitations.
IV-VI compounds show a wide range of electronic and polar instabilities. $Pb_{1-x}Sn_xTe$ demosntrates a highly tunable superconductivity and ferroelectricity which are dependent on carrier density and Sn(Pb) concentration. Furthermore, a topological phase transition is expected at x~0.4, which inverts the conduction and valence bands for Sn rich compounds. I will report on our recent growth efforts of high quality $Pb_{1-x}Sn_xTe$ heterostructures, using a chalcogenide molecular beam epitaxy (Veeco 930) near the topological phase transition (x~0.4). The cross-section high-angle annular dark-field (HAADF) imaging in scanning transmission electron microscopy (STEM) shows abrupt interfaces. X-ray diffraction demonstrates single oriented films. The sheet resistance v.s. temperature demosntrates a metallic-like behavior, dR/dT >0, in doped samples extending to 2 K. The Hall carrier density was measured at various temperatures, resolving the carrier mobility. The carrier mobility is inversely proportional to doping concentration. We report on superconductivity in electron and hole doped $Pb_{1-x}Sn_xTe$ heterostructures and its relation to neighboring ferroelectric and topological phase transitions.

Progress in the Synthesis of Device-Grade Chalcogenide Perovskite Thin Films Corrado Comparotto, Kostiantyn Sopiha, Garima Aggarwal and Jonathan Scragg; Uppsala University, Sweden

Functional inorganic materials combining electropositive group-I or group-II elements with transition metals and p-block anions provide some intriguing properties, for example high dielectric polarizability and ferroelectricity in combination with band gaps in the visible light range.[1] Chalcogenide perovskites such as $BaZrS_3$ are a case in point.[2] At present, they are being explored as robust, earth-abundant and non-toxic candidates for tandem solar cells where the high polarizability might allow for longer charge carrier lifetimes.
In this contribution, the interesting features of chalcogenide perovskites are summarized. Their structural stability is discussed on the basis of computed formation energies, empirical stability rules and experimental literature. The prevailing picture of a broad family of $(Ca,Sr,Ba)(Ti,Zr)(S,Se)_3$ perovskite compounds is shown to be incorrect: in fact, only $BaHfS_3$ and $BaZrS_3$ are expected to crystallize in the perovskite structure under the appropriate for thin-film solar cell deposition [3]. All other compounds favor alterative structures (that may nevertheless be worth exploring).
Furthermore, we report our progress in synthesizing chalcogenide perovskites using sputtering routes. The aim is to produce high-quality material suitable for detailed characterization and future device integration, via a fast and flexible route that can be also adapted for a range of related compounds. The main challenges for sputtering chalcogenide perovskites and other compounds containing electropositive group-I or group-II elements are: a) obtaining low oxygen content, to ensure that intrinsic material characteristics can be measured, and b) achieving good crystallization at moderate temperature, for compatibility with device fabrication. Both of these aims can be met using a two-stage growth process consisting of Ba-Zr metal precursor deposition followed by thermal processing in S vapor, although special adaptations are required, as will be described. With suitable procedures, we have grown $BaZrS_3$ films both on Mo-coated and on insulating substrates, with little to no degradation of the substrate, using growth temperatures below 600°C. Finally, the latest results from charge transport measurements, as well as the additional optical and structural characterization of $BaZrS_3$ thin films, will be presented. The impact of process variations, including the influence of S vapor pressure and addition of p-/n-type dopants, will be reported and discussed.

Understanding Post-Transition Metal Chalcogenide Absorbers—Defects and Beyond-DFT Christopher Savory; University College London, United Kingdom

As we balance the worldwide need for energy with the necessity to move to renewable energy technologies, assembling a diverse array of photovoltaic materials is necessary to overcome such challenges and demands. Silicon is highly abundant and market-dominant, yet energy-intensive to produce and necessitates thick wafers, while established chalcogenide thin-film materials such as CdTe allow strong absorption and the potential for flexible devices but suffer from toxicity and low abundance of constituent elements.[1,2] Recent work, however, has demonstrates a class of emerging chalcogenide absorbers that offer both more sustainable synthesis and promising optoelectronic properties, and could aid the photovoltaic diversity of the future.

In this talk, I will consider our computational investigations into a selection of these post-transition metal chalcogenide solar absorbers – Sb_2Se_3, GeSe and $CuSbS_2$ – with a focus on their excitonic properties and defect chemistries. In the first section of the study, we discuss the use of many-body perturbation theory as route to highly accurate band gap prediction. From our initial success in elucidating the nature of the gap in bulk GeSe,[3] to looking at the absorption in Sb_2Se_3 and the nature of the excitons in $CuSbS_2$, we show how the QSGW method, with the addition of vertex corrections through the solution of the Bethe-Salpeter equation,[4] allows understanding and comparison to optical experiments far beyond that possible with standard Density

Functional Theory (DFT).

In the second section, we explore how the unusual structural and chemical environments available to these chalcogenides can both benefit and hamper the defect tolerance of these materials. Our previous work has highlighted how despite possessing a pseudo-1D structure and potentially benign grain boundaries,[5,6] Sb_2Se_3 suffers from numerous mid-gap defect states that could be hampering open circuit voltage in devices.[7] In this work, we examine strategies for p-type dopability in the material to improve device performance, in collaboration with the University of Liverpool,[8] and present simulations of the defect behaviour of GeSe to discuss how elements of this defect chemistry vary between the different post-transition metal chalcogenides. With this understanding, we critique the applicability of defect tolerance in these materials, and assess the promise of emerging chalcogenide absorbers.

Impact of Cation Disorder on Solar Cell Performance in Ternary Chalcogenides (I-III-S_2; $NaBiS_2$) Seán R. Kavanagh[1], Yi-Teng Huang[2], Robert Hoye[3], David O. Scanlon[4] and Aron Walsh[3]; [1]University College London & Imperial College London, United Kingdom; [2]University of Cambridge, United Kingdom; [3]Imperial College London, United Kingdom; [4]University College London, United Kingdom

I-V-VI_2 ternary chalcogenides have recently attracted growing attention as earth-abundant, nontoxic, and air-stable absorbers for photovoltaic applications.[1] In particular, our recent work on the $NaBiS_2$ & $AgBiS_2$ members of this family has revealed ultra-strong optical absorption for these compounds – *the highest of all current PV materials*.[2,3] A key benefit of such intense light absorption is that it allows for ultrathin (<100 nm) solar cell devices, dramatically reducing material consumption, weight and manufacturing demand, directly lowering the cost and facilitating applications in space for example, in addition to benefitting quantum efficiency and photovoltaic (PV) performance.
Our work on $AgBiS_2$[2] showed the crucial importance of controlling cation distribution and disorder in these materials, yielding record-breaking efficiencies >9% – the highest of any Bi-based solar absorber.[2] However, the impact of disorder on the charge-carrier properties in these materials is remains poorly understood. Herein, we investigate the key properties which dictate the relationship between disorder on the cation sublattice and carrier transport in these materials. We find the band-edge orbital character to be a crucial factor in the sensitivity of carrier localisation (and thus solar cell efficiency) to cation disorder, resulting in ultra-fast carrier trapping, despite slow carrier recombination, in $NaBiS_2$.[3]
This work reveals the critical role of cation disorder in the photovoltaic performance of these systems, alongside key considerations for future research in this area.

Opto-Mechanical Structural Transitions in SnSe Driven by Mid-Infrared Light Pulses Aaron Lindenberg; Stanford University, United States

A central goal in materials research is to develop means for controlling and inducing new phases of matter with unique functionalities. With respect to using light to control matter, previous work has mostly focused on above-bandgap or resonant mode excitation, accessing the imaginary part of the dielectric function. Here we present new experimental results using a suite of advanced spectroscopies to show evidence for a novel optomechanical driving force in the chalcogenide material tin selenide (SnSe) using mid-infrared, below-gap femtosecond optical pulses. Femtosecond time-resolved Raman scattering shows an abrupt suppression of Raman modes above a threshold fluence consistent with a distortion towards the high-symmetry rocksalt phase of SnSe. This is further corroborated by transient reflectivity measurements, time-resolved x-ray scattering, and first principles calculations, thereby defining new possibilities for manipulating the structure and functionality of SnSe and related chalcogenide materials.

3:30 PM EQ04.03.02
Visualization of Photoexcited Dynamics in Chalcogenide Materials Grains using State-Of-The-Art Pump-Probe Microscopy and Spectroscopy Techniques Farnoush Nourigheimasi and Elham Ghadiri; Wake Forest University, United States

IIn this paper, we integrate a combination of modern and complementary ultrafast transient absorption spectroscopy (TAS) and pump-probe transient absorption microscopy (TAM) techniques to discuss the ultrafast photophysics of efficient photovoltaic materials including $Cu_2BaSnSSe$ (CBTSSe) chalcogenides[1,2] and $Cu_2ZnSnS_{4-x}Se_x$ (CZTSSe). CBTSSe is a recently introduced alternative to $Cu(In,Ga)(S,Se)_2$ and $Cu_2ZnSnS_{4-x}Se_x$ (CZTSSe). Pump-probe microscopic imaging enables to localize the photoexcitation patterns and early charge carrier kinetics within the grains of only a few hundreds of nanometers and localize the kinetics of photogenerated carriers in each grain with femtosecond time resolution.

We compare the photoexcitation pattern in CBTS and CZTS films and discuss the excited state relaxation within film grains. For CBTS, we spectrally resolve a sharp ground-state bleaching (GSB) peak, formed around the band edge transition. The pump-probe microscopy images are heterogeneously composed of positive and negative regions identifying excited state absorption and ground sate bleaching in different grains. For CZTS samples, at identical condition, we observe that the pump-probe microscopy images are homogeneously composed of GSB. The broadband spectrum points to broad GSB absorption extended from visible to near infrared region for CZTSSe. Our pump-probe microscopy and spectroscopy results, all point to a reduction in shallow defects and band tailing in CBTSSe relative to CZTSSe films. The charge carrier relaxation resolved in CBTSSe single grains, or over an ensemble of grains, however, remains faster compared to CZTSSe, pointing to the need to perhaps better understand deep traps within this absorber family. Remarkably, we have shown that the unique sensitivity of pump-probe microscopy and sharp electronic transitions allow for detection of small compositional variations,— features that are largely unresolved for ensemble spectroscopy or luminescence measurements.

Pure Spin Photocurrent in Non-Centrosymmetric Crystals—Bulk Spin Photovoltaic Effect Haowei Xu, Hua Wang, Jian Zhou and Ju Li; Massachusetts Institute of Technology, United States

Spin current generators are critical components for spintronics-based information processing. In this work, we theoretically and computationally investigate the bulk spin photovoltaic (BSPV) effect for creating DC spin current under light illumination. The only requirement for BPSV is inversion symmetry breaking, thus it applies to a broad range of materials and can be readily integrated with existing semiconductor technologies. The BSPV effect is a cousin of the bulk photovoltaic (BPV) effect, whereby a DC charge current is generated under light. Thanks to the different selection rules on spin and charge currents, a pure spin current can be realized if the system possesses mirror symmetry or inversion-mirror symmetry. The mechanism of BPSV and the role of the electronic relaxation time are also elucidated. We apply our theory to several distinct material systems, including transition metal dichalcogenides, anti-ferromagnetic $MnBi_2Te_4$, and the surface of topological crystalline insulator cubic SnTe.

