Titanium carbide MXene being the most studied member of the 2D transition metal carbides/nitrides (MXene) family, has found applications in the field of energy storage and energy generation, due to its dynamic but tunable surface chemistry, good hydrophilicity and electrical conductivity. Conductive and clay like, in situ HF etched titanium carbide MXene can be used as supercapacitor electrodes and are prospective candidates in flexible electronics for commercial supercapacitor application. Commercial supercapacitors also require high energy storage capability, for which a high mass loading is necessary. Herein a high mass loading electrode with high areal capacitance has been fabricated using a simple brush coating of clay like titanium carbide MXene on carbon cloth. A controlled alkalization of titanium carbide using a weak base, ammonium hydroxide has been carried out in the synthesis of titanium carbide MXene. The in situ alkalization process reduces the time of synthesis and causes an inherent expansion of the interlayer spacing, making the diffusion of ions easier. The structural, morphological, optical, and electronic properties have been studied using X-ray diffraction, scanning electron microscope, UV visible absorption spectroscopy, X-ray photoelectron spectroscopy analysis and Fourier transform infrared spectroscopy analysis. The prepared MXene has the characteristic (002) diffraction peak and a layered morphology, similar to the open accordion morphology of HF etched MXene. The optical studies indicated ease of delamination from the evolution of the plasmonic peak in the NIR region. XPS and FTIR studies indicated presence of –O, -F and –OH functional groups. Titanium carbide MXene electrode on glassy carbon and on carbon cloth were fabricated. Nafion-assisted coating in glassy carbon electrode was replaced by binder free coating of MXene clay, while using carbon cloth. A simple brush coating onto pre-heated carbon cloth produced uniform films, with good electrochemical performance. The prepared electrode exhibited good gravimetric capacitance of 109 F/g at a current density of 0.5 A/g and areal capacitance of 2500 mF/cm^2 at a current density of 11 mA/cm^2. High mass loading combined with high areal capacitance make the prepared electrode a potential candidate for commercial applications.

Two-Dimensional Titanium Carbide with Interlayer Spacing as Electrode Material for Supercapacitors Meenu Sharma and Atul Bhargav; Indian Institute of Technology Gandhinagar, India

It is essential to investigate novel electrode materials to advance the development of supercapacitors and their implementations in electronic applications. A group of two-dimensional (2D) transition metal carbides and nitrides known as MXenes ($Ti_3C_2T_z$) have earned more attention as electrode materials for industrial supercapacitors. It has the distinctive features that bulk materials lack, such as a large specific surface area, thermal resistive properties, a low energy barrier for electron transport, and a short ion diffusion path, which make desirable electrodes for energy storage devices.
Titanium Carbide ($Ti_3C_2T_z$) is synthesized in this study using a relatively simple chemical method to develop low defects and high-quality MXene while keeping the stacking and interlayer spacers intact. The crystalline structure and surface morphology are investigated by XRD, SEM, TEM and BET analyses. An electrode is fabricated using a synthesized $Ti_3C_2T_z$ as an active electrode material and Ni-foil as a current collector. The layered morphology is confirmed using a field emission scanning electron microscope, and the presence of the elements of the synthesized MXene is verified using energy-dispersive spectroscopy analysis. The specific surface area of MXene is estimated to be 38 m^2g^{-1} using the BET measurement by nitrogen adsorption and desorption isotherm, with a pore volume of 0.4029 cm^3g^{-1} and average pore size of 4 nm. The electrochemical performance of a $Ti_3C_2T_x$ electrode is tested using cyclic voltammetry with a 6M KOH electrolyte.
When used as an electrode for supercapacitors, $Ti_3C_2T_x$ MXene demonstrated an exceptional specific capacitance of 831 Fg-1 at a 2 mVs^{-1} scan rate in the voltage window of 0.0-0.6 V. The layered structures of MXene improve electrolyte ion transport while also providing transition metal active redox sites on the surface. The electrode has remarkable cyclic stability of 97% over 10000 continuous cycles at 50 mV s^{-1}. The findings suggest an appealing strategy for producing two-dimensional nanomaterials-based electrodes and composites for improved implementation and innovative supercapacitor designs.

11:30 AM NM04.12.05
Investigation of Structural and Morphological Properties of Two-Dimensional V_2CT_x (T_x=-OH,-F, Cl) MXene and Its Photocatalytic Activity Monidipa Pramanik, Mukta V. Limaye and Shashi B. Singh; IISER BERHAMPUR, India

Photocatalytic dye degradation is a most promising and cost-effective way to remove organic pollutants from water in various industries. MXene, a new group of two-dimensional materials, has recently gained tremendous attention as a photocatalyst due to its unique surface functionalities, chemical composition, and physicochemical and visible light absorption properties. These properties make MXene a promising catalyst for the photodegradation of organic molecules. In this work, we have synthesized V_2CT_x (T_x = -OH, -F, Cl) MXene by acid etching method and have been characterized by X-ray diffraction, Raman spectroscopy, and scanning electron microscopy to confirm its structural and surface morphological properties. The chemical composition of catalysts was studied by X-ray photoelectron spectroscopy(XPS). The potentiality of photocatalytic degradation of V_2CT_x MXene was studied by UV-Visible spectroscopy using methylene blue (MB) and crystal violet(CV) under visible light irradiation. The degradation performance for 0.01 M MB dye is 97.9% in 45 minutes and for 0.25 M CV is 93% in 60 min under visible light. This work opens a path for studying the catalytic property of V_2CT_x MXene.

Building 3D Architectures from 2D MXenes Suelen Barg[1,2]; [1]University of Augsburg, Germany; [2]The University of Manchester, United Kingdom

2D Materials-based 3D architectures are promising materials for advanced systems of future technologies. Among 2D materials, MXenes (especially their most studied member, $Ti_3C_2T_x$) present a unique opportunity for application via colloidal processing, as they are electrically conductive and chemically active, whilst still being easily dispersed in water. This talk will present an overview of the progress on the development of colloidal approaches towards 3D architectures of tuned microstructures built from 2D MXenes, with emphasis on ice-templating and extrusion-based additive manufacturing (AM) methods. The potential of these methods and materials will be exemplified in specific applications such as in the development of vertically aligned MXene and multi-material architectures for high-rate performance supercapacitors and the development of advanced composites for electrothermal heating.

MXenes as Electrode Materials for High Performance Rechargeable Batteries and Highly Efficient Electrocatalysis Guoxiu Wang and Xin Guo; University of Technology Sydney, Australia

The ever-increasing demand for renewable energy has urged the development of new materials for the new-generation energy storage and conversion. Among all the candidature materials, 2D transition metal carbides, carbonitrides and nitrides (often referred to as MXene) have drawn intensive attention owing to their excellent electrical conductivity and unique chemical and physical properties. Our research shows that MXene can be applied as host materials for anchoring single atoms to be used in electrochemical hydrogen generation [1] and carbon dioxide conversion [2], as well as composite materials for the application in new-generation batteries with excellent electrochemical performance such as in lithium-sulfur batteries [3, 4], lithium-iodine batteries [5], lithium/sodium-selenium batteries [6], sodium-ion batteries [7], sodium-sulfur batteries [8], and potassium-sulfur batteries [9]. Moreover, the careful design of the material architecture of MXenes has endowed the application for the desalination of saline water [10]. The excellent performances indicate that the MXene-based materials are the promising materials for the applications in the field of energy conversion and storage.

Molecular-Level Methylcellulose/MXene Hybrids for Low-Voltage Electrochemical Actuators Shaohua Chen, Jing-Hao Ciou, Fei Yu, Jian Chen, Jian Lyu and Pooi See Lee; Nanyang Technological University, Singapore

Electrochemical actuators (ECAs) can generate deformation and force under very low input voltages, and are promising for various applications such as artificial muscles and soft robotics. $Ti_3C_2T_x$ MXene is a potential active material for ECAs due to its large volumetric capacitance and high electrical conductivity. However, MXene film suffers from unfavorable in-plane actuation performance in aqueous electrolytes because of the high in-plane alignment of MXene sheets and poor wet strength. Here, we fabricated molecular-level methylcellulose/MXene hybrid films with enlarged layer distances by a simple mixing and vacuum filtration process. The hybrid films show improved ambient stability and wet strength in 1 M aqueous Li_2SO_4. Though the charge storage capacity was improved slightly, the hybrid films generated significantly higher in-plane actuation displacements in the aqueous electrolyte. Based on the direct strain monitoring as well as in-situ XRD and ex-situ XPS investigations, the enhanced actuation is ascribed to the enlarged interlayer distance allowing more ions/water to be intercalated/deintercalated and more importantly the large sliding of MXene sheets induced by methylcellulose during the charge/discharge. The assembled soft ECA has a high Young's modulus of 1.93 GPa and generated a peak-to-peak strain difference up to 0.541% and a blocking force of 4.7 times its gravity under 1-V triangular and DC voltages, respectively. The significant actuation enhancement induced by the insulating methylcellulose can inspire the rational design of high performance ECAs based on other nanomaterials.

Pseudocapacitance Through MXene/Solid Electrolyte Interface Masashi Okubo; Waseda University, Japan

All-solid-state energy storage devices with non-flammable inorganic solid electrolytes are a key technology for addressing the safety issues of lithium-ion batteries with flammable organic liquid electrolytes. However, conventional electrode materials suffer from substantial volume change during lithium-ion (de)intercalation, leading to the failure of the interface between the electrode materials and solid electrolytes and then severe performance degradation. In this work, we report pseudocapacitance through a strain-free interface between a solid electrolyte and a transition-metal carbide nanosheet (MXene), where MXene electrodes show negligible structural changes during lithium-ion (de)intercalation. As a proof of concept, we demonstrate the stable operation of an all-solid-state hybrid capacitor (Ti3C2Tx|Li3PS4 glass|LiCoO2).

1:00 PM NM04.14.01

Effect of Alkali Metal Cations on the High Temperature Stability of $Ti_3C_2T_x$ and $Mo_2TiC_2T_x$ MXenes Brian Wyatt[1], Kartik Nemani[1], Matthew Boebinger[2], Zachary Hood[3], Shiba Adhikari[3], Annabelle Harding[1], Wyatt Highland[1], Raymond Unocic[2] and Babak Anasori[1]; [1]Indiana University - Purdue University of Indianapolis, United States; [2]Oak Ridge National Laboratory, United States; [3]Argonne National Laboratory, United States

Two-dimensional transition metal carbides, known as MXenes, have found wide use in energy storage and catalysis applications. Although MXenes have been used in these applications, few studies have investigated the use of MXenes' interior transition metal carbide/nitride core and abundant surface groups as nanosized building blocks toward extreme environment nanoceramics. In this presentation, we illustrate the high-temperature behavior of $Ti_3C_2T_x$ and $Mo_2TiC_2T_x$ MXenes up to 2,000 °C. In addition, we exhibit the role of surface-adsorbed alkali metal cations (Na^+, K^+, Ca^{2+}) on improving the phase stability and controlling the phase transformation of these MXenes using *in situ* two-dimensional x-ray diffraction (XRD^2) up to 1,100 °C using and *ex situ* XRD^2 up to 2,000 °C. We also present the changes in phase transformation of non-decorated and alkali metal cation decorated $Mo_2TiC_2T_x$ MXenes using *in situ* scanning transmission electron microscopy (STEM) up to 800 °C. The combination of *in situ* XRD^2 and STEM methods with *ex situ* XRD^2, x-ray photoelectron spectroscopy, and thermogravimetric analysis demonstrate the effect of alkali metal cations on improving the phase stability and controlling the phase transformation of MXenes. This presentation assists in furthering development of MXenes as a diverse and tunable family of nanoceramics for ultra-high temperature applications.

1:15 PM NM04.14.02
$Ti_3C_2T_x$ MXene-Derived Carbides as Additive Materials for Ultra-High Temperature Ceramics (UHTCs) Kartik Nemani[1,2], Yooran Im[1,3] and Babak Anasori[2,1]; [1]Purdue University, United States; [2]Integrated Nanosystems Development Institute, United States; [3]Indiana University Purdue University, United States

Zirconium diboride (ZrB2) is one of the ultra-high temperature ceramics (UHTC), which are used for applications at temperatures above 2000 C. However, a significant drawback is its poor mechanical properties such as fracture toughness, poor densification behavior and oxidation resistance since monolithic boride is prone to the formation of volatile oxides (such as B_2O_3) at temperatures above 1100 C. In this project, we have investigated a one-pot, surfactant-free, aqueous mixing method to develop homogeneous ZrB_2-$Ti_3C_2T_x$ MXene green bodies and evaluated their sintering behavior. We present the phase transformation of $Ti_3C_2T_x$ MXene to TiC_y at the grain boundaries, the interface interactions between the ZrB_2-TiC_y grains and their densification mechanism. A nominal relative density of 96% is achieved with the addition of 0.5 wt% of MXene to ZrB_2 and sintering of the resulting powder mixture at 1900 C with 50 MPa pressure under vacuum. We discuss a fundamental understanding of the intermediate phase formation and evolution, and their effect on the mechanical properties of the resulting UHTC. This study lays the groundwork for 2D MXenes as compatible materials for UHTC applications that can be used as precursors for carbides in ultra-high temperature applications such as hypersonics, nuclear, and extraterrestrial travel.

1:30 PM NM04.14.03
Hybrid MXene Electrodes with Anomalous Electrochemical Response Armin VahidMohammadi, Kyle Matthews, Teng Zhang and Yury Gogotsi; Drexel University, United States

MXenes are a family of two-dimensional (2D) transition metal carbonitrides, with a general structure of $M_{n+1}X_nT_x$, where M is the transition metal, X is carbon or nitrogen, and T represents the surface terminations (F, O, OH) and n = 1-4 indicates to the number of atomic layers in their structure. Since their discovery, MXenes have shown promising properties for electrochemical charge storage applications and various MXene compositions have been tested in different electrochemical systems, both in their multilayered and delaminated forms. However, usually these materials show capacitive-like response in aqueous electrolytes with the exception of protic electrolytes such as H_2SO_4 where redox peaks and a pseudocapacitive behavior is observed. Particularly, MXenes tested in aqueous neutral electrolytes exhibit quasi-rectangular cyclic voltammograms. In this presentation, we demonstrate that through changing MXenes' electrode structure by hybridizing them with conducting large modifiers, these materials can show anomalous electrochemical response with distinct redox couples in neutral aqueous electrolytes. We primarily show this behavior on hybrid V_2CT_x electrodes, where the free-standing films exhibit a distinct cyclic voltammograms in various alkali cation containing electrolytes with broad cathodic and anodic peaks, unlike pristine V_2CT_x which has a capacitive response. The observed phenomena in hybrid structures indicates a different charge storage mechanism in these electrodes while maintaining the overall amount of the charge that can be stored. Our results open new avenues in understanding the charge storage mechanism in MXene electrodes which can be used to tailor the desired electrochemical response of these materials in different electrolyte systems.

1:45 PM NM04.14.04
MXene-MoS_2 Composite Coatings for Enhanced Solid Lubrication Dario Zambrano, Jose Y. Aguilar Hurtado and Andreas Rosenkranz; Universidad de Chile, Chile

Friction and wear occur in all moving mechanical systems thus greatly contributing towards energy losses and downgraded efficiencies. These aspects together with global warming, diminishing material and raw oil resources as well as more stringent restrictions for the use of certain additives in lubricating oils urgently ask for advanced lubrication concepts. In this regard, solid lubrication has emerged as a promising strategy to tackle these challenges. Very recently, MXene solid lubricant coatings have shown an outstanding wear performance and durability with the potential to outperform all state-of the-art solid lubricants including graphene and MoS_2. Although showing an excellent wear performance, MXene solid lubricant coatings still demonstrate a rather poor frictional performance, which needs further optimization and improvement.
Therefore, we aim at fabricating innovative sandwich-like composite coatings consisting of two different 2D nano-materials ($Ti_3C_2T_x$ and MoS_2) on stainless steel substrates for solid lubrication purposes. As an additional variable, we vary the respective order of the different coating layers ($Ti_3C_2T_x$/MoS_2 and MoS_2/ $Ti_3C_2T_x$). We envision that these sandwich-like composite coatings exhibit enhanced mechanical properties as well as good friction and wear properties at the same time due to the designed sandwich-like structure and synergetic effects originating from individual nano-sheets.
As a first step, single-material solid lubricant coatings (either only $Ti_3C_2T_x$ or MoS_2) with a thicknesses of 600 nm are spray-coated on stainless steel substrates with a particular emphasis on the coatings' homogeneity. Subsequently, the as-deposited coatings are holistically studied regarding their overall quality (roughness and thickness), physicochemical properties (surface chemistry) by complementary materials characterization. Afterwards, the effect of the material ($Ti_3C_2T_x$ or MoS_2) on friction and wear under dry sliding conditions is evaluated in short- (running-in) and long-term experiments (durability). Particular emphasis is laid on the underlying energy-dissipating friction and wear mechanisms. In this regard, the worn surfaces (coatings and counter-bodies) will be fully characterized by complementary characterization to elucidate the formation of potential tribolayers.
After having studied the effect of the underlying material, sandwich-like composite coatings combining $Ti_3C_2T_x$ and MoS_2 are spray-coated on stainless steel substrates. Regarding deposition, concentrations of 4 $mgmL^{-1}$ for MoS_2 and 5 $mgmL^{-1}$ for $Ti_3C_2T_x$ were used, modifying the applied volume to ensure the fabrication of high-quality, thickness and homogeneous sandwich-like composite coatings. To allow for a fair and direct comparison, the sandwich-like composite coatings will be evaluated using the same experimental conditions (materials characterization and tribological testing conditions). The worn composite coatings will be studied by advanced, complementary materials characterization to elucidate the underlying friction and wear mechanisms as well as potential synergetic effects stemming from the different 2D nano-sheets.
Summarizing, sandwich-like composite coatings (MoS_2/$Ti_3C_2T_x$ and $Ti_3C_2T_x$/MoS_2) are expected to improve the interfacial properties and enhance the system's mechanical properties. This is hypothesized to induce synergetic tribological properties thus creating solid lubrication coatings with an enhanced

friction and wear performance at the same time.

Synthesis, Properties and Applications of Nanocrystals in Materials and Life Sciences Horst Weller[1,2]; [1]Hamburg Univ, Germany; [2]Fraunhofer CAN, Germany

Although colloidal nanocrystals of many different materials can be synthesized in high quality in respect of size, shape and crystallinity, our understanding of their formation and the involved chemical reactions is still rather poor. We will present detailed studies on nucleation and growth as well as ion exchange processes in nanocrystals. These include mass spectrometric, optical, electron microscopic and x-ray synchrotron experiments.
Almost all applications of nanocrystals require the control of surface properties in respect of solubility, miscibility, biocompatibility, passivation of surface states as well as electronic and magnetic interaction with the environment. We will show various examples for ligand exchange and encapsulation of quantum dots, plasmonic and magnetic nanocrystals and will report on applications as high-performance ceramics, for display and lighting, electrocatalysis as well as for biolabeling and drug delivery.

11:00 AM *NM05.01.02
Highly Luminescent Lead Halide Perovskite Nanocrystals—Revisiting Their Synthesis and Tailoring Their Surface Chemistry Maksym V. Kovalenko[1,2]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Colloidal lead halide perovskite (LHP) nanocrystals (NCs), with bright and spectrally narrow photoluminescence (PL) tunable over the entire visible spectral range, are of immense interest as classical and quantum light sources. Severe challenges LHP NCs form by sub-second fast and hence hard-to-control ionic metathesis reactions, which severely limits the access to size-uniform and shape-regular NCs in the sub-10 nm range. We show that a synthesis path comprising an intricate equilibrium between the precursor (TOPO-$PbBr_2$ complex) and the [$PbBr_3^-$] solute for the NC nucleation may circumvent this challenge [1]. This results in a scalable, room-temperature synthesis of monodisperse and isolable $CsPbBr_3$ NCs, size-tunable in the 3-13 nm range. The kinetics of both nucleation and therefrom temporally separated growth are drastically slowed, resulting in total reaction times of up to 30 minutes. The methodology is then extended to $FAPbBr_3$ (FA = formamidinium) and $MAPbBr_3$ (MA = methylammonium), allowing for thorough experimental comparison and modeling of their physical properties under intermediate quantum confinement. In particular, NCs of all these compositions exhibit up to four excitonic transitions in their linear absorption spectra, and we demonstrate that the size-dependent confinement energy for all transitions is independent of the A-site cation.
We then show that this synthesis – relying on the labile ligand capping with TOPO-phosphinic acid mixture – makes for a convenient platform for the subsequent surface functionalization with diverse capping ligands [2]. Robust surface functionalization of highly ionic surfaces, as is the case of LHP NCs, has remained a formidable challenge due to the inherently non-covalent weak surface bonding. Leveraging the vast and facile molecular engineering of phospholipids, we present their efficacy as surface capping ligands for LHP NCs. Molecular dynamics simulations and solid-state NMR confirm that the surface affinity of these zwitterionic molecules is primarily governed by the geometric fitness of their anionic and cationic moieties. Judicious selection of the ligands yielded colloidally robust $FAPbBr_3$ and $MAPbBr_3$ NCs and enabled colloids in a variety of solvents, from n-hexane to acetone. Robustness of the surface capping is also reflected in optical properties: NCs exhibit PL quantum yield (QY) above 96% after numerous purifications. NCs are essentially blinking-free at a single particle level.

Symmetry Breaking in Chiral Lanthanide-Based Nanocrystals—A Model System to Study Nucleation and Growth Gil Markovich, Gal Schwartz and Uri Hananel; Tel Aviv University, Israel

Many inorganic compounds crystallize in chiral space groups, such as quartz, for example. Our group has been studying the breaking of left-right symmetry in the formation of nanocrystals of such compounds. We have shown, that using small chiral bio-molecules, which interact with the crystals' building blocks, it is possible to achieve such a symmetry break. In particular, we have been working with the chiral $TbPO_4 \bullet H_2O$ nanocrystals, and have shown that their handedness can be controlled by preparing the nanocrystals in the presence of certain natural chiral molecules, such as tartaric acid.[1] We used circularly polarized luminescence measurements of Eu^{3+} dopant ions in the nanocrystals to follow the handedness and enantiomeric purity of the produced nanocrystals. Using single particle circularly polarized luminescence microscopy we were able to determine the handedness of individual nanocrystals and confirmed that we obtain a single enantiomer of the terbium phosphate nanocrystals when prepared with tartaric acid molecules.[2] This system exhibits ultra-high chirality amplification and can completely break symmetry on seeding with minute amounts of enantiomericaly-pure seed particles. Such effects are typically attributed to autocatalytic effects also termed secondary nucleation. We study the nature of these effects through comparison of symmetry breaking by chiral ligands vs. addition of chiral seed particles. We also obtain important mechanistic information by following the nanocrystals' formation kinetics by in-situ monitoring total luminescence and circularly polarized luminescence over time.[3] We believe that further studies of this model system might shed more light on the nature of nucleation in general and secondary-nucleation in particular.

Non-Hydrolytic Sol-Gel Chemistry to Functional Hybrid Materials Nicola Pinna; Humboldt-Universitat Berlin, Germany

The current trend in various energy applications, ranging from lighting to batteries and electrolizers, lays in the control of structural, physicochemical and morphological properties of materials and their interfaces.
During this presentation, recent strategies for nanostructured materials synthesis, targeting energy and environmental applications will be discussed. Especially, we will focus on one-pot strategies for the fabrication of hybrid and complex nanomaterials focusing on the importance of the organic-inorganic and inorganic-inorganic interfaces.
Among the examples presented, we will discuss the synthesis of complex nanostructures and the stabilization of metastable phases for applications in energy storage and conversion.
We will see that nowadays the available strategies allow a control in terms of composition, crystalline structure, morphology and nanostructuration that would have been unimaginable just few years ago.
Finally, the open challenges the field is currently facing and possible further developments which are needed to meet the always growing demand for high performing materials will be also discussed.

SESSION NM05.02: Advanced Synthesis and Characterization Methods

1:30 PM *NM05.02.01
Localizing Ligands on Nanocrystal Surfaces Kim Dümbgen[1], Ivan Infante[2] and Zeger Hens[1]; [1]Ghent University, Belgium; [2]Istituto Italiano di Tecnologia, Italy

Colloidal nanocrystals synthesized in apolar media are organic/inorganic hybrids that consist of a crystalline core and a surface capping of organic ligands. While the physical properties of individual nanocrystals are mostly determined by the inorganic core, the role of the organic ligand shell cannot be underestimated. Examples range from synthetic aspects to properties of single nanocrystals and nanocrystal assemblies, such as precursor conversion and nucleation and growth kinetics, the passivation of electronic trap states or the realization of high charge carrier mobility. As a result, the question as to how ligands bind and pack to the nanocrystal surface has been central to nanocrystal research for many years. Extensive insight was obtained by introducing innovative experimental methods to identify surface-bound ligands and, more recently, computational approaches to calculate properties of these ligands. An experimental method that stands out for the analysis of ligand binding is nuclear magnetic resonance (NMR) spectroscopy, due to its capability of identifying and quantifying nanocrystal-bound moieties through diffusion-ordered spectroscopy (DOSY) or nuclear Overhauser effect spectroscopy (NOESY). However, while in-situ NMR analysis of ligand exchange gives experimental insight in ligand binding - often formalized through the L-, X- or Z-type classification borrowed from coordination chemistry - understanding ligand packing from NMR data proofed more difficult.

In this talk, we discuss recent progress on the interpretation of the NMR lineshape in terms of ligand packing on nanocrystal surfaces. We take InP nanocrystals synthesized by reacting $InCl_3$ and tris-diethylaminophosphine in oleylamine as a model system. After showing that the resulting nanocrystals have a mixed ligand shell consisting of chloride and oleylamine, we use spectral hole burning to show that the oleylamine ^1H NMR resonances are heterogeneously broadened. Moreover, by recording the relaxation dynamics of spectral holes, we show that the heterogeneous set of bound ligands consists of at least 2 pools that are not in close proximity, are not involved in chemical exchange and feature a different solvation. In practice, when using aromatic solvents, the more solvated pool is retrieved at the upfield side of the resonance, while the less solvated pool at the downfield side. Using molecular dynamics simulations based on a realistic, atomically precise InP model nanocrystal, we identify the most and least solvated pool as ligands bound to edges and facets, respectively. Interestingly, changes of NMR lineshape following partial ligand exchange reactions indicate that the pool of edge-localized ligands can be selectively removed, a result in line with the predicted weaker binding of ligands at those sites.

To conclude, we highlight that ligands may pack in different, static or dynamic ways to nanocrystal surfaces. Since each of these modes will have a different effect on the heterogeneous broadening of NMR resonances of bound ligands, more is to be learned from spectral hole burning and spectral hole burning relaxation than discussed in this talk.

Towards Endogeneous DNP-NMR in Semiconducting Nanoparticles Ran Eitan Abutbul, Daniel Jardon-Alvarez and Michal Leskes; Weizmann Institute of Science, Israel

Many physical and chemical properties of nanomaterials are dominated by the properties of their surfaces. The importance of surfaces stems from the large surface-to-volume ratio of nanomaterials. These materials are synthesized and processed using ligand molecules, which bind and alter the properties of nanomaterials surfaces. Understanding the role of ligands in the rational design of functional nanomaterials is one of the main challenges in this field. The structure and properties characterization of these nanomaterials requires techniques such as TEM, FTIR UV-Vis-IR, and more. Information acquired from these techniques is invaluable, yet it is limited when attempting to probe a ligand-inorganic interface from a collective of nanostructured materials. Solid-state nuclear magnetic resonance (ssNMR) spectroscopy is a powerful tool for probing local structures at the atomic scale. The inherently low sensitivity of NMR could be overcome with dynamic nuclear polarization (DNP). Typically, organic radicals are added as polarizing agents (PA) to the sample in the exogenous approach. Polarization transfer from electron spin to the nuclear spin occurs upon microwave irradiation, thus enhancing the NMR signal. However, when dealing with ligand-coated nanomaterials, the presence of radicals can dramatically affect the interface under investigation and interfere with its characterization.
This work demonstrates the endogenous DNP approach in nanoparticles for the first time. Where the PAs are transition metal ions with unpaired electrons incorporated in the inorganic lattice. Mn-doped CdS nanoparticles were synthesized using the standard hot-injections technique and characterized using TEM, EPR, and ICP-MS. In addition to a significant DNP enhancement for ^{113}Cd nuclei, surface and core moieties were observed. This approach potentially paves the way for advanced characterization of the ligand-inorganic interface for surfactant-coated nanoparticles.

Improving Electron Pair Distribution Function (ePDF) for Nanomaterials—The Case of Iron Oxide Nanoparticles Naga Vishnu V. Mogili[1], Juliana T. Carvalho[1], Murillo H. Rodrigues[1,2], Jefferson Bettini[1], Edson R. Leite[1,2] and João B. Souza Junior[1,3]; [1]Brazilian Center for Research in Energy and Materials (CNPEM), Brazil; [2]Universidade Federal de São Carlos (UFSCar), Brazil; [3]Universidade Estadual de Campinas (UNICAMP), Brazil

Nanomaterials' properties are strongly related to their crystallographic atomic arrangement. Methods to characterize their atomic structure are fundamental to understanding materials' properties and, consequently, controlling their properties and achieving their full performance. However, classical X-ray diffraction (XRD) methods fail to elucidate the nanostructures due to the elevated peak broadening, a challenge that is known as the nanostructure problem. Pair Distribution Function (PDF) analysis obtained by neutrons and X-ray scattering (synchrotron) have been used to study nanomaterials with outstanding performance, but the access to synchrotron data is limited to the general nanoscience researchers. Electrons have become an alternative source as, nowadays, a transmission electron microscope (TEM) is certainly more accessible compared to synchrotrons. Electrons also have higher scattering power offering the advantage of using a small amount of sample , time-efficient data acquisition, and lower costs.[1] On the opposite side, electrons have a higher probability of multiple scattering and inelastic scattering leading to a harder data processing to collect the total scattering in the kinematical regime. Then, advances in implementing the PDF analysis using electron diffraction (ePDF) would be of great importance.[1] ePDF is a technique capable of analyzing materials structure directly in the real space with the *G(r)* profile leading to the probability of occurrence of any pair of atoms within the material by their interatomic distances *r*.[1] Also, ePDF can reveal all nanostructure features, including bulk crystalline region to the surface, which frequently possesses higher atomic disorder.[2] In this work, methods to improve ePDF *G(r)* profile were implemented by comparing the experimental scattering profile $I(Q)_{exp}$, structure factor $S(Q)_{exp}$, and the PDF $G(r)_{exp}$ with calculated $I(Q)_{calc}$, $S(Q)_{calc}$, and $G(r)_{calc}$ for spherical nanoparticles. Size-controlled iron oxide nanoparticles were synthesized to be used as a case study for ePDF data acquisition and processing toward quantitative *G(r)* data analysis. The electron diffraction data acquisition was optimized by collecting the scattering of a self-sustained nanoparticle superlattice membrane to avoid a carbon background. The scattering from the organic ligands (oleic acid) was also removed from the $I(Q)_{exp}$ to acquire only the electron scattering from the nanomaterial. By applying a frequency filter, the contribution of possible multiple and inelastic scattering background on $S(Q)_{exp}$ was removed. Finally, the $G(r)_{exp}$ was multiplied by a constant to achieve approximate the signal with the $G(r)_{calc}$. The final ePDF *G(r)* was compared to a nanostructure model using a structure refinement method in PDFgui software. Several iron oxide nanoparticles were used to test the proposed method, from the as-synthesized magnetite to oxidized maghemite nanoparticles. Excellent structure refinement was achieved with R_w below 14% showing that our new method of ePDF data acquisition and processing can be used as a quantitative atomic structure method for the short-range atomic ordering and the medium-range ordering (< 10 nm) present in nanoparticles. combining regular TEM analysis like morphology (size, size distribution, and shape), high-resolution, and chemical mapping, the ePDF atomic structure analysis adds to TEM a perfect crystallographic characterization tool to solve the nanostructure problem.

High-throughput Materials Synthesis Strategies Towards Accelerated Discovery of Novel Functional Nanomaterials for Green Energy Production Ali Abdelhafiz, Zhichu Ren and Ju Li; Massachusetts Institute of Technology, United States

It has been challenging over the past three decades to find viable energy alternatives with higher efficiency and lower cost to beat the non-friendly and commercially dominant hydrocarbon energy sources. Hydrogen is deemed to be one of the most prominent candidates, as a green fuel. Hydrogen can be generated in abundance from water splitting. Utilization of hydrogen in fuel cells, with no doubt, produces no harmful gases. Nevertheless, the two parts of the technology: hydrogen production and reduction are cumbersome. Both processes rely on kinetically sluggish electrocatalytic reactions. Enormous research efforts have been spent, with thousands of studies presented in literature, despite the technology left with a dim light shed on from commercial and practical point of views. Many materials-related challenges are hindering the flourishing of green hydrogen technology, where poor catalyst durability is a major challenge, despite being made from very expensive elements (e.g., Ir, ru or Pt). Therefore, gigantic effort of research has been devoted to find inexpensive alternatives. Transition metals showed interesting performance towards water splitting (e.g., oxygen evolution (OER)).
Recent research showed that electrocatalysts designed by alloying two or more elements (e.g., transition metals) showed promising enhancement in catalytic activity and durability due to synergistic effects from alloying, such as strain engineering or electron exchange. The potential of the alloying approach is constrained by standard synthesis methods (e.g., wet chemistry and thermal decomposition techniques) due to the governing thermodynamics rules (e.g., miscibility of the different alloying elements). That renders the synthesis of high entropy alloys (HEA), with more than 3 elements, to be complicated and tedious to achieve by those conventional methods.
In the presented talk we are presenting different strategies to synthesize metastable high entropy alloys (HEA) and their outstanding catalytic performance towards OER, in correlation to their unique chemistries and structures. Rapid cycling of temperature from room 25 °C to highly elevated levels (1700 °C),

in conjunction with ultra-rapid cooling, within milli-second range have been demonstrated by different methods including rapid Joule heating, Intense light flashing, and microwave plasma shock. Our results show successful synthesis of non-noble metals HEA NPs, possessing higher catalytic activity than IrO_2 catalyst for OER. The nature of the alloying elements dictates OER activity by promoting different oxidation states of the catalytically active transition metals (e.g., Fe, Ni and Co). In addition, a phenomenal in-situ chemical welding of HEA NP to carbon support, yielded HEA catalysts with two orders of magnitude longer durability than IrO_2. Our developed techniques resulted in formation of super-strong metal-carbide bonds “chemically welding” HEA NP to the catalyst support.
Synthesis of various HEA catalyst and their electrocatalytic performance screening has been carried out by using liquid handler robots and multi-axes robotic arm systems. Moreover, to optimize the design of materials (structure and chemistry), we are using active learning techniques to evaluate the achieved performance results by applying Gaussian process, followed by applying Bayesian Optimization techniques to propose novel chemistries and structures with a higher probability to achieve further improved performances. The presented the study does not open the door only towards developing novel catalysts for energy production. However, it presents a strategy with multiple successfully demonstrated platforms towards accelerated discovery of novel materials. The high-throughput nature of the synthesis protocols presented in this talk can produce tens of thousands of different novel chemistries, at the same time taken by conventional methods to synthesize just a few, at a minimal energy consumption, cost, and manpower.

Structural and Compositional Engineering of Superlattices Comprising Halide Perovskite Nanocubes Maryna Bodnarchuk[1,2], Ihor Cherniukh[1,2], Taras V. Sekh[1,2], Alex Travesset[3], Rainer F. Mahrt[4], Thilo Stoeferle[4], Mariia Svyrydenko[1,2], Viktoriia Morad[2,1], Gabriele Raino[2,1], Rolf Erni[1] and Maksym V. Kovalenko[2,1]; [1]Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zürich, Switzerland; [3]Iowa State University of Science and Technology, United States; [4]IBM Zurich, Switzerland

Colloidal lead halide perovskite nanocrystals (LHP NCs, NCs, A=Cs^+, FA^+, FA=formamidinium; X=Cl, Br, I) have become a research spotlight owing to their spectrally narrow (<100 meV) fluorescence, tunable over the entire visible spectral region of 400-800 nm, as well as facile colloidal synthesis. These NCs are attractive single-photon emitters as well as make for an attractive building block for creating controlled, aggregated states exhibiting collective luminescence phenomena. Attaining such states through spontaneous self-assembly into long-range ordered superlattices (SLs) is a particularly attractive avenue. In this regard also the atomically flat, sharp cuboic shape of LHP NCs is of interest because the vast majority of prior work had invoked NCs of rather spherical shape. Long-range ordered SLs with the simple cubic packing of cubic perovskite NCs exhibit sharp red-shifted lines in their emission spectra and superfluorescence (a fast collective emission resulting from coherent multi-NCs excited states).
When $CsPbBr_3$ NCs are combined with spherical dielectric NCs, perovskite-type ABO_3 binary NC SLs form, wherein $CsPbBr_3$ nanocubes occupy B- and/or O-sites, while spherical dielectric Fe_3O_4 or $NaGdF_4$ NCs reside on A-sites. When truncated-cuboid PbS NCs are added to these systems, ternary ABO_3-phase form (PbS NCs occupy B-sites). Such ABO_3 SLs, as well as other newly obtained SL structures (binary NaCl, AlB_2- and ABO_6 types, columnar assemblies with disks, *etc.*), exhibit a high degree of orientational ordering of $CsPbBr_3$ nanocubes. These mesostructures exhibit superfluorescence as well, characterized, at high excitation density, by emission pulses with ultrafast (22 ps) radiative decay and Burnham-Chiao ringing behavior with a strongly accelerated build-up time. Combining $CsPbBr_3$ nanocubes with large and thick $NaGdF_4$ nanodisks results in the orthorhombic SL resembling CaC_2 structure with pairs of $CsPbBr_3$ NCs on one lattice site. We also implement two substrate-free methods of SL formation. Oil-in-oil templated assembly and self-assembly at the liquid-air interface result in the formation of binary supraparticles.

Controlling the Nucleation and Growth Kinetics of Spheroidal Lead Halide Perovskite Quantum Dots Quinten A. Akkerman[1], Anja Barfüßer[1,2], Maksym V. Kovalenko[3] and Jochen Feldmann[1]; [1]Ludwig-Maximilians-Universität (LMU), Germany; [2]2Empa-Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [3]ETH Zürich, Switzerland

Colloidal lead halide perovskites LHP (LHP) nanocrystals (NCs) have recently become popular light-emissive materials, of practical interest for LEDs, LCDs, lasers, as well as single photon light sources.[1,2] Most studies on LHP NCs focus on relatively large cuboidal NC exceeding 10 nm in size, pointing out the inherent chalange of producing small (sub 10 nm), stable and monodisperse LHP quantum dots (QDs). This problem directly originates from the highly ionic lattice of LHPs, generally resulting in sub second reaction dynamics, making it very challenging to control their growth on an atomic level. Consequently, the current generation of LHP QDs (especially the hybrid organic-inorganic ones) show significantly less excitonic absorption landscapes compared to conventional QDs such as CdSe, even though LHPs have more simplistic band structure. This thus hinders studies into the size-quantization of excitons in LHPs (and possible practical use) as well as understanding of the mechanism of LHP QD formation, which still significantly lacks behind compared to conventional CdSe and PbS QDs.
<!--![endif]---->
<!--[endif]---->To solve this, we developed a room-temperature synthesis, in which the overall QD formation occurred on a time scale of up to 30 min, slowing down the reaction kinetics by several orders of magnitudes compared conventional LHP QD syntheses.[3] The size of these QDs were tunable between 3 and 13 nm range and exhibited a rhombicuboctahedral (spheroidal) shape. These $CsPbBr_3$ QDs, as well as $FAPbBr_3$ and $MAPbBr_3$ exhibited up to four well-resolved excitonic transitions, finally bringing them on par with the highly excitonic absorption landscapes of CdSe and PbS QDs. This slow growth method also allowed for the first time to direct in-situ study the illusive reaction mechanism of LHP QDs, demonstrating the effective separation of the nucleation and growth stages due to the self-limiting formation of an $Cs[PbBr_3]$ intermediate precursors. The slow growth approach was further extended by using an additional in-situ anion exchange step, resulting also in spheroidal $CsPb(Cl:Br)_3$ QDs with any Cl:Br ration and sizes from 4-10 nm.[3,4] These quaternary QDs still exhibited up to five sharp excitonic absorption transitions, further demonstrating the versatility of the slow growth method. Finally, we used such spheroidal 6 nm $CsPbBr_3$ QDs to demonstrate that their respective excitons are confined with respect to their center-of-mass motion. Optical pumping of the lowest confined exciton transition with femtosecond laser pulses therefore not only bleaches all exciton resonances as measured with transient absorption spectroscopy, but also reveals a series exciton-to-biexciton transitions, which is further supported by their temporal dynamics.

Machine Learning-Driven Synthesis Optimizations in Thin Films and Nanoparticles Lena Pilz, Carsten Natzeck, Jonas Wohlgemuth, Peter Weidler, Christof Wöll and Manuel Tsotsalas; KIT, Germany

Metal-Organic Frameworks (MOFs) have attracted much attention in the materials science community due to their high variability combined with well-defined structure. They are constructed from metal nodes and organic linker molecules to form regular, porous networks. [1]
Their preparation is influenced by several interdependent variables (e.g., metal and linker sources, concentration, solvent, modulators, reaction time and temperature, among others). But unfortunately, their pronounced influence, especially on nucleation, crystallisation processes and the resulting porous crystalline structure, is not yet understood. [2] In the last decade, machine learning (ML) methods have proven to be target-oriented and efficient for solving complex problems that cannot be solved with conventional approaches, such as the discovery and optimisation of synthetic parameter spaces for the production of specific MOFs. [3][4]
The idea of this research project is to use machine learning to establish the development of optimised synthesis processes and parameters. In the first part we will demonstrate the feasibility of ML optimization for several nanoparticle systems with the aim to achieve very small particle sizes with low distribution. The second, much more complex optimization is dedicated to the targeted setting of a specific orientation of a thin film with high crystallinity. This involves a great deal of understanding about the influences on the system as well as highlighting the supporting features of automated synthesis. Since it is usually too difficult for humans to vary more than one parameter at a time, machine learning algorithms are the perfect choice here to simultaneously optimize a variety of synthesis parameters that are changed simultaneously.
For this purpose, ranges must first be defined for the synthesis parameters within which they are to be varied. In the first instance the parameters are statistically spread for a defined number of experiments. After the execution and characterisation of each experimental result, new parameters are generated by a genetic algorithm, which recombines the previous parameters based on the evaluation of the results.
This step can be repeated as often as desired until the results are close enough to the desired goal. In the final step, all generated data is evaluated for relevance of the parameters again using a machine learning tool. This provides a lot of information both for biasing variables for similar systems and to understand the influences of the variables on the system.
Since the simultaneous variation of several parameters is possible, the time and money saved cannot be dismissed as an advantage. In addition, mathematically sound data are created at the end, which can be referred to for further experiments. And last but not least, if the possibility existed within the chosen parameters, a system optimised to the desired parameters emerged from this method.

4:15 PM NM05.02.08
Data-Driven Insights from AuNP Synthesis Recipes Sanghoon Lee[1,2], Kevin Cruse[1], Samuel P. Gleason[1], Paul Alivisatos[1], Gerbrand Ceder[1,2] and Anubhav Jain[2]; [1]UC Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Gold nanoparticles are widely used in various applications because their properties are tunable depending on their shapes and sizes. Shape and size control of the AuNPs have been studied, however, the mechanisms of these syntheses are still unclear. In fact, not only are such studies limited in the number of factors and their levels considering the high dimensions of the synthesis space, but the syntheses are not always reproducible, and sometimes different synthesis outcomes are reported with the same recipe. This implies that some “missing factors” contribute to the synthesis outcomes in which are not always controlled nor reported. Therefore, it is crucial to collect a large synthesis dataset to identify i) regions that are easily reproducible through reported recipes, ii) regions with scarce data that need further exploration, iii) regions with conflicting results that in-depth studies to find missing factors are necessary.

In this work, we deliver three things. First, we developed a rule-based parser to extract the precursors and their amounts in the recipes and the resulting AuNP morphology and size, which could be used or easily adapted to not only other nanoparticle syntheses but also solution-based recipes parsing in general. Second, we provide the parsed AuNP synthesis dataset, along with the uncertainty measure for a given point in the synthesis space calculated from the neighboring data points, which one can use as a “map” for synthesis guidance. Lastly, we trained interpretable statistical models from the parsed dataset, which provide data-driven intuitions for the nucleation and growth process of the AuNPs.

4:30 PM NM05.02.09
Detection and Classification of Chiral Self-Assembled Nanostructured Helices in Electron Microscopy Images Using Generalizable Deep Learning Algorithms Anastasia Visheratina[1], Alexander Visheratin[2], Prashant Kumar[1], Michael Veksler[1] and Nicholas A. Kotov[1]; [1]University of Michigan–Ann Arbor, United States; [2]Beehive AI, United States

A chiral object has two mirror-image forms that are non-superimposable in three dimensions. Chirality plays a crucial role in chemistry, biology, and pharmacology, as most of the important biomolecules are chiral (amino acids, proteins, DNA). In 1998, it was discovered that chiral nanostructures could be chiral. Chiral inorganic nanostructures have distinct fundamental importance and are essential for further developing chemical, pharmaceutical, environmental, and biomedical technologies. To date, many researchers are focused on the establishment of the correlations between chiroptical and morphological properties of these materials by using circular dichroism and electron microscopies. A thorough investigation of electron microscopy images requires accumulating many images with their in-depth analysis, which is tedious and the 'manual' image processing is subject to experimentalist bias. Currently, there is a need for novel methods for the structural characterization of chiral nano- and micron-scale inorganic structures.

Here we developed an approach for synthesizing large sets of realistic scanning electron microscopy (SEM) images of chiral self-assembled nanostructured micro-helices of bowtie shape based on very small original SEM image sets (~200 SEM images). We used SEM images of a diverse pool of bowties, which allowed the training of state-of-the-art neural network models with the ability to detect morphological properties of chiral structures of various sizes. We tested the method by generating 10,000 images of bowtie-shaped particles with different chirality and training the YOLOv5 model to differentiate between right and left structures. As a result, this algorithm can reliably identify and classify chiral bowtie-shaped particles with accuracy as high as 94.4%. Furthermore, after training on bowtie particles, this model can successfully recognize *other* chiral shapes with different geometries without re-training. These findings indicate that deep learning techniques can potentially replicate the visual analysis of chiral objects, which opens up a path to other

computational methods capable of accurate automated analysis of a wide range of chiral features at different scales and their implementation in materials discovery for photonics and medicine.

Co-Operative Cation Exchange Reaction in CdS Magic Size Cluster Yuan Yao; Cornell University, United States

Cation exchange has been developed as a post-synthetic method to explore a wide range of nanoparticle composition, phase, and morphology. Traditionally, the cation exchange reaction is explained by the reaction zone theory where the substitutional cations diffuse into the nanoparticle and form a reaction zone "shell" within the nanoparticle. Reaction zone theory implies the cation exchange is diffusion-controlled and the extent of cation exchange reaction is thus controlled by the propagation of the diffusion zone. However, several recent studies in nanoclusters (size <2 nm) find that cation exchange reactions take on discrete transformation steps. For example, the CdSe/Cu cation exchange shows a two steps mechanism, starting with the slow exchange of 1-3 Cu atoms and follow by an avalanche reaction which forms completely exchanged Cu_2Se nanoclusters.
Using the CdS magic size cluster (MSC) as a model system, we investigated the cation exchange reaction mechanism in nanoclusters. The MSC cation exchange with Ag ions reveals a similar two steps reaction mechanism. The cation exchange reaction initiates with 1 to 2 Ag atoms incorporated into the MSC. Once the Ag concentration reaches the critical concentration (~10% Ag), a rapid increase of Ag content is observed followed by a complete phase transformation to Ag_2S. Using MALDI-TOF spectroscopy, we successfully identified two Ag exchanged reaction intermediates (Ag2Cd32S33, Ag1Cd33S33) as well as the fully exchanged nanocluster. X-ray diffraction and X-ray photoelectron spectroscopy also demonstrated a sudden change in crystal structure and electronic structure at the critical Ag concentration and corroborate the MALDI-TOF results. More interestingly, we found the Ag exchanged reaction intermediate has a low energy barrier for further cation exchange with other elements which were difficult to cation exchange. As a result, we used knowledge of this cluster exchange mechanism to successfully exchange Mn into AgCd33S33, to introduce interesting optomagnetic properties.

Reaction Intermediates in the Synthesis of Colloidal Nanocrystals Raffaella Buonsanti; Ecole Polytechnique Federale de Lausanne, Switzerland

Over the past 40 years, scientists have learned to synthesize colloidal nanocrystals of different composition with tunable size and shape. These features dictate the properties of these nanomaterials. Thus, their control is crucial for the discovery of phenomena, many of which contribute to technological advances. One example of the societal impact of this class of materials is the use of semiconductor nanocrystals as the active component in displays with the best color purity on the market. A second example is their use as materials platforms to advance catalyst development. Yet, the synthesis of colloidal nanocrystals still proceeds by trial and error. The search for the reaction conditions to obtain the nanocrystals with the desired composition, size and shape is time consuming and can fail in delivering the target product.