4:00 PM +EQ04.03.04
The Nature of *Metavalent* Bonding in Crystals—The Origin of Emergence of Unusual Properties Umesh V. Waghmare, Raagya Arora and C N. Rao; Jawaharlal Nehru Ctr for Adv Sci Research, India

Phase change chalcogenide materials exhibit a remarkable ability to transform reversibly from a covalently bonded amorphous structure to rocksalt crystalline forms considered to exhibit a distinct type of metavalent bonding. An unusual portfolio of anomalous functional properties emerge in the metavalent rocksalt forms, and their origin and electronic mechanisms are yet to be understood. Here, we present first-principles theoretical analysis of the evolution of metavalent bonding along continuous paths in the structural and chemical composition space, starting from distinct covalent, ionic and metallic states. We show that metavalent bonding arises in rocksalt chalcogenides stabilized in weakly broken symmetry states of the parent covalent metal, a simple cubic crystal of Group V metalloid. High electronic degeneracy at the nested Fermi surface of the parent metal drives spontaneous breaking of its translational symmetry with structural and chemical changes, which mediate strong coupling between conduction and valence bands separated by a small energy gap making metavalent crystals highly conductive, polarizable and sensitive to bond-lengths. Stronger changes is structural and chemical fields, however, evolve them discontinuously to covalent and ionic semiconducting states respectively. We predict them to exhibit anomalous second order Raman scattering, adding to the set of their unusual finger-printing properties. Wannier function analysis reveals multi-centre, mixed bonding and antibonding pp and sp orbital interactions supporting fractional bond-order and high coordination numbers. Our precise picture of metavalent bonding will guide in design of new metavalent materials with improved thermoelectric, ferroelectric and nontrivial electronic topological properties.

4:30 PM EQ04.03.05
High-Temperature Superconductor FeSe Films Enabled Through Flux Ratio Control Maria Hilse[1], Hemian Yi[1], Cui-Zu Chang[1] and Roman Engel-Herbert[1,2]; [1]The Pennsylvania State University, United States; [2]Paul-Drude-Instit für Festkörperelektronik, Germany

FeSe, a bulk superconductor with a T_C of 9 K has attracted a high level of attention over almost one decade since a skyrocketing boost in T_C was reported for a single unit cell (UC) layer of FeSe grown by molecular beam epitaxy (MBE) on $SrTiO_3$(001) to as high as 100 K.[1] FeSe-$SrTiO_3$ heterostructures have since been fabricated by numerous groups in the field but the record T_C proved extremely difficult to reproduce and thus the mechanism behind it still remains concealed. However, after extensive work in the past, the field appears to agree on certain key "ingredients" in the heterostructure sample preparation that are believed essential for the boost in T_C. Those key players are; 1. an ultra-clean substrate surface of specific double layer of TiO_2 termination typically realized by a chemical and thermal *ex-situ* and additional thermal *in-situ* substrate preparation before growth; 2. ultra-thin – one to few unit cell thickness – limit of FeSe layer thickness; 3. a high number of Se vacancies in the FeSe film ensured through post-growth annealing steps carried out under ultra-high vacuum (UHV) for several hours; 4. followed by a suitable capping layer growth in case films need to be characterized *ex-situ* under ambient pressure due to the rapid oxidation of FeSe in air.
In this talk, we present our findings on FeSe thin film growth by MBE and present a roadmap for high-T_C – as high as 20 K in macroscopic *ex-situ* transport measurements – circumventing above mentioned steps 1, 2, and 3 by simple *in-situ* Se/Fe flux ratio control during FeSe growth. For this study, we have been growing FeSe films of 20-UC-thickness at varying temperature and Se/Fe flux ratios and analyzed the structural and morphological properties of the obtained uncapped FeSe films. Se and Fe fluxes were calibrated before each growth using a heated Quartz crystal microbalance (QCM) and tooling factors for the QCM calibration were extracted from physical thickness measurements by X-ray diffraction (XRD). The substrate surface temperature during growth was monitored with high precision by an infrared (IR) camera system. $SrTiO_3$ substrates were cleaned in subsequent ultrasonic baths of acetone, isopropyl alcohol, and DI-water and annealed in air to 980 °C for about 1.5 h in a box furnace to realize an atomic terrace surface morphology and additionally annealed in UHV to 600 °C for 2 h to remove adsorbates. Structural and morphological analysis was carried out *in-situ* by reflection high energy electron diffraction (RHEED) and *ex-situ* by XRD and atomic force microscopy (AFM), respectively within 20 min of taking the samples out of the UHV environment to minimize oxidation of the films. The morphology of the films showed a sensitive dependence on the growth temperature and flux ratio spanning from perfectly smooth and continuous films with atomic terraces at 450 °C growth temperature and a low flux ratio of 2.5 to exclusively disconnected island growth of large height but smooth top surfaces at lower temperatures and/or higher flux ratios. Surprisingly, the tetragonal P4/nmm crystal structure of β-FeSe was maintained for all investigated films and the *in-situ* observed diffraction pattern in RHEED also maintained the streaky pattern characteristic for smooth FeSe films even for the samples with the most pronounced island growth resulting in a root mean

square (rms) AFM roughness of more than 18 nm. Smaller flux ratios than 2.5 resulted in mixed – β-FeSe/elemental Fe – phase samples. FeSe films grown under optimized conditions at 450 °C and a flux ratio of 2.5 (but without any post-growth UHV anneal) and capped with the commonly used FeTe (300 °C) and elemental Te (room temperature) layers yielded superconducting onset temperatures of about 30 K and a T_C of 20 K.

SESSION EQ04.04: Defects and Excited States in Low-Dimensional Materials
Session Chairs: Kunal Mukherjee and Mark Polking
Tuesday Morning, November 29, 2022
Sheraton, 2nd Floor, Constitution A

8:30 AM *EQ04.04.01
Tunable Doping for 2D Materials Electronics Albert Davydov[1], Sergiy Krylyuk[1], Huairuo Zhang[1], Bruce Scruggs[1], Zheng Sun[2], Chandraman Patil[3], Volker J. Sorger[3] and Joerg Appenzeller[2]; [1]National Institute of Standards and Technology, United States; [2]Purdue University, United States; [3]George Washington University, United States

2D materials, including layered metal chalcogenides, enable a broad range of advanced electronic applications. The ability to manipulate electrical properties by doping 2D semiconductors opens a possibility for fabricating ultra-thin p/n junctions and other two-dimensional electronic devices. However, reliable processes for reproducible doping of 2D materials are yet to be developed. This talk will survey various doping approaches of 2D semiconductors from substitutional to electrostatic to charge transfer via surface, followed by the specific example of developing controllable doping of indium selenide layers. The n- and p- type substitutional doping of InSe was conducted via single crystal Bridgman growth using Sn and Zn impurities, respectively. The concentration of Sn atoms in progressively doped n-type InSe samples varied from tens to hundreds of ppm as estimated from the X-ray fluorescence (XRF) and inductively coupled plasma mass-spectrometry (ICP-MS). Electrically active dopant concentration was assessed using van-der-Pauw Hall measurements and compared against the total Sn concentration from XRF and ICP-MS. The talk will conclude with a demonstration of employing electrically tunable indium selenide layers in a p/n homojunction photodetector.

9:00 AM EQ04.04.02
Disorder and Its Effects on Two-Dimensional Transition Metal Dichalcogenides Steven Durbin[1], Krystal R. York[1], Robert Makin[1], Thomas McKnight[2] and Joan M. Redwing[2]; [1]Western Michigan University, United States; [2]The Pennsylvania State University, United States

Semiconductor transition metal dichalcogenides (TMDs) have an inherent tunability where as the number of layers in the material increases, the band gap decreases and becomes indirect. This property gave rise to several band gap engineering studies for these 2D materials such as heterostructures, strain engineering, and twist angle studies. This work instead focuses on adjusting the band gap energy and other properties by tuning the degree of disorder. Disorder in a lattice refers to a state of a crystalline solid in which not all of the atoms occupy their predicted lattice sites. In other words, a completely ordered lattice would have all of the atoms occupy their equilibrium phase position and a completely disordered lattice would have the atoms randomly distributed over the lattice sites. A disordered state can occur even when the material maintains its predicted stoichiometry since antisite defects can preserve the correct composition. Although disorder in the lattice is typically unwanted, it has been shown to be useful in reliably tuning properties such as the band gap.

The degree of disorder has been quantified using the Bragg-Williams order parameter S to better understand the trends between disorder and significant material properties. This work extracts the order parameter of several of the TMD materials using Raman spectroscopy and SEM, with excellent agreement between these two techniques. For all of the materials in this work, there is a clear linear trend between the band gap values and S^2, which has previously been experimentally established for other materials like heterovalent ternary materials such as $ZnSnN_2$ and $MgSnN_2$, binary materials such as InN and GaN, and elementary materials such as Si.

This work focuses on WSe_2 films grown via metal-organic chemical vapor deposition (MOCVD) on sapphire substrates using a multi-step growth process which involved an initial nucleation step, a ripening step, and a final lateral growth step. This process was chosen as it has shown to achieve large-area, lateral growth of MOCVD grown TMDs in the past. Between each film growth, one process parameter was changed in order to determine how that parameter altered the degree of disorder. The process parameters tested were the substrate temperature, H_2Se flow rate, and length of the individual steps. Additionally, S^2 was also compared to the monolayer coverage and the thickness of the domains, which were extracted using atomic force microscopy to determine if these were the main drivers for the changes seen in the degree of ordering. Exploring the role of process parameters in the context of tuning the degree of disorder can not only allow for a dependable way of controlling of the band gap energy, but also could prove to be a reliable way of controlling other electrical properties such as carrier mobility.

The TMD materials analyzed for this study exhibited an expected continuous linear relationship between the band gap values and S^2. The amount of coverage and number of layers had the most discernable impact on the S^2 value, showing that as the number of layers or monolayer coverage increased, so too did the degree of ordering. However, process parameters such as the temperature during the nucleation step, H_2Se flow rate, and chamber pressure seemed to have an impact on the degree of ordering as well. Finally, an unexpected result emerged when adjusting the chamber pressure between film growths, which resulted in an ability to control domain alignment and domain directions.

9:15 AM EQ04.04.03
Explanation of the Opposing Shifts in the Absorption Edge and the Optical Resonance in $CuFeS_2$ Nanoparticles Yuan Yao; Cornell University, United States

$CuFeS_2$ nanoparticles are novel intermediate band semiconductors that possess a prominent plasmon-like absorption feature in the visible region (~2.5 eV),

giant optical nonlinearity, and have the potential for post-synthetic tuning of their absorption band. Despite having similar optical properties to other semiconductor plasmonic materials, the quasi-static optical resonance in $CuFeS_2$ is contributed by collective electronic transitions between filled and unfilled states rather than by a free carrier oscillation.
Size-dependent change of the electronic band structure is one of the key features of nanoparticles in the quantum confinement region, but in $CuFeS_2$ the optical features follow divergent and conflicting trends that have yet to be explained. Namely, when the particle size decreases the optical resonance feature of $CuFeS_2$ shows a small redshift while the band gap blueshifts. Since the 2.5 eV absorption feature is contributed by collective electronic transition, we hypothesized that this feature should be subject to quantum confinement effects through modification of the electronic bands. In this paper, we show experimentally that the optical resonance absorption peak redshifts and the optical band gap blueshifts as the particle size decreases. Then, through density functional theory (DFT) and a tight binding modeling, we elucidate the size dependence of the band structure, especially focusing on the change in the intermediate band. Using a Lorentzian oscillator optical model to simulate the absorption spectrum with inputs from the DFT calculated band structure and band shifts from the tight binding model, we find the size-dependent shifts of the optical resonance peak position in $CuFeS_2$ is due to a tri-band quantum confinement effect that results in both the valence band to intermediate band and intermediate band to conduction band gap expansion that accompanies a decrease in particle size. We also find that the transitions between the intermediate band and conduction band play only a minor role in the optical spectrum. Moreover, the linear optical Lorentzian model predicts the optical resonance peak is tunable across the visible range by partially filling the intermediate band, lowering the conduction band, or expanding the intermediate band.
Overall, in this study, we provide fundamental understandings about the origin of the visible quasi-static resonance in $CuFeS_2$ nanoparticles and elucidate the correlation between the absorption feature shift and the intermediate-band electronic structure. These results are relevant to other quantum-confined intermediate band systems, which have potential use in optical applications as well as photovoltaic devices.