In this talk, I will highlight the importance of identifying the reaction intermediates during the formation of colloidal nanocrystals for the development of a more predictive synthesis to these nanomaterials. By discussing specific examples, I will illustrate that the chemical nature of these intermediates is diverse and that state-of-the-art in-situ techniques combined with theory are often needed to capture those transient species during the synthesis of nanocrystals. Nevertheless, I will use concrete examples to demonstrate that such efforts are worth it as the discovered mechanistic pathways pinpoint the critical steps to enhance the tunability of existing materials and to accelerate the discover of new ones.

N-Heterocyclic Carbene-Based Polymer Coating of Gold Nanoparticles and Luminescent Quantum Dots Neda A. Nosratabad, Zhicheng Jin and Hedi M. Mattoussi; Florida State Univ, United States

Since they were first synthesized by Arduengo and coworkers in 1991, N-heterocyclic carbenes (NHCs) have generated much interest for use as versatile metal-coordinating groups. NHC-presenting molecules exhibit strong coordination interactions with transition metal ions and surfaces by sharing their non-bonding electron pairs with the σ-accepting orbitals of the metal ions. NHC-appended molecules have recently been actively exploited as potentially effective ligands for the surface passivation of various colloidal nanomaterials.
We characterize the coordination interactions between a few representative colloidal nanocrystals, including gold nanoparticles (AuNPs) and luminescent quantum dots (QDs), and one NHC-based polymer ligand. The latter presents multiple NHC groups and several short poly (ethylene glycol), PEG, chains as solubilizing blocks. We find that our NHC-decorated ligands rapidly coordinate onto both sets of nanocrystals, requiring ~ 5-10 min for complete ligand substitution and phase transfer. These Lewis base groups ideally match the soft Lewis acid character of transition metal colloids, promoting strong coordination bonding through soft-to-soft interactions. We combine NMR spectroscopy, fluorescence spectroscopy, high-resolution transmission electron microscopy supplemented with dynamic light scattering to characterize the nature of the binding interactions. Furthermore, the long-term stability of the NHC-stabilized nanocolloids have been tested after phase transfer to water, a highly challenging chemical venue for such groups, due to the moisture sensitive nature of NHC molecules. Data show that our NHC-stabilized nanocolloids exhibit long-term colloidal stability in buffer media while preserving their optical and fluorescing properties for at least one year of storage. We will discuss the ligand design and characterization of the polymer-stabilized nanocrystals under various conditions, with a particular focus on the beneficial effects of multi-coordination interactions.

Nanoparticle-Based Functional Nano-Materials—Modern Inorganic Aerogels Alexander Eychmueller; TU Dresden, Germany

The focus of my talk will be laid on non-ordered superstructures made from nanocrystals. Here, gels and aerogels manufactured from a variety of different nanoparticles have recently proven to provide an opportunity to marry the nanoscale world with that of materials of macro dimensions which can be easily manipulated and processed, whilst maintaining some of the nanoscale properties. This is best demonstrated when using size-quantized semiconductor nanocrystals for the aerogel formation: 3.5 nm sized CdTe nanocrystals display an orange colour (while bulk CdTe is black) which is maintained in a 1 cm^3 aerogel and so is also the emission.[1] In terms of applications, however, gels formed from metal nanocrystals provide a wider field, particularly in electrocatalysis.[2] For this we concentrated our work on the amelioration of the building blocks as a plausible approach to graft aerogels with distinguished properties while preserving the aerogel superiority.[3] In a further study, we prepared and analyzed a new class of hierarchical aerogels composed of multimetallic Ni-Pd_xPt_y nanoparticle building blocks with continuously engineered shape and compositions. This approach results in aerogels with hierarchical structures organizing the nanoscale regulated architecture and macroscale three-dimensional network structure. For gaining highest performance of these catalysts the surface chemistry as well as the formation mechanisms have to be studied and tuned.[4,5] I will conclude my presentation with remarks on a set of more recent findings such as self-healing of metal gels and the formation of 2D-metal meshes.[6] The latter display ligament sizes of 4 – 9 nm which is also the thickness of the meshes, surface coverages between 0.25 and 0.5, and fractal dimensions of 1.4 – 1.7. Those structures hold promise in various fields like sensors, electrodes, electrocatalysis, neural implants (stretchable electrodes), and fractal antennas.

Amalgamation Synthesis of Intermetallic Nanocrystals Jasper Clarysse, Annina Moser, Olesya Yarema, Vanessa Wood and Maksym Yarema; ETH Zurich, Switzerland

Bimetallic compounds are a vast family of materials with >20000 unique members and record-high performance in plasmonic, catalytic, magnetic, and energy storage applications. In strong dissonance, universal synthesis for polymetallic nanocrystals is missing, due to challenges to combine two dissimilar metals at the nanoscale. We overcome this limitation by the amalgamation reaction at the surface of nanocrystals, [1] thus unlocking up to a 1000 of new intermetallic nanocrystals with unprecedented quality for size uniformity, composition control, and phase purity. We show the universality of our amalgamation approach and achieve a row of crystalline and compositionally uniform intermetallic nanocrystals of Au-Ga, Ag-Ga, Cu-Ga, Ni-Ga, Pd-Ga, Pd-In and Pd-Zn compounds. Furthermore, we demonstrate a compositional tunability across phase diagrams (e.g., AuGa2, AuGa, Au7Ga2, and Ga-doped Au nanocrystals for the bimetallic Au-Ga system), while each phase can be prepared with accurate size control and excellent size uniformity. Our new synthetic method is simple, predictive, and generalizable, giving access to a large family of intermetallic nanocrystals with unprecedented quality and flexibility of materials design, thus unlocking a multitude of possibilities for these materials.

Salt-Templated Metal and Metal Oxide Porous Materials John Burpo[1], Felita W. Zhang[1], Veronica M. Lucian[1], Alexa Zammit[1], Edward M. Tang[1], Rosemary L. Calabro[1,2], Enoch A. Nagelli[1], Stephen F. Bartolucci[2] and Joshua A. Maurer[2]; [1]United States Military Academy, United States; [2]U.S. Army Combat Capabilities Development Command-Armaments Center, United States

Pure metal, multi-metallic and alloy nanomaterials enable a broad range of catalytic applications with high surface area and tunable reaction specificity through the variation of metal composition. Synthesizing these materials as three-dimensional porous nanostructures enables control of surface area, pore size and mass transfer properties, electronic conductivity, and ultimately device integration. Discrete and aggregated nanoparticles offer tremendous design flexibility, yet methods to assemble them into extended 3-dimensional structures suffer from several limitations, especially aggregation and diffusion times. Insoluble salts offer a template approach to synthesize of a range of porous noble and transition metal structures and monoliths. Chemical reduction of insoluble Magnus and Vauquelin salt needles formed from the combination of oppositely charged square planar platinum, palladium, gold, and copper ions have been previously demonstrated as templates for mesoporous macrobeam and macrotubes 10's to 100's of micrometers long with square cross-sections ranging from approximately 100 nm to 3 μm.[1-4] The use of insoluble noble metal salt templates was extended to the chemical reduction of copper and nickel transition metal poly-crystalline salts. After chemical reduction, metal gels were rinsed, solvent exchanged in ethanol, and supercritical dried in CO_2 to form aerogels. Metal and metal oxide phase composition varied depending on the sulfate, acetate, and chloride salt template anion. Aerogels were characterized using scanning electron microscopy, energy dispersive x-ray spectroscopy, x-ray diffractometry, nitrogen gas adsorption-desorption with and Brunauer-Emmett-Teller surface area analysis, vibrating-sample magnetometry, magnetic force microscopy, and nanoindentation. Electrochemical performance of copper and nickel oxide aerogels as pseudocapacitors was determined with electrochemical impedance spectroscopy and cyclic voltammetry. The use of salt precursors is envisioned as a synthesis route to a wide range of metal and multi-metallic nanostructures for catalytic, energy storage, and sensing applications.

Polyoxometalates—A Novel Surface Stabilizer for Optically Tunable 2D Systems Ali Jawaid and Richard A. Vaia; Air Force Research Laboratory, United States

2D van der waals systems have attracted significant interest across multi-disciplinary fields ranging from sensors, optical filters, and structurally responsive composites. Access to these materials is paramount for technology development. Technologies that facilitate and expand methods to stabilize monolayers, disperse them into a wide array of matrices (i.e. solvents, polymers) is desirable for facile integration into current bulk manufacturing methods. Despite the advances made in the last decade, access to many systems is limited by liquid phase exfoliation techniques (i.e. H_2O/Surfactant) where surface corrosion, oxidation, hydrolysis are common challenges. In this regard, we demonstrate that polyoxometalates (POMs) can meet exfoliation and stabilization challenges for layered van der waals heterostructures. This is exemplified in their ubiquitous ability to stabilize and exfoliate layered transition metal dichalcogenides (LTMDs); surface adsorption of POMs provide coulombic repulsion between individual layers in bulk crystallites and facilitate gentle delamination without the use of mechanical forces, minimizing surface defects and crystallite scission. POMs can further impart charge transfer to the LTMD surface resulting in tunable absorption edges for modular optics; this is further demonstrated via tuning the affinity of the POM to the LTMD surface to allow adaptive optical responses. The mechanism of surface adsorption, exfoliation, and stabilization can be transferred to colloidal systems outside of LTMDs (graphene, CIPs, MXenes) creating a general exfoliant for robust colloidal 2D systems.

Lead-Free Heterometallic Halide Layered Double Perovskite Nanocrystals Ou Chen; Brown University, United States

Halide perovskite nanocrystals have attracted a great amount of research attention due to their unique optoelectronic properties, leading to a range of potential applications including light emitters, displays, X-ray imaging and solar energy harvesting. In this context, lead-free halide perovskite and perovskite-analogue nanocrystals have emerged as a new category of materials that hold the potential for overcoming the instability and toxicity issues of lead-based counterparts. In this talk, I will discuss some of our recent studies about synthesis, characterization and application of different lead-free halide perovskite and perovskite-analogue nanocrystals. I will focus my talk on crystal phase control, composition and structure tuning, and applications of this special category of materials. Both experimental data and first-principal Density Functional Theory calculation results will be included in the talk.

Engineering Colloidally Stable Blue-Emitting $CsPbBr_3$ Nanoplatelets Using Polysalt/$PbBr_2$ Ligands Sisi Wang, Wentao Wang, Selin Donmez and Hedi M. Mattoussi; Florida State Univ, United States

With their large exciton binding energy and precisely controlled thickness, two-dimensional colloidal perovskite nanoplatelets (NPLs) have attracted attention as promising blue-emitting materials. However, they tend to lose their optical, morphological and colloidal integrity with storage following growth.
Herein, we introduce a strategy using $PbBr_2$-complexed polymers as coating ligands that impart morphological and colloidal stability, while enhancing the photoluminescence quantum yield of the NPLs. The polymers present several ammonium (or imidazolium) bromide anchoring groups and alkyl chains with different length as solubilizing blocks. The presence of the quaternary ammonium salts facilitates the dissolution of $PbBr_2$ in organic solutions, forming polysalt-$[Pb_xBr_y]^{2x-y}$ complexes that strongly interact with the NPL surfaces. We find that these complexes eliminate surface defects, compared to the as-grown materials, and improve their structural and morphological stability. This strategy has yielded blue-emitting samples that maintain color purity with narrow profiles at ~460 nm and with PLQY up to 80%. Additionally, significantly enhanced long term stability of the nanoplatelets under several challenging conditions, including UV irradiation and highly diluted conditions, has been achieved.

Tuning Interparticle Interaction Inside Nanocrystal Superlattices by Solvent Vapor Exposure and Pressure Process Yasutaka Nagaoka and Ou Chen; Brown University, United States

My poster presentation discusses interparticle interactions between nanocrystals in superlattices and superparticles. Especially, recent results on in-situ small-angle X-ray scattering (SAXS) measurements during structural transformation upon solvent exposure, synthesis of superparticles, and the response to high pressure are presented.
Upon evaporating the solvent, superlattices and superparticles are spontaneously formed through nucleation and growth processes. The formation process is influenced by many structural factors of nanocrystals, including their shape, surface, and how the surfactant molecules interact with solvent molecules. The mechanisms are highly complex, involving both kinetic pathways and thermodynamic stabilization. A clear demonstration of the interparticle interactions will be necessary to understand the formation processes. The clarification of the mechanism is especially crucial since current research indicates that the architectures and molecular structures inside nanocrystalline superlattices drastically influence the physical properties such as mechanical and optical properties of the resulting materials, resulting in new structured materials and metamaterials.
In order to better understand the nature of nanocrystal interparticle interactions, we conducted several in-situ experiments monitoring nanocrystal superlattices and superparticles under external stimuli such as solvent vapor exposure and mechanical pressure. Our experiments on solvent vapor exposure examined how cluster-based nanocrystal superlattices respond to different solvent molecules. In our experiments, we demonstrated molecular interactions between surfactant molecules and incoming solvent molecules within nanocrystal superlattices after exposure to solvent vapor, causing a change in the molecular shape of the surfactants. Subsequently, the molecular change triggered superstructural phase transitions and their mechanical properties changed accordingly. We have shown that the post-treatment of the nanocrystal superlattices with solvent vapors can induce orchestrated structural changes from the molecular structure to the superstructure. During our high-pressure experiments, we created a series of superparticles, superstructured nanocrystals with colloidal morphologies, and studied their behavior under pressure. Interparticle interactions under high pressure exhibit a different landscape than those under ambient conditions, leading to many interesting chemical/physical reactions. We present pressure-driven sintering processes in nanocrystal assemblies with different surface states under varied pressure ranges.

Monodisperse Nanocrystal Superparticles Through a Source−Sink Emulsion System Emanuele Marino[1], Sjoerd van Dongen[1], Steven J. Neuhaus[1], Weixingyue Li[1], Austin W. Keller[1], Cherie R. Kagan[1], Thomas E. Kodger[2] and Christopher B. Murray[1]; [1]University of Pennsylvania, United States; [2]Wageningen University & Research, Netherlands

Superparticles made from colloidal nanocrystals have recently shown great promise in bridging the nanoscale and mesoscale, building artificial materials with properties designed from the bottom-up. As these properties depend on the dimension of the superparticle, there is a need for a general method to produce monodisperse nanocrystal superparticles. Here, we demonstrate an approach that readily yields spherical nanocrystal superparticles with a polydispersity as low as 2%. This method relies on the controlled densification of the nanocrystal-containing “source” emulsion by the swelling of a secondary “sink” emulsion. We show that this strategy is general and rapid, yielding monodisperse superparticles with controllable sizes and morphologies, including core/shell structures, within a few minutes. The superparticles show a high optical quality that results in lasing through the whispering gallery modes of the spherical structure, with an average quality factor of 1600. Assembling superparticles into small clusters selects the wavelength of the lasing modes, demonstrating an example of collective photonic behavior of these artificial solids.

Reversible Diffusionless Phase Transitions in 3D Nanoparticle Superlattices Daryl W. Yee, Margaret S. Lee, Joyce An and Robert J. Macfarlane; Massachusetts Institute of Technology, United States

Natural materials often exhibit complex material properties due to hierarchically organized structural motifs at the molecular, nano, micro, and macroscopic size regimes. They have inspired a whole generation of advanced multifunctional synthetic materials that utilize structural hierarchy to reach new property spaces. Self-assembly approaches have been heavily utilized to fabricate these hierarchical materials as its ability to build materials via weak, dynamic interactions between nanometer-sized build blocks provides great control over material structure from the molecular to the micro-scale.

In particular, self-assembled nanoparticle superlattices (NPSLs) — three-dimensional ordered arrays of nanoparticles — have been the subject of significant interest due to their emergent properties that arise from the ordering of their nanoparticle building blocks. As a result, these nanoparticles superlattices are promising materials for a variety of applications, from optoelectronics to energy storage. Multiple methods have been developed to assemble NPSLs, and these crystallization processes have often been guided by chemical intuition derived from the formation of traditional bulk or atomic crystals. Chemical concepts like bond valency or packing factors can be directly analogized to structural features and phenomena observed in NPSLs, suggesting that more complex behaviors like microstructure formation or phase transitions could also be induced. Given that the properties of NPSLs are often governed by their crystal symmetry and lattice parameters, the ability to induce a phase transition to reversibly tune the crystal structure has the potential to lead to dynamic materials with switchable properties for a variety of applications, including optoelectronics, plasmonics, mechanics, and catalysis. As such, there has been significant interest in engineering NPSLs that are able to exhibit reversible polymorphic phase transitions.

Here, we report the assembly of nanocomposite tectons (NCTs), polymer grafted nanoparticles that have supramolecular recognition groups at the chain ends, into unary NPSLs that are capable of exhibiting a martensitic phase transition between a face-centered cubic (FCC) and a body-centered cubic (BCC) structure when the solvent quality is changed. The phase transition is rapid, reversible, and appears to proceed through an order-to-order crystal transition. We show the impact that NCT composition has on the phase transition behavior and discuss the potential mechanisms behind it. Importantly, we demonstrate that the phase transition can be kinetically arrested, allowing both polymorphs to be obtained in the solid form and examined. The BCC phase was observed to maintain the same crystal habit as the parent FCC phase but exhibited significant twinning, analogous to those observed in martensitic transformations. We discuss the impact that twinning has on the mechanical properties of these colloidal crystals, and highlight how these twinned crystals can be used to engineer macrostructures with twinned microstructures. Given the importance of phase transitions and twinning in atomic materials, the ability to replicate them in NPSLs represents a step forward in engineering hierarchically complex materials that can utilize them to augment their properties.

4:30 PM NM05.06.04
Design and Synthesis of Functional Nanostructured Materials via Colloidal Crystallization Yuanwei Li, Wenjie Zhou, Ibrahim Tanriover, Hanxun Jin, Horacio Espinosa, Koray Aydin and Chad A. Mirkin; Northwestern University, United States

Controlling nanomaterial architecture is a versatile way to create materials with tailored properties. Colloidal crystal engineering has emerged as a powerful approach to precisely synthesizing materials with nanoscale architectures. For example, porous crystals are a class of materials with extraordinary properties. Multicomponent crystals provide a promising path forward for the creation of materials with synergistic physical and chemical properties. However, it is still remarkably difficult to synthesize designer multicomponent and porous crystals; moreover, their structure-function relationships remain elusive. Here, we take a materials-by-design approach that takes advantage of programmable DNA interactions to assemble monodispersed nanoparticles

of various shapes into (1) multicomponent co-crystals and (2) porous colloidal crystals, each with targeted chemical, optical, or mechanical properties. We further explore the structure-function relationships among these new materials.

To achieve designer multicomponent colloidal crystals, we have developed a series of polyethylene glycol-DNA ligands that enables the co-assembly of polyhedral nanoparticles and spherical nanoparticles into ordered co-crystals. Specifically, polyhedra of different sizes and shapes (e.g., octahedra, tetrahedra, decahedra, and bi-tetrahedra) are co-assembled based on geometry-inspired designs. Furthermore, polyhedral and spherical nanoparticles of different sizes are co-assembled into a series of novel hierarchical structures, where anisotropic nanoparticles are ordered, while spheres are disordered in the lattices. Using these design strategies, we have discovered eight new co-crystals in the DNA-engineered colloidal crystal family. These results highlight the potential of shape-complementarity design strategies for creating new and unusual colloidal co-crystals.

Utilizing our universal synthetic strategy for directing the site-specific growth of anisotropic seeds into exotic nanoparticle shapes and compositions provides a general pathway to design and synthesize an array of metal hollow nanoparticles that are promising building blocks for the assembly of porous colloidal crystals. These hollow nanoparticles, including nanoframes and nanocages, are subsequently assembled using DNA into open channel superlattices with a range of pore shapes and sizes (i.e.,10–1000 nm). We show that the assembly of hollow nanoparticle superlattices is driven by edge-to-edge DNA interactions. The edge-based assembly design rules that emerged from these studies were used to synthesize 12 open channel superlattices with control over crystal symmetry, channel geometry, and topology. We further show that by controlling the geometry and topology of pores, these superlattices can be used for encapsulating and immobilizing guest species within the host open channel structures, and incorporating inorganic or organic guests with spatial specificity into these porous crystals generates a new kind of host-guest structured material. Indeed, the controllable and tunable porosities and periodicities of open channel superlattices make them promising candidates to realize optical phenomena that are not observed in natural materials. For example, the effective refractivity of a porous Au-Pt cubic-close-packed crystal was found to be negative over a wide spectral range (1050–2000 nm). Finally, we found that porous metallic crystals have higher specific strength and stiffness compared to their solid counterparts, which provides new insights into the design and development of materials that are light but strong. These properties of open channel superlattices represent a new class of mechanical metamaterials, due to their porous, low-density structures and diverse crystal topologies. Overall, our work has made important steps toward the rational synthesis of functional co-crystals and porous crystals with significant implications in optics, catalysis, electronics, biology, and mechanics.

4:45 PM NM05.06.05
Spontaneous Assembly of Magnetic Nanochains Induced by Magnetic Dipole Interactions Yulan Chen and Amal El-Ghazaly; Cornell University, United States

Anisotropically-ordered magnetic nanoparticles (NPs) possess unique physiochemical properties and are important to various applications ranging from data storage to medical technologies. One-dimensional (1D) magnetic nanochain structures have often been produced by applying an external magnetic field during synthesis, where the discrete NPs are aligned into chains. However, this method is severely limited in its ability to scale up in manufacturing for use in practical applications since the reaction vessel size is limited by the magnetic field strength, i.e. size of the electromagnetic coils or magnet. Here, we demonstrate that it is possible to forgo the external magnetic field and only utilize the intrinsic dipole forces of the iron cobalt (FeCo) nanoparticles themselves in the reaction media to assemble them into nanochains during the synthesis process.
A challenging issue in magnetic assembly of dipolar colloids is that the dipolar interactions between individual building blocks are only possible in the near field. As a result, self-assembly of anisotropic nanostructures like chains is difficult to promote in the absence of externally-applied fields or other stimuli. In this work, we establish a method for the self-assembly of magnetic nanochains by investigating the usage of magnetic dipolar interactions between neighboring FeCo NPs in highly-concentrated reaction conditions. The small interparticle distance in this highly-concentrated regime drastically enhances dipole-dipole coupling and enables the large-scale synthesis of magnetic FeCo nanochains without using any templates, surfactants, or external magnetic fields.
The growth mechanism and resulting morphology of these self-assembled 1D nanochains were found to be strongly influenced by the reaction concentration, and analogously the relative strengths of the magnetic dipolar interactions. Magnetic dipolar interactions between NPs depend on particle size, interparticle distance, and their flow velocity in the reaction fluid. We experimentally show how the synergistic effect of the dipole−dipole attractive force and the fluid drag counteractive force is modified through changes to the synthesis conditions, including precursor ratios, total precursor quantity, and spinner rotation speed. Furthermore, through simulation, we illustrate the magnetic and fluid dynamic force landscapes of a single particle to provide insight into the range of reaction concentrations useful for yielding nanochains as opposed to isolated nanoparticles. Future research can take advantage of these intrinsic magnetic dipole forces, in conjunction with other ligand-mediated interparticle interactions, to self-assemble strongly-adhered, 1D anisotropic magnetic nanostructures with additional functionalities, or to fabricate even more complex three-dimensional geometrical arrangements at a commercial scale.

Effect of Inter-Particle Distance in Liquid Phase Benzaldehyde Hydrogenation via Raspberry-Colloid Templated PdAu/SiO_2 Inverse Opals Kang Rui Garrick Lim, Selina K. Kaiser, Sadhya Garg and Joanna Aizenberg; Harvard University, United States

The collective ensemble properties of nanoparticles (NPs) deposited on supported catalysts, defined by design parameters such as NP loading, dispersion, and inter-NP distance, have a pronounced impact on catalytic activity, selectivity, and stability. Traditional preparative methods of precipitation or impregnation entail nucleating NPs on the support. Thereby, a higher metal precursor concentration increases the NP loading but also yields larger NPs, which disguises the direct effects of NP size and inter-NP distance on catalysis. Herein, we use raspberry-colloid templating (RCT) to partially embed pre-formed dilute Pd-in-Au NPs within a macroporous SiO_2 support, ensuring a preserved NP size distribution during preparation and catalysis. By varying the NP loading in the RCT fabrication process, the average inter-NP distance can be altered without modifying the NP size distribution. This enables the independent investigation of the effect of inter-NP distance in liquid phase catalysis.

NM05.07.02
Chiroptically Active Copper Oxide Microstructures via Post-Synthetic Treatment of Copper-Aluminium Layered Double Hydroxides Áine

Coogan[1], Finn Purcell-Milton[1,2], Seán Cardiff[1,1] and Yurii K. Gun'ko[1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Technological University Dublin, Ireland

In recent years, much research has focused on the development of new chiral inorganic nanostructures, including a wide variety of materials, such as nanosheets, nanowires, and tetrapods, among others.[1-3] Layered double hydroxides (LDHs) are a class of ionic 2D nanomaterials that are known for their porous laminar structures and anion-exchange properties. As such, they can host a wide variety of species in their interlayer – including chiral molecules.[4] However, despite this unique property, to the best of our knowledge there are no reports on the development of chiral and chiroptically active LDHs nanostructures with chiral ligands.

In this work, we report the synthesis and investigation of carbonate-intercalated copper-aluminium ($CuAl\text{-}CO_3$) LDH nanosheets. The initial LDH nanomaterials have been synthesised by an easy scalable co-precipitation procedure. Then, the resultant 2D nanomaterials were treated with L- and D-Phenylalanine at room temperature in aqueous conditions, resulting in materials with strong chiroptical activity in the visible region, far beyond the onset of the CD signal from the original ligand. Time-dependent CD and powder X-Ray diffraction (pXRD) studies demonstrate a gradual transformation from achiral LDH nanosheets, to chiral copper (II) oxide (CuO) microstructural materials, exhibiting g-factors of up to 0.0035. We expect that these materials could have potential future applications in enantiomeric separation and asymmetric catalysis.

Synthesis of Gold Nanowires for Stretchable Electronics Laura Seufert[1], Samuel Lienemann[1], Ulrika Linderhed[1,2], Mohammed Elmahmoudy[1], Mary J. Donahue[1] and Klas Tybrandt[1]; [1]Linköping University, Sweden; [2]RISE, Research Institute of Sweden, Sweden

Electrical stimulation in direct proximity to neural tissue is investigated to treat neurological disorders like Parkinson's disease and epilepsy. One major challenge for neural interfaces is the huge mechanical mismatch between the electronics and the tissue. This can be addressed by developing soft and stretchable devices. High performance stretchable conductors can be made from nanowires (NWs) embedded in elastomers like polydimethylsiloxane (PDMS). Silver nanowires (AgNWs) are commercially available in controlled dimensions and have been widely used for stretchable conductors. For biomedical applications, however, AuNWs are needed, and to date there exists no robust method of synthesizing large amounts of high aspect ratio AuNWs. In this work we present a novel synthesis of high aspect ratio AuNWs with smooth surface structure and selective control of the diameter of the nanowires in solution. We investigate how changes to the parameters of the reaction like temperature and concentration influence the material and characterize the nanowires using various imaging and analysis tools. Furthermore, we show the stable performance under cyclic stretching measurements of conductors produced by embedding the novel AuNWs in PDMS and other elastomers. The good performance and biocompatibility of the new material allowed for application in a stimulation experiment as a stretchable conductor.

To address the need for low-cost, transition metal porous nanomaterials for energy storage applications, one strategy is to use naturally occurring cellulose-based templates to better tune material properties such as feature size, pore structure, conductivity, material phase, and mechanical strength. Examples of this approach to control nanostructure and functionality include bacterial cellulose-ferromagnetic cobalt ferrite magnetic aerogels and cellulose nanofiber-palladium aerogels.[1,2] Here, cellulose nanofibers derived from bacteria provide templates to synthesize lightweight, porous, and conductive nickel and nickel oxide aerogels for use as pseudocapacitors. These aerogels were synthesized through $NaBH_4$ chemical reduction of nickel sulfate equilibrated tempo-oxidized bacterial cellulose matts. Supercritically dried aerogels were thermally annealed in air to control the degree of nickel oxide material phase. Aerogels were characterized using scanning electron microscopy, energy dispersive x-ray spectroscopy, x-ray diffractometry, nitrogen gas adsorption-desorption with and Brunauer-Emmett-Teller surface area analysis, vibrating-sample magnetometry, magnetic force microscopy, and nanoindentation. Electrochemical performance was determined with electrochemical impedance spectroscopy and cyclic voltammetry. Due to the low-cost synthesis and tunable properties, these composite cellulose-metal/metal oxide aerogels are expected to provide material solutions to a wide range of energy storage, catalytic, and fuel-cell applications.

Tuning Morphology of Colloidally-Synthesized, Plasmonic Tungsten Oxide Nanostructures for Hydrogen Evolution Activity Gregory Davis[1], Xun Zhan[2] and Rajesh Sardar[1]; [1]IUPUI, United States; [2]Indiana University Bloomington, United States

An energy dense fuel source to replace the reliance of fossil fuels by our society the utmost importance for future generations. Solving this pressing issue by finding a solution which has a low environmental cost to our planet, should be the target of cutting-edge science. The hydrogen evolution reaction (HER) is of great interest due to the energy dense product H_2 gas. Metal oxide nanostructures show tremendous promises as a heterogeneous HER catalyst because of their unique optical and electronic properties which are only prevalent at the nanoscale size. Additionally, these materials offer tunable reactivity and serve as a support and the catalyst simultaneously; this allows for increased simplicity in catalytic systems. Most importantly, nanostructured metal-oxides can be synthesized from earth abundant transition metals, making the process economically more viable as compared to utilizing more expensive noble metals. However, current research does not elucidate a full understanding of morphology on catalytic activity towards the HER.

Specifically relating the crystalline (*hkl*) facets to the optimal HER performance. Herein, we present how shape of colloidally-synthesized plasmonic tungsten oxide nanostructures influence the electrocatalytic HER activity as a function of morphology. The HER activities have been investigated by examining the optical, electrical properties, and crystalline facets of different morphologies such as one-dimensional rods and wires and two dimensional platelets. We determined that the two-dimensional platelets have a tafel slope of approximately 55 to 60 mV/dec and the wires gave a tafel slope of 205 to 215 mV/dec. The overpotential of these two nanostructures was found to be between -0.2V to -0.3V and -0.5V to -0.6V for platelets and wires respectively. This finding presents a distinct difference in electrochemical behavior which is based only on morphology. The ratio of the (*hkl*) facets to HER activity have revealed that the morphology is an important feature which must be addressed when optimizing a metal-oxide catalyst for the HER. As the platelets provide the largest surface to volume ratio of the most catalytic facet while also forming an effective support system owing to the stability of meta-oxide materials. The current work focusing on morphology dependent HER activity would prove interesting to open the door for an efficient and robust HER catalyst for the renewable energy production.

***p*-Block Metal–*d*-Block Metal High-Entropy Alloy Nanoparticles and Their Properties** Masashi Nakamura[1], Dongshuang Wu[1], Megumi Mukoyoshi[1], Kohei Kusada[1], Takaaki Toriyama[2], Tomokazu Yamamoto[2], Syo Matsumura[2], Yasukazu Murakami[2], Yoshiki Kubota[3], Shogo Kawaguchi[4], Toshiaki Ina[4] and Hiroshi Kitagawa[1]; [1]Kyoto University, Japan; [2]Kyushu University, Japan; [3]Osaka Metropolitan University, Japan; [4]JASRI/SPring-8, Japan

High-entropy alloy (HEA) is multiple-element alloy characterized by its large configurational entropy. Its complex physics yields appealing properties distinct from conventional alloy. Thanks to the vast compositional and configurational space, this class of material has greatly enriched the diversity of bulk materials library for more than 15 years.[1] Not like the bulk, however, the development of small-sized HEA nanoparticles (HEA NPs) is still in its dawn stage,[2] and only a few combinations of elements are explored so far.
We have focused on the combination of *p*-block metals (*p*Ms: In, Sn, Bi, etc.) and *d*-block metals (*d*Ms: platinum-group metals (PGMs), etc.) in HEA NPs (denoted as *p*M–*d*M HEA NPs). These 2 groups of elements have contrasting features in electronic structure or thermodynamic properties such as melting points, which should afford uniqueness of *p*M–*d*M system. However, *p*M–*d*M system has been poorly investigated even in binary NPs and much less in more complicated HEA NPs, partly due to difficulty in their synthesis. Here, we first report the synthesis of *p*M–*d*M HEA NPs using a facile wet-chemistry method. The successful formation of the HEA NPs was confirmed by revealing their crystal structure and electronic structure with a series of X-ray based spectroscopies and electron microscopy. The properties of the obtained NPs are also discussed.

Continuous-Flow Synthesis for Extremely Small IrPdPtRhRu High-Entropy Alloy Nanoparticles and Investigation of Their Hydrogen Evolution Catalytic Activity Hiroki Minamihara[1], Kohei Kusada[1,2,3], Dongshuang Wu[1], Tomokazu Yamamoto[4], Takaaki Toriyama[4], Syo Matsumura[4], Loku S. Kumara[5], Osami Sakata[5], Shogo Kawaguchi[5], Yoshiki Kubota[6] and Hiroshi Kitagawa[1]; [1]Kyoto University, Japan; [2]HAKUBI Center, Japan; [3]JST-PRESTO, Japan; [4]Kyushu University, Japan; [5]JASRI SPring-8, Japan; [6]Osaka Prefecture University, Japan

High-entropy alloy nanoparticles (HEA NPs) are of interest in various fields such as energy conversion catalysis.[1] For example, IrPdPtRhRu HEA NPs showed remarkably high hydrogen evolution reaction (HER) activity compared with commercial Pt.[2] Although the smaller HEA NPs are desired for catalytic use, most of the reported synthesis techniques of HEA NPs provide over 10-nm particle size because they stabilize the solid-solution phase under extreme conditions such as high temperature accelerating the atomic diffusion and particle growth.[3,4] In this study, we first synthesized 1.3-nm IrPdPtRhRu HEA NPs, the smallest size of HEA NPs, by a liquid-phase reduction method at room temperature using an originally developed continuous flow reactor enabling inert synthesis conditions. The obtained NPs were characterized by scanning transmission electron microscopy (STEM) and Pair distribution function (PDF) analysis. Elemental maps suggested the successful mixing of five elements at the atomic level. PDF analysis for the obtained NPs indicated an fcc structure with ultrasmall particle size. Moreover, we investigated HER catalytic activity which plays an important role in energy conversion for the development of hydrogen-based energy resources. The 1.3-nm HEA NPs showed 8-times higher activity than commercial Pt which is a benchmark catalyst for HER, which is one of the best HER activities among reported highly active platinum group metal-based catalysts.

Slot-Die Deposition of ZnO:Al Thin Films for Sustainable Optoelectronic Applications Ewan D. Matheson[1], Xinya Xu[2], Yongtao Qu[1], Pietro Maiello[1], Guillaume Zoppi[1] and Neil Beattie[1]; [1]Northumbria University, United Kingdom; [2]WaveOptics, United Kingdom

Slot-die coating is a solution-based method for forming thin films for optoelectronic devices and belongs to a family of coating methods known as pre-metered coating [1]. More traditional techniques such as vacuum-based physical vapour deposition (PVD), involves expensive equipment and is inefficient both in terms of material usage and energy [2]. In contrast, slot-die coating offers room temperature deposition with near 100% material usage efficiency. For thin film electronics, indium tin oxide (ITO) is currently favourite in the transparent conducting oxide (TCO) market, however it is expensive relative to other TCO's [3] and therefore a cheaper alternative is required to reduce the cost of optoelectronic devices. One candidate is ZnO:Al (AZO) which offers similar performance characteristics such as high band gap (3.5 eV), optical transmittance (~80 %) and low resistivity (10^{-4} Ωcm) [4,5].

In this study, slot-die coating was used to deposit AZO nanoparticles on glass. Scanning electron microscopy indicates that the films are homogeneous and densely packed with nanoparticle diameters ranging from 10 – 30 nm. Furthermore, the film thickness was found to be uniform across the substrate and could be controlled within a 30 nm range by adjusting key slot die parameters. X-ray diffraction measurements demonstrate crystallographic reflections from the nanoparticles that correlate with a ZnO reference and exhibit planar orientation. Annealing in an Ar atmosphere from 300 – 500 C, was shown to increase the crystallinity. UV-Vis spectroscopy showed that the films exhibit a blue shift in the optical band gap (4.37 eV) which may be due to quantum confinement. Four-point probe electrical measurements revealed the nanoparticle film to have high sheet resistance due to the high number of interfaces introduced by the nanoparticles, however on a conductive ITO substrate, the cross-section resistivity was observed to be ~4×10^{-2} Ωcm.

Compared to the slot-die deposited nanoparticle film, the PVD AZO film exhibits a larger grain size and a correspondingly lower energy band gap. Typically, PVD AZO film thicknesses range between 100 - 500 nm for optoelectronic devices however the films in this study are relatively thick at 1 µm [6]. X-ray diffraction also indicates correlation with the ZnO reference with sharper and more intense features compared to the nanoparticles, as well as orthogonal orientation. Four-point probe measurements indicates a resistivity of ~$7\text{x}10^{-4}$ Ωcm which is significantly lower than the cross sectional resistivity of the nanoparticles.

In summary, slot-die deposited AZO nanoparticles for application in the manufacturing of high-throughput, low-cost optoelectronic devices, yielded uniform thin films with good optical properties and low materials wastage. Due to the substantial number of grain boundaries introduced by the

nanoparticles, conductivity was reduced compared to the PVD AZO sample. Further investigations will focus on potential approaches to improving the electrical properties of the slot-die films, such as incorporating metal nanoparticles in the film, as well as hydrothermal growth of ZnO nanowires using the slot-die nanoparticle thin film as a seed layer.

One-Pot Synthesis Method of Hyaluronic Acid-Coated Gold Nanoparticles for Controlled Drug Release System Junghun Park and Hyoung-Mi Kim; Korea Institute of Industrial Technology, Korea (the Republic of)

Hyaluronic acid (HA) is a natural linear polysaccharide formed by repeating units of d-glucuronic acid and N-acetyl-d-glucosamine disaccharide. Since HA possesses excellent properties of biocompatibility, biodegradation, non-toxicity, and non-immunogenicity, it has been widely used for cosmetics and pharmaceuticals including drug delivery system. In this study, we newly studied one-pot synthesis of HA-coated gold nanoparticle (HA-AuNP) as drug delivery system. Various types of HA-AuNPs were synthesized using electron-beam irradiated HA, which makes the low molecular weight of HA. Sulfasalazine (SSZ) was used to demonstrate efficiency of drug delivery and controlled release of the HA-AuNP. We first characterized SSZ-HA-AuNP by TEM, UV-vis, DLS, and zeta-potential analysis. As the molecular weight of HA decreased, drug loading capacity and encapsulation efficiency of SSZ increased. Next, we tested time-dependent SSZ release profile at simulated gastric fluids and intestinal fluids. Controlled drug release in simulated intestinal condition over 24 h was observed by anomalous (non-Fickian) drug transport following Korsemeyer-Peppas model. This suggests that HA-AuNP can be used for a stomach dependent-sustain drug delivery system.

NM05.07.11
Rational Design of Dimensionally Stable Anodes for Active Chlorine Generation Hyunwoo Lim[1], Deok Ki Cho[1], Joo Ho Yoon[1], Chan Woo Lee[2] and Jin Young Kim[1]; [1]Seoul National University, Korea (the Republic of); [2]Kookmin University, Korea (the Republic of)

Chlor-alkali electrolysis, which contains chlorine evolution reaction (CER) and hydrogen evolution reaction (HER) as an anodic and cathodic reaction, is a critical industrial process for the production of chlorine gas, caustic soda, and hydrogen fuel. Dimensionally stable anode (DSA) has been exploited as the commercial electrode for CER because of its durable catalytic activity. However, the high precious metal contents of DSA (15 mol% of RuO_2 and 15 mol% of IrO_2) and the anodic corrosion of RuO_2 during the oxygen evolution reaction (OER), which is a side reaction of CER, remain fundamental challenges that must be addressed. Here, we demonstrate that low-temperature annealing of RuO_2 nanoparticles (~1.7 nm) supported on conductive Nb-doped TiO_2 (abbreviated as RuO_2/Nb:TiO_2-A200 NPs) leads to the formation of durable active sites with superior electrocatalytic activity and product selectivity toward chlorine generation (10 and 100 mA cm^{-2} at 22 and 55 mV overpotential with a Faradaic efficiency of 97.3% in 0.6 M NaCl, which is much better than those of commercial DSA). The Nb doping not only enhances the electronic conductivity and suppresses the reactivity related to undesirable water oxidation of the TiO_2 support, but also enables thermal diffusion of Ti atoms into the RuO_2 lattice at the temperature of 200 °C, thereby forming ultrafine solid-solution nanoparticles having an ultrathin TiO_2 surface as a protective layer. This work provides a cost-effective fabrication strategy of stable RuO_2-based electrocatalysts for anodic reactions, as well as additional electrode structural insights into the design principle of DSA.

NM05.07.12
Dynamic Surface Modifications of MOF Nanoparticles via Alkoxyamine Functional Groups Simon Spiegel[1], Ilona Wagner[1], Salma Begum[2], Matthias Schwotzer[1], Isabelle Wessely[2], Stefan Bräse[2] and Manuel Tsotsalas[1]; [1]Karlsruhe Institute for Technology (KIT)/Campus Nord, Germany; [2]Karlsruhe Institute of Technology (KIT), Germany

Metal-organic frameworks (MOFs) have become one of the most popular class of materials, due to their outstanding versatility in composition and functionality, combined with their well-defined crystalline structures. MOFs show promise for diverse applications, ranging from catalysis, organic electronics, gas storage and separation, to biology and medicine. In many of these applications, surface chemistry is a crucial factor for the performance of MOFs. Therefore, the external surface engineering of metal-organic frameworks (MOFs) is an important design strategy, providing access to optimized chemical and colloidal stability. Common strategies for MOF surface modifications include either physical adsorption or chemical association of small molecules or (preformed)-polymers. However, most of the currently employed approaches lack precise control of the polymer density and are unable to dynamically modify the surface on demand.

We introduce alkoxyamines as versatile tool for the surface modification of MOF nanoparticles (NPs). These alkoxyamines can serve as an initiator in nitroxide mediated polymerization (NMP), hence they enable polymerization from the MOF surface. Furthermore, alkoxyamines provide the possibility to dynamically exchange of small molecules via nitroxide exchange reaction (NER).

In our studies we used UiO-66-NH2 as a standard MOF template. The success of surface modification and successive surface polymerization was confirmed via various characterization methods, including time-of-flight secondary ion mass spectrometry (ToF-SIMS), size exclusion chromatography (SEC), attenuated total reflection infrared spectroscopy (ATR-IR) and nuclear magnetic resonance (NMR) spectroscopy.

NM05.07.13
Effect of Acid-Base Modulators on the Crystal Morphology of Zr-UiO-66 Metal-Organic Framework Nanoparticles Burcu Akata Kurc and Saeed A. Khan; Middle East Technical University, Turkey

Metal-organic frameworks (MOFs) are an emerging class of hybrid crystalline porous materials that consist of metal clusters (nodes) connected by organic linkers (struts) to form a three-dimensional molecular framework. MOFs have attracted considerable attention in recent years owing to their exceptional properties. Due to their remarkable design flexibility, ultra-high porosity, large specific surface area, and tunable properties, MOFs are indispensable for potential applications in clean energy, gas adsorption, and catalysis. Zr-UiO-66 is one of the archetypal MOFs with high surface area and chemical and thermal stability. Tuning the surface morphology of Zr-UiO-66 MOF crystals can significantly enhance their catalytic, gas adsorption, and gas sensing properties.

Conventionally, the solvothermal method is used for the synthesis of Zr-UiO-66. Various modifications have been made in the solvothermal route to tailor the morphology of Zr-MOF crystals and reduce the synthesis time. Zr-UiO-66 can be synthesized using different modulators like HCl, HF, acetic acid, and

TEA. This route allows one to speed up the synthesis reaction or induce a desired property, such as creating defects or tailoring crystal morphology.

In this study, UiO-66 was synthesized without and with the presence of acid-base modulators (acetic acid and TEA base). The synthesis of Zr-UiO-66 without a modulator at 80°C resulted in cubic crystals with an average particle size of 125 nm; however, no crystal morphology was observed at a reaction temperature of 120°C. It was interesting to see that octahedral-shaped crystals were obtained for UiO-66 at 120°C in 6 hours when acetic acid (2.4 M) and TEA (2 mM) were introduced into the reacting solution as modulators. SEM images showed discrete octahedral Zr-UiO-66 MOF crystals for acid-base co-modulated synthesis. The role of acetic acid is to engineer the crystal's shape by stopping the crystal's growth in particular directions, thus resulting in octahedral morphologies. TEA plays a role in the nucleation and mono-dispersity of the crystals. TEA also helps in reducing the time of crystal nucleation. The size of the octahedral crystal increased with the concentration of TEA in reacting solution. When the concentration of TEA was increased from 2 mM to 12 mM in the reaction solution, the mean crystal size of Zr-UiO-66 increased. At 12 mM TEA concentration in the precursor solution, the largest average crystal size of 1.02 µm was observed. The crystal size started to decrease as the TEA concentration was increased further. It can be hypothesized that the fast nucleation effect of TEA was dominant and could be the reason for relatively more polydispersity of crystals sizes. However, for 16 mM and 19 mM TEA concentrations, TEA helps obtain monodisperse crystal sizes by creating more and more nucleation points.

The project leading to these results has received funding from the Scientific and Technological Research Council of Turkey (TÜBITAK) under grant agreement 220M002.

The High-Entropy Oxide Nanoparticles Consisting of All 3D Elements Ryohei Kanda[1], Kohei Kusada[1,2,3], Takaaki Toriyama[4], Tomokazu Yamamoto[4], Yasukazu Murakami[4,5], Syo Matsumura[4,5], Shogo Kawaguchi[6], Yoshiki Kubota[7] and Hiroshi Kitagawa[1]; [1]Kyoto University, Japan; [2]The Hakubi Center Kyoto Univ., Japan; [3]JST-PREST, Japan; [4]URC Kyusyu University, Japan; [5]Department of Applied Quantum Physics and Nuclear Engineering, Kyushu Univ., Japan; [6]Japan Synchrotron Radiation Research Institute/SPring-8, Japan; [7]Osaka Metropolitan Univ., Japan

High-entropy oxides (HEOs), which are complex oxides containing five or more metal cations at around the same molar ratio in a single phase, have attracted much attention because of their unique chemical and physical properties, for example, thermoelectric property[1] and Li-ion conductivity[2]. Following the first report in 2019 [3], lots kinds of HEO nanoparticle (NP) have been reported. For example, they consist of only five 3*d* transition elements or of homologous elements. HEO NPs are considered to be a new class of materials such as catalysts, but the syntheses of them have not been well developed because it is difficult to homogeneously mix diverse elements in nano-sized crystals.
Here, we succeeded for the first time in synthesizing HEO NPs consisting of all 3*d* transition elements (Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, and Zn) by a flow reactor with supercritical water. The formation of a single phase of the HEO NPs homogeneously consisting of all the ten 3*d* elements was confirmed by scanning transmission electron microscopy (STEM) and energy dispersive X-ray spectroscopy (EDS). X-ray diffraction (XRD) analysis revealed that all the ten 3*d* transition metals formed a solid-solution spinel oxide (Sc, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn)$_3$O$_4$, which is the same crystal structure as Fe_3O_4. The radial distributions calculated by Fourier transformation from X-ray absorption fine structure (XAFS) data revealed that all 3*d* elements are randomly located at tetrahedral and octahedral sites in spinel structure.

NM05.07.16

Compositional Dependence of Structures and Activity for Hydrogen Evolution Reaction of Platinum-Group-Metal Quinary Alloy Nanoparticles Yuto Maruta[1], Kohei Kusada[1,2,3], Dongshuang Wu[1], Tomokazu Yamamoto[4], Takaaki Toriyama[4], Syo Matsumura[4,5], Okkyun Seo[6], Satoshi Yasuno[6], Shogo Kawaguchi[6], Osami Sakata[6], Yoshiki Kubota[7] and Hiroshi Kitagawa[1]; [1]Kyoto University, Japan; [2]HAKUBI Centre, Kyoto Univ, Japan; [3]JST-PRESTO, Japan; [4]URC, Kyushu Univ., Japan; [5]Grad. Sch. Eng., Kyushu Univ., Japan; [6]JASRI-SPring-8, Japan; [7]Osaka Metropolitan Univ., Japan

Multi-element solid-solution alloy nanoparticles (NPs) have attracted much attention as a new class of catalysts because they have both high activities and stabilities for many kinds of reactions[1-3]. For example, equimolar platinum-group metal (PGM) quinary alloy NPs show an extremely high catalytic activity for hydrogen evolution reaction (HER)[3]. Despite very high compositional designability of multi element alloy NPs, the composition dependence of their crystal and electronic structures, and properties have not been well investigated.
We synthesized PGM quinary alloy NPs with several compositions directly supported on carbon to investigate their compositional dependence of structures and catalytic activity for HER. The compositions of the obtained NPs were analyzed by X-ray fluorescence (XRF). They were also characterized by scanning transmission electron microscopy (STEM) coupled with energy-dispersive X-ray spectroscopy (EDX). The EDX maps confirmed the formation of homogeneous solid solutions. Their crystal structures were analyzed by synchrotron powder X-ray diffraction (PXRD), and their valence-band electronic structures were investigated by hard X-ray photoelectron spectroscopy (HAXPES). In addition, HER was selected as the target reaction and measured by a three-electrode electrochemical measurement. Their compositional dependences of lattice constants, *d*-band centers, and catalytic activities of HER were investigated. We found their lattice constants can be represented by simple linear combination formula, indicating multi-element alloy NPs follows Vegard' law as binary alloy NPs[4]. In contrast, their *d*-band centers change nonlinearly with compositions, mainly because of the complex hybridization of the five constituent elements. Their catalytic activities are not simply correlated with compositions, suggesting different interpretations of the reaction mechanism such as a combination of multiple factors are needed for multi-element alloy NPs.

Improving Electron Pair Distribution Function (ePDF) for Nanomaterials—The Semiconductor CdSe Quantum Dot Case Olavo F. Verruma[1,2], Naga Vishnu V. Mogili[1], Isabela J. Vieira[1], Jefferson Bettini[1] and João B. Souza Junior[1]; [1]National Center for Research in Energy and Materials, Brazil; [2]University of São Paulo State–UNESP, Brazil

Quantum Dots (QDs) are nanometric semiconductor materials under massive study due to their optical and electronic properties controlled by quantum confinement. Cadmium Selenide (CdSe) is being tested in different applications[1], however, nanoparticle crystallographic structure can hinder the efficiency of QDs applications, mostly due to the concentration of defects such as grain boundaries, stacking faults, and vacancies. Besides the core-related defects, the surface of nanomaterials, which behave like a skin that is exposed to the environment, presents a higher concentration of defects created by the lower atomic coordination from atoms at the surface. The small nanoparticle size of QDs makes it more difficult to characterize the crystallographic structure by standard techniques like X-ray Diffraction. Elevated peak broadening and lower intensity of coherent scattering by nanomaterials create broad diffraction peaks almost convoluted with the diffusion scattering. Then, the Pair Distribution Function (PDF) analysis of the total scattering data has been raised as an alternative method to suppress those problems and solve the atomic arrangement structure for nanomaterials[2]. Alternatively, the PDF from electron

diffraction (ePDF) presents itself as an optimal possibility to characterize nanoparticles as the strong electron matter interaction enables the acquiring of diffraction patterns for a known ensemble of nanoparticles, i.e. TEM equipment can collect diffraction by a precise nanoparticle region matching images and elemental composition analysis (EELS and EDS) with ePDF analysis. In this work, CdSe QDs were synthesized using cadmium oxide (CdO), selenium (Se), trioctylphosphonine, oleic acid (OA), oleylamine (OAm), 1,2-hexadecanodiol (HDD) and 1-octadecene as solvent. CdO was added to a three-neck round-bottom flask with OA and solvent. This mixture was heated to 100 °C (10 °C min^{-1}), and kept under a vacuum for 30 minutes, and then heated to 200 °C (10 °C min^{-1}) under a N_2 atmosphere, until the solution becomes translucent. The system was cooled to 100 °C, after that, HDD and OAm were added. The reaction was kept under a vacuum for 30 minutes. Subsequently, the reaction medium was heated at 300 °C (10 °C min^{-1}), under a N_2 atmosphere, and the Se precursor was injected. After injection, instantaneous formation of CdSe was observed and 30 minutes until the temperature began to drop spontaneously. CdSe QDs from 1.9 nm to 4.0 nm were synthesized by modifying the above process and changing precursors/ligands ratio, reaction time, and temperature. Then, using a holey carbon TEM grid a self-sustained QDs membrane was deposited in the TEM grid and the total electron scattering pattern was acquired in a Cs-corrected TEM (Titan Themis). Then, a modified code of eRDF Analyzer software was used to calculate the structure factor $S(Q)$ by normalizing the intensity scattering profile $I(Q)$ with the expected atomic scattering factors. The Reduced ePDF $G(r)$ was obtained by the Fourier Transform of $S(Q)$. Simulated $I(Q)$, $S(Q)$, and $G(r)$ for spherical z-CdSe (zinc blend, cubic structure) nanoparticles were introduced in the eRDF code to guide the data treatment and extraction of the final $G(r)$. The optical properties of CdSe QDs with different sizes were compared with the obtained crystallite size from ePDF $G(r)$ structural refinement using PDFGui software. We have seen that $G(r)$ results lead to smaller crystallite size compared to TEM morphological diameter and the size obtained from the position of the first excitonic peak. The presence of stacking faults is directly related to the lower crystallographic size and the loss of long-range atomic ordering in CdSe QDs. Concluding, ePDF $G(r)$ showed to be a good crystallographic tool for semiconductor CdSe QDs analysis, demonstrating the technique can be used to analyze the atomic structure of small nanoparticles.

NM05.07.20
A Comprehensive Study of Thiolation on Bare Gold Nanoparticles Produced by Laser Ablation in Liquids Jean Y. Tovar Sanchez[1], Maria B. De la Mora Mojica[2], Tupak García-Fernández[3] and Mayo Villagrán-Muniz[1]; [1]Instituto de Ciencias Aplicadas y Tecnología, Universidad Nacional Autónoma de México, Mexico; [2]CONACyT Fellow-ICAT, Universidad Nacional Autónoma de México, Mexico; [3]Universidad Autónoma de la Ciudad de México, Mexico

Gold nanoparticles (Au NPs) have several applications in optoelectronics, catalysis, biosensing, probing and medical therapy. The latter applications require an adequate coupling between the NP and the analyte to optimize its performance: a functionalization. To carry out the functionalization of Au NPs, one of the most used functional groups are thiols, in which functionalization is assumed through the chemical affinity between gold and sulfur. However, the efficiency of this thiolation depends on the properties of the Au NPs surface and the synthesis method. Most of the scientific research oriented to understand and optimize functionalization by different compounds that include thiols is focused on Au NPs obtained by chemical or biological methods, commonly capped with surfactants or in presence of other residuals from the synthesis. This implies another interaction of a layer surrounding the Au NPs with the thiolate compound. Here we study the thiolation mechanism and its consequences in bare Au NPs obtained by laser ablation in liquids (LAL). LAL is a green technique that allow us to obtain Au NPs with high purity. Since the Au NPs surface is not capped, this system let us study the direct interaction between the surface of Au NPs and thiolate compounds, as well as the influence of the surrounding media.
Au NPs thiolated with mercaptopropionic acid at different concentrations were studied by UV-vis-NIR absorbance, Dynamic Light Scattering spectroscopy, Zeta Potential, X-ray Photoelectron Spectroscopy and Transmission Electron Microscopy. The influence of the thiolation in the stability of the colloids is also addressed. A red shift in the absorption band is in general is observed due to the presence of thiols. We observed that the Au NPs obtained by LAL are more sensitive to smaller amounts of thiols than their counterparts obtained by chemical methods. Also, we propose a fast and effective method based on Ellman colorimetric assay to optimize the amount of thiol used for functionalization for AuNPs obtained by LAL.

Organosilane-Based Control Over Chemical and Electronic State on 1D Antase-Like Quat-Derived Nanomaterials Julia Martin[1], Rebecca Ramthun[1], Michelle Frasch[1], Erika Colin-Ulloa[1], Hussein Badr[2], Michel W. Barsoum[2], Lyubov Titova[1] and Ronald L. Grimm[1]; [1]Worcester Polytechnic Institute, United States; [2]Drexel University, United States

Recently discovered quaternary-derived nanomaterials (QDNs) possess a highly anisotropic 1D anatase-like (1DA) structure. While they demonstrate high oxidative stability and catalytic properties, little information exists on interfacial chemistry and electronic properties. We synthesized titanium-based QDNs and utilized ultraviolet photoelectron spectroscopy (UPS) to quantify valence band and Fermi energies as a function of surface treatments. Treatments included rinsing in LiCl as well as organosilane-based derivitization to change local electron density based on the inclusion of electron-withdrawing or electron-donating organic groups. UP spectra reveal moderate n-type doping as well as up to 1 eV shifts in band-edge positioning based on interfacial dipoles resulting from organosilane attachment. We discuss the results in the context of electromagnetic shielding, chemical sensing, catalytic, and photocatalytic applications.

NM05.07.22
Photothermal Study and Stability of Gold Nanoparticles with Different Morphology María F. Amézaga González and Perla E. García Casillas; UACJ, Mexico

Over recent years, some research utilizing gold nanoparticles physicochemical properties for photothermal applications has been conducted and published. The objective of this research is to obtain different morphologies of gold nanoparticles (sphere, roller, and star) to study and compare the colloidal stability and photothermal properties depending on the pH of each nanostructure by activating its resonance plasmon externally with a laser. The three morphologies of gold nanoparticles were synthesized by using and modifying the Turkevich method, the spheres were coated with the polymer polyethylene glycol (PEG) with the help of fluorescein (Fl). The characterization techniques that were used are: 1) Scanning electron microscopy (SEM) that was extracted to characterize the morphology and size of the nanostructures obtained. To obtain a better view of the nanoparticles and their diffraction pattern, it was necessary to use 2) transmission electron microscopy (TEM). 3) Ultraviolet-visible spectroscopy (UV-Vis) allowed obtaining the characteristic absorption spectrum of each gold nanostructure. 4) In Fourier transform infrared spectroscopy (FT-IR), the interactions of the PEG functional groups with the gold nanospheres were observed. Finally, the colloidal stability index (TSI) was evaluated by varying the pH of the regular medium (7) with PBS 1X (pH 7.2 and 7.4) and the photothermal properties were determined with the help of a laser (535 nm) and post- thermal properties of each of the gold nanostructures and the different media (pH). It is important to point out that, adding the polymer polyethylene glycol (PEG) and fluorescein to the gold nanospheres (AuNPs-Fl-PEG), helped to potentiate their colloidal stability at different pH (7.2 and 7.4), being the complex with the TSI more stable in 48 hours. It will also be developed that gold nanorods (AuNRs) are the best option for thermal applications. In closing that the morphology and coating of gold nanoparticles with PEG influence their colloidal stability and their photothermal properties (plasmon resonance) as a function of pH when stimulated with a laser (523 nm).

NM05.07.23
Synergistic Effect Between Single Au Atoms and Tensile-Strained Pd for Higly Efficient Electroreduction of CO_2 to Formate Jinsol Bok[1,2] and Taeghwan Hyeon[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

Among various metal catalysts, Pd is one of the most effective catalysts for the electrochemical reduction of CO2 to formate, a valuable liquid product, at low overpotential. However, Pd metal has intrinsically high CO affinity which makes the metal surface vulnerable to CO poisoning, resulting in rapid deactivation toward CO2 electroreduction. Herein, we design novel catalyst utilizing the interaction between metals and metal−organic frameworks. Atomically dispersed Au on tensile-strained Pd nanoparticles shows significantly improved formate production activity, selectivity, and stability with high CO poisoning tolerance. Moreover, we found that the tensile strain stabilizes all reaction intermediates on the Pd surface, whereas the atomically dispersed Au selectively destabilizes CO* without affecting other adsorbates. As a result, the conventional COOH* versus CO* scaling relation is broken, and our catalyst exhibits about 30-fold enhancement in partial current density and mass activity toward electrocatalytic formate production with over 99% faradaic efficiency, compared to Pd/C at −0.25 V versus RHE.

NM05.07.24
Microfluidics-Assisted Synthesis of Hyper-Branched Nanocrystals with Multi-Steps for the Electrochemical CO_2 Reduction Minki Jun and Kwangyeol Lee; Korea University, Korea (the Republic of)

Flow chemistry, based on microfluidics, has been considered a powerful synthetic method due to precise reaction control, high surface area per reactor volume, and high reproducibility. Also, extremely fast mixing time in flow chemistry can generate unstable reaction intermediates in high concentrations. Herein, we synthesized the hyper-branched hierarchical Cu_2O nanocrystals with numerous steps (h-Cu_2O ONSs) by microfluidics-based ultra-fast mixing of precursor solutions to obtain a very high concentration of CuOH intermediates. Furthermore, computational fluid dynamics (CFD) simulation and analysis were performed to understand the effect of mixing in a flow microreactor on the synthesis of h-Cu_2O ONSs. The prepared h-Cu_2O ONSs exhibited excellent selectivity toward C_2 products during electrochemical CO_2 reduction because of the numerous heterointerfaces between Cu_2O and Cu phases derived from rapid surface reconstruction at stepped structures.

NM05.07.25
Composite Cellulose Nanofiber-Alginate Biotemplated Cobalt Aerogels for Energy Storage and Catalytic Electrodes Felita W. Zhang[1], Paul Trackey[1], Alexa Zammit[1], Galen Mandes[1], Edward M. Tang[1], Rosemary L. Calabro[1,2], Enoch A. Nagelli[1], Stephen F. Bartolucci[2], Joshua A. Maurer[2] and John Burpo[1]; [1]United States Military Academy, United States; [2]U.S. Army Combat Capabilities Development Command-Armaments Center, United States

Biotemplated transition metal aerogels enable tunable porous composite materials to control metal/metal oxide functionalization, conductivity, pore structure, electrolyte mass transport, mechanical strength, specific surface area, and magneto-responsiveness. To demonstrate a solution-based synthesis method to develop cobalt and cobalt oxide aerogels for energy storage and catalytic electrodes, carboxymethyl cellulose nanofibers (CNF) and alginate were mixed to form a composite biopolymer hydrogel that served as a template for cobalt nanoparticle formation via chemical reduction of cobalt salt solutions. The CNF-alginate mixed to form a physically entangled, interpenetrating hydrogel requiring no covalent chemical crosslinking. The hydrogels combine the properties of both biopolymers to exhibit stiffness, flexibility, ease of gel formation, as well as abundant carboxyl groups that bind metal ions to facilitate biotemplating. CNF-alginate hydrogels at different biopolymer weight percents were equilibrated in $CoCl_2$ salt solutions, chemically reduced with $NaBH_4$, rinsed, solvent exchanged in ethanol, and supercritical dried with CO_2. The resulting aerogels were pyrolyzed in N_2 gas and thermally annealed in air to form either Co or Co_3O_4 porous composite electrodes. Aerogels were characterized using scanning electron microscopy, energy dispersive x-ray spectroscopy, x-ray diffractometry, thermogravimetric analysis, nitrogen gas adsorption-desorption with Brunauer-Emmett-Teller surface area analysis, vibrating-sample magnetometry, magnetic force microscopy, nanoindentation, and force-extension modulus testing. Electrochemical performance of cobalt catalysis of the oxygen reduction reaction and Co_3O_4 supercapacitance was determined with electrochemical impedance spectroscopy, cyclic voltammetry, and linear sweep voltammetry. The rapidly synthesized, low cost composite hydrogel solution-based transition metal synthesis approach is envisioned as an approach for a wide range of non-precious metal porous catalytic electrodes to address energy storage, catalysis, and sensing applications.

NM05.07.26
Synthesis of Single-Phase Spinel High Entropy Oxides Nanoparticles with Electrospinning Xiao Han, Vijayaraghavan Sankaranarayanan Nair, Lin Li and Feng Yan; The University of Alabama, United States

High entropy oxides nanoparticles (HEO NPs) exhibit excellent performance in catalysis, energy storage, magnets, and biosensors due to their unique entropy stabilization mechanisms. However, the synthesis of HEO NPs containing five or more immiscible elements with a single-phase structure is still challenging. In this work, we present a new synthesis method to process single-phase HEO NPs including up to eight metal elements by electrospinning and low-temperature annealing in air condition. To mix the incorporated elements uniformly, the nitrate salts are used as precursors in the solution, which is applied to the electrospinning to generate nanofibers. The cations are enveloped in the nanofibers during the electrospinning process. With the following annealing in air at a low temperature, the single-phase spinel HEO NPs can be obtained. The single-phase spinel structure is confirmed by X-ray diffraction (XRD), selected area electron diffraction (SAED), and high-resolution transmission electron microscopy (HRTEM). X-ray photoelectron spectroscopy (XPS) provides the analysis of the oxidation state of the individual elements. In addition, the synthesized HEO NPs exhibit magnetic properties with the highest saturation magnetization with 9.588 emu/g and the highest coercivity with 147.175 Oe.

NM05.07.27
Effective Separation of Inorganic Nanoparticles via a Modified Centrifugation Model Edan Marcial, Silas Wieland, Hannah Brodsky, Krista Dizon and Yiliang Luan; Binghamton University, The State University of New York, United States

Despite the broad use of centrifugation in materials research, the speed and time parameters for the centrifugation of dense nanoparticles (NPs) have been left to be determined by individual labs. Various models have been developed to identify the parameters for separation but have yet to be verified experimentally. Herein, this work presents a modified model for the effective centrifugation of inorganic NPs. To identify the required centrifuge speed and time for effective separation of NPs in nonpolar colloidal suspensions, a model relating the time for centrifugation to the NP's distance from the centrifuge's axis of rotation was derived. This model was first verified by separating half of a perovskite quantum dots raw suspension without agglomeration under the predicted conditions generated from the model. The results were confirmed using UV-Vis and photoluminescence spectroscopy. The effectiveness of the derived model for separating different NPs of varying sizes and densities will also be reported. This research gives a more accessible way to use centrifuges in all labs to separate NPs effectively.

NM05.07.28

Combined Application of Scherrer and Guinier Formulas for Proper X-Ray Determination of Size and Size Distribution in Systems of Monocrystalline Nanoparticles—Case Study CeO_2 Nanocubes Adriana Valério[1], Fabiane J. Trindade[2], Rafaela F. Penacchio[1], Maurício B. Estradiote[1], Cristiane B. Rodella[3], André S. Ferlauto[2], Stefan Kycia[4] and Sergio L. Morelhao[1]; [1]University of São Paulo, Brazil; [2]Federal University of ABC, Brazil; [3]Brazilian Synchrotron Light Laboratory (LNLS/CNPEM), Brazil; [4]University of Guelph, Canada

X-ray diffraction and scattering phenomena are widely used as analytical tools in the optimization and control of nanomaterial synthesizing processes. In systems of monocrystalline nanoparticles with size distribution, the physical meaning of size values as determined by using X-ray methods is still controversial. To answer such fundamental issue, a series of virtual nanoparticles with sizes ranging from 1nm to 90nm were generated and their exact scattering power computed via pair distance distribution function. Calculated X-ray diffraction and scattering patterns from systems of virtual nanoparticles demonstrated that diffraction and scattering phenomena obtain matching results for monodisperse sizes. When a finite size distribution is introduced, the two methods produce differing results. The root of the problem is the different weighting by which each method interpret the size distribution. Once understood, the deviation in resulting size values from scattering and diffraction can be used as input to a simple formula that provides the size dispersion around the system most probable size value. To illustrate this effect and the data analysis procedure, X-ray diffraction and small-angle scattering experiments were applied to solve the size distributions in a series of samples of cubic ceria nanoparticles, revealing systematic changes in the size distribution as a function of synthesis parameters.

NM05.07.29
Size-Controlled Synthesis of Very High Aspect Ratio $Cu_{2-x}Se_y$ Nanosheets Esra B. Karatas Ozkaraca, Rana Ucuncuoglu, Abdelhakim Elmhamdi, Elif S. Gur, Ceren Egemen and Mahmut Aksit; Gebze Technical University, Turkey

Unprecedentedly high aspect ratio nanosheets of $Cu_{2-x}Se_y$ are synthesized by a novel technique based on the modification of previously known co-precipitation methods by hot injection of the Cu precursor. The novel surfactant-free method can produce $Cu_{2-x}Se_y$ nanosheets with up to > 20 µm lateral length and ~10 nm average thickness, resulting in a very high aspect ratio of more than 1000:1. The nanosheet size and aspect ratio strongly vary with Cu:Se atomic ratio in the reactor. Powder X-Ray Diffraction (XRD) patterns obtained from the nanosheet powders have indicated different crystalline phases and/or dramatically different peak intensities depending on the temperature and volumetric ratio of the hot injected Cu precursor solution, whereas such alterations in the hot injection process do not cause noticeable variation in nanosheet size and morphology according to Scanning Electron Microscope (SEM) images. Time-dependent crystal phase and size evolutions of the nanosheets during the reaction are studied by ex-situ XRD and SEM characterization. Low-temperature thermoelectric measurements are performed on rectangular pellets prepared from the produced nanosheet powders. The photocatalytic performance of the synthesized $Cu_{2-x}Se_y$ nanosheets is also evaluated by observing the time-dependent degradation of methylene blue under halogen light in solutions containing known concentrations of the $Cu_{2-x}Se_y$ nanosheets.

NM05.07.30
Controlled Synthesis of Lead and Tin Halide Perovskite Nanocrystals Yasuhiro Tachibana[1,2]; [1]RMIT University, Australia; [2]Osaka University, Japan

Low dimensional colloidal halide perovskite nanocrystals from zero- to two-dimension have recently received extensive attention because of their facile synthesis and the outstanding size-tunable optoelectronic properties. However, iodide-based perovskite nanocrystals that are considered as a light harvester generally show lower photoluminescence quantum yield and poorer stability compared to those of bromide- or chloride-based counterparts. Here, we propose a new synthetic route, namely a two-step injection process, to successfully control $CH_3NH_3PbI_3$ ($MAPbI_3$) nanostructures with a high photoluminescence quantum yield of nearly 100%. Influence of three parameters, (1) the ligand concentration ratio, (2) reaction temperature and (3) precursor ratio, on perovskite morphology and optical property, were systematically investigated. We have found that the ligand concentration ratio drastically changes the morphology and photoluminescence quantum yield/lifetime. The nanoplatelets formed in non-polar solvent (diphenyl ether) show a good stability over 30 days. The formation mechanism of $MAPbI_3$ NCs is proposed by combining the experimental results with a saturation kinetics model.

Lead-free Sn(II) based, $CsSn_2Br_5$, perovskite nanocubes were synthesized using a modified hot-injection method by tuning the injection temperature and reaction conditions. The formation of Sn(IV) based, Cs_2SnBr_6, perovskite nanocrystals (PNCs) from $CsSn_2Br_5$ perovskite nanocubes was observed. X-ray diffraction measurements revealed that oxygen or water molecules in air gradually react with $CsSn_2Br_5$ perovskite nanocubes to form Cs_2SnBr_6 NCs. The stability of Cs_2SnBr_6 NCs was monitored by time-dependent absorption measurements. Both oxygen and water molecules react with the Cs_2SnBr_6 NCs to degrade, however water molecules appears largely to react with the NCs. The stability has been improved by dispersing the Cs_2SnBr_6 NCs in degassed anhydrous solvent.[1]

This work was partly supported by JSPS KAKENHI Grant (19H02813) and (22H02182), and the Collaborative Research Program of Institute for Chemical Research, Kyoto University (grant number 2021-78 and 2022-99), Japan. We would like to acknowledge supports from the Australia-Japan Foundation for the collaborative project between RMIT University and Kyoto University. We also acknowledge supports from ARC DP fund (DP180103815) and ARC LIEF fund (LE200100051), Australia, and Forefront Research Center, Faculty of Science at Osaka University.

Engineering ZnO Nanoparticles as a Substrate for Surface-Enhanced Raman Scattering Samuel O. Adesoye and Kristen Dellinger; North carolina A & T UNIVERSITY, United States

Surface-enhanced Raman spectroscopy (SERS) is an emerging technology that has the potential to become a clinical diagnostic tool; however, there are some shortcomings that limit its widespread use. One such limitation is the substrate that is used to enhance the signal. The commonly used plasmonic substrates like gold and silver often result in aggregation, instability, and off-target effects. Semiconductor nanostructures, on the other hand, could overcome these problems; however, they provide a low signal enhancement. By engineering these semiconductor nanostructures, it is possible to increase their signal enhancement. To achieve this goal, we are developing innovative ways to improve Raman signal enhancement in metal oxides, which include tuning the band gap by substitutional doping and exploring coating with plasmonic materials to create hybrid SERS substrates. In this work, zinc oxide (ZnO) was synthesized by using a co-precipitation method and was doped with magnesium (Mg) with concentrations ranging from 2-10%. To characterize these substrates, the morphology and size distribution of the nanoparticles were obtained using the AURIGA field emission scanning electron microscope (FE-SEM) and dynamic light scattering. X-ray photoelectron spectroscopy (XPS) was used to determine the elemental composition. Optical properties were obtained with a UV-Vis spectrophotometer, while iRaman Prime portable Raman spectrometer (B&W Tek, Newark, DE) was used to acquire the Raman signal. The absorption edge of the Mg-doped ZnO nanoparticles was red-shifted compared to pure ZnO nanoparticles, and the band gap estimated using Tauc's plot also showed a decrease with increasing Mg doping. When 5,5'-dithiobis(2-nitrobenzoic acid) (DTNB) molecule was observed with the various nanoparticle substrates, an enhanced signal was observed for the doped substrates with the 2% doping giving the highest peak. Overall, we

anticipate this work to serve as a platform for improving the use of SERS substrates in molecular sensing and bio-detection applications.

NM05.07.35
Synthesis of Multilayered Fe_3O_4@SnO_2@C Nanocomposites via Amino-Functionalization Gye Sek An, Jae Uk Hur, Jae Rok Shin, Jin Soon Han, Ji Hun Jeong, Su Young Kang, Jong Hun Kim, Jee In Kim and Jiwan Kim; Kyonggi University, Korea (the Republic of)

Nanocomposites composed of different materials can realize original physicochemical and electrical properties that will be fundamental for future technologies. Magnetite (Fe_3O_4) nanoparticles, with unique magnetic and electrochemical properties, have attracted significant attention in many fields, including recording material, bio, electromagnetic interference shielding, and secondary batteries. In particular, tin dioxide (SnO_2), an n-type semiconductor, has a high synergistic effect with Fe_3O_4, so many researchers have tried to combine these two materials. Nevertheless, composite materials composed of only oxide have low electrical conductivity and poor performance, so the help of high-conductivity materials is sometimes required. In this study, a systematic method for fabricating multilayered Fe_3O_4@SnO_2@C nanocomposites via surface treatment/modification and carbonization was proposed. Silane/polymer-based amino-functionalization has been introduced to coat carbon. Also, the carbon layer was formed on the surface of Fe_3O_4@SnO_2 nanoparticles through the dehydration of the carbon precursor using sulfuric acid at atmospheric pressure. Finally, the synthesized nanocomposite's structure, surface properties, dispersibility, and magnetism were evaluated.

NM05.07.37
***In Situ* Formation of PbTe-PbS Core-Shell Nanocrystal 3D Superlattices** Seungho Lee, Mariano Calcabrini, Sharona Horta, Tobias Kleinhanns, Daniel Balazs and Maria Ibáñez; Institute of Science and Technology Austria (ISTA), Austria

Nanocrystals can be arranged into long-range order structures. Common strategies for inducing nanocrystal self-assembly are controlled solvent evaporation and colloid destabilization with anti-solvents. In both cases, purifying the particles and adding controlled amounts of ligands are necessary before inducing the self-assembly process.
Here, we show a method that allows the simultaneous formation of PbTe-PbS core-shell nanocrystals and their assembly into three-dimensional superlattices, all in-situ, during the nanocrystal synthesis. We first provide evidence of the shell formation through powder X-ray diffraction and high-resolution transmission electron microscopy. Additionally, the ordering of the core-shell nanocrystals is observed by in situ small-angle x-ray scattering (SAXS) measurements. We further confirmed that the size of the core PbTe nanocrystals play a pivotal role in the 3D superlattice formation. The methodology present here is simple and may be extended to other material systems.

NM05.07.40
Bioinspired Synthesis of Crystalline Nanomaterials Through Peptoid-Based Approaches Chun-Long Chen; Pacific Northwest National Laboratory, United States

In nature, biominerals (e.g. bones and teeth) are excellent examples of hierarchical materials whose formation and functions are controlled over multiple length scales by high information content biomacromolecules. Inspired by nature, many biomimetic approaches have been developed for the design and synthesis of crystalline nanomaterials. These approaches are attractive because they generate complex, functional materials under mild aqueous synthetic conditions. Despite the advances in developing new approaches for bioinspired materials synthesis, the rules of designing sequence-defined synthetic polymers that lead to the predictable synthesis of crystalline nanomaterials remain unclear.

As one of the most advanced classes of sequence-defined protein-mimetics, peptoids offer tremendous opportunities for bioinspired materials synthesis because tuning peptoid-peptoid and peptoid-particle interactions can be done solely by varying side-chain chemistry. In this presentation, two peptoid-based approaches will be discussed for controlled synthesis of crystalline nanomaterials. ***The first*** involves the design and synthesis of surfacant-like peptoids for controlling formation and morphogenesis of inorganic nanomaterials. ***The second*** approach exploits self-assembling peptoids for controlled synthesis of hierarchically structured hybrid materials. A combination of *in situ* imaging (e.g. *in situ* TEM) and molecular simulations are used to elucidate the important roles of particle attachments during the peptoid-directed formation of crystalline nanomaterials.

Ultrasonic Spray Deposited Co-MOF for Wearable Supercapacitors Oyku Cetin, Tufan Bolukbasi, Mete Batuhan Durukan, Gozde Ozturk and Husnu E. Unalan; Middle East Technical University, Turkey

Supercapacitors are gaining more attention for wearable electronics because of their key properties such as flexibility, reversibility in continuous cycling, high power output. The textile-based flexible supercapacitors are potentially key devices for wearable electronics with their mechanical properties and charge storage capabilities. Herein, high-performance all-solid-state wearable asymmetric supercapacitors (ASCs) are prepared based on ultrasonic spray deposited cobalt metal-organic frameworks (Co-MOF) and iron sulphide/graphene nanocomposites (Fe_xS_y-G NCs) on carbon textiles as the positive and negative electrodes, respectively. Owing to the obtained unique structure of Co-MOF, high reversibility coupled with high specific capacitance of 396 $mF.cm^{-2}$ is achieved. Additional electrochemical data with assemble strategies for long-lasting devices will be correlatively presented.

This work was supported by The Scientific and Technological Research Council of Turkey (TUBITAK) under Grant No:119N344.

NM05.07.42
Gear-Meshing-Type Colloidal Crystallization of Concave Polyhedra Wenjie Zhou, Yuanwei Li and Chad A. Mirkin; Northwestern University, United States

Colloidal crystallization of nanoscale building blocks represents chemists' attempt to mimic, modify, and ultimately recreate highly ordered structures based on what is found in nature. Despite the rising of colloidal crystals over the past decade, the majority of symmetries among which are cubic, tetragonal, or hexagonal. Constrained by the poor understanding of the structure-unit relationship, deliberately constructing colloidal superlattices with low symmetry, especially from highly symmetrical building blocks, still remains an outstanding challenge. Leveraging the DNA-mediated assembly of concave polyhedral nanocrystals, we report a series of rational symmetry reductions through steric hindrance engineering, the *gear-meshing* type colloidal crystallization. Through programming the DNA interactions as well as ligand occupation ratio, we show four types of gear-meshing mode, identified and investigated from in situ and ex situ experiments. This study opens up new opportunities for synthesizing plasmonic metamaterials with close arrangements and low symmetries.

NM05.07.43
UiO-66 and Silane-Based Capping Molecule Have Covalent Attachment Abigail Berube, Nathaniel Keyes, Rebecca Dawley, Shawn Burdette and Ronald L. Grimm; Worcester Polytechnic Institute, United States

An emerging group of nanocontainers, metal-organic frameworks (MOFs), have highly stable and porous structures, thus making them excellent for trap and release of other molecules. Even though this structure is highly favorable, not much is known about their surface chemistry. We have synthesized a zirconium oxide-based MOF verified through powder x-ray diffraction (pXRD) and x-ray photoelectron spectroscopy (XPS) to quantify the surface of the structures to understand what can be placed on or used to 'cap' the porous structures. Silane-based molecules in solution were used to attempt to find a successful monolayered cap for the MOF, verified through XPS sputtering. Temperature programmed desorption (TPD) was used to understand the strength of the bonds between MOF and cap to further understand the surface of the MOF.

NM05.07.44
Microwave Synthesis of Single-Phase Nanoparticles Made of Multiprincipal Element Alloys Siyu Wu[1], Yuzi Liu[2], Yang Ren[2] and Yugang Sun[1]; [1]Temple University, United States; [2]Argonne National Laboratory, United States

Metal nanoparticles of multi-principal element alloys (MPEA) with a single crystalline phase have been synthesized by flash heating/cooling of nanosized metals encapsulated in micelle vesicles dispersed in an oil phase (e.g., cyclohexane). Flash heating is realized by selective absorption of a microwave pulse in metals to rapidly heat metals into uniform melts. The oil phase barely absorbs microwave and maintains the low temperature, which can rapidly quench the high-temperature metal melts to enable the flash cooling process. The precursor ions of four metals, including Au, Pt, Pd, and Cu, can be simultaneously reduced by hydrazine in the aqueous solution encapsulated in the micelle vesicles. The resulting metals efficiently absorb microwave energy to locally reach a temperature high enough to melt themselves into a uniform mixture. The duration of microwave pulse is crucial to ensure the reduced metals mix uniformly, while the temperature of oil phase is still low to rapidly quench the metals and freeze the single-phase crystalline lattices in alloy nanoparticles. The microwave-enabled flash heating/cooling provides a new method to synthesize single-phase MPEA nanoparticles of many metal combinations when the appropriate water-in-oil micelle systems and the appropriate reduction reactions of metal precursors are available.

NM05.07.45
Scalable, Inexpensive, One-Pot, Facile Synthesis of Crystalline Two-Dimensional Birnessite Flakes Hussein Badr and Michel W. Barsoum; Drexel University, United States

Synthesis of two-dimensional (2D) materials that is readily scalable, cost-effective, and eco-friendly is important from both scientific and industrial viewpoints. Currently, these 2D materials are synthesized either by selective etching of relatively expensive layered solids, viz. using a top-down approach, or by autoclaving metal salts/organic compounds. Herein, we describe a near-ambient, one-pot, inexpensive, scalable pathway to convert—through a bottom-up approach—5 different water-insoluble Mn-bearing precursors, viz. Mn3O4, Mn2O3, MnB, Mn5SiB2, and Mn2AlB2, into birnessite-based 2D flakes that, in some cases, are remarkably crystalline. The precursor powders are immersed in 25 wt % tetramethylammonium hydroxide aqueous solutions at 50°C to 80°C for 2 to 4 days. The structures, compositions, oxidation states, and morphologies of the synthesized flakes are determined using a battery of characterization techniques. The synthesized 2D sheets demonstrate reversible O2 electrocatalysis with activities comparable with those of a commercial Pt/C catalyst.

NM05.07.48
Synthesis of Copper (Hydro-) Oxide Modified Nanoceria and Electroanalytical Studies of Performance in a Peroxide Decomposition Reaction Craig J. Neal, Elayaraja Kolanthai, Yifei Fu, Chaimae El Ghazauoi, Samantha Stoltz and Sudipta Seal; University of Central Florida, United States

Cerium oxide has been a staple material within catalysis science and has found substantial use in biomedical applications in its nanoscale form. The utility of nanoscale cerium oxide (nanoceria) stems from its ability to undergo surface-mediated redox reactions at defect sites through inter-conversion between reduced (Ce^{3+}) and oxidized (Ce^{4+}) states. Often, ceria is used as a catalytic material or as an active substrate: undergoing redox reactions and donating/accepting oxygen via formation/destruction of oxygen vacancies at the material (near-) surface. In the presented study, nanoceria is synthesized through a simple alkaline forced hydrolysis reaction in presence of 20 mol% aqueous copper nitrate, resulting in formation of copper oxide/hydroxide surface phases on nanoceria. These surface phases are found to be redox-active: producing substantial (catalase) enzyme-mimetic activity and a consequent redox cycling of $Cu(OH)/Cu(OH)_2$. Enzyme-mimetic activity is demonstrated in chemical assay and reflected in results from UV-Vis spectrophotometry measurements. X-ray photoelectron studies confirm presence of these active hydroxide phases, while electroanalytical voltammetry studies provide insight into the phases' stability in presence of hydrogen peroxide. Tafel analysis and electrochemical impedance spectroscopy were performed to elucidate the observed electron transfer processes. Peroxide decomposition reactions suggest material utility as a therapeutic nanozyme for potential biomedical applications through the scavenging of pathogenic reactive oxygen species.

SESSION NM05.08: Nanoscale Chirality
Session Chairs: Gil Markovich and Anastasia Visheratina
Wednesday Morning, November 30, 2022
Hynes, Level 2, Room 202

8:30 AM *NM05.08.01
Chirality and Complexity of Photonically Active Nanostructures Nicholas A. Kotov; University of Michigan, United States

Nanoscale chirality is a rapidly emerging field in science and engineering. The early observation of strong circular dichroism for individual nanoparticles (NPs) and their assemblies have developed into a rapidly expanding research area on chiral inorganic nanostructures. They encompass a large family of mirror-asymmetric constructs from metals, semiconductors, ceramics, and nanocarbons with multiple chiral geometries with characteristic scales from Ångströms to microns. Versatility in, scales, dimensions and polarizability of the inorganic materials enables their multiscale engineering to attain a broad range of optical and chemical properties. These capabilities as chiral materials enabled their fast technological translation for biosensing and optoelectronics, which, in turn, opened new venues for scientific inquiry into the unifying role chirality at the interface of materials science, biology, chemistry, and physics.
Some of the latest directions in this field is understanding the fascinating relationships between multiscale chirality and structural/functional complexity of biomimetic nanomaterials forming from the spontaneous hierarchical ordering of inorganic building blocks over multiple scales. Empirical observations of complex nanoassemblies are abundant, but physicochemical mechanisms leading to their geometrical complexity remain puzzling, especially for non-uniformly sized components. These mechanisms are discussed in this talk taking an example of hierarchically organized particles with twisted spikes and other morphologies from polydisperse Au-Cys nanoplatelets [1]. The complexity of these supraparticles is higher than biological counterparts or other

complex particles as enumerated by graph theory (GT). Complexity Index (*CI*) and other GT parameters are applied to a variety of different nanoscale materials to assess their structural organization. As the result of this analysis, we determined that intricate organization Au-Cys supraparticles emerges from competing chirality-dependent assembly restrictions that render assembly pathways primarily dependent on nanoparticle symmetry rather than size. These findings open a pathway to a large family of colloids with complex architectures and unusual chiroptical and chemical properties. The design principles elaborated for nanoplatelets have been extended to engineering of other complex nanoassemblies. They include polarization-based drug discovery platforms for Alzheimer syndrome,[2] materials for chiral photonics,[3] biomimetic composites for energy and robotics , CO_2-dispersable catalysis,[4] chiral antiviral vaccines[5] and pharmaceutical quality control [6].

Auger Recombination in Colloidal, Two-Dimensional Semiconductor Nanocrystals Alexandra Brumberg[1], John P. Philbin[2], Benjamin Diroll[3], Eran Rabani[2] and Richard Schaller[1,3]; [1]Northwestern University, United States; [2]University of California, Berkeley, United States; [3]Argonne National Laboratory, United States

Auger recombination (AR), a nonradiative recombination process in which an electron and a hole recombine and transfer its excess energy to a third carrier, negatively impacts the efficiencies of devices made from colloidal semiconductor nanocrystals (NCs) because of fast AR rates. Colloidal, two-dimensional semiconductor nanoplatelets (NPLs) offer a solution to the problem of fast AR rates in colloidal NCs while preserving other benefits of NCs such as band gap tunability and high photoluminescence efficiency. In NPLs, AR rates are reduced owing to quantum confinement in only one dimension with bulk-like lateral dimensions. However, the mix of quantum-confined and bulk-like dimensions in NPLs along the thickness and lateral axes, respectively, makes it difficult to predict their photophysical behaviors. I will discuss our investigations into two aspects of AR in two-dimensional NPLs: (1) the scaling of AR rates with NPL area and volume, and (2) the temperature dependence of AR rates.

1: Both zero- and one-dimensional NCs have been shown to follow a “universal volume scaling” relationship for AR rates as a function of volume. However, both experimental and theoretical efforts have yet to agree on the relationship between AR rate and NPL area and volume. We combine experiment with a new theoretical model to ultimately convey that AR rates scale with NPL area but not volume.

2: Conceptually, AR is expected to transition from temperature-dependent behavior in bulk semiconductors to temperature-independent behavior in QDs as a result of flattened band structure in the latter that facilitates satisfaction of linear momentum conservation. In NPLs, the expected behavior is unknown, and AR as a function of temperature has never been studied. We investigate the temperature dependence of biexciton lifetime and fluence-dependent emission in colloidal CdSe NPLs and compare the behavior to that observed with QDs. For NPLs, upon temperature reduction, biexciton lifetime surprisingly decreases and emission intensity increases nearly linearly with fluence rather than saturating, consistent with dominant radiative recombination rather than nonradiative AR. Notably, this suggests that NPLs differ fundamentally from isotropic NCs, and that AR cannot be assumed to be the dominant recombination mechanism for all NCs across all temperatures.

Morphological Growth Pathways of Peptide-Directed Chiral Gold Nanoparticles Sang Won Im, Dongsu Zhang, Young Min Kim and Ki Tae Nam; Seoul National University, Korea (the Republic of)

Chirality is a ubiquitous property of nature and can be transferred from organic molecules to inorganic crystals by enantiospecific interactions. A representative example is peptide-directed chiral morphology evolution on gold nanoparticle that exhibits chiroptical properties applicable to light polarization control, sensing, and metamaterials. The mechanism of chirality transfer has been revealed, whereby enantiospecific interactions between R/S high-Miller-index plane and L/D peptides breaks mirror symmetry inherent in FCC lattice and induce 432-symmetric geometry. However, understanding the complex morphogenesis starting from achiral seed to final helicoid morphology dependent on the peptide sequences and growth conditions remained a challenge. Here, we defined the growth pathways of helicoid nanoparticles based on both crystallographic analysis and computational modelling. The key of understanding morphological evolution is the relationship between surface Miller indices and morphological change, which appear as 2D trajectories on crystallographic stereographic projection. We discovered that the growth pathways of 432 helicoids determine the formation of high-Miller-index-enclosed intermediated morphologies, and thus are coupled with chiral morphology formation. Further, we confirmed and extended our finding by modelling the chirality evolution by cellular automata and learning the morphogenesis rule. This study provides a comprehensive understanding of chirality evolution on nanoparticles that can be further extended to functional chiral inorganic crystals.

9:30 AM NM05.08.04
Light-Induced Printing of Helical Arrays on Solid Substrates Ji-Young Kim, Connor McGlothin, Minjeong Cha, Zechariah Pfaffenberger, Emine Turali-Emre, Wonjin Choi, Julie S. Biteen and Nicholas A. Kotov; University of Michigan, United States

Chemical structures with helical geometries aligned perpendicularly to the substrate display unique optical, biosensing, catalytic, and mechanical properties but are difficult to produce. At the molecular scale, self-alignment of helices along the surface normal was accomplished for biopolymers with thiol anchors. However, the helical segments had to be pre-assembled and orientational defects were frequent. At the nanoscale, the difficulties are exacerbated because the out-of-plane alignment of nanoscale structures is associated with prohibitively high energy costs. Overcoming the unfavorable thermodynamics by light-guided formation of silver nanocrystallites, the stand-up arrays of homochiral helicoids are produced by illumination with circularly polarized light (CPL). The handedness of the silver helicoids and their polarization spectrum are controlled by the ellipticity and wavelength of the incident photons. CPL-induced printing of centimeter-scale metasurfaces with on-the-fly control of polarization effects was demonstrated using a programmable motorized stage. Substrate versatility and high efficiency of light-to-matter chirality transfer enable rapid engineering of metamaterials with chiral patterns for multiple technologies.

Liquid-Phase Synthesis of Functional Base-Metal Nanoparticles Andreas Reiß, Daniel Bartenbach, Lara-Pauline Faden, Sven Riegsinger and Claus Feldmann; Karlsruhe Institute of Technology, Germany

Nanoparticles of zerovalent transition metals, main-group metals and rare-earth metals can be used for a wide range of applications, including catalysis, hydrogen storage or high-energy materials. Moreover, base-metal nanoparticles can be utilized as highly-reactive starting materials to obtain novel metal compounds.[1,2] To apply base-metal nanoparticles, first of all, they must be made available with high quality and purity.
To this concern, we have established a naphthalenide-driven reduction of simple metal halides in THF, DME or pyridine, which we use to prepare nanoparticles of all transition metals, rare-earths and many main-group metals for the first time.[3-5] The reduction instantaneously results in the nucleation of small sized (1-3 nm) base-metal nanoparticles with narrow size distribution (±0.2 nm). The surfaces of the zerovalent metal nanoparticles are solely functionalised by the solvent (THF/DME) (so-called quasi-naked nanoparticles). Additional surfactants such as long-chained, high-molecular-weight amines or polymers are not needed. The obtained metal nanoparticles are stable in suspension under inert conditions but highly reactive when in contact with air or water. Therefore, they must be handled with great care under strict exclusion of air and moisture.[3-5]
Many of these base metal nanoparticles (e.g. Nb, Ta, rare earth) are now available for the first time. We will show the synthesis strategy, purification, and properties and application of the base-metal nanoparticles.[4,6,7]

Activated Elemental Se—A Viable Synthetic Precursor for a Variety of Targets Kirill Kovnir; Iowa State University, United States

Se-containing nanomaterials often synthesized from toxic and expensive organo-Se precursors. We are reporting a facile alternative utilizing elemental Se which is cheap and non-toxic. Elemental Se reagent has a drawback of low solubility and reactivity resulting in sluggish kinetics at low temperatures. A process of elemental Se activation was developed resulting in stable solution of multiple Se species confirmed with ^{77}Se NMR studies, including R-Se-Se-R and never detected before "naked" Se_2^{2-}. Dynamic equilibrium between the produced Se species allow to perform reactions at wide temperature ranges including room temperature. We have demonstrated the applicability of such activated Se for different targets ranging from few nm CdSe nanocrystals to large 100 mm sized crystals of superconducting FeSe.

11:00 AM NM05.09.05
Engineering of Sub-Nanometer Oxide Shell on Gold Nanoparticles Jean-Marc von Mentlen[1], Jasper Clarysse[1], Annina Moser[1], Dhananjeya Kumaar[1], Olesya Yarema[1], Takumi Sannomiya[2], Maksym Yarema[1] and Vanessa Wood[1]; [1]ETH Zürich, Switzerland; [2]Tokyo Institute of Technology, Japan

Metal oxide shells fully or partially covering gold nanoparticles are intensively studied for a wide range of applications in the fields of catalysis and plasmonics. When carefully designed, these coatings enhance the functionality and stability of the nanoparticles. Yet, facile and well controlled fabrication methods of thin metal oxide layers on metal nanoparticles are still lacking. Currently used methods struggle to produce uniform layers below 1 nm. In this work, we show an easy fabrication process to reliably engineer uniform Ga_2O_3 shells on Au nanoparticles with a thickness ranging from sub- to several monolayers. These thin shells are obtained by a liquid-phase chemical oxidation of alloyed Au-Ga nanoparticles. We demonstrate how the plasmonic properties of the nanoparticles can be used to understand the reaction process and quantitatively monitor the Ga_2O_3 shell growth. Finally, we show as a practical application that the Ga_2O_3 coating prevents the sintering of the Au nanoparticles, ensuring thermal stability up to at least 250°C. Dealloying of bimetallic nanoparticles by in-solution oxidation is a promising approach to obtain controlled metal-metal oxide core-shell nanoparticles.

11:15 AM NM05.09.06
Formation of 3D Magnetic Nanowire Arrays by Cooperative Lateral Growth Fei Chen, Zihao Yang, Ruwen Peng and Mu Wang; Nanjing University, China

Nanowires typically grow along their longitudinal axis, and the long-range order among wires sustains only when a template exists. Here, we report an unprecedented electrochemical growth of ordered metallic nanowire arrays from an ultrathin electrolyte layer, which is achieved by solidifying the electrolyte solution below the freezing temperature. The thickness of the electrodeposit is instantaneously tunable by the applied electric pulses, leading to parallel ridges on webbed film without using any template. An array of metallic nanowires with desired separation and width determined by the applied pulses is formed on the substrate with arbitrary surface patterns by etching away the webbed film thereafter. This work demonstrates a previously unrecognized fabrication strategy that bridges the gap of top-down lithography and bottom-up self-organization in making ordered metallic nanowire arrays over a large area with low cost.