10:00 AM *EQ04.04.04
Dilute Impurities and Bound Excitons in 2D Semiconductors Goki Eda; National University of Singapore, Singapore

Owing to reduced screening, point defects in 2D semiconductors such as monolayer transition metal dichalcogenides (TMDs) can serve as optically addressable quantum dots. However, the density of common defects in TMDs are excessively high, making it challenging to address individual defect states for quantum operations. Accordingly, the physical origin of the localized states also remains elusive, preventing strategic quantum defect engineering. We introduce and optically probe a variety of atomic defects in monolayer TMDs in the dilute limit with the aim to accessing their quantum nature. One example is Nb-doped monolayer WS_2, which is found to exhibit bright sub-gap emission even at ppm concentrations. We show that such emission arises from ionized-acceptor-bound excitons, a three-body charge complex analogous to a negative trion. These bound exciton complexes exhibit sizeable valley selectivity reflecting their partial free exciton character. We further discuss a scanning probe approach to rapidly quantifying impurities in the ultra-dilute limit ($<10^{10}cm^{-2}$) in ambient conditions.

***Ab Initio* Molecular Dynamics Simulation Study of Oxidation of ZrS_2(001)** Liqiu Yang[1], Subodh Tiwari[2], Aravind Krishnamoorthy[1], Rajiv Kalia[1], Aiichiro Nakano[1] and Priya Vashishta[1]; [1]University of Southern California, United States; [2]Schrödinger, United States

Abstract

In transition metal dichalcogenides (TMDC) family, ZrS_2 is known for its superior electrical and chemical catalytic properties. Meanwhile, it is easily oxidized, which brings problems in device processing and long-term stability. Although the ZrS_2 oxidation mechanism and oxide growth kinetics has been investigated recently, the atomistic reaction pathway still lacks fully understood. Here, we report *ab initio* molecular dynamics results for studying the oxidation of ZrS_2. Our simulations show the oxidation of ZrS_2(001) surface to be initiated as the adsorption of an oxygen molecule to the ZrS_2(001) surface, followed by oxygen atoms substituting surface sulfur atoms. The recently reported amorphization-assisted-oxidation is found to be linked to the zirconium atoms bonded with inner layer sulfur atoms. We also found the oxygen transport is assisted by bond switching and ring arrangements. The chemical reaction pathways and atomistic mechanisms provided in this work is valuable for device processing and other layered TMDC oxidation.

Investigation of Oxidation Mechanism in HfS_2 and ZrS_2 TMDs with *In Situ* Transmission Electron Microscopy Alexandre Foucher, Kate Reidy, Wouter Mortelmans, Baoming Wang, Seong Soon Jo, Aubrey Penn, Rafael Jaramillo and Frances M. Ross; Massachusetts Institute of Technology, United States

HfS_2 and ZrS_2 transition metal dichalcogenides (TMDs) are of great interest for their potential applications as semiconductors in field effect transistors (FETs), low-power devices and photodetectors. It has been shown that these materials have higher mobility than MoS_2, which makes them promising materials for optical and electric devices. In particular, the oxidation of HfS_2 and ZrS_2 is critical as it can dramatically change their physical properties. In fact, the oxidation of HfS_2 and ZrS_2 can be useful in creating a dielectric layer adjacent to the semiconductor, as needed in FETs. In this work, we performed *in situ* transmission electron microscopy to investigate the oxidation mechanism of HfS_2 and ZrS_2 under O_2 at elevated temperature and compare with MoS_2. Simultaneous *in situ* SEM and STEM-EDS/EELS analysis was performed to show morphological and chemical changes. We demonstrated that S is replaced by O under these conditions and showed increased surface roughness of 2D HfS_2 and ZrS_2. Modifications of the crystal structure, such as the formation of amorphous layers and islands were also observed. Additionally, 4D STEM was performed to show strain and stress in 2D HfS_2 and ZrS_2 upon oxidation. The impact of oxidation was then correlated with modification in optical properties of the oxide, measured by spectroscopic ellipsometry, and modification in electrical and dielectric properties, measured with MOS device. These results provide guidelines to further improve the stability and performance of devices with ZrS_2 and HfS_2 TMDs.

Water-Based 2D Material Inks for Printed Electronics Cinzia Casiraghi; University of Manchester, United Kingdom

Solution processing of 2D materials allows simple and low-cost techniques, such as ink-jet printing, to be used for fabrication of heterostructure-based devices of arbitrary complexity. Our group has developed highly concentrated, defect-free, inkjet printable and water-based 2D crystal formulations, by exploiting non-covalent functionalization of 2D materials with pyrene derivatives [1]. Examples of printed heterostructures, containing Chalcogenide inks, such as arrays of photosensors, programmable logic memories, amd memristors will be discussed [2-3]. Furthermore, inkjet printing can be easily combined with Chalcogenide materials produced by chemical vapor deposition, allowing simple and quick fabrication of complex circuits on paper, compatible with CMOS technology [4-5].

Generalised Optical Printing of Photocurable Metal Chalcogenides Seongheon Baek and Jae Sung Son; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Optical three-dimensional (3D) printing techniques attract tremendous attention due to the capability of maskless additive manufacturing, enabling cost-effective and straightforward creation of patterned architectures. Despite their potential as alternatives to classical lithography, the printable materials produced by these processes are restricted to photocurable resins, limiting the functioning of printed products and their application regions. Herein, we report a generalised direct optical printing technique to obtain functional metal chalcogenides via digital light processing. We developed universally applicable photocurable chalcogenidometallate inks that could be directly used to create 2D patterns or 3D architectures of various sizes and shapes. Our method may be used to make a wide variety of functional metal chalcogenides for compound semiconductors as well as 2D transition-metal dichalcogenides. Finally, we demonstrate the feasibility of our process that the micro-scale thermoelectric generator with tens of patterned semiconductors was fabricated and evaluated. Our approach shows potential for simple and cost-effective architecturing of functional inorganic materials.

New Functional Metal Chalcogenides Deposited from Solution Yuval Golan; Ben-Gurion University of the Negev, Israel

We review several newly discovered metal-chalcogenide binary phases obtained using solution-based techniques. The new cubic pi-phase of tin sulfide (pi-SnS) reported in 2015 was first obtained using colloidal (surfactant assisted) synthesis, [1] and was later deposited as thin films from aqueous solutions. [2,3] Soon after, the cubic selenide analog, pi-SnSe, was reported. [4] Several “beneficial impurities” were identified, whose presence was found to be essential for stabilization of these metastable phases. [5] More recently, yet another new binary phase of SnSe, the orthorhombic gamma-SnSe, [6] was shown to exhibit intriguing and potentially useful electronic properties. [7] Furthermore, combinatorial liquid flow deposition of metal chalcogenides offers great potential for discovery of new materials and properties. [8] Finally, we will show that caution must be exercised when preparing TEM samples using the dual beam FIB due to sample preparation induced phase transitions. [9]

Infrared PbS Colloidal Quantum Optoelectronics—LEDs and Lasers Gerasimos Konstantatos; ICFO, Spain

Solution Processed CMOS compatible Infrared Optoelectronics is a key enabling technology to revolutionize consumer electronic markets offering unprecedented opportunities for low-cost food quality inspection, environmental monitoring, 3D imaging, automotive safety and night vision applications just to name a few. Recent progress in CMOS compatible CQD photodetectors have addressed the InGaAs image sensor challenge and the next step would be the development of the correspondingly low-cost tunable light sources. In this talk, I will be presenting recent results from my lab at ICFO on highly performant infrared CQD LEDs and downconverting light emitters.
I will present our device architecture approach that allowed us to achieve very high PLQY in conductive solid state QD films that when implemented in a LED stack led to 8% EQE [1]. I will then discuss the optimization of the matrix supply dots that improved charge balance and allowed to reach 8% EQE at high radiance along with a stark improvement in operational stability [2]. I will then elaborate on fine-tuning the energetic potential landscape in the matrix which taken together with optimized optical out-coupling schemes reached a QE of 18% at 1550 nm. The possibility to tune the light spectrum of such QD films by stacking layers of QDs with different bandgaps offers exquisite control over the emission spectrum offering the opportunity to develop solid-state thin film broadband emitters in the SWIR, either optically or electrically excited with implications in SWIR spectroscopy [3].
The second part of my talk will discuss recent progress on infrared CQD lasers comprising doped PbS CQDs integrated in a DFB cavity [4]. Besides this I will present our approach of elongating Auger lifetime by engineering QD solids at the supra-nanocrystalline level offering lasers with improved optical linewidths, reduced thresholds and drastically improved stability [5]. I will also briefly discuss our very recent results of sub-single exciton CQD infrared lasing enabled by optimized doping and adoption of a quantum dot heterostructure.
The last part of my talk, if time allows, will be devoted to a different line of research on how to tune the optical properties of nanocrystals by engineering their atomic configuration. I will show an example of AgBiS2 NCs whereby cation disorder has been homogenized yielding a material with very high optical absorption coefficient. This material has further been optimized in a solar cell stack leading to a record high PCE of 9% for an extremely thin absorber cell of only 35 nm. [6]

Molecular Beam Epitaxy of SnSe Thin Films for Future Optoelectronic Applications Wouter Mortelmans[1], Maria Hilse[2], Qian Song[1], Seong Soon Jo[1], Kevin Ye[1], Derrick Shao Heng Liu[2], Nitin Samarth[2] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]The Pennsylvania State University, United States

Van der Waals (vdW) layered chalcogenides have strongly direction-dependent properties that make them interesting for certain photonic and optoelectronic applications. Orthorhombic tin selenide (α-SnSe) is a triaxial vdW material with strong optical anisotropy within layer planes, which has motivated studies of optical phase and domain switching. As with every vdW material, controlling the phase and orientation of crystal domains during growth is key to reliably making wafer-scale, high-quality thin films, free from twin boundaries. We demonstrate a fast and easy optical method - that applies to all triaxial vdW materials - to quantify domain orientation in single-phase α-SnSe thin films made by molecular beam epitaxy (MBE). We use our method to confirm a high density of twin boundaries in α-SnSe epitaxial films on MgO substrates, with square symmetry that results in degeneracy between α-SnSe 90° domain orientations. We then demonstrate that growing instead on a-plane sapphire, with rectangular lattice-matched symmetry that breaks the α-SnSe domain degeneracy, results in single-crystalline films with preferred orientation, with twin domains all-but-eliminated. We then perform experiments attempting ferroelastic α-SnSe domain switching and epitaxial stabilization of metastable cubic SnSe using other substrates. Our bottom-up SnSe film syntheses by MBE are enabling for future applications of this vdW material that is particularly difficult to process by top-down methods.

Giant Optical Response in Topological Semiconductors with a Mexican Hat Band Structure Mark Polking[1], Haowei Xu[2] and Ju Li[2,2]; [1]Lincoln Laboratory, Massachusetts Institute of Technology, United States; [2]Massachusetts Institute of Technology, United States

The infrared (IR) to terahertz (THz) frequencies are the least developed parts of the electromagnetic spectrum for applications. Traditional semiconductor technologies such as laser diodes and photodetectors are successful in the visible light range but face major challenges in the IR/THz range due to weak light-matter interactions. In this work, we theoretically and experimentally demonstrate that topological insulators (TIs), especially those with a Mexican hat band structure (MHBS), can help overcome these challenges. Materials with a MHBS exhibit optical responses 1−2 orders of magnitude larger than those of normal semiconductors at the optical transition edge. Through first-principles calculations, we have discovered a number of MHBS TIs with bandgaps between 0.05 and 0.5 eV and giant absorption coefficients on the order of 10^4–10^5 cm^{-1} at the transition edge. Single-crystal specimens of one of these candidate materials, $Pb_{0.7}Sn_{0.3}Se$, have been experimentally measured using temperature-dependent spectroscopic ellipsometry over a wavelength range of 1.7-19 μm. These measurements demonstrate a large enhancement in extinction coefficient characteristic of a MHBS in the vicinity of the absorption edge in agreement with theory predictions. Realization of semiconductors with a MHBS is expected to lead to efficient detectors in the IR/THz range.