Advances and Challenges Toward High Efficient Colloidal InP Core-Shell Quantum Dots—Synthesis, Surface Chemistry and Their Applications
Derrick Allan Taylor, Justice Agbeshie Teku and Jong-Soo Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

Semiconductor colloidal quantum dots (CQDs) have made remarkable progress due to their attractive size-tunable electronic and optical properties, low-cost production, high efficiency, and high stability. In particular, Indium phosphide (InP) quantum dots (QDs) have attracted a great deal of attention in next-generation display technologies, owing to their low intrinsic toxicity and tunable emission from visible to near-infrared region. Despite recent progress in improving the optical properties of InP-based QDs, current synthesis methods have often failed to produce InP QDs with high quantum yield and narrow size distributions, a prerequisite for realizing high color pure emissions. Recently, our group report the importance of precisely controlling the reaction kinetics of InP QDs by a two-step growth process to achieve the narrowest size distribution, engineering the shell coating to reduce interfacial defects for high photoluminescence yield quantum yield (PLQY). In this talk, I will introduce the great synthetic progress of InP core-shell QDs, based on the surface chemistry and the interfacial engineering of InP QDs. By optimizing synthesis conditions, the as-synthesized InP QDs core-multishell exhibited a bright green and red emission with a very high quantum yield and the narrowest emission linewidth of more than 90% and less than 33 nm, respectively. Finally, I will discuss the challenges related to the recent developments of InP QLED applications and the challenges for achieving high-performance devices.

Atomically Flat {011} Facets and Phase Tunability of HfO_2 Nanocrystals via an Anhydrous Wet-Chemical Approach Thorsten Ohlerth[1,2], Hongchu Du[2,3], Niclas Schmidt[2,4], Sonam Maiti[2,4], Silvia Karthäuser[2,4], Joachim Mayer[2,3,5], Rainer Waser[2,4] and Ulrich Simon[1,2]; [1]Institute of Inorganic Chemistry, RWTH Aachen University, Germany; [2]JARA – Fundamentals of Future Information Technologies, Forschungszentrum Jülich GmbH, Germany; [3]Ernst Ruska-Centre (ER-C-2), Forschungszentrum Jülich GmbH, Germany; [4]Peter Grünberg Institute (PGI-7), Forschungszentrum Jülich GmbH, Germany; [5]Central Facility for Electron Microscopy (GFE), RWTH Aachen University, Germany

The development of new nanomaterials in industry is driven by the everchanging socioeconomic trends in recent history. As for the IT sector, HfO_2 was introduced in 2007 as gate material in complementary metal oxide semiconductors (CMOS) and still is one of the state-of-the-art materials as of today. As high-κ-dielectric, hafnia has also risen awareness when Müller et al. found that it exhibits ferroelectric behaviour in thin films with a thickness of about 10 nm.[1] While nanocrystalline HfO_2 is usually processed via thin-film deposition techniques like atomic layer deposition (ALD) and chemical vapor deposition (CVD), wet-chemical syntheses in solution envisage three-dimensionally confined nanostructures that are not yet accessible for thin-films. Accordingly, we put our efforts in rationalizing the synthesis HfO_2 nanocrystals (HfO_2-NC) in order to obtain novel hafnia material classes.
Prior to our work, the scientific community developed numerous synthesis protocols for colloidal hafnia.[2] The results of Tang et al. stand out among them, due to the astonishingly monodisperse HfO_2-NCs with sizes below 5 nm in diameter. This sol-gel synthesis approach served as base for subsequent studies, specifically in terms of size effects and crystal twinning behavior. Still, the results of different groups were inconsistent regarding isotropically shaped nanocrystals with the metastable tetragonal (*$P4_2/nmc$*, 137) crystal structure and anisotropically grown monoclinic (space group *$P2_1/c$*, 14) nanorods, that were seemingly obtained under similar conditions. In our work, we resolve these ambiguities by showing that specific heating techniques are crucial for the crystal growth dynamics. Furthermore, we extended the scope of the synthesis by the formation of anisotropic nanoprisms with atomically well defined {011} facets. We present that these nanoprisms tend towards self-assembly alongside their preferred growing direction, which is perpendicular to the aforementioned {011} crystal planes. Contrary to the well-investigated HfO_2 nanorods, these particles showcase no twinning alongside their long-axis dimension, which makes them perfect single orientated nanocrystals with only small size deviations. The particle size distribution, morphology and crystallinity of our HfO_2-NCs was predominantly investigated by means of transmission electron microscopy (TEM), while the role of molecular capping agents was analyzed via X-ray photoelectron spectroscopy (XPS) and thermogravimetric analysis (TGA).
Our findings elucidate the nature for morphology selective growth and phase formation of the well-established sol-gel synthesis. We strive to extend our findings towards other transition metal oxides, premised on the opportunities that our approach for HfO_2 provides.

W/VO_2 Nanoparticles for Thermochromic Polymer Films—A Comparative Study Between Bead Milling of Powders and Hydrothermal Synthesis
Pascal Buskens[1,2,3], Lavinia Calvi[2,4], Ryan Van Zandvoort[1,3], Janique Hupperetz[1,3], Luc Leufkens[1,3], Roberto Habets[1,3], Daniel Mann[1,3], Nicole Meulendijks[1,3], Kimberly Timmers[1,3], Ken Elen[2,4], An Hardy[2,4], Marlies K. Van Bael[2,4], Ioannis Papakonstantinou[5], Gurunatha Kargal Laxminarayana[5], Ivan P. Parkin[5], Romy Van Geijn[1,3] and Roland Valckenborg[1]; [1]TNO, Netherlands; [2]Hasselt University, Belgium; [3]Brightlands Materials Center, Netherlands; [4]IMEC vzw, IMOMEC Associated Laboratory, Belgium; [5]University College London, United Kingdom

Vanadium dioxide displays a structural phase transition (SPT) from monoclinic VO_2 (M) to rutile VO_2 (R) at 68°C, which is reversible [1]. This SPT is accompanied by a metal-insulator transition, which makes this material interesting for application in energy efficient windows. VO_2 (M) is an insulator and transmits solar infrared (s-IR) radiation, VO_2 (R) is metallic and reflects and/or absorbs s-IR light. For application in energy efficient windows, the switching temperature needs to be lowered from 68°C to 15-25°C, which is typically achieved by doping with metal ions such as W^{6+}. To introduce thermochromic W/VO_2 in windows, we aimed at preparing thermochromic PVB polymer films comprising W/VO_2 nanoparticles of a size below 100 nm to

avoid scattering of visible light. These should then be incorporated into PVB via a masterbatch, and the resulting nanocomposite polymer films should be applied to laminate glass and produce insulating glass units with a laminated outboard. Based on the temperature of the outer glass pane and the nanocomposite film, the resulting window should then switch from a s-IR transmissive to a blocking state and *vice versa*. This contributes to a reduction in energy consumption and costs for heating and cooling of buildings in intermediate climates.
To prepare VO_2 and W/VO_2 nanoparticles, we selected two different routes: a hydrothermal synthesis starting from a mixture of organometallic V(IV) and W(VI) complexes, and a top-down processing route based on bead milling of VO_2 and W/VO_2 powders. We successfully prepared thermochromic VO_2 and W/VO_2 nanoparticles using both routes. We characterized their composition, size and shape using X-ray diffraction, laser diffraction, dynamic light scattering, scanning and transmission electron microscopy. Furthermore, we comparatively studied their functional performance focusing on the thermodynamics and kinetics of the SPT [2]. For that purpose, we performed differential scanning calorimetry at various heating and cooling rates. The switching kinetics were determined using Friedman's differential isoconversional method. For undoped VO_2 (M), we found that the activation energy (E_A) of the SPT decreases with increasing difference between the actual temperature of the material and its switching temperature. Furthermore, the activation energy decreases with progressive milling, and kinetic asymmetry is induced. For milled particulate materials, $\left| E_A \right|$ is lower for the switch from VO_2 (R) to VO_2 (M) than for the opposite switch. For hydrothermally synthesized nanoparticles, E_A is in the same order of magnitude, albeit with inverse switching asymmetry. Latter may result from different defects that are introduced during both preparation techniques.
W/VO_2 nanoparticles obtained by bead milling were successfully introduced into PVB via a masterbatch, and the resulting nanocomposite polymer material was processed into films. These were then applied for lamination of glass plates up to 1 square meter in size. Subsequently, pilot scale windows were prepared comprising these laminated glass plates. We started testing these in demo houses to gather information on the performance of the innovative energy efficient window in real environment. Initial results show that the smart window transitions from an s-IR transparent to blocking state as soon as direct sunlight hits the window and ambient temperatures are above 20°C. The transition back to the s-IR transparent state usually happens over night when the glass surface cools down. The window is optimized to reduce energy consumption in moderate climates with cold winters and warm summers, such as in the Netherlands, which can lead to additional energy and cost savings of up to 8% and 23.70 € per square meter per year when compared to state of the art HR++ windows.

4:00 PM NM05.11.04
Hydrothermal Synthesis of Zinc Gallate Nanoparticles—A Reaction Kinetics Study David Beke[1,2], Mátyás M. Rudolf[1], Bence Márkus[2] and Adam Gali[1]; [1]MTA Wigner RCP, Hungary; [2]University of Notre Dame, United States

Zinc gallate ($ZnGa_2O_4$) has attracted increased attention for broad optical applications owing to its excellent thermal and chemical stability and its wide bandgap (»4.4 – 5.2 eV). It is known to act as a phosphor host, with one example being chromium doping of the crystal lattice, which displays a red-infrared luminescence at around 700 nm under a wide UV-Visible or even X-ray excitation. The photon emission process can be prolonged from milliseconds to hours by introducing exciton traps. Such properties make this material a promising candidate for background-free bioimaging. These emitters may be used as a light source to trigger photodynamic or photo-induced therapy deep in the body, where these therapeutic approaches have not yet been accessible. Indeed, optical imaging could be advantageously carried out using a phosphor as a luminescent probe, emitting in the red-infrared part of the spectrum upon X-ray excitation. By using persistent luminescent nanoparticles or the capability of X-ray excitation to cross through the body, the autofluorescence and the absorption of tissue can be avoided. However, the optical properties of the hydrothermally synthesized nanoparticles are strongly influenced by the synthesis parameters.
The most accepted method to synthesize $ZnGa_2O_4$ NPs is the transformation of the oxides or hydroxides of the elements into crystalline spinel oxide. This can be accomplished by applying solvothermal methods at moderate temperatures. However, the reaction mechanism of hydrothermal synthesis of $ZnGa_2O_4$ has not been fully understood. Even though $ZnGa_2O_4$ synthesis is described as the hydroxide phase transforming into the corresponding oxide phase via an endothermic dehydration reaction, we found that the spinel oxide can form without hydroxide precipitation. We studied the reaction kinetics of the crystal growth with and without ultrasmall silicon carbide seeds, and we found a good correlation with the LSW model. More on that. We suggest a temperature-triggered and separated nucleation and crystallization process during the hydrothermal reaction. Reaction-limited nucleation creates an amorphous oxide that crystallizes during the second synthesis step.

Possible Continuous (Successive) Fabrication of Nano-Structured Inorganic Materials via Soft, Solution Processing without Firing of Powders
Masahiro Yoshimura; National Cheng Kung University, Taiwan

Practical devices would be better to be fabricated via continuous and/or successive Processes. Presently,however, they have generally been fabricated artificially and/or industrially by so-called high-technology, where high temperature, high pressure, vacuum, molecule, atom, ion, plasma, etc. using expensive equipments thus they consumed huge amount of resources and energies thus exhausted huge amounts of wastes: materials, heats and entropy. The major reasons might be 1) The reactants should be nano-sized species, 2) high-energy reaction might be required, thus 3) They cost economically and environmentally. To save this tragedy, a) we must consider “Cascade use of Heats”, and b) “Low energy Production of advanced materials via solution-based technologies.” c) Continuous(Successive) Fabrication will be possible in solution process(es).
We proposed in 1995 an innovative concept and technology, “Soft Processing” or “Soft Solution Processing,” which aims low energetic (=environmentally friendly) fabrication of shaped, sized, located, and oriented inorganic materials in/from solutions. When we have activated/stimulated interfacial reactions locally and/or moved the reaction point dynamically, we can get patterned ceramic films directly in solution without any firing, masking nor etching. Direct Patterning of CdS, PbS and CaWO4 on papers by Ink-Jet Reaction method. Furthermore, we have succeeded to fabricate BaTiO3 patterns on Ti by a laser beam scanning and carbon patterns on Si by plasma using a needle electrode scanning directly in solutions. Successes in TiO2 and CeO2 patterns by Ink-Jet Deposition, where nano-particles are nucleated and grown successively on the surface of substrate thus become dense even below 300 C will be presented. Nano-structured films of BaTiO3 and direct carbon patterning in solution will be also talked.[1-3)] They are rather contrasting with recent General Solution Studies :3D Printing and Additive Engineering based upon Firing of Powders after Printing. I may talk about nanocarbon and graphene [4-5)].

Chemically Exfoliated Thin Sheets of β-Bi2O3 Brianna L. Hoff, Guangming Cheng, Graciela Villalpando, Fang Yuan, Nan Yao and Leslie Schoop; Princeton University, United States

Exploring two dimensional (2D) materials is important for further developing the field of quantum materials. However, progress in 2D material development is limited by the ability to make them. Specifically, freestanding 2D materials with bulk non-layered structures remain particularly challenging to prepare. Traditionally, chemical or mechanical exfoliation is employed for obtaining freestanding 2D materials, but these methods typically require layered starting materials. Here we put forth a method for obtaining thin layers of β-Bi2O3, which has a three-dimensional covalent structure, by using chemical exfoliation. In this research, Na3Ni2BiO6 was exfoliated with acid and water to obtain β Bi2O3, less than 10 nm in height and over one μm in lateral size. Our results open the possibility for further exploring β-Bi2O3 nanosheets to determine whether their properties change from the bulk to the nanoscale. Furthermore, this research may facilitate further progress in obtaining nanosheets of non-layered bulk materials using chemical exfoliation.

8:30 AM NM05.12.01
Elucidating Dopant Structure in Single-Atom Doped Transition Metal Dichalcogenides for Catalytic Hydrotreatment Steven L. Farrell[1], Ingrid J. Paredes[1], Srinivas Rangarajan[2], Anatoly Frenkel[3,4] and Ayaskanta Sahu[1]; [1]New York University, United States; [2]Lehigh University, United States; [3]Stony Brook University, The State University of New York, United States; [4]Brookhaven National Laboratory, United States

Tailoring highly efficient catalysts to targeted applications is vital to reduce the carbon footprints of industrial processes; however, understanding and controlling nanostructure influence in catalyst design has proven difficult. Transition metal dichalcogenides, such as molybdenum sulfide (MoS_2), are important commercial catalysts employed in hydrodesulfurization (HDS) and hydrodeoxygenation (HDO) for crude oil and biomass valorization, respectively, due to their widespread availability and sulfur poisoning resistance. Nanoscale MoS_2 forms stable two-dimensional nanosheets with impressive catalytic activity along the nanosheet edge sites. Conversely, most of the non-edge atoms of the basal plane are inert. Thus, there is a strong impetus towards modifying 2D MoS_2 to activate the basal plane. Decorating the surface with singular dopant atoms, such as cobalt, has been shown to enhance catalytic properties of MoS_2 for hydrogenation, especially hydrotreating. However, little is understood about the location of the dopants and their subsequent influence on catalyst behavior. To investigate this gap in knowledge, we study the impact of Co-dopants in MoS_2 on hydrotreating reactions through strictly controlled, tunable in-situ Co doping of MoS_2 nanosheets grown via a bottom–up colloidal hot-injection method. Various Co loadings were studied for HDS of thiophene and HDO of p-cresol, probing the effects of dopant concentration and local structure of single Co atoms using x-ray absorption spectroscopy and density functional theory. We show that the relationship between dopant concentration, location and activity is interrelated, reaction-specific, and non-monotonous with performance peaking at 25% Co. We highlight the specific mechanisms that dictate how and where Co attaches to the surface and its influence on the catalytic performance. Understanding these mechanisms is critical for tailoring future catalysts to specific applications.

8:45 AM NM05.12.02
Nonequilibrium Flow-Synthesis of Immiscible Binary and High-Entropy Alloy Nanoparticles and Investigation of Their Catalytic Properties and Electronic Structures Kohei Kusada[1,2], Dongshuang Wu[1], Tomokazu Yamamoto[3], Takaaki Toriyama[3], Syo Matsumura[3], Yusuke Nanba[4], Michihisa Koyama[4], Okkyun Seo[5], Osami Sakata[5] and Hiroshi Kitagawa[1]; [1]Kyoto University, Japan; [2]JST-PRESTO, Japan; [3]Kyushu University, Japan; [4]Shinshu University, Japan; [5]JASRI, Japan

Solid-solution alloy nanoparticles (NPs), where the constituents mix at the atomic level, show a variety of attractive properties due to their tunable electronic structures. However, the majority of bulk alloy systems are phase-separated types under ambient conditions. We have demonstrated that the nanosize effect offers a chance to find a way out of this metallurgical difficulty; that is, we can obtain metal NPs having new phases that do not exist in bulk states[1-9]. As one of the examples, we successfully synthesized PdRu solid-solution alloy NPs, although Ru and Pd are immiscible elements. The $Pd_{0.5}Ru_{0.5}$ NPs having a similar electronic structure to Rh exhibit comparable NO_x reduction activity, even though monometallic Ru or Pd NPs do not show high activity.[4, 8] Also, very recently we first synthesized high-entropy alloy NPs composed of all eight noble-metal-group elements (NM-HEA NPs) and revealed that the local density of states (LDOS) of every surface atom in NM-HEA are different.[9] Some atoms of the same constituent element in HEA NPs have different LDOS profiles, whereas atoms of other elements can have similar LDOS profiles. In other words, one atom in HEA loses its elemental identity and it may be possible to create an ideal LDOS by adjusting the neighboring atoms. The NM-HEA NPs showed 10.8-times higher activity for hydrogen evolution reaction than commercial Pt/C, which is one of the best catalysts. However, it is still difficult to stably synthesize solid-solution alloy NPs, particularly nonequilibrium alloys that consist of combinations immiscible in the bulk.
We first developed a continuous-flow reactor providing high productivity with high reproducibility of solid-solution alloy NPs composed of immiscible combinations and multi-elements.[9] The designed solvothermal flow reactor enabled us to use lower alcohol as a reductant that cannot be applied in a batch synthesis for these NPs.

Silicon Nanoparticles as *Solid-State* Inhibitors for Methacrylic Autopolymerization Pooria Golvari, Khaled Alkameh and Stephen M. Kuebler; University of Central Florida, United States

Polymerization inhibitors are added to methacrylic monomers to extend their shelf life and often need to be removed prior to use by means of tedious procedures. We report that hydrogen terminated silicon nanoparticles (H-SiNPs) inhibit thermal polymerization of methyl methacrylate (MMA) and allyl methacrylate (AMA) at temperatures as high as 100 °C [1]. As *solid-state* inhibitors, H-SiNPs are advantageous because they can be readily separated from the monomer by centrifugation and/or filtration. The reaction MMA and AMA in the presence and absence of H-SiNPs at various temperatures were

explored using NMR and FTIR spectroscopy. In the presence of Si-H surface groups, methacrylic dimers form as a by-product of inhibition. Additionally, monomers attach to the surface of SiNPs through hydrosilylation of the methacrylic group, forming robust Si-C linkages that are resistant to hydrolysis. In the case of AMA, thermal hydrosilylation enables facile synthesis of free-standing vinyl terminated SiNPs. Catalytic hydrosilylation of H-SiNPs with AMA is being investigated using Kardsted's catalyst (KC). Whereas KC has been extensively utilized for cross-linking of polysiloxanes [2], its effectiveness in facilitating hydrosilylation of olefins with H-SiNPs has not been methodically studied. Preliminary data show that MMA and AMA undergo hydrosilylation through the methacrylic group when high loadings of KC are used, in neat monomer or with toluene as solvent. The effect of solvent is being explored as a means to bias hydrosilylation selectively towards the vinyl group of AMA. This would enable methacrylate-capped free-standing SiNPs with potential applications in photocrosslinkable silicon formulations.

9:15 AM NM05.12.04
3D Atomic Structure of Pt Nanocrystals Related to Their Catalytic Activity and Surface Ligand Adsorption Sungin Kim[1], Dohun Kang[1,2], Jimin Kwag[1], Dongjun Kim[1], Junyoung Heo[1] and Jungwon Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Northwestern University, United States

The surface structure of nanocrystals determines catalytic activities and ligand adsorption behavior. However, it is challenging to precisely investigate the physicochemical behavior because the surface structure of synthesized nanocrystals consists of intricate and low-symmetry surface structures. Here, we revealed 3D atomic structure of sub 3-nm Pt nanocrystals and analyzed surface-related characteristics of the synthesized nanocrystals. First, we constructed 3D maps of the coordination number (CN) and generalized CN (GCN) for individual surface atoms to directly correlate types of constituent surface structures and catalytic activities, respectively. The results reveal that the synthesized Pt nanocrystals are enclosed by islands with nonuniform shapes that lead to complex surface structures, including a high ratio of low-coordinated surface atoms, reduced domain size of low-index facets, and various types of high-index facets. In addition, these intricate surface structures give rise to a wide range of GCN meaning various active sites, which explains the origin of high catalytic performance of small Pt nanocrystals in important reactions such as oxygen reduction reaction. Second, we applied a machine-learning-accelerated ab-initio calculation into the 3D atomic structures of Pt nanoparticles to analyze the complex adsorption behavior of polyvinylpyrrolidone (PVP) ligands on synthesized nanoparticles. Different angular configurations of the large-sized ligands on low-symmetry surfaces are thoroughly investigated. It is revealed that two components of binding affinity, short-range direct bonding and long-range van der Waals interaction, of PVP on synthesized Pt nanoparticles are differently affected by the coordination number of the binding atomic site and surface-exposed local geometry surrounding it. In addition, the adsorption directions of the large-sized ligand have a tendency depending on the types of adsorption centers, despite the low-symmetry surfaces. The results highlight the important contribution of vdW interactions to adsorption behavior of large-sized ligands on nanoparticle surfaces.

9:30 AM NM05.12.05
Water-Soluble Copper (I) Hydroxide Catalysts in Ligand-Free Suzuki-Miyaura Cross-Coupling Reactions Priya Karna[1], Debora Motta Meira[2], Zou Finfrock[2] and Dong-Sheng Yang[1]; [1]University of Kentucky, United States; [2]Argonne National Laboratory, United States

Transition-metal catalyzed Suzuki-Miyaura (SM) cross-coupling is a powerful technique for constructing C-C bonds and has been widely used in the pharmaceutical, agrichemical, and natural product syntheses. Although Pd has been used as the major catalyst for SM reactions, Cu has recently emerged as an alternative to Pd because Cu is inexpensive, less toxic, and easily available. A survey of the literature shows that most Cu-catalyzed SM reactions were carried with organic ligand-stabilized Cu catalysts. For ligand-free reactions, reaction phases and active species of Cu catalysts remain under debate. In this work, we report findings of ligand-free Cu-catalyzed-SM reactions using CuI as a precatalyst and benzene iodide and phenylboronic acid as coupling agents in the presence of potassium hydroxide, water, and polyethylene glycol 300. The catalyst is water-soluble copper (I) hydroxide (CuOH) species in their singlet electronic states as identified by UV-Vis absorption spectroscopy and x-ray photoelectron spectroscopy. It is formed by leaching of Cu(I) nanoparticles, which serve as the reservoir of the Cu(I) catalyst. The Cu(I) nanoparticles are characterized using transmission electron microscopy and extended x-ray absorption fine structure spectroscopy. Catalytically active CuOH catalyst is in the solution rather than on the surface of the Cu precipitate. The soluble Cu(I) species is stable for at least four weeks under ambient conditions, a desirable feature for any catalyst.

Colloidal Synthesis of Size and Composition Controlled Alloy Nanocrystals as Selective Alkyne Semihydrogenation Catalysts Jasper Clarysse, Jordan D. Silva, Seraphine Zhang, Scott Docherty, Maksym Yarema, Christophe Copéret and Vanessa Wood; ETH Zürich, Switzerland

The selective hydrogenation of alkynes to alkenes is an important transformation with applications in both the fine chemical industry (synthesis of vitamins and natural products) and polymer industry (selective removal of acetylene), where alloys are often employed as heterogeneous catalysts. Yet, advances in catalyst formulations that feature high activity, selectivity, durability and broad functional group tolerance and where both noble metals (e.g. Pd, Pt) and metals of environmental concern (e.g. Cd, Pb) are replaced by earth abundant and non-toxic metals are highly desirable. Here, we present the synthesis of uniform Ni-alloy nanocrystals (NCs), which are 3-4 nm in size and feature narrow size dispersions [1]. The nanocrystals are synthesized via an amalgamation seeded growth procedure [2], a generalized colloidal synthesis method developed by us for size and composition controlled nanocrystals of a wide range of alloys. The resulting catalysts are pristine, capped with non-poisoning oleylamine ligands and work as dispersions which are at the interface of homogeneous and heterogeneous catalysis. We find that Ni_3Zn NCs are particularly active and selective for the liquid-phase semi-hydrogenation of alkynes in batch, operating under mild reaction conditions. Furthermore, Ni_3Zn NCs are tolerant to a wide range of functional-groups, allowing the selective conversion of a broad scope of alkynes as studied with high-throughput experimentation. In addition, we show that the investigated substrate scope covers the chemical space of commercial alkynes to a large extend, as evaluated with data science techniques [1].

10:30 AM NM05.12.07
Supercritical Hydrothermal Synthesis of High Entropy Spinel Oxide Nanoparticles as Oxygen Evolution Electrocatalysts Kazuyuki Iwase and Itaru Honma; Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Japan

Hydrogen production via electrochemical water splitting using renewable energies has attracted attention to realize a sustainable society. The electrochemical oxygen evolution reaction (OER) is an important anode reaction in water splitting. To date, non-noble metal oxides composed only of

abundant elements have been extensively studied as OER catalysts since they can function as OER catalysts in alkaline solutions. Among metal oxides, spinel oxides have been widely studied as OER catalysts, as the composition and site occupancies of metal ions can be modulated by the choice of metal precursor and synthesis method to enhance OER activity. However, further enhancement of OER activity is needed.
Recently, high entropy compounds, such as high entropy alloys (HEAs) and high entropy oxides (HEOs), which are solid solutions composed of multiple metal elements (usually more than 5), have also attracted attention as new catalyst platforms. It has been reported that HEAs and HEOs have specific electronic structures due to electronic interactions among constituent metal elements. The electronic structure of catalysts is one of the important determining parameters for the adsorption energies of reaction intermediates and catalytic activities for various electrocatalytic reactions. Therefore, as discussed above, high entropy spinel oxides (HE-SOs) are attractive as OER catalysts. In previous reports, HE-SOs have typically been synthesized by heat treatment of the metal precursors under high temperature, which results in highly crystalized particle formation. On the other hand, a two-step processing using heat treatment of the metal precursor obtained via hydrothermal synthesis can obtain HE-SO nanoparticles. While particle size is one of the important parameters for catalysts, the method for a simple one-step synthesis of HE-SO nanoparticles has been limited.
Herein, we developed a simple one-pot solution synthesis process of HE-SO nanoparticles using a supercritical fluid as a reaction field. The supercritical fluids are attractive as a reaction field to synthesize various kinds of catalysts composed of nanoparticles or nanosheets[1]. In the present work, we have synthesized HE-SOs composed of five transition metals (Mn, Fe, Co, Ni, Zn). Briefly, metal precursor solutions and sodium hydroxide (NaOH) solutions were mixed and transferred into Hastelloy reactors, followed by a heat-treatment at 400 °C for 15 min. Cubic spinel nanoparticles with an average diameter of 18.6 nm in solid solutions were obtained. The valence states and coordination environment (e.g., site occupancies) were analyzed by X-ray absorption fine structure (XAFS). Co, Ni and Zn atoms existed as divalent ions, whereas Mn and Fe atoms exited as trivalent ions. In addition, Mn and Ni atoms selectively existed at octahedral 16d sites, whereas Co and Zn existed at tetrahedral 8a sites. The OER activities of HE-SOs were evaluated by cyclic voltammetry (CV) in O_2-saturated 1M KOH solutions using rotating disk electrode. The onset potential and Tafel slope values were 1.56 V vs. reversible hydrogen electrode (RHE) and 36.7 mV/dec, respectively. The onset potential of the synthesized HE-SO was similar to that of the reported spinel oxides-based catalysts with high OER activity, and the Tafel slope value of the HE-SO was lower than that of the reported spinel oxides. This result indicated that HE-SO functions as an efficient catalyst for OER. To our knowledge, this is the first demonstration of the synthesis of HE-SO nanoparticles by supercritical fluid processing [2]. Further detail of structure analysis and electrochemical characterizations will be discussed in the presentation.

10:45 AM NM05.12.08
Developments of Highly Efficient Electrocatalytic 2D Nonlayered Materials via Ionic Layer Epitaxy Strategy Ziyi Zhang, Yunhe Zhao, Guangyuan Yan, Xin Yin and Xudong Wang; University of Wisconsin - Madison, United States

Many traditional high-performance electrocatalysts, such as precious metals (e.g., Pt, Pb) and metal oxides (e.g., RuO_2, IrO_2), have a nonlayered crystal structure with intrinsic isotropic chemical bonds in three dimensions. Creating 2D morphology from these nonlayered catalytic materials may offer higher impacts on catalyst design by exposing massive surface dangling bonds and active defects. However, compared with van der Waals solids, 2D nonlayered materials synthesis requires the control of kinetics to break the crystal symmetry fostering 2D anisotropy in crystal growth and stabilizing the structures far away from thermodynamic equilibrium. Here, we introduce a solution-based 2D nonlayered materials synthesis technology that distinguishes itself from others with the capability of unit-cell-level thickness control called the ionic layer epitaxy (ILE) technique. In this technology, an ionic surfactant monolayer is used as a soft template at the air-water interface to guide the growth of 2D materials; here, it was found that the control of the surfactant type and packing density in the monolayer brings up a new capability for the unit-cell-level precision thickness control and vacancy concentration tuning of 2D nonlayered material in ILE synthesis, which may enable a more comprehensively quantitative study on 2D electrocatalysis. ILE was recently developed as an effective strategy to synthesize 2D nonlayered materials, such as Pd, La_2O_3, and CoO, and we demonstrated that these are promising electrocatalysts. Owing to the ultrasmall thickness, high crystallinity, and exposure of highly active FCC (100) crystal facets, the 2 nm quasi-square shaped Pd nanosheets (NSs) exhibited a mass oxidation current as high as 1132.6 mA/mg which is more than 30 times higher catalytic activity in formic acid oxidation compared to the commercial Pd black.[1] This offered a promising approach toward rational design and synthesis of ultrathin metallic 2D NSs with enhanced functionality. The ultrathin rare-earth metal-based oxide, La_2O_3 NSs demonstrated a significantly improved oxygen evolution reactions (OER) performance.[2] Due to the ultrasmall thickness, the as-synthesized 2.27 nm La_2O_3 NS exhibits a current density of 10 mA cm^{-2} and a mass activity as high as 6666.7 A g^{-1} at an overpotential of 310 mV, which is three orders of magnitude higher than benchmark OER electrocatalysts, such as commercial IrO_2 and RuO_2. This presents a sustainable way for the development of highly efficient electrocatalysts with largely reduced mass loading of precious elements. Furthermore, 2.5 nm quadrangle-shaped bimetallic Co-Mo-O NSs with a 2:1 Co-to-Mo ratio exhibited an enhanced OER catalytic activity with 3 orders of magnitude higher mass activity compared to commercial IrO_2 and RuO_2 in an alkaline environment, delivered an even lower overpotential of 273 mV at 10 mA cm^{-2}, with a mass activity of 5472 A g^{-1} and a superior turnover frequency of 1.47 s^{-1} (η = 330 mV) due to its ultrasmall thickness.
The ultrathin NSs synthesized via ILE techniques demonstrated a promising strategy for the development of substantial highly efficient 2D electrocatalyst materials that the remarkable mass activity associated with the unique ultrathin structure is particularly valuable for preserving rare and precious catalyst elements that have high costs and low supplies.

Nanoconfinement and Mass Transport in Hollow Structured Pt-Rh Electrocatalysts Towards Efficient and Durable Ethanol Electrooxidation
Kyeong-Ho Kim and Betar Gallant; Massachusetts Institute of Technology, United States

A major challenge of ethanol utilization in fuel cells relates to full oxidation of ethanol to CO_2, which comprises a 12-electron transfer reaction, with the obtained extent of this reaction at room temperature significantly lower due to unique thermodynamic and kinetic challenges of ethanol's C-C bond cleavage step. Consequently, in practice, the Faradaic efficiency (FE) of full oxidation of ethanol to CO_2 is often limited to <20%, with the majority of byproducts being C2 intermediates in which C-C bonds persist: acetaldehyde (H_3C-COH) or acetic acid (H_3C-COOH), which generate only 2 and 4 electrons rather than 12 electrons.
In the ethanol oxidation reaction (EOR) mechanism, the surface coverage of OH functional groups affects reaction selectivity of the C-C bond cleavage step owing to competitive adsorption on the active sites between OH functional groups and each of the two carbons in ethanol for successful C-C bond splitting. While the optimized surface coverage of OH for high EOR selectivity can be achieved by reducing the pH of the alkaline electrolyte, the low concentration of OH^- in bulk solution may lead to undesired decreases in ionic conductivity. Therefore, it is compelling to examine methodologies that allow for decoupling of near-surface vs. bulk electrolyte composition and properties. Hence, to manipulate the surface coverage of OH without modulating the pH of bulk solution, we exploited the high generation rate of H^+ released during EOR, which can create a local acidic environment near the

electrocatalyst surface.
In this study, the critical role of the electrode architecture affecting the EOR selectivity was investigated by controlling the extent of local pH swing manipulated by the different degree of electrode porosity that governs the mass transport of OH^- near the electrocatalyst surface. To modulate the degree of electrode porosity, binary $Pt_{1-x}Rh_x$ electrocatalysts were synthesized into hollow sphere morphologies with different particle sizes (250 and 350 nm) and compositions (x=0.0, 0.4, 0.5, 0.6, and 0.66). The FE of full oxidation of ethanol to CO_2 was systematically compared in terms of different particle size and mass loading of hollow spheres in the electrodes by quantifying the EOR products using NMR and gas chromatography. The higher FE of CO_2 could be achieved by a more acidic environment of the more porous electrode structure with a smaller particle size and higher mass loading of electrocatalysts, suggesting the potential to control the EOR outcomes via electrode structural engineering.

Spin Selective Charge Transport Through Cysteine Capped Iridium Nanoparticles and Its Effect on the Electrochemical Catalytic Activity Carlos Mingoes; Queen Mary University of London, United Kingdom

Highly efficient processes for energy conversion are a necessity to keep up with the growing demand for energy and a sustainable future. Electrocatalysts play a crucial role in this goal and so overcoming their shortcomings are essential. In this study, chiral iridium nanoparticles produced by way of functionalising iridium nanoparticles with L-cysteine in a two step synthesis process, demonstrates the ability to boost catalytic oxygen evolution reaction (OER) though a electron spin polarisation mechanism. As a result of the spin selective nature of the mechanism, potential parasitic species formation such as hydrogen peroxide is hindered, which can lead to prolonged catalyst life-time.

11:30 AM NM05.12.11
Tuning Electronic Structure and Composition of FeNi Nanoalloys for Enhanced Oxygen Evolution Electrocatalysis via a General Synthesis Strategy Yong Wang; Nanyang Technological University, Singapore

Developing low-cost and efficient oxygen evolution electrocatalysts is key to decarbonization. A novel, facile, surfactant-free and gram-level biomass-assisted fast heating and cooling synthesis method is reported for synthesizing a series of carbon-encapsulated dense and uniform FeNi nanoalloys with a single-phase face-centered cubic solid-solution crystalline structure and an average particle size of sub-5 nm. This method also enables precise control of both size and composition. Electrochemical measurements show that among $Fe_xNi_{(1-x)}$ nanoalloys, $Fe_{0.5}Ni_{0.5}$ has the best performance. DFT calculations support the experimental findings and reveal that the optimally positioned *d*-band center of O-covered $Fe_{0.5}Ni_{0.5}$ renders a half-filled anti-bonding state, resulting in moderate binding energies of key reaction intermediates. By increasing the total metal content from 25 to 60 wt%, the 60% $Fe_{0.5}Ni_{0.5}$/40% C shows an extraordinarily low overpotential of 219 mV at 10 mA cm^{-2} with a small Tafel slope of 23.2 mV dec^{-1} for OER, which are much lower than most other FeNi-based electrocatalysts and even the state-of-the-art RuO_2. It also shows robust durability in an alkaline environment for at least 50 h. The gram-level fast heating and cooling synthesis method is extendable to a wide range of binary, ternary, quaternary nanoalloys, as well as quinary and denary high-entropy-alloy nanoparticles.

11:45 AM NM05.12.12
Scalable, Near Ambient Conditions, One-Pot, Facile Synthesis of Carbon-Doped TiO_2-Based Nanofilaments and 2D Flakes, Their Properties, and Potential Applications Hussein Badr and Michel W. Barsoum; Drexel University, United States

Two-dimensional (2D) materials, which possess atomic or nanometer thickness and infinite planner dimensions, thrive on the rich variety of features and properties that are vastly distinctive from their bulk counterparts. Conventionally, bulk synthesis of 2D materials has predominantly been through selective etching of layered solids. Herein and for the first time, we convert – near ambient conditions – a dozen of commercial, cheap precursors into one-dimensional (1D) nanofilaments than self-assemble into 2D flakes. In that, the precursor is simply stirred in tetramethylammonium hydroxide aqueous solution at 50 -80 ° C for tens of hours. The structure, composition, oxidation state, and morphology of the resulting sheets are resolved by density functional theory, X-ray diffraction, X-ray photoelectron, electron energy loss, Raman, X-ray absorption near edge structure spectroscopies, atomic force microscope, scanning, transmission and high-resolution transmission electron microscopies and selected area diffraction. The resulting flakes showed enhanced electrochemical performance as cathodes in both Li-ion battery and Li-S battery. They also found to be biocompatible to human cells but fatal to come types of cancer cells, thus showing potential in biomedical applications. The developed synthesis protocol of 1D and 2D materials in bulk-scale at near ambient conditions is paradigm shifting and will undoubtedly open new and exciting avenues of research and applications.

SESSION NM05.13: Applications-Driven Synthesis of Nanomaterials

Thermochromic Solar Control Coatings on SiO_2-Coated Float Glass for Energy-Efficient Smart Windows Roberto Habets[1,2], Cindy Yeung[1,2], Luc Leufkens[1,2], Fallon Colberts[3], Kathleen Stout[3], Marcel Verheijen[4,5], Zeger Vroon[1,2,3], Daniel Mann[1,2] and Pascal Buskens[1,2,6]; [1]The Netherlands Organisation for Applied Scientific Research (TNO), Netherlands; [2]Brightlands Materials Center, Netherlands; [3]Zuyd University of applied sciences, Netherlands; [4], Eindhoven University of Technology, Netherlands; [5]Eurofins Materials Science, Netherlands; [6]Hasselt University (UHasselt), Belgium

Considering the fact that energy usage for heating and cooling of buildings is a major contributor to the energy consumption of the built environment, there is a clear need for energy-efficient windows. For intermediate climates with hot summers and cold winters, smart windows with switchable solar control properties are ideal.[1] Thermochromic materials are of interest for application in smart windows since their optical properties change based on changing outdoor temperature. In our study, we used VO_2 as thermochromic material because of its reversible structural phase transition from a semiconductive monoclinic to a conductive rutile structure at a defined switching temperature of 68°C. Dopants, such as W, can reduce the switching temperature to values between 15°C and 30°C, which is required for smart windows.[1]
Here, we report a nanocomposite single-layer coating comprising VO_2 and SiO_2, and yielding unrivalled optical properties.[2] We prepared these coatings by dip coating of a SiO_2-coated float glass in an alcoholic solution of a vanadium(IV) oxalate complex and pre-oligomerized tetraethoxysilane, and thermally annealed the dried xerocoat in a two-step process. During thermal anneal of the xerocoat, phase separation occurred which resulted in Si and V rich domains. This process was studied in detail for a series of coatings with varying VO_2/SiO_2 ratio and varying coating thickness using high resolution transmission electron microscopy. We obtained non-scattering coatings with low surface roughness and randomly distributed VO_2 nanodomains,

incorporated in a SiO_2 matrix. They displayed unrivalled optical properties combining $T_{vis} > 60\%$ with $\Delta T_{sol} \geq 10\%$. Additionally, we demonstrate that with a pencil hardness ≥ 4H and a stability in ambient environment of at least 11 months, the coatings are suitable for industrial processing into insulating glass units. With building energy simulations on a typical Dutch building, we demonstrated that the use of smart windows with our thermochromic coatings can lead to energy savings of 24%, which equals annual cost savings of up to 470 € per household.[2]

1:45 PM NM05.13.02
Tuning of Magnetic Nanowire Aerogel Aspect Ratio and Orientation Through Magnetic Field Assisted Synthesis Rosemary L. Calabro[1,2], Malina Hatton[1], Alexa Zammit[1], Felita W. Zhang[1], Edward M. Tang[1], Zachary T. Bone[1], Olivia S. Raykhman[1], Grant Lee[1], Veronica M. Lucian[1], Robert J. Wilson[1], Enoch A. Nagelli[1,1], Peter H. Chapman[1], Stephen F. Bartolucci[2], Joshua A. Maurer[2] and John Burpo[1,1]; [1]United States Military Academy, United States; [2]U.S. Army DEVCOM Armaments Center, United States

Three-dimensional porous transition metal nanostructures offer many desirable properties due to their high surface area, lightweight nature, and reaction tunability through variation of metal composition making them desirable candidates for catalytic and electrochemical applications. However, synthesis of these materials with control over micro and nanostructure, pore size, and phase composition presents limitations due to aggregation, reactant diffusion times, and a need for templates. Magnetic field assisted nanowire aerogel synthesis is a promising alternative to produce structures from ferromagnetic ion precursors that offers advantages such as rapid nanowire growth and control over nanowire aspect ratio and nanowire orientation through tuning of the applied magnetic field strength. This magnetic field assisted synthesis strategy was applied to produce both iron and cobalt aerogels using metal chloride precursors reduced with sodium borohydride in magnetic fields ranging from 0 mT to 160 mT. For the iron nanowire gels, increasing the magnetic field strength resulted in increased nanowire aspect ratios and a higher orientation order parameter (OOP) as determined from image analysis of scanning electron micrographs. At maximum field strengths, nanowire lengths exceeding 50 μm with average diameters of about 70 nm were achieved. For cobalt, the samples prepared in the absence of a magnetic field consisted of irregular spherical particles and as the magnetic field strength increased, the formation of elongated wire-like structures was favored. The magnetic properties of these magnetic gels were analyzed via vibrating sample magnetometry (VSM) and showed that the magnetic field strength used for synthesis influenced the measured coercivities and saturation magnetizations of the gels. These metal gels can be supercritically dried with CO_2 to form aerogels or be pressed into conformal thin films with ambient drying. These nanowires were further used as a sacrificial template for galvanic displacement with noble metals salts such as platinum which allowed for dissolution of the iron nanowires and formation of high surface area platinum nanotubes and electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV) indicate high electrochemical accessible surface areas for catalytic applications. This galvanic displacement may be expanded to prepare numerous metallic and multi-metallic nanostructures while maintaining a similar overall orientation and structure as the sacrificial aerogel template, and we expect this magnetic field assisted nanowire aerogel synthetic method to be able to be expanded to multi-metallic and alloy ferromagnetic materials which will allow further tuning of the electrochemical and magnetic properties for a wide range of applications.

Metallization of Specific Protein Assemblies via Antibody-Guide in Mammalian Cells and *Ex Vivo* Tissues Chang Woo Song, Dae-Hyeon Song, Dong Gyu Kang, Ki Hyun Park, Chan E Park, Hyunwoo Kim, Yoon Sung Nam, Jihyeon Yeom, Seung Min J. Han and Jae-Byum Chang; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Constantly evolved organisms have hierarchical protein structures that are tailored to be suitable for certain functions. As a biotemplating approach, the mineralization of such biostructures has gained popularity in recent decades. Nevertheless, the use of specific proteins as templates has only been proved in very basic organisms, such as viruses and yeasts, and not in multicellular organisms having more complex protein structures. In this study, we propose a method for synthesizing metallic structures that mimick particular protein assemblies in mammalian cells and ex vivo tissues. To enable protein-specific growth of metals, target proteins are labeled with antibodies, which subsequently provide nucleation sites for metal particle growth. Various metal particles, including Au, Ag, Au@Pt (core@shell), and Au@Pd, are synthesized by using microtubules within the cells as templates. The synthesized cells exhibit significantly enhanced mechanical strength and catalytic activity for liquid-phase reactions. In addition, we demonstrate that by employing multiple proteins as templates for metal particle growth in the same cell, greater catalytic activity can be attained. Finally, we expand this method's application to mouse brain, kidney, and heart slices and imitate the unique protein assemblies inside these organs. We believe this technique can promote the transformation of certain protein structures into metallic frameworks in multicellular animals.

2:15 PM NM05.13.04
Surface and Interface Controlled Zero-Dimensional Nanomaterials for Advanced Printed Electronics Jisun Im[1], Gustavo Trindade[2], Richard Hague[1] and Christopher Tuck[1]; [1]University of Nottingham, United Kingdom; [2]National Physical Laboratory, United Kingdom

Inkjet printing of nanomaterials has been demonstrated to fabricate advanced electronic devices such as flexible and wearable electronics, optoelectronics and sensors by allowing the creation of customized device geometry. In particular, zero-dimensional (0D) nanomaterials, most commonly nanoparticles, have shown great potential for printed electronics since they provide unprecedented and desirable material properties due to their high surface area-to-volume ratio and quantum confinement properties.
Here we demonstrate the successful integration of 0D nanomaterials, such as novel metal nanoparticles (silver and gold) and silicon carbide nanoparticles, into Additive Manufacturing (AM) processes to produce flexible electronics with sensing capabilities. The surface and interface engineering of nanoparticles yields not only a dispersion compatible with various types of AM techniques but also tailorable functional properties. We demonstrate high electrical performance stability of inkjet-printed flexible gold electrodes in response to mechanical bending deformation by using gold nanoparticle functionalized with cohesion enhancer. Complex three-dimensional nanocomposite structures have been fabricated using two photon polymerization by modulating the interaction between the surface of plasmonic nanoparticles and the functional groups of polymers for optoelectronics application. Our advanced compositional (XPS and Orbi-SIMS) and morphological analysis (FIB-SEM and TEM) provides an insight into the effect of tailored surface and interface of nanoparticles on 3D printed structures and device performance.

2:30 PM NM05.13.05
Magnetic Nanosheets via Chemical Exfoliation of $K_{2x}Mn_xSn_{1-x}S_2$ Fang Yuan[1], Leslie Schoop[1], Xiaoyu Song[1], Guangming Cheng[1], Nan Yao[1] and Yurij Mozharivskyj[2]; [1]Princeton University, United States; [2]McMaster University, Canada

We report two chemical routes to prepare new magnetically doped two-dimensional (2D) tin sulfides, i.e., $Mn_xSn_{1-x}S_2$ ($x = 0.1-0.2$), as derivatives of $K_{2x}Mn_xSn_{1-x}S_2$. Initial codoping with K ensures high Mn doping in the nanosheets and is additionally aiding exfoliation. In chemical route 1, the parent compound is first reacted with a diluted HCl solution, which dissolves all K and half the Mn atoms, followed by treatment with TEAOH/methanol, which results in exfoliation. In chemical route 2, $K_{2x}Mn_xSn_{1-x}S_2$ treated with I_2 in acetonitrile, leading to the removal of almost all K atoms, followed by dispersing the product in dimethylformamide, which results in partial exfoliation. The composition and structures are characterized using scanning electron microscopy, high-resolution scanning transmission elec- tron microscopy, and selected area electron diffraction. After K removal and before exfoliation, the structure is trigonal (*P*-3*m*) featuring hexagonal slabs with AA stacking and appropriate interlayer space along the c axis. Upon shaking, both

$Mn_xSn_{1-x}S_2$ (x = 0.1−0.2) phases can be exfoliated into thinner flakes, but nanosheets with a thickness of 2.5 nm can only be achieved via chemical route 1. Magnetic susceptibility measurements of the parent, intermediate, and restacked exfoliated products reveal that the manganese magnetic moment saturates at a moderate field, only in the exfoliated material. $Mn_xSn_{1-x}S_2$ nanosheets can be viewed as a magnetically doped derivative of SnS_2, a material that is used as a high on/off ratio transistor, photocatalyst, and electrode material. Therefore, the new layered metal sulfides obtained here may have diverse applications in 2D magnetism, catalysis, or batteries.