Heteroepitaxial Integration and Defect Structure of IV-VI Semiconductors for Infrared Optoelectronics Kunal Mukherjee, Leland Nordin, Jarod Meyer and Pooja Reddy; Stanford University, United States

The IV-VI selenide semiconductor family of PbSe-SnSe-GeSe has rich materials physics and device applications[1]. These semiconductors, spanning the rocksalt and layered orthorhombic phases, have long been studied for their unconventional bonding that yields rare properties compared to silicon and III-V materials. We present our results from epitaxial integration of IV-VI semiconductor thin films together with III-V materials using molecular beam epitaxy to understand how we may harness these properties for emerging applications in near- and mid-infrared optoelectronics.

With attractively low temperatures for epitaxy much below 300 °C, we describe the nucleation and growth of IV-VI materials on III-V substrates and study the formation and properties of extended crystal defects that arise due to integration[2]. We find bright band-edge photoluminescence from PbSe epitaxial films on ~8% mismatched GaAs substrates in the mid-infrared (3–4 µm) at room temperature, despite a threading dislocation density exceeding $10^9/cm^2$. While defects still control the minority carrier lifetime at low injection indicating room for improvement, PbSe samples quickly become Auger-recombination limited at high injection[3]. We present insight into carrier recombination mechanisms in PbSe from temperature, time, and excitation power dependent luminescence studies.
The PbSe/GaAs template also enables us to probe deeper into the growth of thin films of SnSe and the PbSnSe alloys that span orthorhombic-rocksalt phases[4]. We show how the structure of layered orthorhombic and rocksalt films and their defects are set by integration with cubic materials, and present preliminary results exploring this structural phase boundary in epitaxial thin films.

Stopping Resistance Drift with High-Field Electrical Stresses and Study of Electronic Transport in Stable Amorphous $Ge_2Sb_2Te_5$ (GST) Ali Gokirmak, Md Tashfiq Bin Kashem, Raihan Khan, ABM Hasan Talukder, Faruk Dirisaglik and Helena Silva; University of Connecticut, United States

Phase change materials are used for the implementation of the high speed, high density, non-volatile phase change memory (PCM) [1]. However, resistance drift complicates both multi-bit-per-cell implementations and characterization of the amorphous phase of the phase change materials [2,3]. In this work, we stabilized melt-quenched amorphous $Ge_2Sb_2Te_5$ (a-GST) line-cells (stopped resistance drift) with high electric field stresses at low temperatures (T ~ 85 K) [4-6] and performed a comprehensive study on electric field (0 to ~40 MV/m) and temperature (85 K to 300 K) dependent electronic transport.

The a-GST cells show resistance drift in the whole measurement temperature range with drift coefficients linearly decreasing as a function of 1/kT, extrapolating to zero at 61 K [4-6]. In the low-field regime (< 21 MV/m), current-voltage (I-V) characteristics fit well to a temperature dependent hopping transport model and the voltage stresses do not visibly effect resistance drift. In the high-field regime (> 21 MV/m), we observe a stronger exponential response in current and resistance drift is significantly accelerated. High-field stresses stabilize the cells within a few minutes, reaching resistance values that are normally expected to be reached in months by drifting.

In the low-field regime, we model the electronic transport in the stabilized cells assuming that current is limited by emission of trapped charges from a 'source-trap' to a 'receiving-trap' where the activation energy, hopping distance and relative location of the barrier peak are functions of temperature. The model fits the data extremely well. The fit parameters yield carrier activation energies ranging from 0.22 eV to 0.38 eV, hopping distances increasing from ~ 2 nm to ~ 6 nm for 85 K < T < 300 K, comparable to room temperature values reported in the literature [7]. Our models suggest that the barrier peak appears closer to the receiving-trap at lower temperatures and moves towards the midpoint between the source-trap and the receiving-trap with increasing temperature. The electrical conductivity of a-GST at ~1V ranges from ~2×10^{-10} S/cm at 85 K to ~5×10^{-4} S/cm at 300 K and follows the drifted thin film conductivity of the as-deposited a-GST below the glass transition temperature.

In the high-field regime, we observe a stronger current response to electric field, that becomes clearer at lower temperatures. The differential resistances in the high-field regime converge to a single point at 65.6 +/- 0.4 MV/m for all temperatures and the behavior is distinctly different compared to the low-field regime.

The significant change we observe from the low-field to the high-field regime, at a critical electric field of ~21 MV/m, is possibly due to activation of deeper traps or impact ionization of trapped charges. Band-to-band impact ionization and avalanche breakdown are expected to be less likely at this field strength as the mean free paths of the carriers are expected to be relatively small.

Acknowledgments: This work is supported by US NSF grant # 1711626.

Following the Reaction of Chalcogenide Perovskite $BaZrS_3$ Prakriti Kayastha, Giulia Longo and Lucy Whalley; Northumbria University, United Kingdom

The perovskite ABX_3 class of materials shows great promise as photovoltaic materials, with low production costs, high efficiencies, and a wide range of tunability through structural and compositional variation. The most successful of these perovskites are lead-based halide perovskites. However, there are several outstanding questions about the toxicity and stability of these materials. Chalcogenide-based perovskites, with a less toxic transition metal on the B-site, have been proposed to address both of these issues. In particular, $BaZrS_3$ has been recently fabricated in the lab but there are relatively few computational studies to support this experimental work. Here we present results from calculations using Density Functional Theory and finite displacement methods. In particular, we will analyze the electronic structure of $BaZrS_3$ and evaluate the dynamical properties and thermodynamics of this system. We will present the calculated IR and Raman spectra of $BaZrS_3$ and its competing phases, and discuss how these predictions can be used to support the synthesis of the material via ball-milling. With this work, we hope to highlight how electronic structure methods can support experimental work and accelerate materials design.

Observation of Defect and Disorder Driven Resistive Switching Properties in Sb_2Se_3. Jiwoong Yang, Yoonsung Jung and Sanghan Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

Memristor, two-terminal devices in which their resistance state is able to be switched by an applied voltage, have attracted much research attention owing to their possible application to high density Non-Volatile Memory (NVM). Various candidate materials for developing memristor are being studied to extend Moore's law. Specifically, the chalcogenide-based memristors can produce high memory performance with various strategies for defect engineering, so they have been in the spotlight. Antimony selenide (Sb_2Se_3) is an attractive chalcogenide material due to its unique one-dimensional crystal structure and non-toxicity with earth-abundant components. Despite several attempts to develop memory devices using Sb_2Se_3, no studies have succeeded in identifying the mechanism, and only a few on/off ratios in resistive switching has been reported. Here in, we have fabricated Sb_2Se_3 memristor with superior resistive switching properties via pulsed laser deposition (PLD). Controlling the working pressure, the Sb_2Se_3 thin films were grown to have a dot structure with void spaces, and the manipulation gives rise to the resistive switching property. We conducted atomic force microscope (AFM) and scanning electron microscope (SEM) measurements to observe the vacant surface morphology.
The on/off current ratio of the memristive Sb_2Se_3 with the vacant structure showed higher performances (~10^5), compared to that of Sb_2Se_3 with the highly ordered structure (~10^1). It was realized that the on/off resistance ratio varies depending on the applied voltage, and this new memristor switched its resistance state even under microsecond pulsed voltage. Besides, the memory performance was retained continuously after more than 1000 switching cycles. In terms of the conduction mechanism of the memristive Sb_2Se_3, space charge limited conduction (SCLC) was exhibited at the low resistance state, and the Pool Frenkel emission was dominant during the resistive switching process. In summary, we successfully fabricated a novel memristor device based on Sb_2Se_3 with high performance and low power consumption for the first time.

EQ04.07.04
Crystallographic and Electrical Property Improvement of MBE Grown SnTe Films by Introducing ZnTe Buffer Layers Su Nan, Kaito Tusboi, Shotaro Kobayashi, Kota Sugimoto and Masakazu Kobayashi; Waseda University, Japan

SnTe has attracted lots of attentions because it was predicted to be a topological crystalline insulator (TCI) [1]. In the previous study, SnTe films are prepared directly on GaAs (100) substrates by molecular beam epitaxy. By controlling the growth temperature T_{sub} and flux ratio of the elemental source Te and Sn $J_{Te}/J_{Sn,}$ SnTe (100) single domain have been achieved. However, Te segregation could be formed when certain growth parameters were used. The crystallographic properties including the film surface morphology and electronic properties are mainly studied in this study, and the improvement by introducing the buffer layer was evaluated.
SnTe layers were grown using elemental sources by conventional MBE with the molecular beam intensity ratio (J_{Te}/J_{Sn}) between 0.7~2.9. The value was tuned by changing the beam intensity of Te. Most of samples were grown at 240°C. According to the result of X-ray diffraction (XRD) measurement, diffraction peaks originated from SnTe were clearly confirmed. A peak originated from hexagonal Te was also observed when samples were grown with excess Te (J_{Te}/J_{Sn} was between 2.9 and 1.5). In the SEM measurements, Smooth surface was confirmed when the XRD of sample exhibited no Te peak while dotted materials were clearly observed on the surface when the hexagonal Te diffraction peak was observed by XRD. The distribution density of that dot was high when the Te diffraction peak signal intensity was strong. Those dotted materials are presumed to be the segregation of pure Te. Those crystallographic properties were improved after introducing the ZnTe layer between SnTe layers and GaAs substrates. The surface smoothness improvement was noticeable. The surface morphology was measured by AFM, and the RMS of the sample grown on the ZnTe layer was 4.9nm, which was much better than other samples grown directly on GaAs substrates.
A standard Hall measurement was performed at room temperature. The sample that didn't include the Te segregation exhibited the resistivity of about ohm. The resistivity was increased as the presence of Te was distinguished. Based on the literatures, the resistivity of SnTe is about ohm•cm [2], while the resistivity of Te was around 0.3 ohm•cm [3] at room temperatures. The higher resistivity is led by the mixing of Te. As a supplement, X-ray fluorescence measurement was also performed, and a similar trend was observed.
The segregation of hexagonal Te took place with the high flux ratio, which degraded the surface morphology and resulted in the poor electronic property of SnTe films. The precise control of the molecular beam intensity and the substrate temperature are the keys to achieve device quality SnTe films.
The introduction of ZnTe buffer layer has clearly improved the surface morphology of SnTe films. This result was useful for achieving TCI properties and device quality SnTe films.

Effect of Cr Doping on the Phase Stability in MnTe Polymorphic-Change Film Mihyeon Kim, Yi Shuang, Daisuke Ando and Yuji Sutou; Tohoku University, Japan

In manganese-tellurium (Mn-Te) binary system, MnTe compound has four polymorphs named α, β, γ, δ-MnTe, which are known to be p-type semiconductors. Interestingly, it has been reported that drastic changes in electrical and optical properties can be obtained between a stable phase of the α-MnTe (NiAs-type hexagonal structure) and a metastable phase of the β-MnTe (wurtzite-type hexagonal structure). [1-2] In our previous research, we successfully deposited the β-MnTe film by radiofrequency magnetron co-sputtering and the as-deposited β-MnTe thin film shows the polymorphic-change to the α-MnTe at around 455 °C, accompanied by large changes in physical properties. [3] Because such nonvolatile and reversible change of MnTe goes through melting-free process between two crystalline states, it can achieve a high-speed and low-energy phase change, implying that the MnTe is a promising material for phase-change memory devices. Furthermore, recently we revealed that the polymorphic-change of the MnTe film is closely related

to the stress, [4] which suggests that the electrical properties could be controlled by strain. Such strain-induced physical effects in thin film could be used to develop next-generation semiconductor devices for not only low-powered information storage but also sensor applications. However, to realize the strain-induced polymorphic-change accompanying the change of physical properties, the high polymorphic-change temperature of the MnTe film is still remained as a challenge. The sputtered MnTe film stabilizes in a metastable phase of a wurtzite-type hexagonal structure at room temperature. To control the polymorphic-change temperature from wurtzite-type to NiAs-type structure, we focus on tuning the phase stability of the MnTe film by doping transition metal. Chromium (Cr) is a candidate dopant element that could reduce the polymorphic-transition temperature, because Cr-Te binary system has a stable NiAs-type hexagonal structure at a high temperature region. Various compositions of the Cr-Mn-Te ternary thin films were deposited by radiofrequency magnetron co-sputtering. The structural, electrical and optical changes in the Cr-Mn-Te thin films were carried out at the temperature range of 27 - 500 °C to investigate the effect of Cr doping on the phase stability. The polymorphic-change behavior varied with adding Cr, which suggests that Cr dopant could be effective for controlling the polymorphic-change temperature between NiAs-like and wurtzite-like structures.