SESSION NM05.14: Virtual Session I

2:00 PM NM05.14.02
Wet Chemical Synthesis of Patterned Bismuth Ferrite Thin Films by Direct Writing (printing) and Characterization Using Printed Electrodes
Sanjeev Patil[1] and Parasuraman Swaminathan[1,2]; [1]IIT Madras, India; [2]Indian Institute of Technology (IIT) Madras, India

$BiFeO_3$ (BFO) is the only naturally occurring room-temperature multiferroic with high Neel (643 K) and Curie (1103 K) temperatures enabling effective magnetic-ferroelectric coupling, thus opening avenues of non-volatile FRAM (ferroelectric random access memory), spintronics, MEMS and one of three realistic candidates to replace lead zirconate titanate (PZT) in ferroelectric and piezoelectric applications. Owing to lead's toxicity, safety, and disposal hazards, PZT is being phased out, and BFO leads over potassium sodium niobate (KNN) and NBT possess severe volatility and non-stoichiometric defects as well as a narrower operating temperature range due to lower Curie temperatures even after significant doping.
Wet chemical routes proffer the distinct advantage of large-scale production with lower temperatures compared to conventional solid-state reaction and lack of high vacuum requirements as in physical vapor deposition techniques. Of the routes available, sol-gel was chosen due to the flexibility in the choice of nanostructures that could be obtained- from thin films to nanoparticles.
In this work, BFO coatings were deposited on fluorine-doped tin oxide (FTO), indium-doped tin oxide (ITO), and quartz substrates via direct writing using a customized with optimized printing and extrusion parameters. A precursor-based ink was developed that remains stable in dispersion form for up to 9 months without aggregation or any phase separation. Choice of solvent, precursor, solvent-precursor ratio, chelating agent, and temperature were critical, which aided in achieving phase pure BFO at a low sintering temperature of 500 °C for 1 hour. Phase purity was ascertained by structural characterization- XRD, SEM-EDS, Raman spectroscopy, and UV-vis spectroscopy, while the BFO ink characteristics were optimized for printability using contact angle (wettability) and viscosity tests. Optical profilometry confirmed the thickness of films deposited, while UV-vis spectroscopy also indicated optical bandgap in the range of 2.6 to 2.9 eV using Tauc plots.
Traditionally, top and bottom electrodes were deposited by evaporation or sputtering, which necessitated high vacuum and expensive pure gold targets. This work utilized direct writing to print silver nanoparticles as electrodes to get Ag/BFO/ITO, Ag/BFO/FTO, and Ag/BFO/quartz heterostructures to frugally obtain contacts required for electrical characterization. By optimizing extrusion and nozzle parameters during printing, the significantly expensive material loss during sputtering/evaporation was bypassed, while flexibility with the printer allowed for choice of electrode shape (square/circular) and dimension without the need for a mask.

Visible-Light-Active Organic Dye/Alumina-Silicate Nanocomposites for Photobiocidial-Triboelectric Fabric Coating
Dong Uk Lee[1], Sang Bin Jeong[2], Ki Joon Heo[3], Byeong Jin Lee[1], Se Kye Park[1], Jae Hak Shin[2], Jae Hee Jung[2] and Dong Yun Choi[1]; [1]Korea institute of industrial technology, Korea (the Republic of); [2]Sejong University, Korea (the Republic of); [3]University College London, United Kingdom

Controlling airborne microorganisms (called bioaerosols) is vital for protecting public health. In the 21st century, bioaerosols have threatened public health in various forms, from severe acute respiratory syndrome in 2002, to pandemic influenza A in 2009, to Middle East respiratory syndrome coronavirus in 2012 and COVID-19 in 2019 [1]. COVID-19 is still an ongoing threat, with more than 536 million infections and 6.31 million deaths worldwide (as of 15 June 2022) [2]. Therefore, there is a need to develop innovative bioaerosol-inactivating materials. Various fiber-based filters composed of organic or inorganic antimicrobial materials, such as copper, silver nanoparticles, chitosan, and natural products, have been developed to filter against bioaerosols [3]. However, these air filters effectively inactivate only microorganisms in direct contact with antimicrobial agents; therefore, their effectiveness gradually decreases as dust accumulates over the antimicrobial material. In addition, conventional filter disinfection technologies based on ultraviolet (UV) irradiation, plasma, and thermal energy have been developed; however, these technologies require additional energy and devices [4].
Recently, visible-light–driven (VLD) biocidal technologies, based on sunlight or indoor light energy, have been a focus of research in the field of photocatalysis [5]. VLD biocidal surfaces or air filters have been prepared using photosensitizing dyes such as triarylmethane, phenothiazine, and xanthene derivatives [6]. The photosensitizing dyes are inexpensive and have various applications; however, because of their high affinity to water, they easily leach into the environment when they come into contact with moisture [7]. To become incorporated into polymer fibers, the dyes need to be firmly immobilized to guarantee the durability and washability of the fibers.
We introduce a novel fiber functionalization method that uses silica-alumina sol-gel (SAS) to endow a fibrous membrane with photocatalytic biocidal activity and reusability. The transparent SAS matrix immobilizes crystal violet (CV) photosensitizer dye and binds electronegative 1H, 1H, 2H, 2H-perfluorooctyltriethoxysilane (PFOTES) molecules to its surface [8]. Moreover, the SAS matrix enhances the dispersity of the photosensitizers (suppressing self-quenching) and protects them from degradation by ROS, enhancing the photodurability. The SAS/PFOTES-CV (SAPC) nanolayer produced more ROS *via* enhanced redox reaction and showed excellent photobiocidal efficiency (~99.99% for bacteria and a virus) under visible light irradiation (3 h, 7.2 mW cm^{-2}) and photodurability (~83% reduction in bactericidal efficiency for the CV alone but ~0.34% for the SAPC filter after 3 days of light irradiation). Moreover, PFOTES bonded to the SAS thin film increased water resistance and triboelectrification ability of the filter. The SAPC filter maintained its filtration and antimicrobial properties after cyclic washing tests, which demonstrates that the excellent reusability. Our SPAC-based nanolayer coating technology is applicable to various textiles of face masks and protective clothing and can control the spread of COVID-19 and other airborne contagious diseases.

Halide Perovskite and Perovskite-Related Nanocrystals—Synthesis and Optical Properties Liberato Manna; Instituto Italiano di Tecnologia, Italy

Halide perovskite semiconductors can merge the highly efficient operational principles of conventional inorganic semiconductors with the low temperature solution processability of emerging organic and hybrid materials, offering a promising route towards cheaply generating electricity as well as light. Following a surge of interest in this class of materials, research on halide perovskite nanocrystals (NCs) as well has gathered momentum in the last years. While most of the emphasis has been put on $CsPbX_3$ perovskite NCs, more recently the so-called double perovskite NCs, having chemical formula $A^{+}_2B^{+}B^{3+}X_6$, have been identified as possible alternative materials, together with various other metal halides structures and compositions, often doped with various other elements. This talk will also discuss the research efforts of our group on these materials. We will highlight how for example halide double perovskite NCs are less surface tolerant than the corresponding Pb-based perovskite NCs and that alternative surface passivation strategies need be devised in order to further optimize their optical performance. Other topics that will be covered are doping and the role of surface ligands on stabilizing the NCs, including those with alloy compositions, and doping of cesium manganese bromide nanocrystals with rare earths to elicit emission in the NIR region of the spectrum.

Design of NPLs from the Inorganic Core to the Surface Chemistry Corentin Dabard[1], Hong Po[1], Thierry Barisien[2], Benjamin Diroll[3], Juan Climente[4], Benoit Roman[5], Etienne Reyssat[5], José Bico[5], Emmanuel Lhuillier[2] and Sandrine Ithurria[1]; [1]Sorbonne Université, France; [2]Sorbonne Université, CNRS, Institut des NanoSciences de Paris, France; [3]Argonne National Laboratory, United States; [4]Universitat Jaume I, Spain; [5]Université de Paris, France

II-VI semiconductor nanoplatelets are colloidal nanoparticles confined in one dimension which gives them exceptionally narrow optical properties. We are showing that through the design of core/crown/crown heterostructures, it is possible to synthesize nanoplatelets with green and red emissions from a single population. In the CdSe/CdTe/CdSe core/crown/crown NPLs, the exciton either recombine at the interface between 2 semiconductors due to the type II band alignment or in the CdSe area. The ratio of the two emissions can be tuned by the incident power. With increased power, the red emission saturates due to non-radiative Auger recombination thus affecting its emission much stronger than the green one. These NPLs can be introduced in LED. So, the design of the NPLs inorganic core enables to tune their optical properties but their shape can be further modified through the surface chemistry. NPLs with their large lateral dimensions can be considered as flexible substrate for the self-assembly of ligands which originally ensure the colloidal stability of NPLs. The stress brought by surface ligands and the specific zinc blende crystal structure of the NPLs induce a folding of NPLs as helices or twists. We show that an exchange from carboxylate ligands to halides ligands and thiolate ligands enable to unfold CdSe NPLs and to invert the chirality of the helices.

2:00 PM NM05.15.03
Lead Chalcohalides Nanocrystals and Chalcohalide-Perovskite Heterostructures Stefano Toso[1,2], Muhammad Imran[1], Quinten A. Akkerman[1], Beatriz Martìn-Garcia[1] and Liberato Manna[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università Cattolica del Sacro Cuore, Italy

Lead-based colloidal semiconductors, in the form of lead chalcogenide and lead-halide perovskite nanocrystals, are extensively studied for applications in the infrared and visible spectral ranges respectively. Yet, these materials suffer from limitations, motivating the search for alternatives: lead-halide perovskites quickly degrade *in operando* conditions, and the more robust lead chalcogenides can be hardly pushed in the visible range due to the small band gaps. However, there is a class of materials that bridge between lead chalcogenides and perovskites, which has been little studied so far and may hold promises for optoelectronic applications. They are the lead chalcohalides, ternary compounds with general formula $Pb_aE_bX_c$ (E = S, Se, Te; X = F, Cl, Br, I).

In an attempt to investigate these materials, we synthesized and solved the structure of two lead sulfohalides unknown to date ($Pb_4S_3Br_2$ and $Pb_3S_2Cl_2$), which proved to be indirect band gap semiconductors. When tested in photodetectors and solar cells, $Pb_4S_3Br_2$ demonstrated a photoresponse that, albeit modest, encouraged deeper investigations into this class of compounds. Further experiments led us to the synthesis of lead chalcohalide/perovskite heterostructures, that are nanoparticles composed of two connected crystalline domains. Their interface represents the first reported epitaxial connection of lead-halide perovskites with a phase outside the family of cesium lead halides, and is made possible by the intimate structural similarities that $Pb_4S_3X_2$ shares with some of the Cs-Pb-X compounds.

The formation of lead chalcohalide/lead perovskite heterostructures has a strong impact on the behavior of both materials. On the one hand, it quenches the otherwise bright photoluminescence of the perovskite, suggesting a delocalization of carriers on the chalcohalide domain that might be exploited for photo-harvesting. Moreover, the $Pb_4S_3Br_2$-$CsPbI_3$ epitaxial interface stabilizes the labile $CsPbI_3$ perovskite, potentially solving a well-known of perovskite-based photovoltaics. On the other hand, the perovskite exerts a strong templating effect on the chalcohalide domain, producing a complete phase selectivity for the case of lead sulfochlorides: $Pb_3S_2Cl_2$ nanocrystals forms when the perovskite is absent, while $Pb_4S_3Cl_2$/$CsPbCl_3$ heterostructures when it is present

(note the different stoichiometry). This approach could be pushed a step further, as we discovered how to selectively etch the perovskite domain of the heterostructures, hence obtaining phase-pure $Pb_4S_3Cl_2$ nanocrystals that could not be obtained by direct synthesis due to the competitive nucleation of $Pb_3S_2Cl_2$.

These results motivate further research on lead chalcohalides, and pave the road for the advanced control over the synthesis of colloidal inorganic nanomaterials through epitaxial templating.

2:15 PM NM05.15.04
Synthesis of MIL-Modified $BiFeO_3$ Nanocrystals for Enhancement of the Photoinduced Antibacterial Activity Under Visible Sunlight Irradiation Luca Pulvirenti, Cinzia Lombardo, Mario Salmeri, Maria Teresa Cambria and Guglielmo G. Condorelli; University of Catania, Italy

Antibiotic resistance is a critical challenge for modern medicine, although several approaches have been developed to address this serious global problem. Among these, one of the most promising systems involves the use of light-activated antibacterial agents, which, to be effective, must be irradiated with very intense visible light sources or UV radiation. However, this condition is not always easy to recreate.
Against this background, we research discusses a nanometer hybrid material consisting of nanoparticles of bismuth multiferroic ferrite (BFO) modified through the growth of Metal-organic frameworks of the MIL (Materials Institute Lavoisier), which can be activated by natural sunlight irradiation. The obtained system retains both nanometric dimensions and the intrinsic photo degradative properties of BFO that are increased by the presence of Fe-based MIL.
In our paper we argue that the chemical characterization conducted through various complementary techniques (X-ray-diffraction, thermogravimetric analysis, FT-IR and X-ray photoelectron spectroscopies) confirmed the anchorage of the organic component.
The antibacterial activity was carried out on both Gram-positive and Gram-negative species with the method of the microdilutions in liquid medium, setting up serial dilutions to the doubling of each nanocompound in the range of [100 - 0,20 µg/ml]. Our experiments demonstrate that when incubated in the dark or after pre-illumination with UV-C, the nanoparticles did not exhibit any bacteriostatic or bactericidal activity even at the highest concentration tested (100µg/ml). The antibacterial activity of the BFO@MIL against the Gram-positive species shows a significant increase in MIC (Minimum Inhibitory Concentration) and MBC (Minimum Bactericidal Concentration) values compared to BFO, confirming the photoactivating efficacy of this material following exposure to natural sunlight.
In particular, the BFO@MIL shows a reduction in MBC value (>100 to 0.39 µg/ml and >100 to 0.20 µg/ml) on two tested strains of Staphylococcus (*S. Haemolyticus* ATCC 29970 and *S. Aureus* ATCC 25923 respectively). Therefore, BFO@MIL tested on another strain of Staphylococcus (*S. Haemolyticus* ATCC 31874) shows different MIC and MBC values (0,39 to 0,20 and >100 to 0,39 µg/ml respectively)
In addition, the most relevant aspect for this material is the ability to inhibit the growth of four *E. Coli* strains (more resistant), although at the maximum concentration tested (100 µg/ml).
These results suggest that the new nanocomposite BFO@MIL has been successfully developed and has been an effective antibacterial agent against a wide range of microorganisms.

2:30 PM NM05.15.05
Enabling Applied Process Control of Solution Deposition of Hydroxyapatite Using JMP® Software Brid Murphy[1,2] and Mick A. Morris[1,2]; [1]Trinity College Dublin, Ireland; [2]SFI Centre for Advanced Materials and BioEngineering Research, Ireland

Authors:
Bríd Murphy[1,2]and Michael A. Morris[1,2]
AMBER Research Centre, CRANN Institute, Trinity College Dublin, Dublin 2, Ireland
School of Chemistry, Trinity College Dublin, Dublin 2, Ireland
Abstract:
In any novel coating technique, there are various dependencies pertaining to process and coating outcome. This results in complex dependencies on a range of interacting variables which can be extremely challenging to understand. Achieving such an understanding for solution deposited hydroxyapatite would facilitate ramping up of a lab-based system to an industrial scale system with controlled repeatability.
This work shows how automated computational models of raw data can be used to generate applied process controls for solution deposition of hydroxyapatite.
JMP® statistical software is used to build a design of experiments with process parameters as factors and characterisation data as responses. The visualisation of this data through multivariate analysis and regression modelling shows links within and between factors and responses. The DOE yielded a model for the complex solution deposited HA process which is subsequently automated using JMP Scripting language.
Some findings from the model include: (i) how initial substrate roughness influences oxygen atomic percentage of the films, (ii) how substrate roughness affects the proportionality between indicative spectroscopic peaks and (iii) how initial solution pH affects the weight of coating formed whereas temperature has little effect.
An industrial scale system could use the findings of this model to apply control limits to processing parameters leading to repeatability of coatings across separate batches. Separately, findings of this model highlight links that would be scientifically significant and worth pursuing in further research.

6:30 PM NM05.16.01
Seedless One-Pot Synthesis of Gold Nanotriangles by Non-Thermal Liquid Phase Reduction Method Mao Hamamoto, Tomoki Yasu, Asahi Kimura, Haruki Toya and Hiromasa Yagyu; Kanto Gakuin University, Japan

Gold nanotriangles (GNTs) with edge lengths of hundreds nanometer exhibits a strong absorption peak at the wavelength of approximately 600 nm due to localized surface plasmon resonance of nanoparticles. Since the peak wavelength of GNTs lied in long wavelength in comparison with spherical GNPs and the transmitted color of solution is blue, GNTs shows an improved detection on immunochromatography.

GNTs can be synthesized by the seed-growth method [1] and non-seed method [2]. In the seed method, GNPs with a few nanometer particle sizes are pre-synthesized as a seed material and the seed are grown by adding gold ion solution, capping agent, and reducing agent. In the non-seed method, GNTs can be synthesized by one pot using thermal liquid-phase reduction with citrate acid. However, since thermal reduction requires precise temperature control of the solution and the reduction rate of gold ions affects to the edge lengths of GNTs, the non-seed method is difficult to realizing a stable synthesis of GNTs with edge lengths of hundreds of nanometer. In order to stably synthesize GNTs by non-seed and non-thermal liquid-phase reduction method, we demonstrated the synthesis method using reducing agent with composition of citrate acid and tannin acid.
Solution-A was a mixture of 0.21 mL hydrogen tetrachloroaurate tetrahydrate aqueous solution (29.7 mM) and 4.8 mL cetyltrimethyl ammonium bromide (CTAB) aqueous solution (9.15 mM). Solution-B was a mixture of 128 µL sodium citrate acid solution (100 mM), 0.1 to 0.5 mL tannin acid solution (5.88 mM), and 7.5 mL distilled water. Solution-A and solution-B were mixed for 10 min in the 100 mL glass beaker with the mixing speed 700 rpm. In this experiment, the volume of sodium citrate acid solution was fixed, and the volume of tannin acid solution changed 0.1 to 0.5 mL. Following 3 days of stasis post synthesis at room temperature (23°C), the visible light absorption spectrum of the as-synthesized GNTs was recorded to analyze the peak wavelength. The edge lengths and yield of triangles (number of GNTs/total number of particles) of the as-synthesized solution after 3 days was evaluated by TEM observation.
From UV-visible absorbance spectra of solution, the solution with 0.1 mL of tannin acid solution exhibited purple color and the absorption peak at the wavelength of approximately 584 nm. The solution with 0.2 mL of tannin acid solution showed blue color and the strong absorption peak at the wavelength of approximately 619 nm. The solution with 0.3 to 0.5 mL of tannin acid solution indicated dark brown color and weak absorption peak. Moreover, the same color solution was obtained even if it was synthesized three times under the same conditions. From TEM observation, the synthesized solution confirmed that GNTs were observed in all solutions. The average edge length depends on volume of tannin acid solution and showed 127 nm with coefficient of variation of 0.74 for the solution with 0.2 mL of tannin acid solution. The yield of the triangles was 40.1 % for 0.1 mL tannin acid, 41.7 % for 0.2 mL tannin acid, 48.5 % for 0.3 mL tannin acid, and 24.8 % for 0.5 mL tannin acid. In thermal reduction method without tannin acid solution, the success rate of synthesis GNTs was 5 % and yield of the triangle was 30 %. These results confirmed that GNTs can be stably synthesized by seedless and non-thermal liquid-phase reduction method using tannin acid solution.

6:45 PM NM05.16.02
Direct Patterning of Functional Ceramics on Conducting Substrates by Local Activated via Electro-Discharge Soft Solution Processing Sumanta Kumar Sahoo[1], Yu-Cyuan Hou[1], You-Yu Chen[1], Kripasindhu Sardar[1], Satoru Kaneko[2], Kou-Shuo Chang[1] and Masahiro Yoshimura[1]; [1]National Cheng Kung University, Taiwan; [2]Kanagawa Institute of Industrial Science and Technology (KISTEC), Taiwan

The modern electronic, ionic, and energy devices fabrication industry has been involved in the patterning of a wide range of ceramic nanostructures by various sophisticated methods, such as physical vapor deposition, chemical vapor deposition, advanced lithographic techniques, ink-jet printing, spin-coating, etc. on conducting substrates. These techniques were either requiring a vacuum system, immature material processing, non-ambient atmosphere conditions, or multiple steps of batch processing in the semiconductor industry. Mostly, vacuum-based fabrication involves solid-gas-solid materials transformation, which involves significantly high thermodynamical energies than real activation energies needed in materials processing. Again, the simplified fabrication process such as ink-jet printing, 3D printing, spin coating, etc., were involved in multi-step processes, and heating. This powder dispersion material process is not efficient in fabrication technology due to immature materials synthesis techniques. Therefore, most of today’s synthesis as well as fabrication techniques are not environment friendly, as well as economically viable, which is a severe concern for a future sustainable society. Herewith, we are proposing a single-step soft solution processing for direct patterning of various functional ceramics (TiO_2, $BaTiO_3$, Al_2O_3, ZrO_2, $ZrTiO_4$, etc.) nanostructures onto a conducting substrate(s). A modified Pechini’s process has been adopted for cationic metal(s) polymer complex solution, which is used as an electrolyte. These electrolytes have been locally activated by using a strong electric field by a high precision automated three-dimensional motorized sharp metal probe and are directly micropatterned on various conducting substrates (silicon, stainless steel, aluminum foil, transparent conductive films, etc.). The localized in-situ plasma formation, as well as redox reactions of metal(s) ion enabling in forming thin-films of various ceramic nanostructures. This one-step fabrication process of direct patterning is very cost-effective and environmentally benign because of the copious amount of materials used and no use of pre/post-processing materials techniques in various printing. Various physicochemical analyses were carried out on the micro-patterned functional ceramic nanostructures. Furthermore, mechanical, and electro-analytical studies were performed to explore the functional behavior of the micropatterns.

Chirality, Stability and Optoelectronics from Nanoscale Interface of Hybrid Perovskites Angshuman Nag; Indian Institute of Science Education and Research (ISSER) Pune, India

Colloidal nanocrystals show surface-related phenomena owing to the small size of the crystal. In difference, hybrid perovskites like $(C_4H_9NH_3)_2PbI_4$ have layered crystal structure with periodic nanoscale interfaces between the inorganic $\{PbI_4\}^{2-}$ and organic $C_4H_9NH_3^+$ layers. Chemical compositions of such nanoscale interfaces can be designed in numerous ways yielding novel functionalities.[1-2] For example, chirality can be induced from the organic sublattice to the inorganic one through such nanoscale interfaces. Consequently, the optical and optoelectronic properties, that mainly contributed by the inorganic sublattice, also attains chirality.[3] In this talk, I will discuss about the composition-structure-chiroptic property relationships in a series of chiral 2D, 1D, and 0D hybrid perovskite derivative systems. The non-centrosymmetric crystal structure also leads to reasonably strong optical nonlinearity and has potential for bulk photovoltaics. I will also discuss about how non-covalent interactions (cation-p or halogen-halogen) can make such low-dimensional hybrid metal halides completely water-stable for years.[4-5] It is to be noted here that the nanoscale physical and chemical properties mentioned here is governed by low-dimensional crystal structure of the hybrid system, and not by the size of the crystal.

Pathways of Formation of Colloidal Semiconductor Magic-Size Clusters and Quantum Dots Kui Yu; Sichuan University, China

Colloidal semiconductor binary II-VI metal (M) chalcogenide (E) quantum dots (QDs) have been produced together with magic-size clusters (MSCs), sometimes. For the past 40 years, the QD synthesis has been carried out largely as an empirical art, with limited knowledge about the pre-nucleation stage. Recently, we proposed a two-pathway model to explain the co-production of QDs and MSCs. The LaMer model of the classical nucleation theory (CNT) can be used to understand one pathway, which involves the formation of monomers (Mo) and fragments (Fr) that lead to the nucleation and growth of QDs. The other pathway is multi-step based, which involves the self-assembly of M and E precursors, followed by the M-E covalent bond formation inside each assembly that results in the precursor compound (PC) of MSCs. The PC can transform to ultra-small QDs with enhanced particle yield, binary MSCs, and alloy MSCs. Our studies bring an in-depth understanding of the coproduction of QDs and MSCs and of the prenucleation stage of QDs, contributing to the promotion of the solution synthesis of functional nanomaterials from an empirical art to a science.

Structural and Magnetic Characterization of Transition Metals-Substituted Cobalt Ferrite Nanocrystals Alondra Cartagena Toledo, Charielice M. Bonilla Pérez and Yarilyn Cedeno-Mattei; University of Puerto Rico at Ponce, Puerto Rico

Cobalt ferrite is a versatile nanomaterial that has been explored due to its wide range of potential applications (technological, biomedical, environmental, among others). It can be synthesized using different methods such as hydrothermal, sol-gel, and coprecipitation. Ferrites at the nanoscale can be optimized by tuning characteristics such as: crystal size, composition, cationic distribution, and shape. The cationic distribution and interaction between them will affect and modify the magnetic properties of ferrites. Accordingly, transition metal (TM) ions were used to substitute Co ions according to $TM_xCo_{1-x}Fe_2O_4$, where 'x' corresponds to the atomic fraction of transition metal. Ni^{2+} and Mn^{2+} were selected as Co substituting species based on the similitude between the ionic radius of Co^{2+} (0.82 Å), Ni^{2+} (0.78 Å), and Mn^{2+} (0.91 Å). In addition to the ionic radii, the coordination number and magnetic nature of Mn and Ni species were considered. All ferrite samples were prepared by the conventional coprecipitation method. Mn and Ni atomic fractions, 'x', between 0.0 and 1.0 were evaluated.
Introducing foreign ions into the spinel structure will cause a change into the superexchange interaction (occurs via intermediate atoms or ions, in this case, oxygen). It is a type of inter-particle interaction that allows the magnetic moments in a solid to interact with each other. This interaction will vary depending on the element causing changes into the magnetic properties (coercivity and saturation magnetization) due to different electronic configuration. X-Ray Diffraction (XRD) and Vibrating Sample Magnetometry (VSM) results confirmed the strong influence of crystal size, ferrite composition, and lattice distortion on the corresponding magnetic properties at the nanoscale. XRD results suggest there was no a remarkable crystal growth by increasing the incorporation of Mn ions. The substitution of Co^{2+} by Mn^{2+} caused an increment in the cubic lattice parameter, 'a', attributed to the slightly larger ionic radius of Mn respect to Co. In contrast, the incorporation of Ni ions systematically increased the average crystallite size from 11 nm to 18 nm. A decrease in lattice parameter was observed as the Ni atomic fraction increased. It is attributed to the smaller ionic radius of Ni respect to Co. VSM results show a tailor in coercivity and saturation magnetization. Coercivity values between 14 and 2583 Oe, as well as saturation magnetization values ranging between 10 and 67 emu/g were obtained.

Scalable Synthesis of Large 2D Transition Metal Layered Hydroxides Lu Ping, Gillian E. Minarik, Hongze Gao and Xi Ling; Boston University, United States

The first successful exfoliation of graphene[1] in 2004 sparked a dramatic increase in 2D materials research and the repertoire of 2D materials family has since expanded. 2D crystals composed of single or few atomic layers display unique chemical, optical, and electronic properties compared with their bulk 3D counterparts due to the quantum confinement effect at the 2D limit[2]. Two–dimensional (2D) transition metal layered hydroxides (TM–LHs), a class of materials composed of transition metal centers sandwiched between layers of coordinating hydroxide anions have attracted considerable interest for their potential in developing clean energy source[3,4] and storage technologies[5,6]. However, 2D TM–LHs with desired large domain size for electronic devices are not achieved yet, owing to challenges in reproducibility of 2D morphology and long-range crystallinity, limiting the domain size of previously reported samples (<5 μm)[7,8]. Here, we report repeatable synthesis of 2D α–$Ni(OH)_2$ crystals of lateral size ∼20 μm with ∼8 atomic layers derived from a condition-controlled hydrothermal process. A detailed investigation on the influence of the most critical synthetic conditions, including soaking temperature, starting pH, and cooling rate, on the domain size, crystal phase, and morphology was performed, providing mechanistic insights into the formation of 2D α–$Ni(OH)_2$ under hydrothermal reaction conditions. Moreover, the optical band gap energy of the synthesized 2D $Ni(OH)_2$ flakes is extrapolated as 2.55 eV from optical absorption measurements, suggesting the insulating nature. Electrical measurements further confirmed the insulating nature of the synthesized flakes, and a dielectric strength of up to 3.2 MV/cm was collected on a 4.9 nm flake (∼6 atomic layers), which makes it a promising candidate for gate dielectric materials for 2D FETs devices. Furthermore, the crystal fields and orientations of 3d transition metals were compared and analyzed to evaluate the applicability of this method to other 3d first–row TM–LHs. 2D $Co(OH)_2$ was successfully synthesized following the same pathway, promoting the hydrothermal method as a facile, generalizable method for large–scale preparation of 2D TM–LHs. This work demonstrates a scalable pathway to synthesize large 2D TM–LHs flakes from simple methods and paves the way for the fundamental physical properties study and device applications of the 2D TM–LHs.

10:45 AM NM06.01.03
Epitaxial Growth of Single-Crystal Hexagonal Boron Nitride Multilayers on Ni(111) Kyung Yeol Ma[1,2], Leining Zhang[2,1], Rodney S. Ruoff[1,2,1], Manish Chhowalla[3], Feng Ding[2,1] and Hyeon Suk Shin[1,2]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Institute of Basic Science (IBS), Korea (the Republic of); [3]University of Cambridge, United Kingdom

Large-area single-crystal monolayers of two-dimensional (2D) materials such as graphene, hexagonal boron nitride (hBN) and transition metal dichalcogenides have been grown. hBN is considered to be the 'ideal' dielectric for 2D-materials-based field-effect transistors (FETs), offering the potential for extending Moore's law. Although hBN thicker than a monolayer is more desirable as substrate for 2D semiconductors, highly uniform and single-crystal multilayer hBN growth has yet to be demonstrated. Here we report the epitaxial growth of wafer-scale single-crystal trilayer hBN by a chemical vapour deposition (CVD) method. Uniformly aligned hBN islands are found to grow on single-crystal Ni(111) at early stage and finally to coalesce into a single-crystal film. Cross-sectional transmission electron microscopy (TEM) results show that a $Ni_{23}B_6$ interlayer is formed (during cooling) between the single-crystal hBN film and Ni substrate by boron dissolution in Ni. There are epitaxial relationships between hBN and Ni23B6 and between $Ni_{23}B_6$ and Ni. We also find that the hBN film acts as a protective layer that remains intact during catalytic evolution of hydrogen, suggesting continuous single-crystal hBN. This hBN transferred onto the SiO_2 (300 nm)/Si wafer acts as a dielectric layer to reduce electron doping from the SiO_2 substrate in MoS_2 FETs. Our results demonstrate high-quality single-crystal multilayered hBN over large areas, which should open up new pathways for making it a ubiquitous substrate for 2D semiconductors.

11:00 AM NM06.01.04
First Observation of Suspended AA-Stacked Hexagonal Boron Nitride Grown on GaN Substrate by Metal-Organic Chemical Vapor Deposition Seokho Moon[1], Adrien Rousseau[2], Francis N. Odongo[1], Youngjae Kim[3,4], Yunjae Park[5,6], Jiye Kim[1], Jaewon Kim[7], Pierre Valvin[2], Jaehee Cho[8], Feng Ding[5,6], Jaedong Lee[3], Si-Young Choi[1], Bernard Gil[2], Guillaume Cassabois[2] and Jong kyu Kim[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]CNRS-Universite de Montpellier, France; [3]Daegu Gyeongbuk Institute of Science and Techology, Korea (the Republic of); [4]Korea Institute for Advanced Study (KIAS), Korea (the Republic of); [5]Ulsan National Institute of Science and Technology, Korea (the Republic of); [6]Institute for Basic Sciecne, Korea (the Republic of); [7]Samsung Advanced Institute of Technology, Korea (the Republic of); [8]Jeonbuk National University, Korea (the Republic of)

Hexagonal boron nitride (h-BN), an insulating two-dimensional layered material, has attracted great attention due to its fascinating properties and promising applications across the fields of photonics, quantum optics, and electronics. Given the layered structure of h-BN, various polytypes exist with high-symmetry stacking sequences where successive layers are rotated or translated, leading to a variety of physical properties. Almost all h-BN layers, either synthesized by various growth techniques or exfoliated from h-BN crystal, exhibit the AA′-stacking sequence, in which neighboring layers are arranged such that B and N atoms alternate along the *c*-axis,[1–3] due to its thermodynamic stability.[4,5] Although theoretical and experimental research on other h-BN polytypes including Bernal (AB) BN[5,6] and rhombohedral BN[7] were carried out, there is virtually no experimental observation of the h-BN with AA stacking where individual layers are periodically aligned along the c-axis without translation or rotation, because it is not likely to be formed in thermodynamic point of view.
Here, we report the growth of few-layer AA-stacked h-BN on a 2-inch epitaxial gallium nitride (GaN) wafer by using metal-organic chemical vapor

deposition (MOCVD). The h-BN has a very unique feature, in which 6~7-layer h-BN with AA stacking sequence is suspended on GaN nanoneedles. The formation of the AA-stacked h-BN is confirmed by the fifth-order aberration-corrected scanning transmission electron microscopy (Cs-STEM), unique deep ultraviolet photoluminescence (PL) spectra, and density-functional theory (DFT) calculation. A triangular configuration irrespective of layer number in Low-angle annular dark-field (LAADF)-STEM image and the interlayer distance slightly larger than that of exfoliated AA′ stacked h-BN in cross-sectional bright field (BF)-STEM image of the suspended h-BN film clearly show the AA stacking configuration. In addition, The band-edge phonon-assisted recombination PL spectra at 4 K reveal key fingerprints brought by the AA-stacked h-BN including the vertical translation of the bandgap, different lineshape and scattering amplitude of phonon replica, and the abscence of typical defect-related emission below 5.6 eV compared to exfoliated AA′ stacked h-BN, which is consistent with DFT calculations. The mechanism of the formation of such unique and unprecedented atomic stacking will be discussed with nanoscopic optical and structural characterizations and theoretical calculations.

11:15 AM NM06.01.05
MOCVD Growth of Large-Scale TMDCs and Heterostructures Suhee Jang, Wonjun Chang and Won Il Park; Hanyang University, Korea (the Republic of)

Heterostructures (HSs) based on atomically thin two-dimensional transition metal chalcogenides (TMDCs) have gained increasing attention due to their chemical stability and unique interactions between materials, together with the applications in many fields such as electronics and optics Despite the advances in the fabrication of vertical HSs through multiple steps of mechanical exfoliation and transfer, this approach suffers from fabricating 2D HSs on a large scale and precious control of the size, position, and the number of layers. In this study, we studied the large-area direct growth of TMDCs and their HSs (e.g., graphene/TMDC and TMDC/TMDC)using metal-organic chemical vapor deposition. We found that two mechanisms appear in the formation of heterogeneous structures: (1) epitaxial growth within the grain and (2) selective growth on defects. The formation of a two-dimensional heterogeneous structure with unique characteristics was verified by analyzing the structural, bonding, and interaction characteristics between various types of graphene/TMDCs and TMDC/TMDC HSs. We confirmed that the 2D HSs with abrupt heterointerface were uniformly grown over large-area using SEM, TEM, Raman, and PL analysis. By analyzing how the crystallinity of TMDC grown directly on the graphene changes depending on the crystalline direction of the graphene, we confirmed the epitaxial growth tendency in the process of forming heterogeneous structures. In particular, the TMDC HSs selectively grown on graphene defects possesses ion channels comprising (i) van der Waals interlayer gaps for optimal Li+ extraction and (ii) negatively charged vertical inlets for cation attraction.

11:30 AM NM06.01.06
Two-Dimensional Indium Nitride Realized via Confinement Heteroepitaxy Furkan Turker[1], Chengye Dong[1], Zachary Trdinich[1] and Joshua A. Robinson[1,1,2]; [1]The Pennsylvania State University, United States; [2]Two-Dimensional Crystal Consortium, United States

Novel confinement techniques facilitate the formation of non-layered two-dimensional (2D) III-V semiconductors, e.g. GaN, with thickness-dependent optoelectronic properties. However, a gap lies in the experimental demonstration of 2D InN with its true atomic structure. Here, we demonstrate the formation of highly crystalline bilayer InN, at the bilayer quasi-free-standing epitaxial graphene (QFEG)/SiC (0001) interface via intercalation of metallic In and subsequent nitridation. Our scanning transmission electron microscopy (STEM) studies show that 2D InN is epitaxial to the underlying SiC (0001) with R3M space group, verified via Density Functional Theory. Furthermore, vertical transport studies on QFEG/2D InN/n-SiC demonstrate that the ohmic behavior of the QFEG/SiC transforms into tunneling junction via 2D InN intercalation. Importantly, electron energy loss spectroscopy (EELS) and transport analyses demonstrate that the band gap of 2D InN is ~2 eV, which is significantly larger than the one of bulk InN (0.7 eV). These results suggest strong quantum confinement effects for the InN in 2D limit.

SESSION NM06.02: Synthesis of 2D Materials and Heterostructures II
Session Chairs: Nicholas Glavin and SungWoo Nam
Monday Afternoon, November 28, 2022
Hynes, Level 2, Room 207

1:30 PM *NM06.02.01
Wafer-Scale Growth and Integration of Two-Dimensional Transition Metal Dichalcogenides Minsu Seol, Min Seok Yoo, Junyoung Kwon, Sang Won Kim and Kyung-Eun Byun; SAIT, Samsung Electronics, Korea (the Republic of)

So far, two-dimensional (2D) transition metal dichalcogenides (TMDs) have received great attention for their use as channels in electronic devices. The confined charges in atomically thin channels allow improved electrostatic gate control and reduced short-channel effects, which could facilitate continued transistor scaling. However, the integration of 2D TMDs with Si CMOS platforms has been a great challenge owing to the lack of high-throughput and large-scale production, proper characterization and integration processes for TMDs.
In this talk, we present our works on the growth, characterization, and integration of 2D TMDs. First, we demonstrate high-throughput production of 6~8-inch wafer-scale monolayer MoS_2 and WS_2 via a pulsed metalorganic chemical vapor deposition technique, using $Mo(CO)_6$, $W(CO)_6$, and $(C_2H_5)_2S_2$ as precursors. Periodic interruption of the precursor supply allowed successful regulation of secondary nucleation even under high growth rates, and as a result, wafer-scale monolayer MoS_2 and WS_2 were obtained within 12 min. Second, we present non-destructive characterization of wafer-scale TMDs. In particular, we used spectroscopic ellipsometry for analyzing both TMD and the dielectric thin film deposited on TMD at the same time. Third, we exhibit integration of TMDs as a channel of the field-effect transistor (FET). Thanks to the well-stitched continuous structure over the whole wafer, the as-grown TMDs can be transferred onto any desired substrate with minimal degradation via reliable wafer-scale de-bonding and bonding processes. On the basis of

our transferred TMD films, we demonstrate 8-inch wafer-scale batch fabrication of FETs via standard photolithography, and they showed uniform electrical performance with > 90% yield. Additional challenges on materials growth and device fabrication will also be discussed.

2:00 PM NM06.02.02
Wafer-Scale Synthesis of Monolayer 2D Polymers for Ultrathin Membranes and Heterostructures Yu Zhong[1], Baorui Cheng[2] and Jiwoong Park[2]; [1]Cornell University, United States; [2]The University of Chicago, United States

2D polymers are made by cross-linking molecules into a 2D network which can be viewed as organic analogs of 2D atomic crystals. They are not only a new library of 2D building blocks for making vdW heterostructures but also offer unlimited structural tunability on the molecular level. In this talk, I will introduce a synthetic approach to synthesizing monolayer 2D polymers on a large scale. This approach incorporates key features necessary for scalable and facile processing, including large-area synthesis, ambient growth conditions, and compatibility with established patterning and integration methods. The 2D polymer films can serve as the thinnest semipermeable membranes, which deliver a record high osmotic power generation density. Furthermore, I will show the programmed assembly of hybrid organic-inorganic 2D heterostructures with monolayer precision. This approach allows for integrating versatile molecular building blocks into layered nanomaterials to develop ultrathin electronic devices.

2:15 PM *NM06.02.03
Synthesis and Application of Multifunctional Two-Dimensional Materials Jun Lou; Rice University, United States

Two-dimensional (2D) materials, such as Graphene, h-BN and MoS_2, are promising candidates in a number of advanced functional and structural applications, owing to their exceptional electrical, optical, electrochemical and mechanical properties. Scalable growth of high quality 2D materials is crucial for their adoption in technological applications the same way the arrival of high-quality silicon single crystals was to the semiconductor industry. While CVD growth of wafer-scale monolayer graphene and TMDs has been demonstrated, considerable challenges still remain. In this talk, we first demonstrate the importance of real-time monitoring 2D crystal growth morphology as an underpinning for understanding, diagnosing and controlling the CVD process and environment for 2D material growth [1]. Using a micro-CVD setup facilitated by machine learning algorithms, the mapping of MoS_2 crystal shapes in the growth parameter space "encodes" a wealth of information, the deciphering of which led to better understanding of the fundamental CVD growth mechanism of 2D TMDs.

Next, we show that high quality ultrathin h-BN films are impervious to oxygen diffusion even at high temperatures and can serve as high-performance oxidation resistant coatings for nickel up to 1100ºC in oxidizing atmospheres. The corrosion passivation performance in Na_2SO_4 solution of bare and h-BN coated copper indicates that such h-BN films could effectively suppress the anodic dissolution of copper. Inspired by these successes, we demonstrate the.

2:45 PM BREAK

3:15 PM NM06.02.04
2D Molybdenum Dichalcogenides by Atomic Layer Deposition Raul Zazpe[1,2], Jaroslav Charvot[1], Ludek Hromadko[1,2], Hanna Sopha[1,2], Jhonatan Rodriguez-Pereira[1,2], Filip Bures[1] and Jan Macak[1,2]; [1]University Pardubice, Czechia; [2]Central European Institute of Technology, Czechia

2D semiconductor transition metal dichalcogenides have attracted considerable attention due to their layered structure, suitable band gap, electrochemically active unsaturated edges and relatively good stability against photocorrosion. These properties result promising for different applications including, Li-ion batteries, photocatalysis and hydrogen evolution reaction (HER). Apart from the widely studied 2D MoS_2, 2D selenide and telluride equivalents, $MoSe_2$ and $MoTe_2$, have recently gained considerable interest due to their higher electrical conductivity, wider inter-layer distance and narrower bandgap as compared to MoS_2, high surface area and close to zero Gibbs free energy edges for hydrogen adsorption.
Unlike sulfide dichalcogenides, the lack of Se and Te precursors have prevented the synthesis of selenide and telluride dichalcogenides by ALD. In order to surpass such impediment, we present a set of novel in-house synthesized Se and Te compounds, which were successfully combined with commercial Mo precursor to synthesize $MoSe_2$ and $MoTe_2$ by ALD [1-5]. The as-deposited ALD $MoSe_2$ and $MoTe_2$ on substrates of different nature were extensively characterized by different techniques, which confirmed the chemical composition and revealed the growth of 2D flaky nano-crystalline $MoSe_2$ and $MoTe_2$. In parallel, $MoSe_2$ and $MoTe_2$@TiO_2 nanotube layers (TNTs) heterostructures were fabricated in a simple and fast fashion to explore and exploit the $MoSe_2$ and $MoTe_2$ photo- and electrocatalytic properties. TNTs act as excellent photoactive supporting material providing a high surface area, unique directionality for charge separation, and highly effective charge collection.
The presentation will introduce and describe the synthesis of the 2D Mo dichalcogenides, the corresponding physical and electrochemical characterization and encouraging results obtained in HER [4,5], photocatalysis [4-6] and Li-ion batteries [7].

Bio-Inspired Curved Artificial Visions Using Ultrathin Layered Materials Dae-Hyeong Kim[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Although recent efforts in device designs and fabrication strategies have resulted in meaningful progresses to the goal of the high-performance artificial vision, significant challenges still exist in developing a miniaturized and highly-sensitive artificial vision that enables the wide field-of-view (FoV) and/or

amphibious imaging. This is mainly due to bulky, heavy, and multiple lenses employed in the conventional wide-angle imaging devices. In this talk, inspired by structural and functional features of the natural visions, novel wide FoV artificial visions using curved ultrathin image sensor arrays are introduced. The bio-inspired artificial visions offer the wide FoV, a miniaturized module size, minimal optical aberrations, a deep depth-of-field, an enhanced light sensitivity, and an amphibious imaging capability in a simple integrated device format. Theoretical analyses in conjunction with imaging demonstrations have corroborated the validity of the proposed concept. These bio-inspired artificial visions are expected to provide new opportunities for the advanced electronics and robotics.

CVD Synthesis and Properties of Monolayer Lateral Heterostructures and Janus TMDs Andrey Turchanin; Friedrich Schiller University Jena, Germany

Lateral heterostructures (LH) of monolayer transition metal dichalcogenides (TMDs), as well as Janus TMDs, open broad avenues for the engineering of novel nanomaterials for both basic research and applications. In this presentation, I will give an overview of our recent progress on the one-pot synthesis based on chemical vapor deposition, characterization of the basic properties, and device applications of these 2D materials including such systems as LH $MoSe_2$-WSe_2 and Janus SeMoS, and other related systems. A particular focus will be placed on the correlation between their structural and electronic/photonic properties. It will be also demonstrated how these advanced 2D materials can be employed in a variety of devices including phototransistors, rectifiers, photodetectors, ambipolar and anti-ambipolar transistors, electroluminescent light emitters, *etc*.

High Yield, Bottom-Up/Top-Down CVD Synthesis of 2D Layered Metal Selenides—A Promising Class of Materials for Applications in Electronics and Electrochemistry Gilbert D. Nessim; Bar Ilan University, Israel

Since the excitement about graphene, a monolayer of graphite, with its 2010 Nobel Prize, there has been extensive research in the synthesis of other non-carbon few/mono-layers exhibiting a variety of bandgaps and semiconducting properties (e.g., n or p type). The main approaches to deposit few/monolayers on a substrate are: (a) bottom-up synthesis from precursors using chemical vapor deposition (CVD) or (b) top-down exfoliation (liquid or mechanical) of bulk layered material.
Here we show a combined bottom-up and top-down approach where (a) we synthesize in one step high yields of bulk layered materials by annealing a metal in the presence of a gas precursor (sublimated selenium from selenium powder) using chemical vapor deposition (CVD) and (b) we exfoliate and deposited (dropcast or Langmuir Blodgett) few/mono-layers on a substrate from a sonicated mixture of our material in a specific solvent. It is interesting to note that, besides the structure being 2D layered, the properties of the nanomaterials synthesized slightly differ from the materials with the same stoichiometry synthesized using conventional chemical methods (e.g., solvothermal).
In this talk, we will discuss the chemical synthesis, the very extensive characterizations, and the lessons we learned in making multiple metal selenides (Ag-Se, Cu-Se, W-Se, Mo-Se, etc.). We will see how we integrated these new materials into sensors, as functional coatings, and into electrochemical devices (see selected published papers below).

Van der Waals Contact Interface and Band Alignments Study of Bi Contacts on Variable Transition Metal Dichalcogenides Seong Yeoul Kim, Xinglu Wang, Roy Joy and Robert M. Wallace; The University of Texas at Dallas, United States

The issue of high contact resistance (R_c) has remained an unsolved issue for transition metal dichalcogenides (TMDs) and it became more significant in sub-nano channel lengths. While the recent findings on bismuth (Bi) metal contacts on MoS_2 have reported remarkably low contact resistance and high on-current density, these results are not yet fully established.[1] It is necessary to first understand the interfacial chemistry and the band alignment between Bi and TMDs because the Fermi level may vary depending on the interfacial properties.[2]
In this work, the interface properties of Bi/TMDs (MoS_2, $MoSe_2$, WS_2, and WSe_2) are investigated by utilizing an *in-situ* ultrahigh vacuum (UHV) cluster

system including X-ray photoelectron spectroscopy (XPS) and an e-beam evaporator.[3] Metallization and interface analysis was conducted within UHV conditions to allow the precise investigation of the Bi/TMDs interface made possible by suppressing the effect of contamination from the ambient. Band alignments were investigated by using XPS core-level shift and valence band maximum spectra of the Bi/TMDs interface. The Fermi levels of the Bi/TMD interfaces are formed close to the conduction band minimum for all investigated TMDs after Bi deposition. Additionally, it was found that bonding associated with interfacial reaction of Bi/TMDs was below the limit of XPS detection (< 1 at. %). Based on the atomic force microscopy (AFM), Bi metal follows a Volmer-Weber (VM) growth mode consistent with a lack of interaction between Bi and TMDs. Ultimately, these results show that Bi forms van der Waals (vdW) interface with n-type contact properties on variable TMDs semiconductor materials.