Steep-Switching Operation Condition for Field-Effect Transistor with Series-Connected Phase-Transition Device Chaeho Lim[1], Junmo Park[1], Seunghyun Park[1], Yejoo Choi[2], Chahnghwan Shin[2] and Hyoungsub Kim[1]; [1]SungKyunKwan Univ., Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Steep-switching hybrid phase-transition field-effect transistors (hyper-FETs) have recently been introduced as one approach to breaking through the subthreshold swing limit of 60 mV/dec [1]. However, there are few reports on the effect of the electrical properties of the constituent FETs and phase-transition devices on the switching behavior of hyper-FETs. In this presentation, the boundary conditions for steep-switching operation were studied by comparing the hyper-FETs with various resistance ratios of each constituent device (FET and phase-transition devices). The n-channel metal-oxide-semiconductor FETs (MOSFETs) with various channel lengths (0.5-5 mm) and widths (0.5-5 mm) were prepared, and their drain pads were wired to the phase-transition devices using a probe station. The phase-transition device was fabricated separately by vertically stacking a $GeTe_6$ film (insulator-metal transition material) and an upper metal-electrode on a heavily doped Si substrate in the form of a 3 mm*3 mm crossbar pattern. The followings are some important observations that will be discussed in detail. The steep slope mode appeared only in a very narrow range of the applied drain voltage, and it consisted of a two-step increase in drain current, i.e., an initial turn-on of the MOSFET followed by abrupt switching of the phase-transition device. Most importantly, because two different types of devices were connected in series, the drain voltage distribution of the two devices was the most critical parameter for a successful steep-switching behavior.

γ-GeSe—A New Hexagonal Polymorph of Group IV-VI Monochalcogenides Joong-Eon Jung[1], Sol Lee[1], Han-gyu Kim[1], Yangjin Lee[1], Je Myoung Park[2], Jeongsu Jang[1], Joonho Kim[1], Sangho Yoon[3], Arnab Ghosh[1], Jinsub Park[1], Minseol Kim[2], Woongki Na[2], Jonghwan Kim[3], Hyoung Joon Choi[1], Hyeonsik Cheong[2] and Kwanpyo Kim[1]; [1]Yonsei university, Korea (the Republic of); [2]Sogang University, Korea (the Republic of); [3]Pohang University of Science and Technology, Korea (the Republic of)

The family of group IV–VI monochalcogenides has an atomically puckered layered structure, and their atomic bond configuration suggests the possibility for the realization of various polymorphs. Here, we report the synthesis of the first hexagonal polymorph from the family of group IV–VI monochalcogenides, which is conventionally orthorhombic. Recently predicted four-atomic-thick hexagonal GeSe, so-called γ-GeSe, is synthesized and clearly identified by complementary structural characterizations, including elemental analysis, electron diffraction, high-resolution transmission electron microscopy imaging. The electrical and optical measurements indicate that synthesized γ-GeSe exhibits high electrical conductivity, which is comparable to those of other two-dimensional layered semimetallic crystals. The newly identified crystal symmetry of γ-GeSe warrants further studies on various physical properties of γ-GeSe.

Metal Chalcogenide Electrocatalysts for Hydrogen Peroxide Electrosynthesis and the Electro-Fenton Process Hongyuan Sheng[1,2], R. Dominic Ross[1], J. R. Schmidt[1] and Song Jin[1]; [1]University of Wisconsin-Madison, United States; [2]University of California, Los Angeles, United States

Hydrogen peroxide (H_2O_2) is a powerful oxidant and disinfectant with many applications, but its chemical production poses environmental and safety concerns. Decentralized electrosynthesis of H_2O_2 via the selective two-electron oxygen reduction reaction ($2e^-$ ORR) is attractive, which demands high-performance and cost-effective electrocatalysts that are active, selective, and stable in acidic and neutral solutions where H_2O_2 is stable. Metal chalcogenides are an emerging class of $2e^-$ ORR catalysts with diverse and tunable structural motifs for optimizing H_2O_2 electrosynthesis, yet they remain underexplored with poorly understood structure-property relationships. Here, we present our recent computational design and experimental developments of metal chalcogenide-based acidic and neutral $2e^-$ ORR catalysts [1-4], and the resultant new mechanistic understanding and rational catalyst design rules for guiding future catalyst discoveries. The many fundamental and practical factors at the reaction, catalyst, electrode, and device level that impact H_2O_2 electrosynthesis performance are systematically discussed. Metal chalcogenide-based acidic $2e^-$ ORR catalysts can also enable efficient electro-Fenton process for environmental remediation [2,3] and biomass valorization [4].

Morphological Control of 2D Hybrid Organic–Inorganic Semiconductor AgSePh Watcharaphol Paritmongkol[1,1], Woo Seok Lee[1,1], Wenbi Shcherbakov-Wu[1,1], Seung Kyun Ha[1], Tomoaki Sakurada[1], Soong Ju Oh[2] and William Tisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]Korea University, Korea (the Republic of)

Silver phenylselenolate (AgSePh) is a hybrid organic–inorganic two-dimensional (2D) semiconductor exhibiting narrow blue emission, in-plane

anisotropy, and large exciton binding energy. Here, we show that the addition of carefully chosen solvent vapors during the chemical transformation of metallic silver to AgSePh allows for control over the size and orientation of AgSePh crystals. By testing 28 solvent vapors (with different polarities, boiling points, and functional groups), we controlled the resulting crystal size from <200 nm up to a few μm. Furthermore, choice of solvent vapor can substantially improve the orientational homogeneity of 2D crystals with respect to the substrate. In particular, solvents known to form complexes with silver ions, such as dimethyl sulfoxide (DMSO), led to the largest lateral crystal dimensions and parallel crystal orientation. We perform systematic optical and electrical characterizations on DMSO vapor-grown AgSePh films demonstrating improved crystalline quality, lower defect densities, higher photoconductivity, lower dark conductivity, suppression of ionic migration, and reduced midgap photoluminescence at low temperature. Overall, this work provides a strategy for realizing AgSePh films with improved optical properties and reveals the roles of solvent vapors on the chemical transformation of metallic silver.

Photoresponse Effect and P-Type Doping of WS_2 Monolayers Through *In Situ* Niobium Incorporation Neileth J. Stand Figueroa, André do Nascimento Barbosa, Cesar A. Diaz Mendoza and Fernando Lazaro Freire Junior; Pontifícia Universidade Católica do Rio de Janeiro, Brazil

Two-dimensional (2D) transition-metal dichalcogenides (TMDs) have been widely studied due to their physical and chemical properties. WS_2 monolayers are atomically thin sheets of isolated sulfur-tungsten-sulfur sandwich arranged in a hexagonal honeycomb-like structure. When imagined from a top-view perspective, this arrangement and bonding make each atomically thin sheet interact very weakly with either the substrate or any adjacent material layer through van der Waals forces. One of the most remarking properties of some TMDs, such as the WS_2, is the indirect-to-direct bandgap transition when a single atomically thin layer of WS_2 is isolated from the bulk structure. Its bandgap is modified from an indirect bandgap of circa 1.4 eV to a wider direct bandgap of 1.9 eV, with a superior quantum yield compared to MoS_2 monolayers. However, ordinary chemical vapour deposition synthesis yields n-doped WS_2 monolayers, and a roadmap that allows controlling the substitutional doping is of fundamental importance to widen the possibilities of applications in electronics and optoelectronics. In this study, *in situ* Nb doping of WS_2 monolayers was performed through the chemical vapour deposition (CVD) method controlling the Nb and W precursor mass ratios. X-ray photoelectron spectroscopy (XPS) measurements were performed to demonstrate substitutional doping of monolayer WS_2 with Nb. The main effects of Nb incorporation in the lattice were the enhanced luminescence of the doped samples, which was directly related to the Nb_2O_5:WO_3 ratio. Although Raman data using the blue line did not indicate any changes, an overall redshift of the photoemission peak of ~ 30 meV, together with the redshift of 300meV obtained by XPS, suggest that the WS_2 was doped p-type.

Synthesis and Characterization of Germanium Telluride Nanowires Alam Saj[1], Shaikha Alketbi[1], Sumayya M. Ansari[1], Inas Taha[1], Dalaver H. Anjum[2], Baker Mohammad[2] and Haila M. Aldosari[1]; [1]United Arab Emirates University, United Arab Emirates; [2]Khalifa University of Science and Technology, United Arab Emirates

Random access memories (RAMs) made from phase change materials (PCMs) are a promising alternative for the flash memory technology, currently dominating the memory market due to its many appealing traits such as non-volatility, fast read/write performance, excellent scalability, and compatibility with complementary metal–oxide–semiconductor (CMOS) architectures. In fact, the scalability of PCMs is driving this class of materials to be the next successor in the memory industry in the near future. Germanium telluride (GeTe) material is one of the most viable PCMs in this context. In this work, the phase change material GeTe nanowires were fabricated using the vapor–liquid–solid (VLS) growth method. Gold (Au) nanoclusters deposited by a novel approach that has not been used before were used as the metal catalyst to grow GeTe nanowires, which yielded the synthesis of the smallest < 15 nm GeTe nanowires reported to date.
First, size-controlled Au nanoclusters were synthesized using inert gas condensation and dc magnetron sputtering. The impact of magnetron discharge power (*P*), inert gas flow rate (*f*), and aggregation length (*L*) on the diameter and yield of Au nanoclusters was thoroughly investigated. To generate small < 5 nm Au nanoclusters, low *P*, small *L*, and large *f* were needed, and vice versa to produce larger nanoclusters. Optimization of source parameters produced monodispersed nanoclusters of an average size range of 1.7 ± 0.2 nm to 9.1 ± 0.1 nm. Results indicated that Au embryos grew into large nanoclusters via a two-body collision mechanism.
Afterward, the bottom-up synthesis of size-controlled GeTe nanowires growth via Au-catalyzed VLS technique was done by controlling various parameters, namely, growth pressure, inert gas flow rate, growth time, growth temperature, and type of substrate used. GeTe nanowires with an average diameter of ~ 13 nm were produced, the smallest reported to date.
Various characterization techniques were employed to characterize the GeTe nanowires and Au nanoclusters, such as transmission electron microscopy (TEM), scanning electron microscopy (SEM), electron energy loss spectroscopy (EELS), grazing-incidence X-ray diffraction (GIXRD), etc.

Molecular Design of Low Dimensional Silver Organoselenolate Semiconductors Tomoaki Sakurada[1,2] and William Tisdale[1]; [1]Massachusetts Institute of Technology, United States; [2]AGC Inc, Japan

Metal organochalcogenolates (MOCs) have gained a renewed interest as a novel class of hybrid organic-inorganic semiconductors. In contrast to halide perovskites and transition metal chalcogenides, MOCs have strong covalent bonding between organic and inorganic components, offering a unique platform for tuning excitonic properties. Recently, silver phenylselenolate (AgSePh) has attracted attention because of its multiple exciting properties such as narrow blue luminescence, in-plane anisotropy, large exciton binding energy, earth abundant elemental composition, and a scalable synthesis. In this presentation, we will show a new family of AgSePh derivatives with introduced organic functional groups. With modified organic ligands, morphology transformation from 2D sheet to 1D chain structure was induced. We will discuss the effect of organic functionalization on the optical and electronic properties of AgSePh, and show the application of this knowledge toward designing new MOC compounds with improved capabilities

9:15 AM EQ04.08.02
Low-Temperature and Solvent-Free Synthesis and Thin-Film Deposition of Semiconducting Silver Chalcohalide Antiperovskites Paz Sebastia-Luna[1], Nathan Rodkey[1], Joaquin Calbo[1], Adeem S. Mirza[2], Sigurd Mertens[3], Koen Vandewal[3], Enrique Orti[1], Monica Morales-Masis[2], Francisco Palazon[1] and Henk J. Bolink[1]; [1]University of Valencia, Spain; [2]University of Twente, Netherlands; [3]Universiteit Hasselt, Belgium

Lead halide perovskites have shown outstanding properties when applied in optoelectronic devices, such as solar cells and light-emitting diodes. Nevertheless, the presence of highly toxic lead together with their low environmental stability might become a bottleneck for their commercialization. Herein we present the synthesis, thin-film deposition, and characterization of silver chalcohalide antiperovskites, as potential alternative optoelectronic materials. Their general formula is Ag_3SX, where X represents a halide. These compounds have potential applications in IR photodiodes and solar cells. We report the fast and solvent-free mechanochemical synthesis of the Br- and I-based species. A proof-of-concept solar cell device is presented via the pulsed-laser deposition of the Ag_3SI powders, achieving a low yet promising power conversion efficiency of 0.07 %.