Strain-Resilient Field-Effect Transistors Based on Wrinkled Graphene/MoS_2 Heterostructures Hyunchul Kim, Kevin Zhao and Arend M. van der Zande; University of Illinois at Urbana-Champaign, United States

Realizing stretchable field-effect transistors (FETs) and integrated circuitry requires new materials that are simultaneously strain resilient yet have high electronic mobility. Two-dimensional (2D) materials are one of the most promising materials for flexible and stretchable FETs because of their extraordinary mechanical, electrical, and optical properties. For example, transistors from 2D heterostructures or with ALD grown gates on flexible substrates have been shown to accommodate strains of up to 1.5% and have device mobilities of 233 cm^2/Vs[1,2]. Meanwhile, leveraging principles of wrinkling, crumpling or kirigami have all been used to impart stretchability of well above 100% by leveraging the ultra-low bending modulus of 2D materials to minimize strain through 3D deformation[3]. These strategies have been used to demonstrate stretchable devices like electrodes, photodetectors, or strain sensors. The next step with enormous potential for high mobility yet stretchable integrated circuitry is to bring the 3D deformation with 2D heterostructures together to demonstrate stretchable FETs which leverage all the strengths of 2D materials.
In this work, we fabricated stretchable FETs on a soft substrate where 2D materials formed all the active electronic layers. Patterned graphene forms the electrodes and local gate, while MoS2 serves as the transistor channel. ALD HfO_2 is the dielectric layer and also serves as the mechanical support. The entire structure is less than 15 nm thick, so it has a very low bending modulus, enabling easy 3D deformations that minimize strain. To achieve stretchability, we leveraged the principles of self-assembled wrinkling and kirigami. Transferring the device onto the pre-strained elastomer and releasing the strain induces wrinkling of the devices with wavelengths of 7.7 microns, smaller than the transistor channel. We patterned kirigami cuts onto the electrodes and between devices, which serve to help relieve strain and guide the wrinkling patterns. We examined the electrical properties of the FETs under compression and stretching. The initial experimental data shows that before applying strain, the FET on current was 0.14 μA, while the on/off current ratio was ~10^3. The current device performance is limited by high contact resistance, which has been shown can be much lower in graphene-contacted MoS2 devices on hard substrates, and can likely be improved. As a very promising sign, the electrical performance did not change for up to 21% compression.
This work provides a new strategy of strain-resilient 2D heterostructure FETs, which opens up new applications like strain-resilient integrated circuits, as well as fundamental investigations of how heterogeneous strain will affect electron transport.

Highly Stretchable van der Waals Thin Films for Adaptable and Breathable Electronics Xiangfeng Duan; University of California-Los Angeles, United States

The integration of electronic systems with irregular, soft objects is of increasing interest for many emerging electronic applications including ubiquitous electronics for internet of things and bioelectronics intimately interacting with living organisms. The conventional electronics are typically made from hard inorganic materials cannot be easily integrated with soft biological structures due to the intrinsic mismatch in mechanical properties, permeability and environmental adaptability. Although the hard inorganic materials can be made flexible in the ultrathin membrane format, they are hardly stretchable and fundamentally incapable of forming conformal interface with irregular geometries with non-zero Gaussian curvatures due to the topological limitations. Here we I will discuss a unique design of highly stretchable van der Waals thin films (VDWTFs) for microscopically adaptable membrane electronics. Assembled from solution-processable two-dimensional (2D) nanosheets, the VDWTFs feature bond-free vdW interactions among the staggered nanosheets, with a sliding and rotation degree of freedom between neighbouring nanosheets to ensure extraordinary mechanical flexibility, stretchability, malleability and adaptability to irregular surface topographies. Additionally, the staggered nanosheet architecture features a highly interconnected percolation network of nanometre-scale channels with an excellent permeability. The freestanding VDWTFs show an excellent mechanical match with soft biological tissues, naturally adapting to microscopic topographies and directly merging with dynamically changing organisms with highly conformal interfaces, endowing living organisms with electronic functions, including leaf-gate and skin-gate VDWTF transistors. With excellent conformability and adaptability to skin textures, the skin transistors allow for high fidelity monitoring skin potentials and electrophysiological signals with excellent signal-to-noise ratio and superior immunity to motion artifacts.The VDWTFs thus define a new platform of electronic membranes readily adaptable to different form factors, and can open up exciting opportunities for many emerging electronic applications.

Insertion of a Layered Electride for Low-Resistivity 2D Semiconductor Contacts Fouad Kaadou, Mohammad Rafiee Diznab, Ethan Gysbertsen, Adrian Rumson, Erin Johnson and Jesse Maassen; Dalhousie University, Canada

A major challenge for 2D semiconductor-based devices is achieving low-resistance, barrier-free metal contacts. Parasitic contact resistance can significantly degrade device performance, including switching speed and power consumption. Some of the issues hindering the formation of ohmic contacts to 2D semiconductors include: weak van der Waals bonding to many metals leading to tunneling barriers, strong chemical bonding to metals that significantly alter the electronic states of the atomically-thin semiconductor, and Fermi-level pinning. New strategies to form low-resistivity ohmic contacts that eliminate Schottky/tunneling barriers are needed, such as phase engineering [1], Fermi-level depinning [2] and semimetal contacts [3].

In this talk, we focus on the insertion of a 2D electride between the metal and the 2D semiconductor, to promote charge transfer and eliminate the potential barrier to facilitate electron transport [4]. Layered electrides are ionic solids with loosely-bound conducting electrons located in the interstitial regions between the atomic layers, and on their surfaces when exfoliated to form 2D electrides. Using density-functional theory we explore the electronic properties of semiconductor-electride-metal heterojunctions, with an emphasis on monolayer MoS_2 as the 2D semiconductor, Ca_2N as the 2D electride and gold as the metal. An analysis of the charge transfer, exfoliation energy, band structure and electrostatic potential demonstrates that Ca_2N donates nearly all of its surface charge resulting in the metallization of the MoS_2 and a barrier-free contact. By comparison, the electride-free MoS_2-Au contact displays a large tunneling barrier and Fermi-level pinning. These findings suggest that introducing a layered electride in the 2D semiconductor-metal interface is a promising strategy towards achieving ultralow-resistivity, ohmic contacts.

Hydroxide Vapor Phase Deposition for Low-Defect-Density 2D TMDs Growth Yi Wan and Li Lain-Jong; The University of Hong Kong, Hong Kong

Two-dimensional (2D) semiconducting monolayer materials such as transition metal dichalcogenides (TMDs) MX_2 (M=Mo, W; X=S, Se) are considered promising as channel materials to extend the Moore's Law in the post-Si era. Recently, wafer-scale single-crystal TMD monolayers have been demonstrated by chemical vapor deposition (CVD), which shows homogeneous electrical performance due to the decreased grain boundaries. Nevertheless, the abundant point defects in TMD monolayers like vacancies and impurities introduced during the synthetic processes limit their electrical quality. Thus, innovative endeavors on growth reactions to realize low-defect-density growth are urgently needed. Here, we reported that adopting extremely pure metal precursor in combination with hydroxide vapor phase deposition (OHVPD) enables the growth of low-defect-density TMD monolayers. The PL spectra show the superior optical quality of OHVPD-TMD monolayers (i.e., WS_2 and MoS_2) with higher peak energies and narrower FWHM compared to conventional CVD samples. The scanning tunneling microscopy (STM) images show that the transferred OHVPD-TMD monolayers have one order of magnitude lower defect density compared to samples prepared by the CVD method. The field effect transistor (FET) devices based on OHVPD-WS_2 monolayers reach a peak electron mobility of ~200 cm^2/Vs at room temperature, and ~800 cm^2/Vs at 15K. The on-state current of short-channel-length devices (100 nm) reaches a value of ~400 mA/mm. Based on STM and device measurements, the as-grown high-quality TMD monolayer films are less susceptible to subsequent film transferring and device fabricating processes.

Electrical Transparency of Tungsten Disulphide-Graphene Heterostructures Sayanti Samaddar, Olga Kazakova, Alexander Tzalenchuk and Cristina E. Giusca; National Physical Laboratory, United Kingdom

Vertical heterostructures of tungsten disulphide on graphene (WS_2/graphene) are relevant for optoelectronic, spintronic, and valleytronic devices, all requiring detailed knowledge of the electronic interface properties.
We investigated the electrical nature of such interfaces without conventional device integration and associated fabrication that is often detrimental to the structural integrity of monolayer materials, by using a four-probe scanning tunnelling microscope. The measurements provided important insights into the electrical transport properties of monolayer WS_2 synthesized by chemical vapour transport on epitaxial graphene, featuring a Schottky-type contact between the metallic probe and WS_2, but Ohmic transport in the WS_2/graphene heterostructure, and a highly transparent interface evidenced by the measured four-probe resistances.
The electrical transparency of the WS_2/graphene interface is of considerable significance to a range of applications related to ultrathin electronics and optoelectronics seeking to overcome challenges associated with achieving optimized and reliable contacts to atomically thin materials.

Intrinsic High-Order Ionic Layered Superlattices in 2D DJ-Phase Oxide Perovskites Kyungjune Cho[1], Haena Yim[1], Takhee Lee[2], Ji-Won Choi[1] and Seungjun Chung[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

2D layered materials have emerged as promising materials due to their attractive physical properties[1]. In addition, the vast variety of promising 2D material candidates, including graphene, h-BN, TMCs, MAXenes, and nanosheet family, and the ability to realize heterostructures with a high degree of freedom provides us huge opportunities freeing up the structural design of functional devices and their material combinations. These attractive properties offer tremendous possibilities to expand the functionalities of 2D material-based devices for various future applications.[1]
In this sense, novel 2D layered materials are always welcome. Recently, layered oxide perovskites have gained huge attention by means of their high stability and tunability. Additionally, an oxide perovskite monolayer was successfully exfoliated by ion-exchange methods from Dion-Jacobson (DJ) phase ($A'A_{n-1}B_nX_{3n+1}$) bulk perovskite crystals, immersing themselves into the world of 2D materials. Innately, perovskite materials are highly tunable in their compositions. Not only that, as well as other 2D layered materials, low-dimensional perovskite layers are expected to exhibit novel physics, which means that exploring their intrinsic material properties is highly demanded.[2]
In this presentation, we will introduce unprecedented intrinsic high-order ionic layered superlattices in 2D DJ-phase oxide perovskites. We have confirmed that these exfoliated 2D DJ perovskite layers are compatible with the conventional 2D vdW platform by successfully picking them up with the PDMS stamp which has been conventionally used in the field of 2D vdW materials. Owing to the design freedom of the vdW platform, we could fabricate vertical junction devices with 2D DJ-phase oxide perovskite $Sr_2Nb_3O_{10}$ flakes employing graphene (Gr) electrodes which are known to be suitable for investigating intrinsic properties of materials due to their passive nature. From the systematic measurement of electronic properties of the vertical junction devices, the intrinsic high-order ionic layered superlattices in few-layer SNO flakes could be found. During the ion-exchange process for exfoliation, there will always be few-layer flakes that are not fully exfoliated. Thus, this a few-layer SNO flake (HSNO) has alternative layers composed of positively charged proton layers (H^+) and negatively charged SNO layers ($Sr_2Nb_3O_{10}^-$) forming ionic layered superlattices. These superlattices can introduce quantum wells along the z-axis, resulting in the resonance tunneling through the quantum wells formed through the vertical junction and huge charge trapping in the energy well structures. Additionally, unprecedented memristor devices and artificial synaptic devices will be shown as potential applications by virtue of quantum wells and their charge trapping behavior from the intrinsic ionic superlattices. We believe that our results pave the way for understanding emerging 2D layered DJ oxide perovskite materials.

Graphene Heterostructure Field Effect Transistors Encapsulated by Isotopically Pure Hexagonal Boron Nitride Aroop K. Behera[1], Ayaz Ali[2,3], C. Thomas Harris[4,4], Douglas V. Pete[4,4], Eli Janzen[1], Ozhan Koybasi[2], James H. Edgar[1], Branson D. Belle[5] and Suprem R. Das[1,1]; [1]Kansas State University, United States; [2]SINTEF DIGITAL, Norway; [3]University of Sindh, Pakistan; [4]Sandia National Laboratories, United States; [5]SINTEF, Norway

Graphene, an atomically layered 2D semimetal has been a prime focus of study in the last two decades for its use as a channel material in field effect transistors (FETs) due to its high carrier mobility originating from graphene's linear band dispersion. Recent studies have also shown that enhanced electrical mobility, low contact resistance and ballistic transport can be achieved in graphene by fabricating one-dimensional edge contacts in a graphene channel encapsulated by hexagonal boron nitride (hBN)[1]. Furthermore, low frequency noise (LFN) studies on such hBN encapsulated graphene heterostructure field effect transistors (HFETs) have shown ultra-low noise in carrier rich regions[2]. However, most of the studies on graphene-based HFETs incorporate hexagonal boron-nitride with naturally occurring boron isotopic concentration. Boron, a constituent element in hBN, has two isotopes, ^{10}B and ^{11}B. Naturally occurring hBN has a boron constituent ratio of 20% ^{10}B and 80% ^{11}B. In this presentation we will discuss a comparative study that we performed on both the temperature dependent transport and LFN of single layer graphene (SLG) HFETs encapsulated in natural and isotopically pure hBN. Understanding the carrier physics of SLG in different isotopically pure encapsulated geometries will aid us in engineering low-noise graphene-based FETs for future digital electronics.

Synthesis of 2D Crystals and Structures for Electronic Devices Xi Ling and Kyungjune Cho; Boston University, United States

Developing new type of 2D materials remains highly desirable given their versatile properties and applications in electronic nanodevices. Conventional 2D materials such as graphene and transition metal dichalcogenides, whose bulks are van der Waals layered materials, have been realized through top-down mechanical exfoliation and self-limited in plane growth using chemical vapor deposition (CVD), thanks to the weak binding among layers in their bulks. Consequently, unprecedented properties have been observed in the monolayers compared to the bulk. However, the majority materials in nature, are atomically bonded in three-dimensional mode. Synthesizing atomically thin 2D crystals of these materials using the conventional synthetic strategies remains a great challenge. In addition, although progress has been made in successful synthesis of a library of van der Waals 2D materials such as graphene and transition metal dichalcogenides, there are still a lot of members in the family underexplored. Driven by the need of high crystallinity and scalable 2D materials for electronic devices, as well as a low thermal budget growth condition enabling the 3D monolithic integration, our group focuses on developing effective synthesis strategies for various 2D crystals with diverse electronic properties. In this talk, I will first introduce the atomic substitution method where we chemically convert layered metal chalcogenides such as MoS2, WS2 and GaS, to ultrathin metal nitrides such as MoN_x, WN_x, and GaN. The thickness of the obtained nitrides can be tuned by using different number of layers of metal chalcogenides, providing a platform for the study of their fundamental properties at quantum region and for the application in nanoelectronics devices. Moreover, the conversion process is investigated using transmission electron microscope, where edge and surface conversion are observed, leading to the formation of lateral and vertical heterostructures. Particularly, a mask-assisted method is used to obtain the MoS_2-MoNx-MoS_2 lateral junction, where metallic MoNx serves as the electrode for semiconducting MoS_2 field-effect transistors (FET). Second, I will introduce our recent work on realizing ultrathin 3d metal hydroxides with long-range ordering. The UV-vis. spectra bandgap and electrical measurements show the semiconductor behavior of the materials.

1:30 PM NM06.04.01
Giant Intrinsic Spin-Orbit Torque and Device Applications Based on Topological van-der-Waals Ferromagnetic Metal Fe_3GeTe_2 Kaixuan Zhang[1], Jingyuan Cui[1], Hyun-Woo Lee[2] and Je-Geun Park[1]; [1]Seoul National University, Korea (the Republic of); [2]Pohang University of Science and Technology, Korea (the Republic of)

Electrical control of magnetic states triggers a new era of spintronic applications and device functionalization. Compared to conventional purely magnetic-field-controlled information switching, the current-controlled device in principle allows much lower power consumption, larger memory density, and higher speed. Current-driven spin-orbit torque is an emergent key player for the so-called spin-orbit-torque-Magnetic-Random-Access-Memory (SOT-MRAM), which is the most promising commercial on-chip magnetic-RAM in the near future[1]. Unfortunately, the switching current density and power dissipation remain too high for conventional magnet/heavy-metal based SOT-MRAM[1], stimulating us to exploit new systems with large SOT.

We thus turn attention to the van-der-Waals (vdW) magnetic materials, which have rapidly flourished to become star members in the field of two-dimensional materials and device physics recently[2-7]. Among all the magnetic vdW materials, Fe_3GeTe_2 is special as the only topological ferromagnetic vdW metal[8], exhibiting well-behaved ferromagnet behavior with a coercivity of several kOe, and prominent anomalous Hall effect with large Berry curvature. Spin-orbit torque and anomalous Hall effect share similar physical scenarios associated with spin-orbit coupling, rendering Fe_3GeTe_2 an ideal

testbed for large intrinsic spin-orbit torque.

Here we discover[9] that an in-plane current can tune the hard ferromagnet state to a soft one in the nanoscale Fe_3GeTe_2 devices, through a substantial reduction of coercive field. This surprising finding is possible because the in-plane current produces a highly unusual type of gigantic spin-orbit torque for single Fe_3GeTe_2 itself without an additional heavy-metal layer. Such spin-orbit torque is directly related to the large Berry curvature and so its band topology. Furthermore, we demonstrate a working model of new magnetic memory based on the principle of our discovery in Fe_3GeTe_2, where highly efficient nonvolatile switching and multi-level states by the tiny current are achieved[10]. Taking one more step forward, we develop this memory model to an all-vdW classic three-terminal SOT device, where the magnetic information can be written by spin-orbit torque and read by tunneling magnetoresistance separately. Our surprising discovery and systematic investigation depict a prototypical route from fundamentally important physics to practical device applications, and also bring the exciting magnetic vdW materials to sharpen spintronics.

Spin Selective Robust Layered Heterostructur in Oxygen Evolution Reaction Yang Li[1,1], Yan Wang[1], Andrew F. May[2], Jong Chan Kim[3], Hu Young Jeong[3], Jieun Yang[4] and Manish Chhowalla[1]; [1]University of Cambridge, United Kingdom; [2]Oak Ridge National Laboratory, United States; [3]Ulsan National Institute of Science and Engineering, Korea (the Republic of); [4]Kyung Hee University, Korea (the Republic of)

Quantum phenomena such as spin polarization and topological protected states have been widely studied for electronics. Spin polarized, and topological protected active sites also offer opportunities for reducing thermodynamic potential and kinetics of reactions as well as increasing the lifetimes of catalysts. However, quantum effects have yet to be widely exploited in catalysis because the electrochemical environment in which reactions are performed destroys quantum coherence. Thus, catalytically active quantum materials that are protected by electrochemically and quantum mechanically transparent layers are required. Here we show two-fold enhancement in the oxygen evolution reaction (OER) current (at 1.7 V versus reversible hydrogen electrode) through spin selective catalysis using two dimensional $Fe_{3-x}GeTe_2$ (FGT) as the catalyst and graphene or hexagonal boron nitride (hBN) as the quantum coherent protective layer. FGT is typically highly unstable in air and electrolytes used for OER, but our experiments show that the reaction can be performed when protected by catalytically inactive graphene or hBN layers. Our results show that spins in FGT can be polarized in the presence of a magnetic field at room temperature, and spin information at active sites can be transmitted through graphene and hBN with thicknesses of up to 6 nm. This electrochemical and spin information transparency of graphene and hBN allows the reaction to proceed in a kinetically enhanced manner on the surface of these layers – even though they are not catalytically active for the OER reaction. Our results provide new insight into spin selective catalysis and on the electrochemical and quantum transparency of graphene and hBN, which could lead to integration of quantum materials for catalysis.

Printable Memristive Neurons from Solution-Processed Hexagonal Boron Nitride Lekai Song[1], Pengyu Liu[1], Jingfang Pei[1], Songwei Liu[1], Yang Liu[1], Shuo Gao[2] and Guohua Hu[1]; [1]The Chinese University of Hong Kong, China; [2]School of Instrumentation Science and Optoelectronics, Beihang University, China

Biological neurons capable of performing complex non-linear operations with high efficiency inspire recent rapid progress in neuromorphic computing. The realization of artificial neurons is key to enabling neuromorphic electronics and systems. Current approaches may, however, lead to complicated device and circuitry designs as well as switching operations. Herein we demonstrate simplified leaky integrate-and-fire (LIF) neurons with printable volatile threshold switching memristors from solution-processed hexagonal boron nitride (hBN).

We start with hBN exfoliation via liquid-phase exfoliation, followed by ink formulation in isoproposal/2-butanol. The ink is finely tuned to suit versatile printing techniques, such as maskless inkjet printing and high-speed slot-die coating. The memristors are then printed by sandwiching the hBN as the switching medium between silver electrodes. We note that this approach can allow wafer-scale memristor array printing at high speed. The printed hBN memristors exhibit a volatile threshold switching with a threshold voltage of ~1 V, an on/off ratio of $>10^6$, and a switching speed of <1 μs, arising from the ultrafast formation and disruption of silver ion filaments in the hBN switching medium. With such an ultrafast volatile threshold switching characteristic, the memristors are then integrated into a simple resistor-capacitor (RC) charging circuit to construct artificial LIF neurons. Notably, the forming-free nature of the memristors endows the simple circuit design, while the high switching ratio eases the peripheral circuit burden to distinguish the conductance change. When fed with electrical spikes of variable frequencies, the capacitor would charge and accumulate the spikes to a membrane potential beyond the threshold voltage of the memristor and lead the memristor to switch and “fire” an electrical spike. After the firing, the memristor would spontaneously reset due to a potential drop, preparing for subsequent firings. Besides, the LIF neurons can perform spatial summation of multiple temporal inputs, allowing us to implement logic operations of the spikes. The leaky integrate-and-fire and spatiotemporal behaviours successfully mimic the biological neurons and, importantly, fit well into activation functions that could be exploited as non-linearity to artificial neural networks to solve non-linear problems. As such, we integrate our LIF neurons into a three-layer spiking neural network by simulation, and after training, achieve classification of MNIST hand-written digits with an accuracy of >95%.

Our approach can be scaled to wafer-scale manufacturing, and the printed volatile threshold switching memristors can be conveniently integrated as simplified artificial neurons for neuromorphic computing. The printing method can also be potentially integrated into advanced CMOS and MEMS

technologies for neuromorphic circuits with high-level integration and complexity. We believe our neurons provide various possibilities for neuromorphic technology development, from intelligent microprocessors and system-on-plastic to biomimetic electronics, sensors, and even brain-computer interfaces.

2D/3D Heterostructures for Low-Power Logic and Memory Devices Deep M. Jariwala; University of Pennsylvania, United States

The isolation of a growing number of two-dimensional (2D) materials has inspired worldwide efforts to integrate distinct 2D materials into van der Waals (vdW) heterostructures. While a tremendous amount of research activity has occurred in assembling disparate 2D materials into "all-2D" van der Waals heterostructures and making outstanding progress on fundamental studies, practical applications of 2D materials will require a broader integration strategy. I will present our ongoing and recent work on integration of 2D materials with 3D electronic materials to realize logic switches and memory devices with novel functionality that can potentially augment the performance and functionality of Silicon technology. First, I will present our recent work on gate-tunable diode[1] and tunnel junction devices[2] based on integration of 2D chalcogenides with Si and GaN. Following this I will present our recent work on non-volatile memories based on Ferroelectric Field Effect Transistors (FE-FETs) made using a heterostructure of MoS_2/AlScN[3, 4] and I also will present our work on Ferroelectric Diode devices also based on thin AlScN.[5]

Two-Dimensional Violet Phosphorus—A p-Type Semiconductor for (Opto)Electronics Antonio Gaetano Ricciardulli[1], Ye Wang[1], Sheng Yang[2] and Paolo Samori[1]; [1]University of Strasbourg, France; [2]Max Planck Institute for Solid State Research, Germany

The surge of two-dimensional (2D) materials overwhelmed the field of conventional semiconductors for (opto)electronics, owing to their unique electrical and optical features, condensed in the atomic limit.[1] In this framework, novel paradigms in fundamental and applied research have been unveiled by the assembly of 2D *p*-*n* junctions. However, the landscape of 2D semiconductors is currently dominated by *n*-type materials. In contrast, only few p-type 2D species have been reported so far. As a result, the lack of diversity severely hinders the full exploitation of 2D systems beyond the state-of-the-art. To respond to the demanding quest for novel 2D materials endowed with *p*-type characteristics, we have synthesized high-quality *p*-type 2D violet phosphorus (VP) in a feasible fashion.[3] First, a strategy to grow pure VP crystals on the centimeter-scale was designed. Then, thin VP sheets were delaminated via sonication-assisted liquid-phase exfoliation. The yielded flakes exhibited thicknesses down to the monolayer limit and large lateral size up to 2 μm. Our method enabled the successful development of VP-based thin-film electronics. Field-effect transistors (FETs) exhibit distinct *p*-type transport characteristics with air stable hole mobilities up to 2.25 $cm^2 V^{-1} s^{-1}$ and a high I_{on}/I_{off} ratio of 10^4 at room temperature, exceeding most of the reported thin-film 2D materials. Proof-of-concept photodetectors displayed a photoresponsivity of 10 mA W^{-1} and a response time down to 0.16 s. Finally, VP was integrated as PMOS working material in a complementary metal oxide semiconductor (CMOS) logic circuit, which output an outstanding voltage gain of ∼17. Our work predestines VP as an enticing and versatile *p*-type candidate for next-generation more-than-Moore (opto)electronics.

Observation of Intrinsic Avalanche Multiplication in Ambipolar WSe_2 and its Application to Low-Subthreshold Swing Impact Ionization Transistors Jaeyoung Kim[1], Kyungjune Cho[2], Keehoon Kang[1] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Recently there has been a growing number of studies that have incorporated the merits of avalanche multiplication with two-dimensional (2D) materials in the form of avalanche photodetectors and transistors [1,2]. Previous studies have mainly focused on developing high-performance devices with unipolar semiconductor as the active material. However, fundamental understanding of the multiplication process in ambipolar materials is required for optimizing material selection, as well as establishing novel architectures. In ambipolar WSe_2 field-effect transistors (FETs), two distinct phenomena of ambipolar transport and avalanche multiplication can occur, and both exhibit secondary rise of output current at high lateral voltage. We distinguished between these two competing phenomena using the method of channel length modulation [3]. In long channel length devices, minority charge carriers are accumulated near the drain side of the channel, and the critical voltage is modulated in equal amounts as the gate voltage. In contrast, short channel length devices undergo carrier multiplication at high lateral voltages, and the breakdown voltage is insensitive to change in the gate voltage. Through the use of electrostatic gating, we extracted multiplication characteristics from both electron- and hole-induced avalanche multiplication in WSe_2 and compared the results with conventional semiconductors. Furthermore, we demonstrate the implementation of intrinsic multiplication process into device application of impact ionization transistor through selective channel gating, which enables low subthreshold swing to overcome the thermionic limitation of transistors. Our study provides a simple and robust method to examine carrier multiplication in ambipolar materials and will foster the development of novel, atomically thin electronic devices utilizing avalanche multiplication.

Switchable Operation Mode and Deterministic Light-to-Voltage Conversion in a Two-Dimensional Semiconductor/Metal Heterostructure Mingde Du, Xiaoqi Cui, Luojun Du, Bin Zhang and Zhipei Sun; Aalto University, Finland

van der Waals (vdW) heterostructures based on two-dimensional (2D) materials have been extensively studied for optoelectronic applications, and most of the reported devices work with a sole mechanism. The emerging metallic 2D materials provide us with new options for building functional vdW heterostructures via rational band engineering design. Here we investigate a vdW semiconductor/metal heterostructure, in which the electron affinity of the semiconductor and the work function of the metal are elaborately selected. Electrical characterization verifies the exceptional rectifying effect of the

heterostructure diode. Further photocurrent mapping indicates that the photoresponse mechanism is switchable between photovoltaic device and phototransistor, or in another word, the metal plays an alternative role. Specifically, this device works in a photovoltaic manner under reverse bias, whereas it turns to a phototransistor under forward bias. Interestingly, the open-circuit voltage (Voc) generated under photovoltaic operation is independent of gate voltage (Vgate), indicating that the metallic 2D material on the bottom plays a role of effective dielectric screening. This Vgate-independent photovoltage is quite useful for an on-chip light-to-voltage conversion, where a deterministic voltage is expected under constant light illumination. Our results demonstrate the valuable application of 2D metals in functional devices, as well as switchable operation mode and deterministic light-to-voltage conversion with 2D semiconductor/metal heterostructure.

Designing Novel Electronic and Optoelectronic Properties in 2D Layered Materials by Strain and Plasmonic Engineering Nai-Chang Yeh, Duxing Hao, Wei-Hsiang Lin and Daniel Anderson; California Institute of Technology, United States

In this talk we will show that valley-Hall transistors based on nanoscale strain-engineered monolayer graphene can exhibit quantum oscillations as well as quantum valley-Hall and quantum anomalous Hall effects (QVHE and QAHE) in the absence of any external magnetic fields. These findings associated with strain-induced giant pseudo-magnetic fields (PMFs) can pave the way towards realizing low-dissipative topological electronics, spintronics and optoelectronics in graphene with controlled strain superlattices. We will also demonstrate that the use of plasmonic vortices and backgate voltages can dramatically enhance the photoluminescence intensity and the degree of valley polarization in monolayer transition-metal dichalcogenide (TMD) WS_2 at room temperature. This approach can be further employed to develop novel opto-valleytronic/spintronic devices for topological photonic applications. Finally, we will describe new strategies to optimize the electronic and photonic properties of monolayer TMDs by post-CVD processing.

4:30 PM NM06.04.09
Complex Strain Profiles and Electronic Mobility Enhancement in Two-Dimensional Monolayers Using Patterned Stressor Layers Yue Zhang[1], Mohammad A. Hossain[1], Kelly Hwang[1], Joe Maduzia[1], Paolo Ferrari[1], Tara Pena[2], Stephen M. Wu[2,2] and Arend M. van der Zande[1,3]; [1]University of Illinois Urbana Champaign, United States; [2]University of Rochester, United States; [3]University of Illinois at Urbana-Champaign, United States

Recently, strain has emerged as a means to control material properties on an unprecedented scale. Two-dimensional materials (graphene and other van der Waals materials) are ideal “ultrastrength” materials systems for tuning properties via strain: they host rich quantum behavior, offer exquisite access to strain manipulation in individual atomic layers, and sustain enormous strains. Yet, most techniques for generating strains, like templated substrates, nanoscale bubbles, microscale wrinkling, or nanoindentation can apply large or localized strains, but are difficult to pattern or design. Moreover, many applications of strain engineering, such as mobility enhancement and directed exciton diffusion are limited due to the specialized substrates used in most of these methods. A recent promising trend borrows from the decades old techniques from the semiconductor industry using deposited stressor layers to generate tensile or compressive bi-axial strain on 2D materials on hard substrates[1], enabling new methods of 2D strain engineering that are compatible with device engineering and CMOS technology.
Here we explore the mechanical boundary conditions and shape affect the strain induced in the 2D material by deposited stressors, and how the induced inhomogenous strains affect the optical and electronic properties of the material. First, we used e-beam lithography to deposit patterned oxide stressors (30 to 80 nm thick MgO) on top of large, continuous exfoliated monolayer molybdenum disulfide (MoS_2). We explored different shapes (squares, triangles, circles, etc.) of the stressors and out-of-plane boundary conditions, with smallest feature down to sub-50 nm. We employed hyperspectral Raman mapping to get spatial maps of the characteristic in-plane and out-of-plane phonon modes of MoS_2, then measured the position dependent peak shifts to extract the local strain and doping profile of the MoS_2 near localized strains. The MgO stressor induces tensile strain in the MoS_2 monolayer of up to 0.8%, and we observed a large, shape dependent strain gradients of > 0.2 %/μm near the edge of stressor, leading to complex strain profiles under and near the stressors. Using photoluminescence mapping, we found that the patterned tensile strain induces position dependent shifts in the bandgap of > 60 meV, with the bandgap closely following the patterned strain profile. Using finite element analysis (FEA) simulations, we explored how interfacial boundary conditions and stressor shape determine the resulting strain profiles, giving the potential for designable strain profiles.
Next, inspired by the strain-based mobility enhancement in silicon transistors, we investigated how strain engineering with the stressors to improve the performance in monolayer MoS_2-based field effect transistors (FETs). Preliminary data shows significant mobility enhancements of > 2x, though we are still working to deconvolve the relative contributions from strain, doping and dielectric screening created by the stressor layers. These results point to a promising strategy new strategy device-compatible strain engineering of electronic and quantum properties in 2D materials.

4:45 PM NM06.04.10
Large-Scale Characterization of 2D Material Flakes—Automation, Shape Parameters and a Route to Standardization Thales Fernandes[1], Helio Chacham[1], Joyce Santos[1], Mariana Prado[2], Elisangela Silva-Pinto[3], Luiz Cancado[1] and Bernardo R. Neves[1]; [1]University Federal-Minas Gerais, Brazil; [2]UFOP, Brazil; [3]IFMG, Brazil

The imminent 2D materials revolution will require industrial-scale quantities of well characterized flakes, which are the preferred morphology for many applications such as smart paints, composites, cements and others. The large-scale production of such flakes is a rapidly evolving field, with remarkable improvements in several comminution processes like liquid-phase exfoliation. However, massive production also requires massive characterization, which, unfortunately, has advanced in a much slower pace, creating a bottleneck for widespread industrial applications. In the present work, we bring a new methodology based on measurement automation and well-defined shape parameters that efficiently characterizes statistically-relevant 2D material quantities (> 10,000 flakes) and brings meaningful information about their representative morphology, including the effects of several production parameters with the use of an intuitive representation system [1-3]. More specifically, using graphene and talc as representative 2D materials, we demonstrate a semi-automated atomic force microscopy (AFM) protocol that rapidly reveals the precise morphology of tens of thousands of flakes [1]. In addition to conventional size parameters (flake area, volume and thickness), we propose a set of dimensionless shape parameters that correctly map to actual and relevant flake dimensions: three pertinent size parameters (thickness, maximum and minimum calipers) normalized by the cube root of flake volume [2, 3]. The statistical distributions of all parameters are thoroughly analyzed, unveiling the effects of typical production steps (centrifugation and different comminution processes) [2,3]. For example, flake thickness-wise, centrifugation leads to more symmetrical shapes, but, unexpectedly, it also leads to more asymmetrical length-wise shapes [2, 3]. Finally, we also propose a three-dimensional representation system – topological vectors – that enable a straightforward, yet precise, visualization and comparison of any set of parameters for different samples [3].
More important than their specific findings for each 2D system investigated in these three studies [1-3], it is their demonstration of a general and robust analysis framework that stands out as their most relevant contribution. The easiness of implementation of the automated AFM protocol coupled with the

breadth of the proposed shape parameters and the topological vectors representation system create a simple, yet powerful, characterization path for thorough and straightforward representation and comparison of any 2D material flake system. In other words, these three works [1-3] pave the way to a feasible route towards standardization of the morphological characterization of 2D material flakes.

Metal-Graphene Interface in Evaporative-Deposition Growth of Various Metals on Graphene Zhien Wang, Haozhe Wang, Jiadi Zhu, Xudong Zheng and Jing Kong; Massachusetts Institute of Technology, United States

Graphene, the first member in 2D materials family, has very unique electrical, optical and mechanical properties, which opens up vast opportunities for applications. The understanding of metal-graphene interface is crucial for many research and applications, but hasn't been understood thoroughly due to the difficulty in characterization. Here we observed that when depositing 8-15 nanometers metal onto CVD (chemical vapor deposition) grown graphene, for certain types of metal there is a change in optical contrast compared to the area without graphene underneath, but for others such change is not noticeable. In this work we carried out various investigations to understand the reasons behind the phenomena and explored their potential applications.

NM06.05.02
Infrared Photodetectors Based on van der Waals Materials Wei Yan[1], Brett C. Johnson[2,3], Kenneth Crozier[2] and James Bullock[2]; [1]The University of Melbourne, Australia; [2]MELBOURNE UNIVERSITY, Australia; [3]RMIT University, Australia

Optoelectronic devices that collect or emit photons in the short-wave infrared (SWIR, 1.4−3 μm) band are used in fields such as imaging, thermophotovoltaics, and optical communication. Presently, these application spaces are dominated by materials such as $In_xGa_{1-x}As$ and $Hg_{1-x}Cd_xTe$, which have been engineered over decades to provide near-unity quantum efficiencies. Despite the maturity of these technologies, there are still fundamental roadblocks intrinsically associated with the use of three-dimensional (3D) semiconductors. In SWIR photodetectors, these limitations impose tradeoffs between sensitivity and cost or size. As such, there is significant interest in the exploration of alternative materials with the potential to overcome such limitations. Recently, a suite of two-dimensional (2D) van der Waals materials with bandgaps in the short-, mid- and long-wave IR regions have demonstrated surprisingly high figures-of-merit for photodetection.
The self-terminated, layered structure of van der Waals materials introduces fundamental advantages for IR optoelectronic devices. These are mainly associated with the potential for low noise while maintaining high internal quantum efficiency when reducing IR absorber thicknesses. In this study, we introduce a new van der Waals material candidate, zirconium germanium telluride ($ZrGeTe_4$), to a growing family of promising IR van der Waals materials.
We find the bulk form $ZrGeTe_4$ has an indirect band edge around ~0.5 eV, in close agreement with previous theoretical predictions. This material is found to be stable up to 140 °C and shows minimal compositional variation even after >30 days of storage in the humid air.
We demonstrate a simple proof of- concept broad spectrum photodetectors with responsivities R (λ) above 0.1 AW^{-1} across both the visible and short-wave infrared wavelengths. This corresponds to a specific detectivity D^* of ~10^9 cm $Hz^{1/2}$ W^{-1} at λ = 1.4 μm at room temperature (V_{SD} > ±0.5 V, V_G = 0 V). These values are remarkably high, especially considering the infancy of this material's exploration. These devices show a linear photoresponse vs illumination intensity relationship over ~4 orders of magnitude, and fast rise/fall times of ~50 ns, also verified by a 3 dB roll-off frequency of 5.9 MHz. Laser beam induced current (LBIC) analysis reveals that the device behaves as a set of two opposing photodiodes, whereby current can be collected at either side of the device by choosing the V_{SD} bias direction.
As the first demonstration of photodetection using $ZrGeTe_4$, these characteristics measured on a simple proof-of-concept device show the exciting potential of the $ZrGeTe_4$ for room temperature IR optoelectronic applications.

NM06.05.03
Detection of Odor Molecule Gas Using Graphene Field-Effect Transistor Modified by Self-Assembling Peptide Yui Yamazaki[1], Tatsuru Hitomi[1], Kou Yamada[2], Yoshiaki Sugizaki[2], Atsunobu Isobayashi[2], Hideyuki Tomizawa[2] and Yuhei Hayamizu[1]; [1]Tokyo Institute of Technology, Japan; [2]Toshiba Corporation, Japan

Detection of agricultural products and foods at an airport is vital for quarantine. In this sense, sensing volatile organic compounds (VOCs) is gaining more interest in continuously monitoring the prohibited materials brought into a country. Commercial VOC sensors are inexpensive and can be mass-produced, but they detect various odors and are not selective. Therefore, it is crucial to develop a sensing system for VOC gas with high sensitivity and selectivity. Graphene, a typical two-dimensional material, has been expected to be applied to biosensors because of its excellent electronic properties and high specific surface area. Many studies have been conducted on VOC sensors based on graphene field-effect transistors (GFETs), such as a NO_2 gas sensor with ppm-order sensitivity [1]. Furthermore, polymer-functionalized graphene surface increased the sensitivity to specific gasses [2]. Despite the progress of the VOC sensors based on graphene FETs, it is still necessary to improve their selectivity and sensitivity simultaneously. We attempted to detect odor molecules using self-assembled peptides selectively. It is known that some engineered peptides form a uniform self-assembled film on a two-dimensional material [2]. These peptides physically adsorb onto surfaces and modify the surface without compromising graphene's intrinsic electronic properties, indicating that self-assembled peptides are promising to functionalize GFET biosensors. In the experiments, we developed multiple kinds of peptides with unique amino-acid sequences and investigated the electrical response of GFETs functionalized by these peptides. After self-assembling peptides on the surface of GFETs, we tested GFET response against several types of odor molecules such as methyl salicylate, methyl propionate, and limonene. The conductivity change was found to increase for all odor molecules as the concentration of odor molecules in carrier gas increased. The principal component analysis (PCA) successfully classified the difference in GFET responses depending on odor molecules and peptide sequences. We believe that the designability of the

peptide sequence allows us to produce highly sensitive and selective detection of molecules in gasses for a variety of other molecules.
This work was supported by the Cabinet Office (CAO), Cross-ministerial Strategic Innovation Promotion Program (SIP), “An intelligent knowledge processing infrastructure, integrating physical and virtual domains” (funding agency: NEDO).

Van der Waals Schottky Gated MoS_2 Metal-Semiconductor Field-Effect Transistor at the Schottky-Mott Limit Yeon Ho Kim[1], Wei Jiang[2], Donghun Lee[1], Yeonsu Jeong[3], Jong Chan Kim[4], Woong Huh[1], Tae Soo Kim[5], Jae-Pil So[1], Hong Gyu Park[1,1], Kibum Kang[5], Hu Young Jeong[4], Seongil Im[3], Tony Low[2] and Chul-Ho Lee[1,1]; [1]Korea University, Korea (the Republic of); [2]University of Minnesota, United States; [3]Yonsei University, Korea (the Republic of); [4]Ulsan National Institute of Science and Technology, Korea (the Republic of); [5]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Van der Waals (*vdW*) semiconductors such as transition metal dichalcogenides (TMDs) have emerged as a promising material for next-generation electronics due to excellent gate coupling and immunity to short channel effects even at the ultimate scaling. To achieve a high-performance electronic device, the gate stack that enables the effective electrostatic control of the TMD channel is necessary. In this regard, the metal-semiconductor junction can be a promising alternative to a conventional metal-oxide-semiconductor structure. Nevertheless, control of the metal-*vdW* semiconductor junction is still challenging because of the unavoidable Fermi-level (E_F) pinning effect induced by numerous gap states. Here, we propose a new device architecture of *vdW* metal-semiconductor field-effect transistors (MESFETs) using a Schottky gate junction between the TMD and the surface-oxidized metal. The *vdW* MESFETs exhibit the sub-1V operation with the subthreshold swing of ~60 mV/dec and negligible hysteresis. These intrinsic Boltzmann-limited FET characteristics are attributed to forming the E_F pinning-free gate stack at the Schottky-Mott limit. Furthermore, we experimentally and theoretically confirm that E_F depinning can be achieved by suppressing metal-induced gap states at the interface between the oxidized metal and the transferred TMD channel.

NM06.05.05
Toward Wafer-Scale Growth of Sb_2Te_3 Films via Low-Temperature ALD for Self-Powered Broadband Photodetector Jun Yang[1,2], Samik Mukherjee[1] and Kornelius Nielsch[1,2]; [1]Leibniz Institute for Solid State and Materials Research Dresden, Germany; [2]Technische Universität Dresden, Germany

P-type Sb_2Te_3 thin film was deposited on a wafer-scale by atomic layer deposition (ALD) at 80 °C using $(Et_3Si)_2Te$ and $SbCl_3$ as precursors. The good crystal quality, low defect, and excellent uniformity of low-temperature ALD processed Sb_2Te_3 was supported by Raman, Transmission Electron Microscopy (TEM), and X-ray photoelectron spectroscopy (XPS) measurements. Furthermore, high-performance self-powered broadband photodetectors based on Sb_2Te_3/Si heterostructure were fabricated. The photodetector has a wide detection range of visible (405 nm) to near-infrared (1550 nm). Meanwhile, a high responsivity of 4287 mA/W at 405 nm, and a quick rise time of 98 μs (t_{rise}) were obtained under 0 bias voltage. The rapid response speed is benefited from enhanced photogenerated carriers’ separation by a strong built-in electric field[YJ1] between p-type Sb_2Te_3 thin film and n-type Si heterostructure. The temperature-dependent performance of Sb_2Te_3/Si photodetector was thoroughly examined. The photodetector exhibits steady ON/OFF behavior even at a high temperature of 473 K, confirming the suitability of our photodetector device for logic circuit application under a harsh environment. The Sb_2Te_3/Si heterostructure self-powered photodetector with excellent performance based on the ALD process shows the great potential application in optoelectronic devices.

Heterogeneously Integrated 2D-Silicon Heterostructures for Bioresorbable, Wireless Neurochemical System Jaehyung Shim[1], Seung Min Yang[1], Hyun-U Cho[2], Tae-Min Jang[1], Gwan-Jin Ko[1], Jeongeun Shim[2], Tae Hee Kim[3], Jia Zhu[4], Sangun Park[3], Yoon Seok Kim[1], Su-Yeon Joung[1], Jong Chan Choe[1], Jeong-Woong Shin[1], Joong Hoon Lee[1], Yu Min Kang[2], Huanyu Cheng[4], Youngmee Jung[3], Dong Pyo Jang[2], Suk-Won Hwang[1] and Chul-Ho Lee[1]; [1]Korea University, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of); [4]The Pennsylvania State University, United States

Although evaluation of degenerative brain diseases and regulation of essential functions in the body are closely related to neurotransmitters, many studies have been conducted to indirectly observe these biochemical messengers by monitoring physical, mechanical, and electrophysiological parameters rather than direct observation. Here, we report a heterogeneous integration of bioresorbable 2D transition metal dichalcogenides and silicon-based neurochemical analyzer for implementing a fully implantable brain-integrated system that enables simultaneous wireless monitoring of the temporal-dynamic behavior of dopamine and related parameters. Extensive investigation of molybdenum/tungsten disulfide (MoS2/WS2) nanosheets and catalytic iron nanoparticles (Fe NPs), along with theoretical modeling tools, highlights the underlying mechanisms of robust chemical and target-specific responses to the neurotransmitters. Systematic characterization demonstrates the reversibility, stability, and long-term operating performance of degradable bioelectronics, and the sensitivity and selectivity of degradable bioelectronics are superior to those of non-degradable materials. A complete in vivo experimental comparison, including the case with carbon fiber electrodes, demonstrates its potential as a clinically accessible tool for related neurodegenerative diseases.

Graphene-based Field Effect Transistor Array for Detection of Gaseous Disease Biomarkers Through Impedance Measurements Dominic J. Wales, Bruno Gil Rosa, Haijie Tan and Eric Yeatman; Imperial College London, United Kingdom

For biomarker sensing applications, in the solution and gas phases, functionalized graphene field-effect transistors (gFET) have been employed as sensors for selective detection of biomarkers due to graphene’s high sensitivity towards immobilized molecules.[1,2] However, a drawback of this approach is potentially poor sensor repeatability and/or shelf life due to degradation of the functionalisation.[2–4] However, the alternative of using pristine graphene is not suited for discriminative detection of vapour biomarkers due to low sensitivity.[5]

Therefore, to overcome these drawbacks of both functionalised and pristine graphene gas sensors, we present the use of an AC impedance unfunctionalized gFET biosensor for gaseous biomarker sensing toward breathomics application. Our novel approach builds on the enhanced sensing capabilities demonstrated in our earlier AC impedance gFET sensor work,[6] builds on the work of Liu *et al.*,[7] and incorporates a quantitative structure-property relationship (QSPR) approach for development of predictive discriminative sensor response models.[8] In addition, we also explore the incorporation of the low-frequency spectral noise modality to further enhance discriminative sensing.[9]

Effect of a Graphene/MoS_2 Heterointerface on the Phase Transition Induced by Lithium Intercalation Maria Bambrick-Santoyo, Mengjing Wang, Joshua Pondick, Natalie Williams, Serrae Reed and Judy Cha; Yale University, United States

Two-dimensional transition metal dichalcogenides (2D TMDCs) are promising for a wide range of energy and electronic applications including batteries, photovoltaics, catalysis, sensing, and memory. One method of modifying the properties of 2D TMDCs is through electrochemical intercalation—as Li ions are inserted into the interlayer gaps of the host material, a structural and electronic phase change is induced. Recent Li intercalation studies of molybdenum disulfide (MoS_2) indicate that a 2D heterointerface, such as graphene above MoS_2, suppresses the intercalation-induced phase transition from the semiconducting 2H phase to the metallic 1T' phase by as much as 0.6 V extra electrochemical voltage compared to bare MoS_2 [1, 2]. Such a delay presents an opportunity to design a novel device architecture in which the electrochemical intercalation is used as a knob to turn on and off a switching device. To test this, we studied a new geometry of MoS_2 / graphene heterostructures: a flake of MoS_2 with a narrow strip of graphene placed on top across the middle of MoS_2. We used *in situ* Raman spectroscopy and optical characterization to monitor the phase transition in these heterostructures. This design was expected to yield a flake with the central graphene-covered region remaining 2H while the neighboring uncovered regions transformed into 1T' at the phase transition voltage of MoS_2, creating a metallic (1T') / semiconducting (2H) / metallic (1T') pattern. Surprisingly, however, the graphene-covered region of MoS_2 did not require additional voltage to transition from the 2H to the 1T' phase, in contrast to our previous observations. This surprising result might come from a difference in device architecture: Pondick *et al*. performed intercalation experiments with electrodes contacting both MoS_2 and graphene, whereas our electrodes only contacted MoS_2. We hypothesize that the voltage supplied indirectly to graphene through contact with an MoS_2 flake may not be sufficient to intercalate Li into graphene, essentially eliminating graphene's effect on the phase transition. To test this hypothesis, we have designed a device with electrodes directly contacting both MoS_2 and graphene. In this study, we thus show that the graphene / MoS_2 heterostructure has wide applications—for example, it could yield the design for a transistor with a changeable channel length based on the electrochemical voltage applied.