9:30 AM EQ04.08.03
Solution-Processing of $BaMS_3$ (M = Ti, Zr, Hf) Materials—A Low-Temperature Route to Chalcogenide Perovskites Jonathan Turnley, Kiruba Catherine Vincent, Apurva A. Pradhan, Shubhanshu Agarwal, Madeleine C. Uible, Suzanne C. Bart and Rakesh Agrawal; Purdue University, United States

While CdTe and $Cu(In,Ga)(S,Se)_2$ have already proven to be industrially relevant semiconductors, there is broad interest in finding the next generation of metal chalcogenides that are composed of earth-abundant elements, have high intrinsic stability, and have excellent optoelectronic properties. It has been proposed that the sulfide perovskites may satisfy these criteria. $BaZrS_3$ is the most studied option from this family of materials. Like the halide perovskites, $BaZrS_3$ has a direct bandgap in the range of 1.7eV to 1.8eV, a high absorption coefficient, and is computationally predicted to be defect tolerant. But unlike the halide perovskites, $BaZrS_3$ and is known to be highly stable.
To date, the biggest challenges for the chalcogenide perovskites are related to their synthesis. For $BaZrS_3$, many synthesis methods rely on solid-state reactions or the sulfurization of $BaZrO_3$. In both cases, high temperatures exceeding 800°C are often required. This creates challenges for producing semiconductor devices as most common substrates and contact layers are incompatible with these temperatures. Additionally, these extreme synthesis methods may limit research into related chalcogenide perovskites. For example, there are few reports on the synthesis of $BaHfS_3$, all requiring temperatures of at least 1100°C.
Because of the challenges in chalcogenide perovskite synthesis, this work seeks to develop a low-temperature and solution-based deposition approach for $BaMS_3$ (M = Ti, Zr, Hf) materials. To achieve this, we began with the targeted synthesis of a soluble barium thiolate that can be coated and thermally decomposed into BaS films. The addition of MH_2 nanopowders creates a precursor slurry that can be deposited from the solution-phase. Subsequent sulfurization allows for the conversion to the ternary $BaMS_3$ material at temperatures below 600°C. Additionally, we investigate alternative delivery methods of the metal hydride precursor in pursuit of device-quality thin films.
In conclusion, this works seeks to take steps towards chalcogenide perovskite semiconductor devices by lowering the synthesis temperature while utilizing a simple solution-based approach.

10:15 AM EQ04.09.01
Novel Applications of ZnTe as an Ovonic Threshold Switching and as a Phase Change Material Oleg Maksimov[1], Katherine Hansen[1], Harish Bhandari[1], Guy Wicker[2], Habeeb Mousa[3], Saidjafarzoda Ilhom[3] and Helena Silva[3]; [1]Radiation Monitoring Devices, United States; [2]Ovshinsky Innovation, United States; [3]University of Connecticut, United States

The advent of 3D Xpoint non-volatile memory technology has stimulated investigation of novel materials that exhibit efficient and reliable threshold switching behavior. The 3D Xpoint architecture requires each memory element, typically made from phase change material, to be connected in series with a selector element, typically using an ovonic threshold switching (OTS) device [1]. Complex quaternary chalcogenide alloys, such as GeAsSeTe, are usually utilized as selector elements. Ternary chalcogenides, such as $Ge_2Sb_2Te_5$, are used in memory elements. Deposition of these alloys with the exact composition is a non-trivial process. Besides a conformal thin film growth technique both for memory and selector chalcogenides may be beneficial for vertical integration of non-volatile memory.

It was recently demonstrated that polycrystalline thin films of binary chalcogenide ZnTe exhibit switching behavior and have a strong potential for the application in the memory technology in threshold switching devices [2, 3]. Motivated by this report, we conducted study of ZnTe thin films deposited via Atomic Layer Deposition. Upon characterization, we observed that, in addition to the OTS behavior, these exhibit phase change switching with high-speed phase transitions. Such dual behavior of ZnTe opens the opportunity to fabricate both memory elements and selector elements from the same material greatly simplifying the fabrication process.

Optimizing Binary to Quaternary Chalcogenides for Ovonic Threshold Switching Selectors in Neuromorphic Applications Jong-Souk Yeo, Chaebin Park, Sang-Heon Park, Deok-Jin Jeon, Young-Min Kim and Su-Bong Lee; Yonsei University, Korea (the Republic of)

Brain-inspired neuromorphic computing has recently emerged as the next-generation information technology that facilitates the innovation from the conventional von-Neumann computing to neuromorphic in-memory computing with remarkable efficiency, operating speed as well as memory density. Realization of neuromorphic computing is possible within the 3D cross-point (X-Point) memory architecture that consists of resistive-switching memory cells to demonstrate synaptic behavior within highly dense structure. However, the adoption of an additional selector cell to each memory cell, thus having

1-selector-1-resistor (1S1R) array, is necessary to ensure reliable operation of the 3D X-Point memory avoiding the issue of sneak current that hinders stable reading and programming of data. For a successful 1S1R integration, the selector is required to meet scalability, short delay time, high on/off ratio, thermal stability, and endurance.
Ovonic threshold switching (OTS) selector based on amorphous chalcogenide film, among many candidates, is considered to have the potential in achieving the aforementioned requirements as demonstrated by S. R. Ovshinsky in 1968. However, optimization of the OTS selector is a difficult task due to the lack of understanding in the switching mechanism behind the OTS phenomenon. In our work, chalcogenide-based OTS selectors ranging from binary to quaternary material systems have been investigated to establish the knowledge on the elemental role to optimize selector performance. Beginning with the binary material system of Si-Te and Ge-Te, the role of Si on thermal stability and of Ge on switching performance are established. Upon proceeding to ternary material systems of Si-Ge-Te as well as N-doped Si-Te and Ge-Te, enhanced features of OTS selectors are achieved that satisfies the selector requirements in electrical performance as well as thermal stability and cyclic endurance simultaneously. The integration of all the elements in the quaternary N-Si-Ge-Te system exhibited the most outstanding characteristics that excel in every device parameter. The investigation of chalcogenides from binary to quaternary material systems enhances our understanding on the elemental roles, thus enabling to optimize the overall performance of OTS selectors for neuromorphic applications.
This research was supported by the Ministry of Trade, Industry & Energy (MOITIE)/Korean Evaluation Institute Industrial Technology (KEIT) (Project No. 10080625) and Korea Semiconductor Research Consortium (KSRC) program for the development of the future semiconductor devices, and by Samsung Electronics Co. Ltd. (Project number IO2102021-08356-01).

10:45 AM *EQ04.09.03
Antimony Trisulfide Programmable Photonics—From Local Structural Transitions to Programmable Photonics Robert Simpson[1], Ting Yu Teo[1], Alyssa Poh[1], Li Lu[1], Yunzheng Wang[1], Jing Ning[1], Parikshit Moitra[2] and Joel Yang[1]; [1]Singapore University of Technology and Design, Singapore; [2]A*STAR Institute of Materials Research and Engineering, Singapore

Chalcogenides that exhibit substantial property contrast between different structural phases are of interest for data storage and programmable photonics applications. The most successful data storage materials, such as those that lie along the GeTe-Sb2Te3 pseudo-binary compositional tie-line, have a small bandgap and concomitantly, a large optical absorption in the near infrared and visible wavelengths. New phase change materials with a wider bandgap need to be developed for the visible and N-IR photonics applications.
Antimony trisulfide (Sb2S3) is an Earth abundant material that is transparent to visible and near infrared light (N-IR). Switching the material between amorphous and crystalline states causes radical property changes that deem it useful for programming the response of visible and N-IR photonics devices. We have demonstrated how Sb2S3 can be used to program high resolution micro-displays, dielectric metasurfaces, hyperbolic metamaterials, waveguides, and all-optical neural networks. This presentation will discuss these demonstrations and the underlying structural transitions that are responsible for the property contrast in Sb2S3.

11:15 AM *EQ04.09.04
Low-Power Memory Devices Based on Superlattice Chalcogenides Asir Intisar Khan, Xiangjin Wu, Alwin Daus, Sumaiya Wahid and Eric Pop; Stanford University, United States

Phase change memory (PCM) technology could play an important role in future high-density computing systems, including neuromorphic computing. However, PCM based on traditional chalcogenides like $Ge_2Sb_2Te_5$ (GST) requires relatively large power consumption and suffers from resistance drift [1]. This talk will address our recent efforts to tackle these challenges using various types of superlattice PCM (SL-PCM) materials, made of alternating ultrathin (~nm) layered chalcogenides. From a device perspective, we have demonstrated memory with superlattices based both on $GeTe/Sb_2Te_3$ [2] and GST/Sb_2Te_3 [3,4], showing up to ~10x lower reset current density and 10x lower resistance drift than control GST PCM with the same mushroom cell structure. We uncovered that the quality of the interfaces within the SL plays an important role in the memory behavior [3,4]; in other words, more good-quality interfaces means better thermal and structural confinement, but interfacial intermixing degrades the drift coefficient. Given that thermal confinement plays such an important role in low-power behavior, we also demonstrated SL-PCM with the lowest switching current density to date (~0.1 MA/cm^2) on flexible polyimide substrates, which have ultralow thermal conductivity [5]. Importantly, all our SL-PCM devices show multiple resistance states and scalability with the bottom electrode diameter, offering further promise in ultra-scaled devices.
From a materials perspective, extensive transmission electron microscopy (TEM) revealed van der Waals (vdW)-like interfaces in the superlattices, which facilitate the electro-thermal and structural confinement [2-4]. We found lower cross-plane thermal conductivity and higher electrical anisotropy of the polycrystalline SL stack compared with polycrystalline GST, due to the internal interfaces within the SL [6]. We also explored lateral transport in chalcogenide films and multilayers, measuring good Hall mobilities for $GeTe/Sb_2Te_3$ superlattices (~18 $cm^2V^{-1}s^{-1}$), 2–3x higher than the other films [7]. These results provide key insights towards new superlattice material design and optimization, and could pave the way to high-density storage and neuromorphic applications using superlattice PCM materials.

11:45 AM EQ04.09.05
Chalcogenide-Superlattice Interfaces and Intermixing Modulating Phase-Change Memory Performance Asir Intisar Khan[1], Xiangjin Wu[1], Christopher Perez[1], Byoungjun Won[2], Il-Kwon Oh[2], Mehdi Asheghi[1], Kenneth E. Goodson[1], H.S. Philip Wong[1] and Eric Pop[1,1]; [1]Stanford University, United States; [2]Ajou University, Korea (the Republic of)

Phase change memory (PCM) based on chalcogenide-superlattices has shown promise with the low-power operation and low resistance drift required for neuromorphic computing applications [1-3]. However, the effects of the *internal* chalcogenide-superlattice interfaces (interface density and degree of intermixing) on superlattice PCM devices are not well understood to date, especially when these interfaces are very dense, just a few Angstroms apart.

Here, we uncover a key correlation between the internal superlattice (SL) interfaces and superlattice PCM (SL-PCM) device performance using nanometer-thin layers of $Ge_2Sb_2Te_5$ and Sb_2Te_3. We uncover that both switching current density and resistance drift coefficient decrease as the SL period thickness is reduced (i.e., higher interface density) – however, interface intermixing within the SL increases both. The signatures of distinct vs. intermixed interfaces also show up in scanning transmission electron microscopy (STEM), X-ray diffraction (XRD), and thermal conductivity measurements of our SL films.

To understand the role of SL interfaces, we sputtered alternating layers of phase-change chalcogenides Sb_2Te_3 (ST) and $Ge_2Sb_2Te_5$ (GST) with varying period thicknesses, while keeping the total stack thickness fixed (~65 nm). High-resolution STEM images of a 2/1.8 nm/nm ST/GST SL, reveal atomically sharp interfaces separated by van der Waals (vdW) gaps, representing a good quality SL. In contrast, an ST/GST SL with the sub-nm thin period (0.5/0.45 nm/nm) shows stronger intermixing within layers, more stacking faults, and rougher interfaces. We note that for this SL, the individual ST/GST layers are

smaller than the unit block thicknesses of ST (1 nm) and GST (1.8 nm); therefore, a higher intermixing is expected. XRD spectra for the as-deposited SLs confirm their polycrystallinity, while non-out-of-plane peaks appear in the more intermixed SL spectra.

The measured thermal conductivity of our SLs decreases with the increasing number of interfaces i.e., with decreasing period thicknesses from 16/14.4 nm/nm (4 interfaces) to 2/1.8 nm/nm (32 interfaces). This is attributed to the vdW-like gaps impeding cross-plane thermal transport [4]. However, the thermal conductivity increases for more intermixed SL films due to loss of vdW-like gaps within the SL, also evident from our STEM.

Electrical measurement of our fabricated mushroom-cell ST/GST SL-PCM devices (110 nm bottom electrode diameter) reveals that the reset current (I_{reset}) decreases with an increasing number of SL interfaces, due to improved heat confinement. Low and high resistance states of the devices also increase with more interfaces pointing to higher cross-plane resistivity due to more interfaces. However, a larger I_{reset} in the more intermixed SL-PCM (0.5/0.45 nm/nm) highlights the detrimental effect of intermixing within SL layers. Resistance drift coefficient (v) also shows a clear trend with the number of interfaces with v decreasing from GST (no internal interfaces) to SL with 4 interfaces to ST/GST SL with 32 interfaces. On the other hand, deliberate intermixing within SL (0.5/0.45 nm/nm) increases v. Utilizing such correlation between SL-PCM key performance indicators and SL interface property, we simultaneously achieve low switching current density (3-4 MA/cm^2) and low resistance drift coefficient (0.002) in ST/GST SL-PCM, approaching the best corner on the PCM technology.

In summary, we demonstrated that the key material and thermal properties of SLs are controlled by the number of interfaces and their degree of intermixing, which ultimately plays a crucial role in controlling SL-PCM device performance. These results also provide key insights towards new superlattice material design and optimization for SL-PCM technology.

SESSION EQ04.10: Chalcogenide Perovskites
Session Chairs: Rohan Mishra and Robert Simpson
Wednesday Afternoon, November 30, 2022
Sheraton, 2nd Floor, Constitution A

1:30 PM *EQ04.10.01
Growth and Characterizations of Chalcogenide Perovskite Thin Films for Optoelectronics Hao Zeng; SUNY-Buffalo, United States

Recently chalcogenide perovskites have emerged as a new family of semiconductors. With their strong ionicity and defect tolerance, strong light-matter interactions, direct band gap in the visible, high stability, and low toxicity, they have shown promise for opto-electronic applications. However, synthesis of high-quality thin films of such materials remains challenging, partially due to the presence of refractory metal elements such as Zr and Hf. In this talk, I will give a brief overview of the progress made in the past two years in realizing chalcogenide perovskite thin films. I will then discuss our efforts to synthesize $BaZrS_3$ and other perovskite thin films using pulsed laser deposition and magnetron sputtering, their charge transport and optical properties, and preliminary results on device fabrication and characterizations. Finally, I will layout challenges that need to be addressed to make these materials technologically relevant.

2:00 PM EQ04.10.02
Low-Temperature, Solution-Based Synthesis of Luminescent Chalcogenide Perovskite $BaZrS_3$ Nanoparticles and Their Phase Stability Ruiquan Yang, Alexander Jess, Calvin Fai and Charles J. Hages; University of Florida, United States

Chalcogenide perovskites are an emerging earth-abundant, non-toxic, and robust semiconductor family with the potential to compete with hybrid perovskites as a high-quality photovoltaic absorber. Promising optoelectronic properties have been identified from theory for a number of chalcogenide perovskite compounds. Additinally, increased covalent bonding in the lattice relative to halide perovskites results in enhanced structural stability. However, the cost of structural stability for chalcogenide perovskites can be associated with a high crystallization energy barrier for these materials. As a result, a low-temperature, solution-based synthesis route ideal for realistic semiconductor fabrication has eluded researchers in this area for c. 60 years. In this work, we present the first bottom-up colloidal synthesis of chalcogenide perovskite nanoparticles, demonstrated here for $BaZrS_3$ which is known to crystallize in the desired distorted perovskite crystal structure. The nanoparticles were synthesized in organic solvent at 330 °C using single-source, reactive metal-dithiocarbamate precursors with a low thermal decomposition temperature, confirmed with XRD, Raman spectroscopy, and HRTEM. The nanoparticles (10-20 nm) are found to be comprised of smaller (3-5 nm) crystalline domains. Promising optoelectronic properties for the nanoparticles are measured, with photoluminescence decay times as high as 4.7 ns.

In addition to the described synthesis, we present a compelling phase stability analysis of sulfide-, selenide-, and telluride-based chalcogenide perovskites based on ionic radii and electronegativity arguments -- related to their increased covalent bonding. A modified tolerance factor for chalcogenide perovskites is proposed, accounting for the expected variations in the bond lengths of constituent atoms in the ABX_3 (X = S, Se, Te) structure. Resulting structural predictions are in good agreement with experimentally reported ABS_3 and $ABSe_3$ phases. This analysis is a useful tool to identify undesirable phases as well as motivate further experimental research into several unrealized perovskite materials.

2:15 PM EQ04.10.03
Stabilizing $BaZr(S,Se)_3$ Chalcogenide Perovskite Alloys by Molecular Beam Epitaxy Ida Sadeghi, Dennis Kim, Jack Van Sambeek, James LeBeau and Rafael Jaramillo; Massachusetts Institute of Technology, United States

Chemical intuition, first-principles calculations, and recent experimental results suggest that chalcogenide perovskites are an outstanding class of semiconductors. Chalcogenide perovskites feature the large dielectric response familiar in oxide perovskites, but also have band gap in the VIS-IR and

strong light absorption [1]. Preliminary results suggest that chalcogenide perovskites feature excellent excited-state charge transport properties familiar in halide perovskites, while also being thermally-stable and comprised of abundant and non-toxic elements. Nearly all experimental results on chalcogenide perovskites to-date were obtained on powder samples and microscopic single crystals, and thin film synthesis is in its infancy. The history of complex oxide science teaches us that advances in fundamental understanding and development for applications will hinge on the availability of high-quality, controllable thin film synthesis, and that the best film quality and control is achieved by molecular beam epitaxy (MBE).

We recently reported the first epitaxial synthesis of chalcogenide perovskite thin films by MBE: $BaZrS_3$ films on (001)-oriented $LaAlO_3$ substrates [2]. The films are atomically-smooth, and scanning transmission electron microscopy (STEM) data show an atomically-abrupt substrate/film interface. The sulfide perovskite film has a pseudo-cubic lattice constant more than 30% larger than the oxide perovskite substrate. This strain is fully accommodated by a remarkable, self-assembled interface buffer layer that enables epitaxial growth of strain-free films, and that the propensity for buffered epitaxy can be controlled by the H_2S gas flow during growth.

We further demonstrate control of the band gap by alloying $BaZrS_3$ with Se. We have made the first epitaxial $BaZrS_{(3-y)}Se_y$ films with varying Se composition, up to and including a pure selenide perovskite $BaZrSe_3$. $BaZrSe_3$ is theoretically predicted to be stable in a non-perovskite, needle-like phase with very low band gap. We instead stabilized perovskite $BaZrSe_3$ film on a $BaZrS_3$ buffer layer grown on $LaAlO_3$ substrate using MBE. We support these findings with experiments including high-resolution STEM, high-resolution X-ray diffraction (HRXRD), and photocurrent spectroscopy (PCS). The films are smooth with an Rms roughness ranging from 0.65 to 3 nm. The out-of-plane HRXRD measurement confirmed the presence of the perovskite $BaZrS_3$ buffer layer and the perovskite $BaZrS_{(3-y)}Se_y$ in the films. The in-plane XRD measurements and reciprocal space maps showed that the $BaZrS_{(3-y)}Se_y$ layer grows strained, however, $BaZrSe_3$ grows relaxed on the $BaZrS_3$ buffer layer. The PCS measurements on the $BaZrS_{(3-y)}Se_y$ films showed bandgap tunability, with bandgap decreasing from 1.57eV (y=1) to 1.50eV (y=1.3) to 1.49eV (y=2) with increasing Se content.

This work sets the stage for developing chalcogenide perovskites as a family of semiconductor alloys with properties that can be tuned with strain and composition in high-quality epitaxial thin films, as has been long-established for other semiconductor materials.

Skinny Polar Vortices in Quasi-1D Chalcogenides Rohan Mishra[1], Gwan Yeong Jung[1], Guodong Ren[1], Boyang Zhao[2], Huandong Chen[2], Di Xiao[3] and Jayakanth Ravichandran[2]; [1]Washington University in St. Louis, United States; [2]University of Southern California, United States; [3]University of Washington, United States

Large polar vortices that span several 10's of nanometers in dimensions have been reported in several polar systems such as ferroelectric superlattices and nanowires. In this talk, we will report on the possible formation of atomically thin polar vortex-antivortex pairs in a quasi-1D chalcogenide, BaTiS3. We will discuss results from first-principles electronic structure calculations and phenomenological modeling that show the various competing structural distortions that can stabilize atomically thin vortices. We will discuss the evolution of such vortices with temperature, strain and electric field. We will end with experimental findings that provide indirect evidence of the presence of skinny vortex-antivortex pairs in BaTiS3 crystals.

4:00 PM EQ04.10.05
Spectroscopic Evidence for the Formation of Polarons in BaZrS3 Omer Yaffe; Weizmann Institute, United States

Chalcogenide perovskites combine relatively low band gaps (1.4-2 eV, typical for compound semiconductors) with very high dielectric constants (50-100, typical for insulating perovskite oxides).
We hypothesize that the high polarizability of chalcogenide perovskites stems from large-amplitude thermal fluctuations that also lead to the formation of polarons from photo-excited charge carriers.
In this talk, I will present a test of this hypothesis through a spectroscopic study of single crystals of the prototypical chalcogenide perovskite $BaZrS_3$. Using temperature-dependent Raman scattering, we establish that the structural dynamics of the crystal are similar to those of insulating oxide perovskites $SrTiO_3$ and $CaTiO_3$. Using resonant Raman scattering, we show that photo-excited carriers induce significant symmetry breaking in the crystal lattice - this is experimental evidence for polaron formation. Finally, from temperature-dependent photoluminescence, we show the strong effect of phonons on excited-state recombination pathways.

4:15 PM EQ04.10.06
Perovskite Chalcogenide Thin Films for Photovoltaic Devices Kevin Ye, Jack Van Sambeek, Ida Sadeghi and Rafael Jaramillo; Massachusetts Institute of Technology, United States

Chalcogenides perovskites are candidate materials for solar energy conversion technologies due to their promising optoelectronic properties and chemical stability [1–3]. The prototype chalcogenide perovskite $BaZrS_3$ is a semiconductor with direct band gap of E_g = 1.9 eV, and Shockley-Read-Hall recombination lifetime exceeding 50 ns demonstrated in single crystals; we have also recently demonstrated that E_g can be reduced continuously to 1.4 eV through alloying with Se.
Here we present results of making and testing $BaZrS_3$ thin-film solar cells in a substrate architecture, as long-established for CIGS technologies. We deposit $BaZrS_3$ thin films on Mo metal rear contact layers by reactive physical vapor deposition using H_2S. The deposition is similar to our demonstrated synthesis by molecular beam epitaxy (MBE) [4], but $BaZrS_3$ can also be grown as polycrystalline, non-epitaxial, single-phase thin films. We deposit *n*-type CdS contacts by chemical bath deposition, followed by sputtering ZnO and ITO layers in typical dot-cell geometry. We report results of completed solar cell device tests (I-V and EQE), and quantitative loss analysis based on measured optical and electrical properties of isolated thin-films and device semifabricates. We conclude with an outlook for improving device performance and comments on future manufacturability of chalcogenide perovskite solar cells.