NM06.05.09
Tunable Synthesis of Large 2D α-Ni(OH)2 with Mechanistic Insights for Intra-Plane Growth of 2D Transition Metal Layered Hydroxides Gillian E. Minarik, Lu Ping and Xi Ling; Boston University, United States

As a long-used electroactive material in rechargeable batteries,[1,2] nickel hydroxide ($Ni(OH)_2$) has an ongoing history of addressing critical applications in clean energy production and storage.[3,4,5] $Ni(OH)_2$ belongs to the family of transition metal layered hydroxides (TM-LHs), an isostructural class of materials in which six-coordinate transition metal centers occupy a trigonal lattice, held in the vertical dimension by weak dispersion forces. The weak, non-covalent interactions in the *c*-direction give rise to sheet-like layers which stack to form bulk material, with pure and intercalated forms designated α- and β- phases respectively.[2] In a manner analogous to van der waals (VdW) crystals, pioneers in the recent advent of two-dimensional (2D) materials research,[6,7] the relatively weak interlayer interactions pose TM-LHs as logical candidates to be isolated with mono- and few-atom thickness. However, while Ni(OH)2 boasts an extensive repertoire of syntheses, its 2D form remains largely unstudied due to challenges in reproducing sufficient domain size (>5 μm) and long-range crystallinity.[4, 8, 9, 10] Here, we report repeatable growth of round single-crystalline 2D α-$Ni(OH)_2$ nanosheets (thinnest ~6 atomic layers) with unprecedented lateral domain size (average ~20 μm) by mixed treatment under hydrothermal conditions and urea hydrolysis. The morphology, structure and quantum properties were examined and determined by Optical Microscopy (OM), Scanning Electron Microscopy (SEM), Atomic Force Microscopy (AFM), Powder X-Ray Diffraction (PXRD), Transmission Electron Microscopy (TEM) and Ultraviolet-visible Spectroscopy (UV-Vis). Our study also involves systematic control of parameters including precursor ratio, starting pH, soaking temperature, and cooling rate to elucidate the dominating factors for crystal growth, with emphasis on promoting *ab* in-plane isotropy. Resulting crystals were characterized by OM and PXRD, illustrating α-β phase transition at higher pH and reaction temperature with controlled adjustment of unit cell dimensions, owing to varying degrees of hydration and foreign-ion intercalation. Using a heterogeneous precipitation model, we harness these condition-dependent results to propose in-plane versus out-of-plane growth mechanisms based on edge-on substitution of hexaaquanickel(II) species in solution. Furthermore, we provide general guidelines for tuning the domain size, thickness, phase-dependence, and morphology of 2D $Ni(OH)_2$ crystals through adjustment of key parameters, illustrating the great synthetic flexibility afforded by the urea-hydrothermal approach. We further applied our understanding to the synthesis of other 2D TM-LHs such as $Co(OH)_2$. Our detailed synthetic investigation introduces a tunable and scalable pathway to synthesize large 2D TM-LHs flakes from simple methods and opens the 2D TM-LHs as an exciting addition to 2D materials research for future studies on the opto-electronic device applications.

High Mobility Patterned MoS_2 Semiconductor Using Jet-Printing on a High-K Gate Dielectric in Thin-Film Transistor Woon-Seop Choi and Thi Thu Thuy Can; Hoseo University, Korea (the Republic of)

Recently, transition-metal dichalcogenides (TMDs) have attracted much attention as new materials for electronics devices, electrocatalysts, photocatalysts,

sensors, batteries, and bio-applications. Most TMDs are two-dimensional (2D) materials with a single layer. Bonds between each layer are made up of Van der Waals bonds, while intra-layer atoms bind together as covalent bonds.
Chemical vapor deposition (CVD) with sulfur gas is the most popular method for synthesizing large- scale 2D materials with high quality. Various MoS_2 can be obtained from this method using various precursors with different properties, process temperatures, and substrate materials. Solution process methods show advantages for preparing films with large size, high throughput, low cost, thickness control, and an environmentally friendly process. Even though there is sulfur in the precursors of the solution-process synthesis methods, supplementing the sulfur that is lost in the high-temperature CVD process is unavoidable.
Solution synthesis of MoS_2 precursor followed by direct printing could be an effective way to make printed electronic devices. A linear MoS_2 pattern was obtained by an electrohydrodynamic (EHD)-jet printer with a sol-gel system without chemical vapor deposition. The morphology of the MoS_2 after a transfer process was maintained without wrinkles or cracking, resulting in a smooth surface compared with that of spin-coated films. EHD-jet printed MoS_2 was transferred onto high-k dielectric Al_2O_3 and used as a semiconductor layer in thin film transistor (TFT) devices. The printed MoS_2 TFT has relatively good electrical characteristics, such as a linear field effect mobility, current ratio, and low subthreshold swing of 50 $cm^2\ V^{-1}\ s^{-1}$, 7.39×10^6, and 0.7 V $decade^{-1}$, respectively. This new methodology can be applied to multifarious devices and has the potential for scalability in 2D materials.

Two-Dimensional Manganese at the Epitaxial Graphene/6H-SiC Interface Chengye Dong, Furkan Turker, Alexander Vera, Ke Wang and Joshua A. Robinson; The Pennsylvania State University, United States

Two-dimensional (2D) metals are of interest due to unique properties, including superconductivity, enhanced charge-density-wave order, and magnetism[1]. However, synthesizing these materials and environmental sensitivity are continued bottlenecks toward exploring these materials in ambient, and including them in a range of applications. Recent advances in intercalating metals at the epitaxial graphene (EG) – silicon carbide (SiC) interface inspired our recent works, dubbed "confinement heteroepitaxy (CHet)", to synthesize scalable, environmentally stable 2D metals that exhibit distinct properties from their bulk counterparts[2,3]. For example, 2D Ag confined between EG and SiC is a 2D semiconductor with 1 eV band gap [2].
Here, we will discuss our advances toward realizing large-area, atomically thin manganese (Mn). 2D Mn between EG and SiC is predicted to be magnetic, and a Dirac half metal enabling the quantum anomalous Hall effect [4,5]. Therefore, experimental realization of 2D Mn will be beneficial for exploring and understanding its structures, properties and potential applications in information storage and quantum devices. Herein, the effect of parameters, such as temperature, time and pressure, on intercalation efficiency are discussed. Ideal conditions for Mn intercalation at the EG and quasi-freestanding EG (QFEG) on 6H SiC is identified to be near-atmosphere pressure argon at 1000 °C for 2 hours. X-ray photoelectron spectroscopy (XPS) results confirm that Mn-Mn and Mn-Si bonding exist, and high-resolution transition electron microscopy indicates that monolayer Mn can form at the EG/SiC interface. However, we also find Mn diffuses into the top 2-3 SiC layers for QFEG. Since the SiC surface of QFEG is passivated by H atoms which likely de-intercalate from interface, leaving Si dangling bonding during the CHet process, such dangling bonds may accelerate Mn diffusion into SiC. In addition, DFT calculations are conducted to corroborate and aid in proposing a mechanism of our observations. We will also discuss magneto-optical Kerr effect microscopy and magnetic force microscopy related to magnetic properties of 2D Mn.

Copper-Aluminum Layered Double Hydroxides with Different Morphologies and Compositions as CO_2 Reduction Electrocatalysts Tomo Hirano, Kazuyuki Iwase and Itaru Honma; Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Japan

Electrochemical CO_2 reduction reaction (CO_2RR) has attracted attention as a reaction that can convert CO_2 to value-added products, such as carbon monoxide (CO) or hydrocarbons, under ambient conditions (i.e., room temperature and atmospheric pressure). For CO_2RR catalysts, improving the selectivity of the desired CO_2RR products and suppressing the competitive electrochemical hydrogen evolution reaction (HER) are important. Copper (Cu) is the only material that produces various kinds of products, such as carbon monoxide (CO), formate ($HCOO^-$), methane (CH_4), and ethylene (C_2H_4). Previously, alloyed Cu-aluminum (Al) catalysts are suggested to show high CO_2RR activity.[1] In addition, it was also reported that Cu-based oxides could catalyze CO_2RR in high efficiencies.[2] Therefore, in the present work, we focused on Cu-Al based layered double hydroxides (Cu-Al/LDH) which is Cu and Al based oxide materials with two dimensional structure. We designed various Cu-Al/LDHs with different sizes and morphologies by changing the synthesis conditions and evaluated the CO_2RR activity.
Cu-Al/LDHs with different compositions and morphologies were synthesized by controlling the synthesis condition by modifying the reported co-precipitation method.[3] The Cu-Al nitrate solutions (Cu/Al molar ratio of 3.0) were added dropwise to the sodium carbonate solutions at the desired temperature (e.g., 30 ~ 150°C) and solution pH (e.g., 4 or 8). The CO_2RR activities were evaluated with a custom-made gas-diffusion electrode (GDE) setup using 1 M $KHCO_3$ solution as an electrolyte with continuous CO_2 flow.
First, Cu-Al/LDHs were characterized by powder X-ray diffraction (XRD) pattern. For all samples, peaks assignable to the LDH structures were observed at 10.2° or 11.7°, though (003) peaks position shifted when the solution pH changed. Although the small peaks corresponding to malachite ($Cu^{2+}{}_2(CO_3)(OH)_2$) were observed as byproducts, no clear peaks ascribed to Cu or Al-based oxides were observed. These results indicated that Cu-Al/LDHs were successfully synthesized. As the temperature and solution pH of LDH synthesis increased, the full width at half maximum (FWHM) for the (003) peaks of LDH decreased. This result indicated that LDH synthesized under high temperature possessed larger sheet size, which were also confirmed by transmission electron microscope (TEM) images. X-ray photoelectron spectroscopy (XPS) measurements suggested that interlayer anions of LDH changed from NO_3^- to CO_3^{2-} as pH of the solution increased. This result showed good agreement with the peak shift of the (003) of the XRD measurements.
Next, CO_2RR activities were investigated. CO and $HCOO^-$ were detected as major CO_2RR products. H_2 was also detected as a HER product. Cu-Al/LDH synthesized under high temperature with a larger sheet size showed a faradic efficiency for CO generation of 42% and that for $HCOO^-$ of 22% at 50 mA.[4] In addition, the Cu-Al/LDHs with larger sheet sizes tend to show higher faradaic efficiencies for CO_2RR. Based on previous reports, low-coordinated Cu sites (i.e., edge Cu atoms in Cu nanoparticles) are considered active sites for HER. This result suggested that the basal plane of LDHs functioned as active sites for CO_2RR and sheet size of LDHs is an important determining parameter of CO_2RR for Cu-Al/LDHs.

NM06.05.13
Photovoltaic and Photo-Capacitance Effects of WSe_2 Thin Films Donghyeon Lee and Sanghan Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

The layer number dependent bandgap reported in two-dimensional (2D) materials provide an extra degree of freedom to tune the optical properties of photodetectors. 2D transition metal dichalcogenides (TMDs) have been considered as the appealing candidates for photodetection owing to their strong light-matter interactions and the layer number dependent electrical and optical properties. Among them, tungsten diselenide (WSe_2) attracted significant research interest for its high quantum efficiency and reasonably high carrier mobility. Recent study of WSe_2 photodetector is mainly focused on enhancing photocurrent generation by manipulating the metal-semiconductor contacts due to Schottky barrier formation of WSe_2 with most metal contacts. However, there is lack of study of photo-induced electrical properties of WSe_2 other than photocurrent generation, such as photo-capacitance, photo-impedance, etc. Revealing the mechanisms of the photo-induced electrical properties of TMDs other than photocurrent is crucial to understand the fundamentals of the light-matter interactions in TMDs.

Here, we investigate the photo-induced effects of WSe_2 film deposited by pulsed laser deposition technique on Si substrate with top ITO electrode. We observed the photo-capacitance effect on the fabricated film with as large as ~75% enhancement in capacitance under the white light illumination, accompanied by photocurrent. These effects will give an additional dimension to the application potential of WSe_2 in fields such as photoelectric memory devices, which employs the capacitance change stimulated by light.

First-Principles Study of H_2 Adsorption Mechanism on Defective $MoSe_2$/Graphene Heterostructures Wadha K. AlFalasi and Nacir Tit; United Arab Emirates University, United Arab Emirates

Transition metal di-chalcogenide monolayers (TMD-MLs), a novel class of the 2D materials, exhibit tremendous properties such as their tuneable band gap, high surface to volume ratio, appropriate carrier mobility, large spin-orbit coupling and thermal stability which make this class of 2D-materials a promising leading candidate for many applications. In gas-sensing field, the TMD-graphene hetero-structure provides adsorption sites with excellent interaction with gas molecules. Moreover, our recent studies have shown that magnetization is easily triggered/induced in $MoSe_2$ MLs through either metal vacancies or TM-substitutional doping. The chemisorption of molecules on such sites would affect the magnetisation, which further enhances the gas response. In the present work, the spin-polarised density-functional theory (DFT) is applied to investigate the adsorption of hydrogen-gas molecules on 4 different adsorbent monolayer and hetero-structures: (1) $MoSe_2$ ML with single vacancy of Mo "$MoSe_2$:V_{Mo} ML"; (2) Mn-doped $MoSe_2$ ML "$MoSe_2$:Mn ML"; (3) $MoSe_2$:V_{Mo}/graphene hetero-structure; and (4) $MoSe_2$:Mn/graphene hetero-structure. The results of phonon spectra, adsorption energy, spin-polarised band structures, magnetisation, charge exchange using Bader analysis will be presented. Furthermore, benchmarking with experimental and theoretical data existing in literature will be presented. The results should contribute in improving the performance of hydrogen gas-sensors and energy-storage applications.

NM06.05.15
Graphene-Based Closed-Loop Neurotechnology for Treatment of Movement Disorders Nicola Ria[1,2]; [1]ICN2, Spain; [2]The University of Manchester, United Kingdom

Neural activity in the central nervous system is governed by neural oscillations. The anomaly in the frequency bands of the oscillations can lead to pathological conditions of the nervous system due to impaired cognitive functions and memory. In particular, in Parkinson's disease (PD), an increase in the power of beta oscillations in the subthalamic nucleus (STN) is observed, and in previous studies it has been proposed as a potential biomarker. Stimulation with electrodes implanted in the STN (deep brain stimulation - DBS) can alter the power of beta oscillations, thus aiding in the treatment of the disease.

For this reason, I have designed and fabricated neural probes with a new generation of graphene oxide electrodes called EGNITE. The porosity of this material increases the active surface of the electrodes and this allows to inject a very high density current compared to traditional platinum electrodes. An activation process is required to exploit the entire surface also contained within the pores. The electrochemical characterization highlights high performance in terms of charge injection limit, impedance and stability. This neural probe also has the ability to record brain activity and even detect single peaks due to the small size of the electrodes (25 μm) and the high signal-to-noise ratio. The ultimate goal will be to develop a closed-loop system for recording and pacing precisely when it is necessary to effectively treat PD symptoms such as tremor.

The structure of the device consists of a very thin layer of polyamide which makes the device very flexible. The flexibility improves biocompatibility and allows the use of the device for longer periods with better performance in terms of measured signal quality and stimulation efficacy. The flexibility of the device requires the use of a silicon shuttle as a rigid support to penetrate the brain. The attachment is made with biocompatible and soluble glue like hydrogels or polyethylene glycol to be able to detach the shuttle once insertion is complete.

We performed some acute experiments on rats in the University of Manchester (nanomedicine laboratory) with some very good initial results. The applied stimulation protocol can temporarily suppress beta oscillations which are biomarkers of Parkinson's disease.

The objectives of the project are very ambitious;
We want to improve the efficacy of therapy by providing personalized treatment with closed loop technology (CLT) that makes parameter setting automatic and adaptive. While traditional DBS systems continuously provide pulsed pacing at a high rate, CLT incorporates pacing feedback control based on measures of pathological brain activity. This strategy has the advantage of stimulating only when needed, potentially reducing the negative side effects associated with continuous stimulation.
Another important goal is the understanding of the PD biomarkers available to close the feedback loop and provide control strategies for stimulation. Specifically for the stimulation parameters, we will study the effects of the temporal spacing or distribution of the stimulation pulses. The temporal pattern is an important parameter for the optimization of the response to DBS because its modulation can alter the encoding of the speed of the neural response.

NM06.05.16
Direct Growth of Hexagonal Boron Nitride for Silicon-Based Resistive Switching Memory Jiye Kim[1], Seokho Moon[1], Hokyeong Jeong[2,1], Jaewon Kim[3,1], Chang-Won Choi[1], Inyong Hwang[1], Jaesub Song[1] and Jong kyu Kim[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Samsung Electronics Memory Division, Korea (the Republic of); [3]Samsung Advanced Institute of Technology, Korea (the Republic of)

Hexagonal boron nitride (h-BN) has been regarded as a promising material for next-generation energy-efficient resistive switching (RS) memories due to its excellent thermal conductivity, reliability, and stability. CVD-grown h-BN films on metal foil substrates have been widely studied for RS memories. However, the transfer of such CVD-grown h-BN films onto a target substrate is necessary for device fabrication, which accompanies various deformation

of h-BN films such as tears, wrinkles, and other impurities, degrading the performance of devices.
Here, we present the direct growth of h-BN on 2-inch highly doped silicon (Si) substrate by metal-organic chemical vapor deposition (MOCVD) for realizing a transfer-free h-BN-based RS memory. The few-layer h-BN grown on Si act as the RS medium in a metal-insulator-semiconductor (MIS) structure, exhibiting both unipolar and bipolar resistive switching behaviors depending on metal electrodes. The transfer-free, direct-grown h-BN-based RS memory shows excellent reliability and low variability. The switching mechanism of h-BN-based RS memories will be discussed with various h-BN active media having various defects characteristics which were controlled by modulating MOCVD growth parameters.

NM06.05.17
High Performance and Broadband Photodetector Based on Transition Metal Dichalcogenides van der Waals Heterostructures Ahmed R. Elbanna[1,2], Zeng Wang[1], Yuanda Liu[1], Qing yang Steve Wu[1], Zi En Ooi[1], Mengting Jiang[1], Jisheng Pan[1], Ze Xiang Shen[2,2,2] and Jinghua Teng[1]; [1]Institute of Materials Research and Engineering, Agency for Science, Technology and Research (A*STAR), Singapore; [2]Nanyang Technological University, Singapore

Photodetectors (PDs) are used in various applications, such as pollution detection, imaging, defence, optical communication and chemical analysis, determined by their detection bands. The emerging two-dimensional materials and their hybrid systems have great potential for PDs thanks to their unique optoelectronic properties. The semi-metallic graphene has a broadband absorption from UV to terahertz. However, graphene-based PDs suffer from low absorption (2.3 % for monolayer) and high dark current, which is not favourable for PDs. The semi-insulating hexagonal boron nitride is only used for photodetection in the UV band due to its large bandgap. Meanwhile, the transition metal dichalcogenides (TMDs) semiconductors show higher absorption than graphene. However, their operational wavelength is limited by the bandgap of the material (in the visible range for most of the TMDs). The band energy of van der Waals heterostructures can be engineered by using different TMDs with the appropriate band alignment. Here, we report SnSe2/MoS2 heterostructure PD operating in the wavelength range from deep UV to IR. Our heterostructure PD not only shows broadband detection but also a higher performance than the parent materials and other reported PDs.

NM06.05.18
Layer Controlled MoS_2 Synthesis Using Multi-Step Metal Organic Chemical Vapor Deposition Hyun-geun Oh, Donghoon Moon and Gwan-Hyong Lee; Seoul National University, Korea, Korea (the Republic of)

The large-scale growth of semiconducting transition metal dichalcogenides (TMDs) thin film is the basis of commercialization of two-dimensional materials. For this, metal organic chemical vapor deposition (MOCVD), which can supply precursors in gas phase, provides synthesis process of uniform wafer-scale TMDs monolayer film. In addition, it is necessary to control the number of layers of TMDs to provide various device fabrication and usability. Here we report the layer controlled MoS_2 synthesis using multi-step MOCVD process. Multi-step consists of nucleation step and lateral growth step. One cycle can synthesize monolayer. Therefore, we can synthesize the desired number of layers of MoS_2 through cycle iteration. The as-grown MoS_2 samples were characterized with raman spectroscopy, photoluminescence (PL), transmission electron microscope (TEM) and atomic forced microscopy (AFM). Our work will be a step towards the revelation of mechanism of TMDs growth and the synthesis of high quality MoS_2 film.

NM06.05.19
Atomic Layer Deposited Elemental Chalcogen Thin Films, Two-Dimensional Tellurium Changhwan Kim[1], Namwook Hur[1], Jiho Yang[2], Saeyoung Oh[1], Hu Young Jeong[1], Bonggeun Shong[2] and Joonki Suh[1,1]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Hongik University, Korea (the Republic of)

Tellurium, an emerging van der Waals solid, has been spotlighted in electronics, optoelectronics, and spintronics owing to its physico-chemical properties such as robust chirality, intrinsic in-plane anisotropy, superior field-effect hole mobility and fast resistive switching. To fully implement such potentials into real-world applications, atomic layer deposition can be an ideally suited process compared to other vapor-phase synthetic methods thanks to its deposition mechanism and self-limiting surface reaction. Herein, we demonstrate wafer-scale tellurium thin films with exceptional homogeneity and controllability of thickness through the newly developed low-temperature ALD process. It is enabled by (*i*) introducing the co-reactant to alleviate the size effect of ligands and (*ii*) repeating the identical pulses to minimize the spatial blocking originating from inhibitors such as by-products and physisorbed molecules. With our synergistically designed process, film morphologies (*e.g.,* surface coverage and roughness) were remarkably improved and as-deposited poly-crystalline film exhibited the high crystallinity on the SiO_2/Si substrate despite the low deposition temperature (~50 °C). Our work can extend the options for tellurium films with conformality, scalability and crystallinity at low temperature.

NM06.05.21
Gas Sensitivity Changes by Defect Kind on Graphene Gas Sensors Sunmog Yeo, Young Jun Yoon, Jun Mok Ha and Chang-Goo Kang; Korea Atomic Energy Research Institute, Korea (the Republic of)

Generally speaking, defects generate negative effects on the materials or devices so that researchers try to fabricate more perfect materials or devices. However, well controlled defects give rise to various effects on the materials including optical, electrical, and magnetic effects. By tailoring these effects, many useful performances have been enhanced in photo detector, chemical sensor, catalyst and biomedical areas. On the other hands, because graphene consists of carbon atoms with sp2 hybridizations, defects in graphene generate more dangling bonds on graphene. This means that there are more possibilities for gas molecules to adsorb on graphene. In fact, a DFT calculation shows that the defected graphene has more adsorption energy, meaning that a graphene gas sensor with defects has more sensitivity. In this paper, we present that the sensitivity of the graphene gas sensor depends on the defect kind. We produce defects on graphene using ion bombardment with various ion sizes such as H^+ and N^+. In addition, we compare the amount of defects by Raman spectroscopy and measure the sensitivities of the graphene gas sensors which have the similar amount of defects produced by different ions. We discuss the sensitivity changes by defect kind for the graphene gas sensors.

NM06.05.22
20 nm Nanogap Gas Sensors with Fast Response and Fast Recovery Yutaka Majima and Yexiao Sun; Tokyo Institute of Technology, Japan

Pt-based nanogap electrodes with a gap separation of 20 nm were fabricated by electron beam lithography (EBL). Using these electrodes, nanogap gas sensors were fabricated by combining sensing materials. A bottom-contact and top-contact nanogap gas sensor was fabricated. The response and recovery of the gas sensor were found to be strongly dependent on the gap separation. With the nanogap gas sensor, a large electric field equivalent to the breakdown voltage of the sensing material can be applied with the application of a few volts.The proposed method of fabricating robust ultrafine nanogap electrodes opens the possibility of developing various nanogap gas sensors with fast response and fast recovery.

NM06.05.23
Physical Vapor Deposition of Conductive Two-Dimensional Metal–Organic Framework Thin Film Seoungmin Chon[1], Ryo Nakayama[1], Shunta

Iwamoto[1], Shigeru Kobayashi[1], Ryota Shimizu[1] and Taro Hitosugi[2,1]; [1]Tokyo Institute of Technology, Japan; [2]The University of Tokyo, Japan

Metal–organic frameworks (MOFs) are porous materials that consist of coordinated metal ions and organic ligands. Among various MOFs, two-dimensional (2D) electrically conductive MOFs attract considerable attention owing to diverse applications such as electrocatalysts, energy storage devices, and chemiresistive sensors [1]. For such device applications, the fabrication of the conducting MOF thin films is desired using physical vapor deposition (PVD), which is a solvent-free process different from the conventional wet processes. So far, a few papers reported a conductive MOF monolayer on metallic substrates by PVD [2,3]. However, conductive MOF thin films have never been fabricated on insulating substrates by PVD. In this study, we utilize infrared-pulsed laser deposition (IR-PLD) as a physical vapor deposition method and fabricate a conductive 2D MOF thin film, $Cu_3(HHTP)_2$ (HHTP = 2,3,6,7,10,11-hexahydroxytriphenylene) on an insulating Al_2O_3 substrate.

$Cu_3(HHTP)_2$ thin films were deposited on Al_2O_3 (0001) substrate (3 mm × 5 mm) using IR-PLD [4,5]. $Cu(OAc)_2$ (copper acetate anhydrate) and HHTP were used as precursors for a metal ion and a ligand. Each powder is mixed with IR absorbing agent (Si powder) and then, pelletized in the Ar-filled glovebox. The pellets are transferred to the IR-PLD chamber with no exposure to air to prevent degradation. The thin film is deposited in a multilayer form: alternate deposition of HHTP and $Cu(OAc)_2$ is repeated 5 times. Each thickness of the HHTP and $Cu(OAc)_2$ layers is fixed to 10 nm and 8 nm, respectively, to satisfy the stoichiometric molar ratio of $Cu_3(HHTP)_2$. The substrate temperature is 150 °C and post-deposition annealing is continuously performed in the deposition chamber at 150 °C for 30 min. After the post-deposition annealing, the black film with the thickness of ~90 nm is obtained. The fabricated thin films were characterized by IR spectroscopy, and ultraviolet-visible (UV–vis) optical transmittance spectroscopy. The electrical conductivity of thin films is measured by the four-terminal method.

An IR spectrum of the film indicates the formation of $Cu_3(HHTP)_2$ from HHTP and $Cu(OAc)_2$ precursors. Precursor-derived peaks disappeared: neither the O–H band of HHTP (3,200–3,500 cm^{-1}) nor C=O band of $Cu(OAc)_2$ (~1,580 cm^{-1}) are observed. Instead, C–O stretching (1,174 cm^{-1}) and C–H scissoring vibration (1,421 cm^{-1}) appeared, which are similar to bulk $Cu_3(HHTP)_2$ [6]. Thus, we confirm that alternate layers of HHTP and $Cu(OAc)_2$ precursors are reacted to form $Cu_3(HHTP)_2$. Next, UV-vis optical transmittance spectra show a decrease in transmittance at 600–650 nm, which can be attributed to the ligand-to-metal charge transfer absorption band of $Cu_3(HHTP)_2$ [7]. The electrical conductivity of the fabricated $Cu_3(HHTP)_2$ thin film is 1.1×10^{-1} S cm^{-1}. This is comparable to those of $Cu_3(HHTP)_2$ thin films prepared by wet processes (1.0×10^{-3} to 2.9×10^{-1} S cm^{-1}) [8,9]. These results show that electrically conducting 2D $Cu_3(HHTP)_2$ thin film is successfully fabricated on the insulating Al_2O_3 substrate by IR-PLD.

High Yield Shear Exfoliation of MoS_2 Nanosheets by Green Chemistry Esra B. Karatas Ozkaraca, Abdelhakim Elmhamdi, Rana Ucuncuoglu, Naim Kurtuldu and Mahmut Aksit; Gebze Technical University, Turkey

Exfoliation of layered materials offers a diversified supply of 2D crystals with features beneficial in applications ranging from electronics and energy storage to photocatalysis. Here we report scalable, high yield, and simple liquid shear exfoliation of molybdenum disulfide (MoS_2) nanosheets from the commercially available bulk powder using several different, naturally available, and biodegradable long-chain hydrocarbons (LHCs). The exfoliated nanosheets can be isolated from the LHCs by centrifuging and washing with acetone or simply by evaporation of the LHCs by heat treatment upon centrifuging. The exfoliated nanosheets can be size separated by varying the centrifuge rotation speed with different corresponding yields. Liquid shear exfoliation parameters such as liquid mixing speed and time significantly affect the nanosheet production yield values depending on the nanosheet thickness. The nanosheet thicknesses are evaluated by XRD-Scherrer Broadening crystal size analysis that is corrected for instrumental broadening. After 4 hours of liquid shear exfoliation at maximum liquid mixing speed, 8% of the final product consists of MoS_2 nanosheets with an average thickness of 51 nm, whereas 32% of the final product has an average thickness of 105 nm. Specific surface areas of the final products are measured by the Brunauer-Emmett-Teller (BET) method for comparative analysis of the nanosheet thicknesses. Raman Spectroscopy is also performed on the nanosheet products to evaluate Raman peak shifts associated with nanosheet thickness.

NM06.05.26
Metal Cocatalyst Dictates Electron Transfer in Ag-Decorated MoS_2 Nanosheets Bo-An Chen, Sylwia Ptasinska and Prashant Kamat; University of Notre Dame, United States

Two-dimensional transition metal dichalcogenides such as atomically thin MoS_2 nanosheets are useful as low-cost solar energy conversion materials. Colloidally stable few- and monolayer MoS_2 nanosheets in dimethylformamide were prepared via an electrochemically-assisted liquid phase exfoliation approach. These nanosheets were further modified with Ag nanoparticles using photocatalytic reduction of Ag^+ ions. A methyl viologen redox couple was employed as a probe to determine the rate constants of photoinduced forward electron transfer (k_f) and dark back electron transfer (k_b) processes to establish the role of Ag cocatalyst in promoting photocatalytic reduction. The competition between these two processes dictates the buildup of a steady-state concentration of the reduction product (methyl viologen radical) under visible light irradiation. The k_f and k_b rate constants increase with increasing Ag nanoparticle loading but with different dependencies, yielding a maximum reduction efficiency of 4.4%. At higher Ag loadings, the reduction yield decreases as back electron transfer dominates over the forward electron transfer process. Establishing the role of noble metal cocatalyst in the photoinduced charge transfer processes of Ag-MoS_2 hybrid composites offers design strategies to maximize the photocatalytic performance of semiconductor-metal heterostructures.

NM06.05.27
Star-Shaped WS_2 Monolayers with Twin Grain Boundaries Promoted by Molybdenum Atoms Na Zhang[1,1,1], David Sanchez[1], Nadire Nayir[1,1,2], Yanzhou Ji[1], Tianyi Zhang[3], Ke Wang[1], Da Zhou[1], Mingzu Liu[1], Zhuohang Yu[1], Adri C.T. van Duin[1,1] and Mauricio Terrones[1,1,1]; [1]The Pennsylvania State University, United States; [2]Karamanoglu Mehmetbey University, Turkey; [3]Massachusetts Institute of Technology, United States

Monolayers of transition-metal dichalcogenides (TMDs) exhibit fascinating properties that make them attractive in optics, electronics[1], spintronics, and valleytronics[2], and it is of vital importance to understand and control their morphology to tune their physical properties[3]. However, the origin of their

morphology evolution is still highly elusive, which hinders the synthesis of desired morphologies for specific applications. Herein, we report the controllable synthesis and formation mechanism of star-shaped WS_2 monolayers by artificially adding trace concentrations of molybdenum using a liquid-phase precursor-assisted approach. Fluorescence imaging and photoluminescence (PL) mapping of six-arm stars revealed bright lines between adjacent arms. To correlate the morphology and optical properties with the microstructure, dark-field transmission electron microscopy (DF-TEM) was implemented to confirm the presence of polycrystal domains with a 60° lattice misorientation and a mirror twin grain boundary. Detailed analysis of the grain boundary and molybdenum atom distribution was assessed using high-resolution, high angle annular dark-field scanning transmission electron microscopy (HAADF-STEM). The relationship of the growth morphology of WS_2 stars and the molybdenum to tungsten ratio of the precursor was also carefully investigated. In corroboration with the experimental results, we further developed a multiscale model which combines density functional theory and the Wulff construction, for the observed morphology evolution of $WMoS_2$ domains as a function of local chemical environment during growth. Our study provides further insights into controlling the morphology of crystalline TMD monolayers.

NM06.05.28
Investigating Substrate Effects on WTe_2 Thin-Film Growth David Hynek[1], Elifnaz Onder[1], James L. Hart[2], Gangtae Jin[2], Mengjing Wang[2] and Judy Cha[2]; [1]Yale University, United States; [2]Cornell University, United States

WTe_2 is a 2D transition metal dichalcogenide, which exhibits large magnetoresistance, superconductivity, and quantum spin Hall states, and is a predicted type-II Weyl semi-metal, making it an ideal candidate material to study for next-generation electronic and spintronic devices. Currently, wafer-scale growth of 2D transition metal tellurides such as WTe_2 remains difficult to achieve due to the lack of stable Te precursors for processes such as atomic layer deposition (ALD) and metal-organic chemical vapor deposition (MOCVD), and an incomplete understanding of the growth dynamics such as the effects of substrate interactions during growth. For scalable and reproducible synthesis to be achieved, more mechanistic studies are needed.
Here, we investigate the role of the growth substrate (sapphire and SiO_2) on the direct synthesis of WTe_2 thin films. Previously, we showed that the choice of growth substrate impacts the phase stability and large-scale uniformity for transition metal ditelluride films such as $MoTe_2$ (*CrystEngComm* **2021**, *23*, 7963–7969.). WTe_2 thin films are synthesized using methods previously developed by our group for the large-scale growth of $MoTe_2$ (*ACS Nano* **2021**, 15, 410–418) where ALD grown WO_x precursor thin films are converted to WTe_2 by annealing at high temperatures in a tellurium-rich environment. Using a range of characterization techniques such as Raman spectroscopy, transmission electron microscopy, and x-ray photoelectron spectroscopy, we find that there are impacts from the substrate on the growth dynamics of WTe_2 thin films that range from changes in optimal growth time to differences in morphology for films with the same starting oxide precursor thickness on sapphire vs SiO_2.

NM06.05.29
Ultrasonic Spray Deposited 1T-MoS2 for In-Plane Microsupercapacitors Deniz Keskin, Mustafa C. Gorur, Mete Batuhan Durukan and Husnu E. Unalan; Middle East Technical University, Turkey

The rapid growth of portable, flexible and wearable small devices and integrated electronics has increased the need for on-chip and small-scale energy storage devices such as micro-supercapacitors. Micro-supercapacitors can be integrated into series or parallel with miniature electronic devices and provide long life and fast charge/discharge rate. Moreover, by using the interconnected coplanar electrode architecture, rate capacity and power density can be further increased as the structure provides a high active surface area. Molybdenum disulfide (MoS_2) attracted lots of interest with successful demonstrations in applications such as electrocatalysts, transistors, and especially energy storage devices. 1T- MoS_2 is metallic and has favorable electrochemical properties owing to the layers' ability to expand and intercalate ions with high electrical conductivity. In this work, the ultrasonic spray coating method was used for the deposition of 1T- MoS2 thin films on desired substrates. Firstly, a result of 264 F/g specific capacitance was obtained through cyclic voltammetry with a 5 mV/s scan rate in a three-electrode setup with a KOH electrolyte. Then, a simple laser ablation method was utilized to fabricate interdigitated finger electrodes to obtain 1T-MoS_2 micro-supercapacitors. The capacitive behavior of 1T- MoS_2 was investigated through cyclic voltammetry, galvanostatic charge-discharge, and impedance spectroscopy. Detailed analysis of the capacitive behavior will be presented with the comparison of patterning and amount/thickness of the active material. With the integration of micro-supercapacitors, many forward-looking flexible, wearable and portable devices in various applications can be developed.

This work was supported by The Scientific and Technological Research Council of Turkey (TUBITAK) under Grant No:220M003.

NM06.05.31
Phase-Selective Heteroepitaxy of Tetravalent-Doped Ruddlesden-Popper Structure $La_{n+1}Ni_nO_{3n+1}$ Thin Films Akifumi Matsuda[1], Yuki Goto[1], Kazuya Kawamura[1], Kenta Kaneko[1], Satoru Kaneko[2,1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

Ruddlesden-Popper phase nickelates with formula $A_{n+1}Ni_nO_{2n+1}$ also exhibit noteworthy electronic properties based on their 2D-layered perovskite structure and mixed valence state of Ni ions[1]. Recently, $Nd_{1-x}Sr_xNiO_2$ and $La_{1-x}Ca_xNiO_2$ thin film was reported to reveal superconductivity, which material is composed of NiO_2 layers with square-planar coordination reduced from the Ruddlesden-Popper structure of $NdNiO_3$ and $LaNiO_3$[2,3]. The layer number "n" in Ruddlesden-Popper phase $La_{n+1}Ni_nO_{3n+1}$ has an impact on physical properties such as conductivity via modification of Ni-ion valence. Thus, phase-selective epitaxial growth of $La_{n+1}Ni_nO_{3n+1}$ thin films is of importance. In addition, property control of $La_{n+1}Ni_nO_{3n+1}$ by doping divalent impurities to substitute La^{3+} has been studied as mentioned above. Obtaining further knowledge of the effect of aliovalent doping to epitaxial lanthanum nickelate films on their crystal growth and structure would advance understanding and control of properties in 2D-layered nickelates. In this study, phase-selective epitaxial formation of Ruddlesden-Popper structure $La_{n+1}Ni_nO_{3n+1}$ (n=2, 3, ∞) was obtained by control of growth rate and O_2 pressure. In addition, the effect of tetravalent doping on structure and property was also investigated.
The thin films were grown by pulsed laser deposition (PLD) technique equipped with a KrF excimer laser (λ=248 nm). Sintered target of Sn^{4+} and Hf^{4+} doped (0.625 at% for each) $La_4Ni_3O_{10}$ was used as well as the pure one. Single crystal $LaAlO_3$ (100) and $NdGaO_3$ (100) substrates were used with respect to their small planar lattice mismatch of 1.94% and 0.34% with $La_{n+1}Ni_nO_{3n+1}$ (001), respectively. Laser fluence was fixed at ~1.2 J/cm^2, and repetition was varied from 2 to 10 Hz. The growth took place in partial O_2 pressure (pO_2) of 0.1–50 Pa at substrate temperature up to 750°C. According to the XRD measurement, epitaxial growth of $La_3Ni_2O_7$ (n=2) in which crystal Ni^{2+} and Ni^{3+} contents are balanced and $LaNiO_3$ (n=∞) comprising only Ni^{3+} was obtained on $LaAlO_3$ (100) by PLD at 680°C in pO_2 of 10 and 50 Pa, respectively. $La_4Ni_3O_{10}$ (n=3) film was epitaxied on $NdGaO_3$ (100) by PLD at 700°C in pO_2 of 10 Pa and subsequent O_2-annealing at 950°C; the imbalance of Ni^{2+} and Ni^{3+} required more controlled oxidizing condition in the crystal growth. The epitaxial relationships were as follows; $La_3Ni_2O_7$ (001)<110>//$LaAlO_3$ (100)<001>, $LaNiO_3$ (001)<110>//$LaAlO_3$ (100)<001>, and $La_4Ni_3O_{10}$ (001)<110>//$NdGaO_3$ (110)<001>. Thus, phase-selective epitaxy of tetravalent-doped Ruddlesden-Popper structure $La_{n+1}Ni_nO_{3n+1}$ (n=2, 3, and ∞) films

was obtained. The dopants in the films slightly shifted diffraction peaks to lower angle, that substitution of Ni-ions with ratio smaller than La^{3+} was suggested. The Sn and Hf doped $La_3Ni_2O_7$, $La_4Ni_3O_{10}$, and $LaNiO_3$ epitaxial thin films in this study demonstrated increasing resistivity along decrease of measurement temperature. The resistivity of above mentioned epitaxial thin films were 1.2×10^{-3}, 1.1×10^{-3}, and 5.4×10^{-4} Ωcm, respectively at room temperature, which was improved compared to previously reported bulk materials. The results of detailed structural analyses and property measurement, as well as the effect of post-depositional thermal treatment would also be discussed.

Atomistic Synapse Networks on Atomically Thin van der Waals Photo-Memtransistors Geonho Mun[1,2], Seok Young Min[1,2], Seung-Young Seo[1,2], Cheolhee Han[1,2], Suk-Ho Lee[1,2], Heonsu Ahn[1,2], Feng Ding[2], Seyoung Kim[1] and Moon-Ho Jo[1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

We report a new type of atomistic synaptic networks on an atomically thin van der Waals (vdW) heterostructure, where the two-dimensional (2D) tungsten disulfide (WS2) semiconductor serves as a gate-tunable photoactive layer between a pair of single-layer graphene electrodes, as we dubbed a photo-memtransistor. A train of ultraviolet (UV) pulses on to the WS2 memristor generate dopants in atomic-level precision, enabling reconfigurable modulation of the channel conductance. Such photo-induced conductance modulation can be explained by a parallel resistor network model, enabling the accurate operation of the synaptic dynamics of the memristor. In addition, we show that such device operation is not only limited to WS2, but generally realized in other 2D vdW semiconductors. In this work, demonstration of atomically thin photo-memtransistor arrays, where the synaptic weights can be tuned in atomistic precision, provides implications for a new type of artificial neural networks for parallel matrix computations with a high integration density.

NM06.05.33
Large-Scale Heteroepitaxial Growth of 2D Single-Crystalline WSe2/WS2 Suk-Ho Lee[1,2], Cheolhee Han[1,2] and Moon-Ho Jo[1,2]; [1]IBS, Korea (the Republic of); [2]POSTECH, Korea (the Republic of)

We report atomic layer-by-layer growth of epitaxial van der Waals (vdW) semiconductor WSe_2/WS_2 superlattices (SLs). Metal-organic chemical vapor deposition (MOCVD) enables vertically stacking of atomically thin semiconductors with programmable stacking periodicities.
Moreover, single-crystalline vdW semiconductor growth was achieved on stepped substrate. Systematic studies for single-crystalline homoepitaxial stacking will be discussed. VdW epitaxy was kinetically controlled to achieve anisotropic two-dimensional growth without interlayer atomic mixing, resulting in the tunable two-dimensional (2D) vdW electronic systems. Each monolayer stacking was verified by transmission electron microscope (TEM) studies & optical characterization (photoluminescence, absorbance). Finally, we show electronic & optoelectronic property of our WSe_2/WS_2 vdW superlattices. Our work suggests on synthetic material platform of 2D vertical p,n junction devices & multiple quantum well devices.

NM06.05.34
Designing Carbon Cluster for Graphene Growth by Molecular Dynamics—Selection of Substrate Material, Crystal Orientation Satoru Kaneko[1,2,3], Manabu Yasui[1], Masahito Kurouchi[1], Chihiro Kato[1], Satomi Tanaka[1], Takashi Tokumasu[4], Shigeo Yasuhara[5], Tamio Endo[5], Musa Can[6], Ruei-Sung Yu[7], Kripasindhu Sardar[2], Sumanta Sahoo[2], Masahiro Yoshimura[2], Akifumi Matsuda[3] and Mamoru Yoshimoto[3]; [1]KISTEC, Japan; [2]National Cheng Kung University, Taiwan; [3]Tokyo Institute of Technology, Japan; [4]Tohoku University, Japan; [5]Japan Advanced Chemicals, Japan; [6]Istanbul University, Turkey; [7]Asian University, Taiwan

The stability of amorphous carbon in the CVD condition causes co-exisitance of graphene and intrinsic contamination on the surface of the CVD graphene. However, carbon dioxide as a gentle oxidant selectively eliminates intrinsic contamination to form *superflat* surface of a chemical vapor deposition (CVD) graphene as post annealing process[1]. Pulsed laser deposition (PLD) is one of popular physical vapor deposition (PVD) methods with much wider atmospheric environment compared to the CVD. Carbon clusters are generated in a plume by PLD, however, with suitable substrate and crystal orientation, graphitic clusters can be designed to reach and flatly cover the surface of substrates. Molecular dynamics was employed to select suitable substrate of candidates, and graphene was experimentally deposited on the candidate substrates in carbon dioxide atmosphere.

In order to select suitable substrate with suitable crystal orientation for graphene growth, absorptive stability was estimated on carbon cluster designed on candidate substrates; Si(001), Si(111), MgO(100), Al2O3 and SrTiO. Absorptive stability was evaluated by absorption energy between carbon cluster and candidate substrate. Absorption energy was evaluated to be

Etot_sub + Etot_cluster - Etot_supercell,

where Etot_sub and Etot_cluster were total energy of subs and graphitic cluster, and Etot_supercell was total energy of supercell consisting of cluster placed on candidate substrate. The details of estimation of absorption energy was found in elsewhere[2]. As carbon clusters, a carbon atom, six membered ring (6-ring), and 6 six membered rings (nano graphene) were placed on candidate substrates.

The absorption energy of graphene on SrTiO(001) and Si(001) were estimated to be 570 and 550 kJ/mol, respectively. Although graphene grew on SrTiO substrate while DLC related materials grew on Si(001), there was not much difference in absorption energy between SrTiO and Si substrates. However form of six-ring on each substrates was remarkably different after optimal structure in supercell. After optimizing supercell of six ring placed on Si(001), the six ring did not lie on silicon substrate flatly but it stood up vertically on the substrate while a six ring flatly lied on SrTiO substrate. Actually in our experiment, AFM image revealed the growth of nano balls on the surface of silicon substrate while graphene grew with “layer by layer growth” on SrTiO substrate[3]. Among candidate substrate, Si(001), Si(111), MgO(100), Al2O3(001) and SrTiO3, molecular dynamics showed 6-ring and nanographene flatly cover the surface on only SrTiO3 substrate. AFM images on Si, Al2O3 and MgO showed rough surface with Sa ~4.34, 5.63, 4.1 nm, respectively. For graphene growth on SrTiO3 substrate showed Sa ~63 pm.

In order to select suitable substrate, evaluation of absorptive stability can be good guideline not only for graphene but other functioning materials on variety of substrates. Evaluation of variety of combination of carbon materials and substrates is in progress.

Switchable Bulk Photovoltaic Effect in Rhombohedral Transition Metal Dichalcogenides Homobilayers Ji-Hwan Baek[1], Seong Chul Hong[1], Yeon Ho Kim[2], Yeonjoon Jung[1], Chul-Ho Lee[2] and Gwan-Hyong Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

Recently, the ferroelectric property in bilayer rhombohedral phase (3R) transition metal dichalcogenides (TMDs) bilayers was reported both theoretically and experimentally due to the inversion symmetry breaking, while the net electrical polarization in the 2H phase is zero due to the presence of the inversion symmetry. The spontaneous electrical polarization direction of 3R-TMDs is determined by a stacking sequence of metal (M) and chalcogen (X) atoms, XM- or MX- stacking, where every X atom on the top layer is located over the M atoms on the bottom layer in the XM stacking and vice versa. Not only the ferroelectricity but a bulk photovoltaic effect can be induced from this intrinsic polarization in 3R TMDs bilayers without built-in potential. Here we fabricated 3R TMDs bilayers devices with near-zero twist angle which have triangular domains of the XM and MX stacking are formed alternately, and an area of those domains can be modulated by applying external out-of-plane electric field, because the stacking sequence of M and X atoms are aligned along the direction of the external electric field. As a result, the opposite direction of photocurrent was obtained by changing the sign of the applied gate voltage.

Comparison of Pt Nanosheet and Pt Nanoparticles-Decorated Graphene in Aliphatic Alcohol Sensing Properties Yusuke Hamanaka, Takahisa Tanaka and Ken Uchida; The University of Tokyo, Japan

1. Introduction
Detection of aliphatic alcohols in air is important due to its potential application to human health monitoring or safety management in industrial processes. As the material of chemiresistive sensors for aliphatic alcohols such as methanol or ethanol, Pt has attracted a lot of attention because it facilitates the oxidation reaction. In fact, Pt has been utilized for gas sensor applications in the form of nanosheets or nanoparticles [1][2]. However, it has not been fully investigated how the structures, such as nanosheets and nanoparticles, of Pt affect the sensor performance and sensing mechanisms. In this study, we fabricated two different Pt-based aliphatic alcohol resistive sensors. One is Pt nanosheet, and the other is Pt nanoparticles-decorated graphene field effect transistor (Pt-GFET). We evaluated and compared the performance of these two kinds of Pt-based sensors against aliphatic alcohols: ethanol and heptanol.