Analysis of Potential Induced Degradation Mechanism in CIGS Thin-Film Solar Cells Solhee Lee, Soohyun Bae, Se Jin Park, Yoonmook Kang, Donghwan Kim and Hae-Seok Lee; Korea University, Korea (the Republic of)

Looking at the global photovoltaic (PV) market, the world's PV installation amounted to over 100 GW in 2018, and the increasing trend continued, the installation amount of 150 GW is predicted in 2020 without the influence of COVID-19. In order to increase the economic feasibility of the energy generation source, high energy conversion efficiency, low module degradation rate, and long life must be satisfied. Therefore, in order to ensure long-term reliability of PV module for stable power supply, it is essential to understand and prevent degradation factors. Potential induced degradation (PID) is one of degradation phenomena that has been a problem in the last few years, and it is reported that PV module power is degraded in a short time. The process of PID generation based on the reported literatures is as follows. In the situation where the PV modules are connected in series due to the voltage generation above 600 V corresponding to the system voltage, the frames of modules are also grounded for safety and supporting reasons. And then, a relative potential difference between the grounded electrodes and solar cells inside the modules occurs, and the potential difference increases toward the end of the serial connection. The phenomenon that the leakage current flows in solar cells having a negative potential difference compared to the frame, and eventually the power of the modules decreases, is called PID.
In the case of crystalline silicon solar cells, the mechanism of PID has been identified in both p-type and n-type cases. In CIGS thin film solar cells, since the absorption layer is p-type and Na is injected to some extent to improve the efficiency during solar cell fabrication, it can be expected that Na, like silicon solar cells, can affect the PID mechanism of CIGS solar cells. Indeed, looking at the previous research data on the PID mechanism, the degradation was greater in the case of the sample with high Na concentration and low resistivity. Research to clarify the PID mechanism of CIGS solar cells has been actively conducted until recently. By dark current-voltage (I-V) measurement before and after PID, soda-lime glass (SLG) substrate samples increased diode saturation current and decreased shunt resistance than borosilicate glass (BSG) samples. It can be interpreted by Na effect. In addition, due to secondary ion mass spectrometry (SIMS) and C-V measurement, it was analyzed that the cations accumulate at the junction, thereby decreasing the charge carrier concentration and changing open-circuit voltage (V_{OC}) and efficiency. It is represented through TOF-SIMS 3D tomography in which Na was segregated into a grain boundary after PID. However, the cause of PID in CIGS solar cells has not been clearly defined, and the explanation for the recovery is insufficient. At the cell level, for example in the case of CIGS, accurate understanding of the monolithic series connection structure and PID is an important requirement to resolve degradation fundamentally.
In this study, the PID phenomenon in CIGS module was implemented at cell level to identify the PID mechanism. In particular, the effect of the cover glass on the front of the module structure was excluded, and the research was conducted focusing on the PID phenomenon caused by the glass used as the substrate. First, after devising three voltage application structures for the CIGS cell, voltage was applied to each structure for a certain amount of time, and the voltage application structure was determined while observing changes in the solar cell characteristics. Second, after conducting PID and recovery experiments on the defined structure, PID and recovery tendency were analyzed through light I-V, dark I-V, EQE, and C-V measurements. Changes in the characteristics of the CIGS solar cell by PID were explained as the degradation due to the voltage by comparing with the characteristics in another sample where only temperature was applied.

EQ04.11.02
Investigating the Impact of Intrinsic Defects on Cu_2SiSe_3 for PV Applications Adair Nicolson[1], Seán R. Kavanagh[1,2], Graeme Watson[3], Robert Palgrave[1] and David O. Scanlon[1]; [1]University College London, United Kingdom; [2]Imperial College London, United Kingdom; [3]Trinity College Dublin, The University of Dublin, Ireland

Metal chalcogenides have seen renewed interest in recent years with the hope that they will deliver stable, non-toxic thin-film solar cells with efficiencies that can match silicon and halide perovskite-based devices.[1] To this end we have begun an initial investigation into the electronic and optical properties of Cu_2SiSe_3, and it has shown initial promise as a photovoltaic absorber with a calculated band gap of ~1.52 eV and a maximum efficiency of 30% for a 1.5 mm film.

However, a promising band gap and absorption coefficient is not sufficient to determine if a new material will achieve high efficiencies in devices. Non-radiative recombination processes, driven by defect states in the band gap, can drastically reduce carrier lifetimes, and thus performance.[2] Therefore, in this project we investigate all potential intrinsic defects in Cu2SiSe3 to determine how they may affect carrier lifetimes and thus device performance.[3]

EQ04.11.03
Material Design of Monolithic Water-Splitting Device Using Chalcogenide Semiconductors Kana Ueda, Daiki Kanamori and Mutsumi Sugiyama; Tokyo University of Science, Japan

Chalcogenide semiconductors such as $Cu(In,Ga)Se_2$ (CIGS) and Cu_2SnS_3 (CTS) are used for manufacturing inexpensive thin-film solar cell materials. However, several reports suggested that these materials were inappropriate for photocatalysis owing to their inferior underwater crystal quality and mismatch of band-lineup. Moreover, a water-splitting device requires an external power supply for photoelectrochemical (PEC) performance.

In the future, power generation using hydrogen will be required for not only large-scale systems but also small ones. For example, a small amount of

hydrogen through ultra-small fuel cells is sufficient for driving IoT devices. Therefore, chalcogenide-used water-splitting is a candidate for several applications because chalcogenides have strong durability under vending, heat-cycle, or irradiation. However, the onset potential of photoelectrodes using CIGS or CTS is small due to the small bandgap of the materials. Water splitting with solar and photoelectrochemical cells has been reported to increase the onset potential. Therefore, a monolithic structure for interconnecting solar and PEC cells on the same substrate and fabricating them simultaneously would be appropriate. In this presentation, a new CIGS and CTS thin film based monolithic water-splitting device without external power supply will be proposed. We used chalcogenide materials for both solar cells and water-splitting PEC; hence, fabrication cost and processes of this device was reduced.

The monolithic water-splitting device consisted of a CIGS or CTS solar cell with ZnO:Al / ZnO / CdS / CIGS or CTS / Mo / SLG structure and a photoelectrode with CdS / CIGS or CTS / Mo / SLG structure. The PEC performance in an aqueous solution of 0.1 M NaOH (pH = 9.5) was measured. A Pt wire was used as the counter electrode. Using the CIGS monolithic water-splitting device, the representative onset potential increases to 0.9 V_{RHE}, and the photocurrent density of the device increases to 0.14 $mAcm^{-2}$ at 0 V_{RHE}. These results represent a preliminary step toward the potential application of a monolithic water-splitting device using CIGS and CTS.

EQ04.11.04
Band Gap Tunable Inkjet-Printed Buffer Layers for Cu(In,Ga)(S,Se)$_2$ Solar Cells Alice Debot and Phillip J. Dale; University of Luxembourg, Luxembourg

Buffer layers are essential in thin film solar cells to help form the pn junction and ensure good band alignment between the absorber and the window layers. Inkjet printing has recently gained interest as a deposition method of buffers because of its near 100% material utilization. Compared to a traditional chemical bath deposition (CBD), inkjet printing requires around 50 000 times less solvent and 6500 times less material for synthesising the same buffer layer surface area. Cleaner chemistry and lower waste is an important aspect in industrial production. Various buffer materials can be inkjet-printed and annealed to form layers that when completed into full devices achieve similar efficiencies to the commonly found CBD CdS. We recently deposited Zn(O,S) buffer layers (which is the material used in the current Cu(In,Ga)(S,Se)$_2$ (CIGS) world record) on CIGS attaining an efficiency higher than the reference CdS [1]. We also showed that In_2S_3 buffer layer can be inkjet printed on CIGS with similar efficiency to a CdS reference device [2] and now we can report here, a printable CdS buffer layer, giving 87% relative efficiency compared to the CBD reference.

CBD deposited buffer layers tend to exhibit band gaps close to their literature bulk values. Here, we show that inkjet printed materials annealed at different temperatures, can exhibit significantly higher values, up to 0.3, 0.7 and 0.9 eV above the bulk band gap for In_2S_3, CdS and Zn(O,S) materials. Previously, it has been shown for silicon that nanoparticles embedded in an amorphous matrix also show higher bandgaps than the bulk value, and this was shown to be a quantum confinement effect [3], irrespective of the crystalline to amorphous matter ratio [4].

To investigate if there is a quantum confinement effect for the inkjet-printed buffer layers the crystal coherence length, a proxy for grain size, was measured with grazing incidence x-ray diffraction (GIXRD) on buffer layers with different band gaps. The exciton Bohr radius of Zn(O,S), CdS and In_2S_3 are calculated to be 1.6, 2.6 and 4.8 nm respectively, based on effective masses values found in literature. Nanoparticles with a radius smaller than the mentioned sizes should then show an increased band gap compared to the bulk value. The Brus equation was used to evaluate the increase of the band gap due to quantum confinement. This approach is simplistic but is considered as a good first qualitative analysis. A variation in the grain radius of In_2S_3 from 3.8 to 3.1 nm increased the band gap by 0.3 eV as predicted using the Brus equation. A similar result was found for Zn(O,S). The grain size of CdS couldn't be extracted for band gaps approaching 3 eV because of a low signal to noise ratio in the diffractograms. This is expected since such a high band gap must result from a 1.5 nm grain radius which would result in a very broadened diffraction peak. Thicker samples could increase the signal to noise ratio, enabling the extraction of the grain size.

A buffer with a wide band gap is preferred to avoid parasitic absorption in the blue region of the solar spectrum thus increasing short circuit current. The ability to tune the band gap via quantum confinement might offer a new way to use relatively narrow band gap buffer layers, such as In_2S_3, and CdS, without them having a parasitic absorption. However, device performance may be impacted by band alignment issues, affecting the open circuit voltage. We will prepare devices where we vary the grain size of the buffer layers and investigate how this affects the solar cell performance.

EQ04.11.05
Effect of Zn-Doped Tin Monosulfide Thin Film Using Atomic Layer Deposition Soo Yeon Kang, Yeonsik Choi, Jangho Bae, Jungtae Kim and Hyeongtag Jeon; Hanyang University, Korea (the Republic of)

Tin monosulfide (SnS), a direct band gap semiconductor compound, has recently
received great attention due to its unique properties. In addition, SnS is a promising monochalcogenide two-dimensional materials, each layer consists of a van der Waals (vdW) bonding. Because of low cost, abundant in nature, and non-toxic substance, it is becoming a candidate for future multifunctional devices such as solar cells, optical sensors, batteries, biomedical science and transistors. Among them, it is mainly used in light conversion applications because of its good absorption properties. The most commonly used phase for photovoltaic devices is the orthorhombic α-SnS (herzenbergite), *p* type, which is characterized by a direct optical transition of 1.3~1.6 eV.

The addition of an impurity to the SnS compound has a unique effect on structural, optical, and electronic properties of SnS semiconductor. But there are very few reports on the zinc (Zn)-doped SnS thin films prepared by ALD. Atomic layer deposition (ALD) can be an ideal method for the high conformality with its self-limited reaction. In addition, ALD is a promising method to increase atomic scaling thickness controllability by adjusting the process cycle. With these advantages, we used atomic layer deposition super-cycle Zn-doping. SnS cycle and ZnS cycle are alternately used during a super-cycle process. The number of ZnS cycle varies according to the doping concentration of Zn. The total number of cycles SnS:ZnS is repeated until the desired film thickness is reached.