2. Method
2.1. Fabrication of Pt nanosheet
3-nm-thick Pt was deposited on 90-nm-thick SiO_2 layers above bulk Si substrate by electron beam deposition. The length and width of the nanosheet were 3400 μm and 200 μm, respectively. Then, Cr and Au were also deposited as electrodes in the same manner.

2.2. Fabrication of Pt-GFET
Graphene transistors with the channel of 200-μm length and 50-μm width were fabricated using a monolayer graphene grown by chemical vapor deposition. Then 0.5-nm-thick Pt was deposited by electron beam deposition and annealed at 250 °C in N_2 atmosphere for 30 min to agglomerate it.

2.3. Alcohol sensing measurement
The sensing measurements were performed by measuring the resistance change of the sensors as the sensor responses during continuous exposure to dry air, 100-ppm ethanol or 100-ppm heptanol in dry air. Sensor outputs, namely the resistance change of the sensors, were measured at 200 °C using a Keithley 2636A source meter at constant biases. The constant biases were 0.1 V and 0.05 V for Pt nanosheets and Pt-GFETs, respectively.

3. Results and Discussion
Pt nanosheets and Pt-GFETs showed the resistance change under ethanol and heptanol atmospheres, demonstrating that both the devices worked as aliphatic alcohol sensors. Pt nanosheet showed the greater responses than Pt-GFET for both the alcohols. Although the magnitude of the response was small, Pt-GFET showed a larger response to heptanol than to ethanol, which differs from the fact that the responses of Pt nanosheet to these alcohols were almost the same. This may arise from the attractive interactions between graphene and the analytes. Graphene attracts aliphatic alcohols through CH/π interaction [3], and the interaction would be stronger as alkyl chain length increases. Therefore, the stronger adsorption of heptanol on graphene may facilitate the reaction of heptanol with Pt. This indicates that in designing gas sensors using Pt nanoparticles, the interaction between the supporting material and the analyte may have a significant influence on the sensor performance. In the same manner, it may be possible to enhance the sensitivity of Pt nanosheet sensor by choosing the substrate material that has a stronger interaction with the analyte.

4. Conclusion
In this study, we evaluated the sensor performance of Pt nanosheet and Pt-GFET against ethanol and heptanol. While the Pt nanosheet sensor showed almost the same response to these alcohols, Pt-GFET sensor showed a greater response to heptanol with a longer alkyl chain.
We plan to further investigate the effect of substrate material on sensor performance of Pt nanosheet. In addition, we will compare the response and recovery speed to elucidate the reaction mechanisms.

Towards Recyclable Nanofiltration Membranes—Oxidised Boron Nitride-Layered Double Hydroxide Hybrid Membranes for Water Purification and Photocatalysis Áine Coogan[1], Natalia Garcia Doménech[1], Quentin Fedix[2], Amy Donlan[1], Finn Purcell-Milton[1,3] and Yurii K. Gun'ko[1]; [1]Trinity College Dublin, The University of Dublin, Ireland; [2]Institut universitaire de techonolgie Clermont-Auvergne, France; [3]Technological University Dublin, Ireland

Access to clean water has becoming increasingly scarce in recent years due to various factors, such as increasing population density, urbanisation, climate change and inequality, among others. The development of new, inexpensive, and reliable methods of the removal of various pollutants and toxins from water is vitally important. In recent years, the emergence of 2D nanomaterial-based nanofiltration (NF) membranes has become an exciting prospect for water purification.[1] In particular, boron nitride (BN)-based membranes have been shown to be very effective in the removal of various dyes from water, that are often leached into wastewater by the textile industry.[2] While these membranes show excellent performances for the removal of the dyes, they suffer from one major drawback – normally they are not reusable. The interest in layered double hydroxides (LDHs) has experienced a resurgence in recent years,

due to their ease of synthesis and tunability, which gives rise to a vast number of applications, ranging from biomedical, to electronic, to catalytic.[3-6]

Here we report a variety of LDHs (including Cu- and Cr- containing LDHs) which have been synthesised by co-precipitation techniques. These LDHs were used as components for production of hybrid NF membranes with oxidised BN (BNOx). These membranes have been prepared by exfoliation and vacuum filtration. The novel, hybrid BNOx-LDH membranes exhibited retentions of up to > 99% for methyl orange (MO) dye. These membranes also demonstrated photodegradation of the dye under UV and visible light conditions. By observation of the colour change of different MO-loaded membranes over time, as well as kinetic studies, we show that the strong photocatalytic properties of these membranes are as a result of the presence of LDHs. We believe this work represents a significant step towards achieving the goal of high-performance, recyclable, and cost-effective nanofiltration membranes.

Numerical Study of a Capacitive Graphene Oxide Humidity Sensor with Etched Configuration Meriam Mohammedture; TII, United Arab Emirates

The geometrical dependence of humidity sensors on sensing performance has not been quantitatively outlined. Furthermore, the etching effect on humidity sensors is still elusive due to the difficulty in separating the effects of the geometrical change and etching-induced porosity on the overall performance. Here, we use COMSOL Multiphysics to perform a numerical study of a capacitive graphene oxide (GO) humidity sensor, with emphasis on the dimensions and etching effect on their sensing performance. GO is a useful and promising material in detecting humidity because of its selective superpermeability to water molecules. The mechanism of improved sensing performance of the etched humidity sensors is discussed in terms of the morphological profile and the effective permittivity including the etching-induced porosity effect. Our study shows that as compared to the unetched sensors, isotropic etching achieves the lowest response time of 1.011 s at 15.75% porosity, while vertical etching achieves the highest capacitance sensitivity of 0.106 fF/RH %.

NM06.05.39
Thermal Sculpting of 2D TMDs Nanocircuits for Large-Scale Nanoelectronics Giorgio Zambito, Maria Caterina Giordano, Matteo Gardella and Francesco Buatier de Mongeot; University of Genoa, Italy

Two-dimensional (2D) Transition Metal Dichalcogenide semiconductors (TMDs) have recently gained lots of interest as promising platforms for new-generation electronic and optoelectronic devices [1-5]. In most cases, proof-of-concept devices have been fabricated by exploiting mechanically exfoliated flakes, which suffer from stochastic positioning and shape, along with limited size at the microscale. Also, the re-shaping of 2D materials represents an interesting possibility for tailoring optoelectronic properties of 2D TMDs, as well as enabling the fabrication of devices with controlled geometries.
One way to achieve such re-shaping of exfoliated microflakes is based on state-of-the-art lithography combined with chemical etching (i.e., subtractive approach) which introduces contaminations of the 2D material and, although effective for proof-of-concept device, is not suitable for scalable devices.
In this work we show a novel additive nanofabrication approach for creating deterministic TMDs nano-circuits based on few-layer MoS_2, through the combination of large-area Ion Beam Sputtering growth and thermal-Scanning Probe Lithography (t-SPL) [6]. This latter technique enables the control of a hot silicon nanoprobe (radius ~ 10nm) which can be transiently heated by Joule effect and employed as a high-resolution lithographic tool. Indeed, we exploit t-SPL to write deterministic nanopaths onto a sacrificial polymer layer. These nanopatterns spread over a large-area substrate are homogeneously coated by a few-layer MoS_2 film via a custom-made physical deposition system based on the Ion Beam Sputtering of a MoS_2 target. This additive approach allows us to fabricate well-defined few-layer MoS_2 nanopaths with sharp-edges, that are deterministically located over large-scale substrates. After high temperature recrystallization the few-layer TMDs nanopatterns show clear Raman spectroscopy features and optoelectronic response characteristic of the few-layer 2H-MoS_2 semiconducting phase.
We finally engineered high-resolution 2D TMDs nanodevices to investigate the electronic transport properties of these layers via Kelvin Probe nanoscopy and conductive – AFM imaging. The high-resolution imaging of the local electronic response demonstrates that these few-layer MoS_2 nanocircuits are endowed with competitive transport properties and represent a suitable platform for ultra-thin semiconducting interconnections in integrated electronic and optoelectronic devices.
In conclusion, we demonstrate a novel route for large-area growth and deterministic nanopatterning of few-layer TMDs, which represents an enabling technology for the future fabrication of in-series devices based on 2D semiconducting Van der Waals materials.

Nanostructuring of WS2, MoS2 and PdS by Salt-Assisted Milling in NaCl and KCl Tabbetha A. Dobbins and Denise Omoruyi; Rowan Univ, United States

Salt-assisted milling has been reported in the literature to yield individual, exfoliated, layers of transition metal dichalcogenide (TMDs). TMDs are commonly used as catalysts in methane conversion to liquid fuels and for hydrotreatment to reduce sulfides, nitrides, and aromatics yielding. Bond strength is a key parameter for catalytic efficiency. Bond strength scales inversely with bond length (in many materials). In this work, XAFS is used to quantify bond length. Nanoconfinement will improve efficiency of reaction by permitting longer times for methane interaction with the catalyst. USAXS is used to measure catalyst size. This project measures bond length, electronic structure, and particle sizes for the nanostructured transition metal dichalcogenide (TMD) catalysts MoS2, PdS and WS2. Published literature gives a mechanism for the effectiveness of salt-assisted milling based on mechanical interactions with no data reported on Na/K-M, Na/K-S (where M = Mo, Ti, or W) chemical interactions.[1] Results gained will yield new insights to the literature. If M-S bond lengthening is observed, it could explain the hierarchy of catalytic efficiency among the TMDs.

Size and Quality Enhancement of 2D Semiconducting Metal–Organic Chalcogenolates by Amine Addition Watcharaphol Paritmongkol, Tomoaki Sakurada, Woo Seok Lee, Ruomeng Wan, Peter Müller and William Tisdale; Massachusetts Institute of Technology, United States

The use of two-dimensional (2D) materials in next-generation technologies is often limited by small lateral size and/or crystal defects. Here, we introduce a simple chemical strategy to improve the size and overall quality of 2D metal–organic chalcogenolates (MOCs), a new class of hybrid organic–inorganic 2D semiconductors that can exhibit in-plane anisotropy and blue luminescence. By inducing the formation of silver–amine complexes during a solution growth method, we increase the average size of silver phenylselenolate (AgSePh) microcrystals from <5 μm to >1 mm, while simultaneously extending the photoluminescence lifetime and suppressing mid-gap emission. Mechanistic studies using ^{77}Se NMR suggest dual roles for the amine in promoting the formation of a key reactive intermediate and slowing down the final conversion to AgSePh. Finally, we show that amine addition is generalizable to the synthesis of other 2D MOCs, as demonstrated by the growth of single crystals of silver 4-methylphenylselenolate (AgSePhMe), a novel member of the 2D MOC family.

NM06.05.42
TiO_2-Based 1D Nanofilaments and 2D Flakes—Bottom-up, Scalable Synthesis and Their Electronic Structures Revealed by Transient and Steady-State Optical Absorption and Photoelectron Spectroscopy Hussein Badr[1], Erika Colin-Ulloa[2], Julia Martin[2], Ryan Hanna[2], Michelle Frasch[2], Rebecca R. Ramthun[2], Michel W. Barsoum[1], Ronald L. Grimm[2] and Lyubov Titova[2]; [1]Drexel University, United States; [2]Worcester Polytechnic Institute, United States

We recently demonstrated scalable, one-pot synthesis of TiO_2-based one-dimensional, 1D, nanofilaments that self-assemble in two-dimensional flakes, 2D. Simply, we immerse a dozen of cheap, earth-abundant, non-toxic, water-insoluble, precursors such including TiC, TiN, $TiSi_2$ in tetramethylammonium hydroxide aqueous solution at 50-80 °C for tens of hours. The resulting structures, morphologies, chemical compositions were characterized using a battery of characterization techniques. That study revealed a large band gap energy, **E**g ≈ 4.0 eV, and the presence of intra-gap defect states based on Tauc plots of UV-Vis absorbance data. Here we probe the electronic structure with a combination of transient absorption (TA) spectroscopy with sub-band-gap, visible-light illumination as well as ultraviolet photoelectron spectroscopy (UPS). UP spectra demonstrate a work function of 4.0±0.3 eV vs vacuum and a Fermi energy of 3.8 ± 0.1 eV with respect to the valence band edge. Sub-gap optical excitation in 1D/2D nanostructures synthesized from TiC results in photoexcitations with lifetimes in excess of nanoseconds. In combination with the established oxidative stability, long-lived visible photoexcitations and optical emission bring forward possible applications of 1D/2D nanostructures in photocatalysis and optoelectronic applications.

NM06.05.43
Solution-Processable Fabrication of Nanoporous Ag Structures and Patterns by Coating, Printing and Imprinting of Ionic Ag Ink Layers Toward Functional Electronic, Photonic and Sensing Applications Minwook Kim, Kwangjun Kim and Jong G. Ok; Seoul National University of Science and Technology, Korea (the Republic of)

Silver films possess excellent thermal and electrical conductivity and form unique nanoporous morphology based on high surface tension when melting, spurring many applications in flexible electrodes, optics, and sensors. However, the conventional vacuum deposition process for forming a silver thin film entails limitations in substrate material and area, low productivity, and high process cost. Addressing these issues, we demonstrate cost-effective and scalable solution-processable manufacturing of nanoporous silver thin films based on the coating of ionic Ag ink and its mild thermal annealing for Ag reduction [1]. The process can be implemented through spin coating of ionic Ag ink and heat treatment (~180 °C) on various substrates such as silicon, glass, and polymer films. By tuning ink concentration, coating speed, and annealing temperature, the thin film's surface morphology (porosity) and thickness can be quantitatively controlled. This also leads to facile control of optical transmittance and electrical conductivity of the nanoporous silver thin film. Moving forward, we can create the patterned Ag structures by adopting various lithography techniques involving photolithography and nanoimprint lithography. For instance, a polydimethylsiloxane (PDMS)-made mold can be used for transfer printing and soft contact nanoimprinting of solution-processable nanoporous silver thin films [2]. Controlling the strain of a PDMS mold at contact further enables the modulation of printed/imprinted silver patterns for specific uses (e.g., tuning of resonance wavelength). Another useful function of the nanoporous Ag film is that it can be used as a seed layer for hydrothermal synthesis of zinc oxide nanowires (ZNWs) [3]. Practically utilizing this method to developing flexible and transparent sensors, ZNWs can be selectively grown on photolithography-patterned Ag mesh or interdigitated electrodes. Many diverse devices and systems can benefit from this work, including but not limited to sensors, electronics, photonics, and energy harvesters, some of which are in progress for future reports.

Fast and Efficient Electrochemical Thinning of Ultra-Large Supported and Free-Standing Molybdenum Disulfide Layers on Gold Surfaces Nicolli Freitas[1], Bianca Rocha Florindo[1], Vitória M. Freitas[1], Maria H. Piazzetta[1], Carlos A. Ospina[1], Jefferson Bettini[1], Mathias Strauss[1], Edson R. Leite[1], Angelo L. Gobbi[1], Renato S. Lima[1] and Murilo Santhiago[1,2]; [1]Brazilian Nanotechnology National Laboratory, Brazil; [2]Universidade Federal do ABC, Brazil

Molybdenum disulfide (MoS_2) is a very promising layered material for electrical, optical and electrochemical applications. Among different preparation routes, electrochemistry has gain interest due to its simple, fast, scalable and simple instrumentation. However, obtaining large-area monolayer MoS_2 that will enable the fabrication of novel electronic and electrochemical devices on the basal plane is still challenging. In this work, we explored the high affinity

of MoS_2 by gold surfaces and reported a fast electrochemical method that promotes the thinning of bulk MoS_2 down to a monolayer. By selecting a proper applied potential, more than 90% of the bulk regions can be removed from large-area MoS_2 crystals while preserving the first layer attached to the electrode. The thinning process was confirmed by optical microscopy, atomic force microscopy, photoluminescence, and Raman spectroscopy. The hyphenation of electrochemistry and optical microscopy revealed that the thinning process starts at the edges and moves in the direction of the center of the flake and it was used to estimate the thinning area and thinning rate. Finally, we will demonstrate the preparation of large-area and free-standing MoS_2 monolayers using microfabricated microhole-structured Ni/Au meshes [1].

Magnetic Property Transition of Layered Antiferromagnet $MnPS_3$ via Organic Ion Intercalation Min-kyung Jo[1,2], Seorin Cho[1], Jun Woo Choi[3], Gichang Noh[3,1], Eoram Moon[1], Jeongtae Kim[2], Kibum Kang[1] and Seungwoo Song[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of)

Since the discovery of the intrinsic vdW magnets with atomic thickness in 2017, they have gained much attention as potential materials for high-speed and low-power spintronic devices. The intercalation is an effective property tuning method of vdW materials in that it leads to a high amount of charge doping, or the vacancy formation in the lattice depending on the intercalation mechanism, and interlayer expansion. Because these parameters are highly related to the exchange interaction between magnetic atoms, intercalation could result in the magnetic property change of 2D materials. In this study, we tuned the magnetic properties of a layered Heisenberg antiferromagnet $MnPS_3$ via the facile intercalation method of the TMA^+ (tetramethylammonium) ion. After intercalation, $MnPS_3$ showed a ferrimagnetic behavior with Curie temperature at ~35 K in contrast to the pristine antiferromagnetic behavior with Neel temperature at ~78 K. The drastic change in magnetic property was attributed to the formation of Mn^{2+} vacancies in exchange for the insertion of TMA^+ ions. The corresponding magnetic-phonon coupling effect was compared between the pristine and intercalated $MnPS_3$ by analyzing the temperature-dependent Raman spectrums.

NM06.05.47
Near-Unity Valley Polarized State in Gd-Doped WSe_2 Monolayers Byeong Wook Cho[1,2], Seong-Gon Kim[3] and Young Hee Lee[2]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Center for Integrated Nanostructure and Physics, Korea (the Republic of); [3]Mississippi State University, United States

Abstract: Monolayer transition metal dichalcogenides (TMDs) have been regarded as an ideal platform to utilize valley degree of freedom with their inherent spin-valley locking. However, a robust valley polarization, which is essential for potential valleytronic devices, has been only accessible by complicated device structure or external field. Here, we observe near-unity valley polarization in WSe_2 monolayers substitutionally doped with rare-earth Gd atoms synthesized by chemical vapor deposition. The emission from strongly valley polarized state persists up to ~100K, maintaining its high polarizability. It is expected that the emissions are originated from spin up (down) Gd band coupled with conduction band edge at K (K') valley. This finding paves a new way to manipulate valley degree of freedom in monolayer TMDs by means of substitutional doping.

NM06.05.48
The nanoscale thermal properties of isotopically enriched hexagonal boron nitride William D. Hutchins and Patrick E. Hopkins; University of Virginia, United States

In the manufacturing process of semiconductors it is important to catalogue the changes made to a material at all stages of production due to the precise nature of their applications. Titanium Dioxide (TiO2) is among the most useful semiconductors due to its uses in a variety of applications ranging from pigments to photocatalysis. A major step in the synthesis of thin TiO2 films is the annealing process which increases crystallinity and forms a homogeneous structure. Thus it is important to study the effects of annealing temperature, and holding time to produce higher quality films. Recent works in thin TiO2 films focus on crystallography and morphological and optical band-gap phenomena using X-ray diffraction, optical transmission spectroscopy, and electron microscopy, etc. In this work, we use ultrafast pump-probe techniques to study the electron-phonon interactions of un-annealed and annealed TiO2 films. We find a correlation between these thermal properties and crystal structure.

We use time-domain and steady-state thermoreflectance techniques to map the grain structure and measure the thermal conductivity trends. To study the electron-phonon response a multi-frequency infrared pump probe technique is used. Investigating the ultrafast thermal dynamics of TiO2 with different annealing parameters allow us to build out a database for how the morphological structure changes, how this structure effects the thermal and optical phonon space, and the dynamic changes caused by an absorption process: the electron-phonon re-normalization. Our findings open a potential window for future investigations about using thermal characterization for annealed semiconductor.

SnS_2 Quantum Dots Decorated on Monolayer MoS_2 for High Performance Broadband Photodetector Chandra S. Kolli[1,2], Venkatarao Selamneni[1], Bárbara Alejandra Muñiz Martinez[2], Andres De Luna Bugallo[3] and Parikshit Sahatiya[1]; [1]Birla Institute of Technology & Science Pilani, Hyderabad Campus, India; [2]Centro de Investigación y de Estudios Avanzados del Instituto Politécnico Nacional, Mexico; [3]Universidad Nacional Autónoma de México, Mexico

Two-dimensional (2D) materials have great optical and electronic properties, which make them excellent for photodetectors and give them a lot of potential uses. Even if there are several approaches to increase the photodetector's responsivity, the electromagnetic spectrum's limited photodetection spectral range is the primary issue limiting the performance of photodetectors. Quantum dots (QDs) of tin sulfide (SnS2) are wide band gap semiconductors in the ultraviolet and visible spectrums; they display a high optical absorption coefficient and considerable photoconductivity. In addition, recent research reveals

that due to their surface effects and quantum confinement, QDs have excellent local photon trapping capabilities, making them ideal light absorbers that increase the performance of photodetectors combining with them 2D materials. In this study, a 0D/2D SnS2-QDs/monolayer MoS2 hybrid for high-performing and wideband (UV, VIS, and NIR) photodetection is created. Utilizing chemical vapor deposition (CVD), monolayer MoS2 is formed on SiO2/Si, and SnS2-QDs are spin-coated processes made using an inexpensive solution process. The increasing 0D/2D MoS2-SnS2 photodetector device performance may be attributed to the band bending and built-in potential formed at the junction of SnS2-QDs and MoS2, which increases the booster and parting efficacy of the photoexcited charge carriers. The mixed-dimensional construction also reduces the photodetector's dark current. The decorated SnS2-QDs on monolayer MoS2 not only enhance the device's performance but also expand its spectral range into the ultraviolet zone. The UV, Visible, and NIR photoresponsivity of the device are 280 A/W, 450 A/W, and 180 A/W, respectively. Due to the high absorbance of a single layer of MoS2, the devices' highest responsivity was seen in the visible spectrum. The measured reaction time of the fabricated device is 80 milliseconds fast response time. The implementation of the 0D–2D mixed-dimensional heterostructures presented here will expand the design space for next-generation optoelectronic applications, as demonstrated by our results.

Printed Graphene FET Biosensors for Multi-Analyte Detection Benji Fenech Salerno, Martin Holicky, Chengning Yao and Felice Torrisi; Imperial College London, United Kingdom

The rise of point-of-care (PoC) diagnostic technology has been insistent and clear. Accelerated by the COVID-19 pandemic, the healthcare industry is transitioning to a future of increased diagnostic digitisation, democratisation, and decentralisation.[1] The World Health Organisation (WHO) set out seven key criteria for PoC devices in the early 2000s.[2] For maximum impact, tests had to be Affordable, Sensitive, Specific, User friendly, Rapid and robust, Equipment-free and Deliverable to end-user, or ASSURED in short. These criteria were revised in 2019 to REASSURED, emphasising the need for Real-time connectivity and Ease of sample collection as well.[3]

Within this context, graphene is an ideal material to develop biosensors as it can be made in a stable, biocompatible manner which supplemented by its high-mobility, semi-metallic electronic properties make it well suited for sensing of biologically relevant analytes.[4] Moreover, graphene can be dispersed as inks, which in combination with other 2D materials (conducting, insulating and semiconducting) offers a route for economical, flexible printed electronics devices on a wearable platform.[5], [6]

In this work, we demonstrate printed graphene field effect transistor (GFET) biosensors for the detection of multiple analytes. Using liquid phase exfoliation (LPE), we optimised an environmentally sustainable graphene-polymer ink. Inks can be tailored to shown concentrations of 0.1 mg/mL to > 10 mg/mL, to allow for variable deposition techniques. Raman spectroscopy indicated that the inks comprised of electronically decoupled layers of graphene. The lateral flake size was characterized by AFM, SEM and TEM, with a likely modal average of 200 nm within a range of flakes extending to 500 nm and mean flake thickness of < 5 nm. The high-quality inks were printed to fabricate transistor devices with reliable and replicable manufacturing, with intra-batch variation of FET electronic properties of < 5 %. The GFETs were subsequently optimised pH detection (resolution of < 0.05 pH), Na^+ (detection limit < 1 µmol/L) and enzymatic substrates.

Graphene Bioimpedance Tattoos for Blood Pressure Monitoring Dmitry Kireev[1], Kaan Sel[2], Bassem Ibrahim[2], Roozbeh Jafari[2] and Deji Akinwande[1]; [1]The University of Texas at Austin, United States; [2]Texas A&M University, United States

Monitoring complex health-related electrophysiological signals such as arterial blood pressure (BP) in ambulatory settings is essential for a proper understanding of health conditions, predominantly cardiovascular diseases. Moreover, continuous long-term monitoring of BP for patients with sleep apnea, stroke, or hypertension is essential to understand their health risk factors and build preventative care routines. While conventional ambulatory BP monitoring devices exist, they are uncomfortable, bulky, and intrusive. The common drawbacks of all these systems are their bulkiness and incompatibility with skin’s elastic properties, causing sensor’s displacement during usage, consequently requiring frequent system re-calibration.
Here, we present a unique wearable BP monitoring platform that leverages imperceptible atomically-thin and electrically conductive graphene electronic tattoos (GETs) as the main building block. The GETs are placed over the radial and ulnar arteries on the wrist and subsequently used as current injection and voltage sensing electrodes, measuring arterial bioimpedance. In contrast to any other wearable system, the atomically thin, lightweight, and skin-conformable GETs do not apply any external tension onto the skin during the operation, and able to perform long-term and nocturnal measurements without discomforting the subjects. Using bioimpedance modality allows us to disregard the tattoo-skin interface, which is typically 2-4 orders of magnitude larger compared to tissue impedance, and record only from the areas of interest. Employing a machine learning regression model on the recorded bioimpedance value, we yield effective beat-to-beat detection of diastolic and systolic BP values with IEEE grade-A accuracy. Besides BP, we show that the same Bio-Z signal can be post-processed to estimate person’s RR in an entirely wearable and non-invasive manner.

3D Printing of Polyvinylidene Fluoride and Layered MoS_2 Composites for Piezoelectric Sensing Md Nurul Islam[1], Rifat Hasan Rupom[1], Aqsa Nazir[1], Rigoberto C. Advincula[2,3], Narendra Dahotre[1], Wonbong Choi[1,1] and Yijie Jiang[1]; [1]University of North Texas, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Flexible and stretchable piezoelectric sensors have numerous applications in wearable electronics, healthcare, and structural health monitoring. Most of them are made from piezoelectric polymer materials such as polyvinylidene fluoride (PVDF) and it's copolymers that have limited piezoelectric response. Recent discoveries in two-dimensional materials as high-performance piezoelectric materials provide a promising route to formulating novel composites for sensors and actuators. Here, we develop nanocomposites using PVDF and layered molybdenum disulfide (MoS_2) into 3D printable, stretchable, and

flexible piezoelectric sensors. Ink is formulated by distributing layered MoS_2 into PVDF by high-power vacuum mixing to achieve desired rheological properties for direct ink writing (DIW) 3D printing. We harness the shear stress-induced PVDF dipole mechanical poling and nanomaterial alignment during DIW printing for piezoelectric sensitivity enhancement. A remarkable 87.5% improvement in piezoelectric coefficient is achieved in 3D printed PVDF compared with casted samples. Furthermore, we observe enhancement up to 8.1 and 4.3 times increment in the piezoelectric coefficient for nanocomposites with 8 wt% MoS_2 loading over casted and 3D printed neat PVDF. We thoroughly examine the piezoelectric response enhancement of PVDF by β phase enhancement mechanism as a function of MoS_2 fraction as well as the heterogeneous strain distribution in PVDF-MoS_2 nanocomposite via numerical simulations. In this presentation, we will discuss the experimental analysis and its mechanistic study along with the piezo sensor performance from 3D printed MoS_2-PVDF composite.

Implantable Aptamer-Graphene Microtransistors for Real-Time Monitoring of Neurochemical Release *In Vivo* Guangfu Wu and Yi Zhang; University of Connecticut, United States

The real-time monitoring of neurochemical release in vivo plays a critical role in understanding the biochemical process of the complex nervous system. Current technologies for such applications, including microdialysis and fast-scan cyclic voltammetry, suffer from limited spatiotemporal resolution or poor selectivity. Here, we report a soft implantable aptamer-graphene microtransistor probe for real-time monitoring of neurochemical release. As a demonstration, we show the monitoring of dopamine with nearly cellular-scale spatial resolution, high selectivity (dopamine sensor >19-fold over norepinephrine), and picomolar sensitivity, simultaneously. Systematic benchtop evaluations, ex vivo experiments, and in vivo studies in mice models highlight the key features and demonstrate the capability of capturing the dopamine release dynamics evoked by pharmacological stimulation, suggesting the potential applications in basic neuroscience studies and studying neurological disease-related processes. The developed system can be easily adapted for monitoring other neurochemicals and drugs by simply replacing the aptamers functionalized on the graphene microtransistors.

Graphene E-Tattoos for Wireless and Mobile Electrodermal Activity Sensing Enabled by Heterogenous Serpentine Ribbons Nanshu Lu; The University of Texas at Austin, United States

Electrodermal activity (EDA) is a skin conductance change that indicates psychological or physiological arousal and has been used as a quantitative index of mental stress levels for decades. State-of-the-art EDA devices suffer from short-term wearability when mounted on the palm or low signal fidelity when measured off palm. Our previous innovation of sub-micron-thick, transparent graphene e-tattoos (GET) [http://dx.doi.org/10.1021/acsnano.7b02182, http://dx.doi.org/10.1038/s41699-018-0064-4] is ideal for long-term unobstructive and imperceptible EDA sensing on the palm. The filamentary-serpentine-shaped GET is so thin and so soft that it is imperceptible optically and mechanically. However, there still lacks mechanically robust electrical connection to interface GET with rigid circuit boards [http://dx.doi.org/10.1088/2053-1583/ab4c0f]. To overcome the orders of magnitude mismatch of stiffness between them, we introduce a novel interface design of heterogeneous serpentine ribbons (HSPR), which refer to serpentine GET overlapping with a serpentine gold ribbon. In comparison with heterogeneous straight ribbons (HSTR), a maximum of 50 folds of strain reduction in GET using HSPR have been confirmed. When the HSPR is clamped end-to-end and subjected to uniaxial tension, its resistance only doubles after 42% of applied strain, which is determined as the stretchability. We also provide a guideline to predict the stretchability of HSPR based on FEM. Furthermore, to prevent the damage of the gold ribbon to contact with the rigid circuit board, a reusable conductive soft interlayer is employed and works both as a vertical via and a mechanical buffer layer which could isolate the mechanical scrubbing from the rigid watch. Finally, the combination of HSPR and a conductive soft interlayer between the GET and a rigid EDA watch enables ~15 hrs of continuous and ambulatory EDA monitoring. This method offers a remedy for the long-standing interconnect challenges between ultrathin e-tattoos and rigid electronics, which could significantly enhance the practical use of e-tattoos.

Graphene-Based Wearable Sensor for Healthcare Monitoring Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Biosignals, such as skin temperature, EEG, and ECG, provide information regarding the general condition of the human body and facilitate the diagnosis of various diseases. In this talk, we present a wearable thermal patch with dual functions of continuous skin temperature sensing and thermotherapy for effective self-care treatment and an EEG/EKG sensor with clinical diagnostic function to monitor for abnormal brain and cardiac rhythms in patients. The thermal patch consists of a graphene-based capacitive sensor, a graphene thermal pad, and a flexible read-out board with a wireless communication module. The wearable sensor continuously monitors the temperature variation over a large area of skin area with high resolution and sensitivity and performs thermotherapy via the graphene-based heater mounted at the bottom of the device. Animal studies prove that the proposed system can be used to diagnose various diseases. In addition, EEG/ECG sensor consists of graphene electrodes and read-out circuits with a wireless communication module. The sensor attached to the skin of the head and chest continuously monitors EEG and ECG from the brain and heart. This technology could be useful in the development of convenient and wearable healthcare devices.

11:00 AM NM06.06.10
Covalent Organic Frameworks as Selective AC-Impedimetric Sensor Materials David Moore[1,2], Nicholas Glavin[1], Lucas K. Beagle[2,1] and Ly Tran[2,1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc., United States

Covalent Organic Frameworks (COFs) films hold much promise in material research due to the breadth of properties they possess. They are inherently porous, and clever synthesis can construct nanosheets of almost any pore size or functionalization. Consequently, the have the inherent ability to be species-selective in several ways, such as size, chemical affinity, and tunable physisorption. This is excellent for sensing, but most COFs have the drawback of being insulative, thus making it challenging to form them into direct sensors. Various approaches have been used in literature, but in this talk we will discuss building upon a novel real-time impedance spectroscopy approach that can be sensitive to femtofarad level changes in capacitance to observe changes in permittivity of the COF film as analytes adsorb to the COF directly. Practical challenges and limitations as well as comparisons to other techniques will be discussed.

SESSION NM06.07: 2D Material Sensors II

1:30 PM *NM06.07.01
Additive Manufacturing of Two-Dimensional Material Inks for Ubiquitous Sensors Mark C. Hersam; Northwestern University, United States

Two-dimensional (2D) materials have emerged as promising candidates for next-generation electronic [1], quantum [2], and sensing technologies [3]. With properties ranging from insulating (e.g., hexagonal boron nitride) to semiconducting (e.g., transition metal dichalcogenides) to conducting (e.g., graphene), nearly any electronic device can be fabricated by properly assembling 2D materials into heterostructures [4]. While device prototypes have been demonstrated on idealized research-scale samples, scalable manufacturing remains a challenge for 2D materials. In parallel, the field of printed electronics has made significant progress towards roll-to-roll additive manufacturing based on organic and nanoparticle inks. This talk will explore recent work aimed at uniting these efforts by designing electronic inks that combine the superlative electronic properties of 2D materials with the scalable manufacturing of printed electronics. To achieve this objective, multiple design goals have been concurrently pursued including exfoliation (i.e., optimizing yield, throughput, and flake size), ink formulation (i.e., engineering solvents and stabilizing surfactants and polymers for aerosol, inkjet, gravure, screen, and 3D printing), printed structure morphology (i.e., controlling film morphology and microstructure following printing via solvent evaporation, solvent additives, and curing conditions), and control of interfacial properties (i.e., minimizing interfacial resistance in conductive inks, maximizing capacitance in dielectric inks, and maximizing mobility for semiconductor inks). By achieving high levels of 2D material ink homogeneity and printing fidelity, a variety of high-performance applications have been achieved including electronics, photodetectors, supercapacitors, batteries, and sensors [4-9].

Amplification-Free Detection of SARS-CoV-2 and Respiratory Syncytial Virus Using CRISPR Cas13a and Graphene Field-Effect Transistors
Huijie Li, Guangfu Wu, Zhengyan Weng and Yi Zhang; University of Connecticut, United States

The clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated (Cas) systems have recently received notable attention for their applications in nucleic acid detection. Despite many attempts, most current CRISPR-based biosensors in infectious respiratory disease diagnostic applications still require target preamplifications. This study reports a new biosensor for amplification-free nucleic acid detection via harnessing the trans-cleavage mechanism of Cas13a and ultrasensitive graphene field-effect transistors (gFETs). CRISPR Cas13a-gFET achieves the detection of SARS-CoV-2 and respiratory syncytial virus (RSV) genome down to 1 attomolar without target preamplifications. Additionally, we validate the detection performance using clinical SARS-CoV-2 samples, including those with low viral loads (Ct value > 30). Overall, these findings establish our CRISPR Cas13a-gFET among the most sensitive amplification-free nucleic acid diagnostic platforms to date.

2:15 PM NM06.07.03
Inkjet Printed Graphene Sensors for Electrochemical Detection of Phosphates Rajavel Krishnamoorthy, Thiba Nagaraja and Suprem R. Das; Kansas State University, United States

Phosphate is an essential element in our eco-systems, regulating biochemical reactions starting form living matter/biological cells to environmental presence such as in soils. Both limitation as well as over exposure of phosphates can cause detrimental consequences. As such, continuous monitoring of electrochemically inactive phosphates in real samples is crucial for studying number of applications, such as soil health to human health. The present study aimed at developing graphene-based inkjet printed electrochemical sensors to identify different phosphate ions. Large scale exfoliation of few-layer graphene material was synthesized by liquid phase exfoliation from bulk stacked graphite samples, with an effort to achieve highly conductive graphene inks. Defined patterns of sensing electrodes were fabricated using additively manufactured graphene inks with aid of inkjet printing method. The few-layers of exfoliated graphene was uniformly patterned onto the flexible substrate and forms low resistive conducting network. Structural and morphological characterizations are provided to aid large charge transfer in electrochemical cell. Molybdenum based redox electrochemical species on printed graphene electrodes was applied for wide concentration range detection of phosphates using cyclic voltammetry and amperometry. The performance of inkjet printed electrodes was validated with commercial electrodes by different electrochemical sensor characterization parameters such as sensitivity and limit of detection which showed superior results. The additive manufacturing and phosphate sensing performance of graphene based inkjet printed electrodes could be further utilized for monitoring real-time phosphate sensing using a portable hand held potentiostat.

2:30 PM *NM06.07.04
Integrated Biosensor Platform Based on Graphene Transistor Arrays for Real-Time High-Accuracy Ion Sensing Mantian Xue[1], Charles Mackin[2], Wei-Hung Weng[1], Jiadi Zhu[1], Yiyue Luo[1], Shao-Xiong Lennon Luo[1], Ang-Yu Lu[1], Marek Hempel[1], Elaine McVay[1], Jing Kong[1] and Tomas Palacios[1]; [1]Massachusetts Institute of Technology, United States; [2]IBM Almaden Research Center, United States

Smart sensors, such as sweat sensors, targeting various physiologically relevant biomarkers in biofluids have recently demonstrated great potential for health-tracking and medical diagnosis. Two-dimensional (2D) materials are particularly promising in biochemical sensing applications thanks to their large-surface-to-volume ratio, which allows the sensor channel to be readily modulated upon chemical changes near the surface, translating chemical signals into the electrical or optical domain with enhanced sensitivity. Graphene is the most widely studied material among all 2D materials. It has the largest surface-to-volume ratio and exhibits a number of promising characteristics. Despite advances in material synthesis, large-area integration of devices based on graphene and other novel materials still suffer from strong device-to-device variability caused by intrinsic defects, gate oxide nonuniformities, and parasitic effects. Device fabrication also introduces additional variability in sensor response from batch to batch. Here we demonstrate an approach to overcome the challenges in 2D material-based sensing devices and achieve high performance and enhanced functionality. Rather than focusing on the improvement of intrinsic material quality, fabrication uniformity and surface functionalization, we develop a high-density graphene-based sensor array platform to overcome the large degree of variability of advanced materials. We fabricate arrays (16×16) of graphene devices to provide more than 200 working sensing units for each chip, and configure them into multi-ion sensors by functionalizing the surface with three different ion-selective membranes (ISMs). Ionized calcium, potassium, and sodium were chosen as analytes of interest due to their commonplace in diagnostic tests and their physiological importance in blood, urine, and sweat. We demonstrate near-ideal sensitivity, excellent reversibility, and large detection range for each type of sensor

despite non-uniformity in individual devices. The variations and imperfections in material synthesis and device fabrication can be leveraged by statistical analysis and machine learning algorithms. A profile-matching calibration method utilizing sensor non-uniformity and redundancy is introduced to eliminate the need for multiple calibration solutions, which is especially useful for sensing applications targeting portability and field use. A Random Forest algorithm is used to quantify analyte concentrations in the presence of multiple-ions. The abundance (N>200) and multiplexity of sensors and sensor types are shown beneficial for improving model accuracy. We demonstrate that system-level co-design of sensing arrays and algorithms significantly improves sensor performance thus enabling rapid prototyping and in-depth data analysis in spite of the limitations present in graphene and other advanced 2D materials.

3:00 PM BREAK

4:00 PM *NM06.07.06
Roll-to-Roll Production of Two-Dimensional Electronic Pathogen Sensors Christopher Muratore; University of Dayton, United States

Materials with high surface-to-volume ratios demonstrate exquisite sensitivity and detection limits in diverse molecular sensing applications. Integration of nanowires, nanotubes, and two-dimensional (2D) semiconductors into sensing devices, however, presents challenges inhibiting product development. For example, thousands of trials are required to obtain government approval for point of care diagnostics, yet producing a suitable number of 2D devices via conventional synthesis and fabrication techniques to meet this is not feasible. To realize applications of 2D transducers in ubiquitous low-cost diagnostic devices, new fabrication approaches are required. Processes for high-rate (>10^6 per day) mass-production of low-cost two-dimensional electronic medical diagnostic devices with limits of detection rivalling PCR will be presented. Rapid and inexpensive sensor chip fabrication relies upon laser pattering and crystallization processes in a roll-to-roll physical vapor deposition system. In addition to electronic properties responsive to molecular attachment, the composition of 2D MoS_2 or other transition metal dichalcogenides with tunable sulfur vacancy density facilitates direct functionalization for highly selective analyte binding with antibody fragments or even smaller molecules for enhanced sensitivity. A large supply of unfunctionailzed diagnostic devices may therefore be stored to be functionalized with any selective binding agent on-demand to immediately reduce the impact of future disease outbreaks. Materials for large-scale device fabrication were selected to ensure recyclability of the devices for reduced waste stream impact in anticipation of large numbers of devices are consumed daily. A combination of fundamental studies to highlight the role of defects in 2D MoS_2 on the sensitivity and dynamic range of the 2D devices is shown via extensive testing of thousands of mass-produced device measurements of biologically significant concentrations as low as 10 fg/mL of viral proteins and/or other biomarkers as low 10 fg/mL in the presence of interference protein concentrations >10^{12} times higher than those of the target analytes. Response times for most analytes are 2 minutes or less. Detection of multiple analytes on an array of sensors fabricated on a single flexible chip is straightforward as the laser pattering steps dictating device architecture are adjustable by directing the automated pattering laser with a modified electronic drawing possessing the desired features. Integration of other processes to facilitate production exceeding a million devices daily, such as *in situ* device quality control via high throughput Raman spectroscopy and chip singulation tools is shown for high-yield, low-cost production of devices performance meeting stringent requirements for quantitative analysis of biological samples.

4:30 PM NM06.07.07
Chemiresistive 2D Materials Decorated Angstrom-Level Porous Graphene Oxide for Exceptional Surface Activity Ji-Soo Jang; Korea Institute of Science and Technology, Korea (the Republic of)

Recently, intrinsically metallic two-dimensional (2D) materials have gained major recognition as surface active layers, taking advantage of the abundant highly active adsorption sites and fast charge transfer even at room temperature (RT)[1]. Of such materials, black phosphorous (BP) has a puckered orthorhombic 2D atomic structure with extremely high hole mobility (10,000 $cm^2V^{-1}s^{-1}$) and large surface area[2-3]. 2D MXene is another promising candidate for surface reactors, offering a significantly high electrical conductivity, chemical versatility via surface functionalization, and favorable signal-to-noise ratio (SNR) during operation[4]. Therefore, 2D BP and MXene have triggered enormous research interests in catalysis, energy storage, and chemical sensing. However, unfortunately, low stability of these 2D materials under practical operating conditions remains a critical bottleneck, particularly as they are prone to oxidization under moisture[5-6].

In order to guarantee minimal oxidation/deterioration of such BP or MXene required for reliable performances, various encapsulation/protection methodologies have been introduced recently. Nonetheless, adding specific passivation layers was found to prohibit the efficient permeation of any desired molecules to the underlying 2D materials, thus greatly hampering the desired surface activities. Till date, there seems to be an inevitable tradeoff between material performance and chemical stability for the 2D active materials.

Here, we present ultra-stable 2D heterostructures obtained from decorating BP and MXene with few-layer holey graphene oxide (FHGO) membranes. In the resulting system, FHGO serves as a multifunctional passivation layer that shields BP or MXene from oxidative degradation, while allowing the selective diffusion of target gas molecules through its micropores and towards the underlying 2D material. Through a case study of dilute NO_2 sensing, we demonstrate that our hetero-2D structures show greatly enhanced sensing performance under humid conditions, where exceptionally fast sensing speed and response are consistently observed, and high stability is impressively retained upon repetitive sensing cycles for 1,000 min. These results corroborate the efficacy of material decoration with porous FHGO membrane, and suggest this to be a generalizable strategy towards reliable high-performance applications of 2D conductive materials.

SESSION NM06.08: Poster Session II: 2D Layered Materials and Heterostructures

NM06.08.01
Graphene via Contact Architecture for Vertical Integration of vdW Heterostructure Devices Yongjun Shin[1], Junyoung Kwon[2] and Gwan-Hyong Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of)

Two-dimensional (2D) devices and their van der Waals (vdW) heterostructures attract considerable attention owing to their potential for next-generation logic and memory applications. In addition, 2D devices are projected to have high integration capabilities, while maintaining nanoscale thickness. However, the fabrication of 2D devices and their circuits is challenging because of the high precision required to etch and pattern ultrathin 2D materials for

integration. Here, the fabrication of a graphene via contact architecture to electrically connect graphene electrodes (or leads) embedded in vdW heterostructures is demonstrated. Graphene via contacts comprising of edge and fluorinated graphene (FG) electrodes is fabricated by successive fluorination and plasma etching processes. A one-step fabrication process that utilizes the graphene contacts is developed for a vertically integrated complementary inverter based on n- and p-type 2D field-effect transistors (FETs). This study provides a promising method to fabricate vertically integrated 2D devices, which are essential in 2D material-based devices and circuits.

NM06.08.02
Wafer-Scale Growth of Ultra-Thin $SnSe_x$ (x=1,2) by Low-Temperature MOCVD Sungyeon Kim[1], Hoyeon Cho[1], Seonhwa Jeon[2], Jaewon Kim[1], Kyungmin Ko[1], Swati Singh[1], Sungkyu Kim[3] and Joonki Suh[1,2]; [1]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Sejong University, Korea (the Republic of)

Two-dimensional van der Waals (vdW) crystals are a recently emerging class of electronic materials, and among them, Mo-, W-based transition-metal dichalcogenides (TMDs) have been successfully synthesized in the form of wafer-scale thin films until now. On the other hand, the group IV metal chalcogenides including Sn-based compounds have been limited in their applications with small flakes or thick films despite their promising properties. The reason is that the absence of suitable precursors and low growth temperature made it difficult for the materials to diffuse on the substrate and grow into a large-area thin film. In this work, we demonstrate gas-phase synthesis ultra-thin $SnSe_x$ (x=1 and 2) films with high crystallinity and wafer-scale homogeneity. It is enabled by low-temperature metal-organic chemical vapor deposition (MOCVD) in which relatively compact and non-toxic methyl ligand precursors are used. Also, we overcome the temperature mismatch between high precursor decomposition temperature (~650°C) and low growth temperature (~200°C) by designing the separate functional zones with independent thermal control. Through this preferable growth condition, $SnSe_2$ ultra-thin film (3~5 nm) can be ultimately synthesized in wafer-scale. Afterward, n-type $SnSe_2$ thin film can be polarity change to p-type SnSe by thermally induced phase transition in inert and stable condition. SnSe thin film can also keep high crystallinity and homogeneity across the wafer despite the crystal structure change. Both n-type $SnSe_2$ and p-type SnSe thin films can be applied as p-n junction channel array with type II band alignment. This study will serve as a stepping stone to accelerate the electronic and thermoelectric device applications of high quality $SnSe_x$ (x=1,2) thin film in the wafer-scale.

NM06.08.03
Epitaxial Single-Crystal Growth of Transition Metal Dichalcogenide Monolayers via Atomic Sawtooth Au Surface Jina Lee[1], Soo Ho Choi[1], Soo Min Kim[2], Ki Kang Kim[1] and Young Hee Lee[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sookmyung Women's University, Korea (the Republic of)

Two-dimensional (2D) layered materials such as graphene, transition metal dichalcogenides (TMDs), and hexagonal boron nitride have attracted attention due to their distinctive physical and chemical properties. Therefore, many applications such as high-performance field-effect transistors, atomically thin pn diodes, and Coulomb drag transistors have been investigated. However, such applications are currently only available with a lateral size of up to a few tens of micrometers. Therefore, the growth of single-crystal 2D materials is highly desired to manifest intrinsic physical and chemical properties over the whole region. While wafer-scale single-crystal hexagonal boron nitride film has been successfully grown on liquid Au and vicinal Cu surfaces, an ideal growth platform for diatomic transition metal dichalcogenides has not been established to date. Here, we report the single-crystal growth of monolayer TMD films on atomic sawtooth Au substrates. The atomic sawtooth Au surface, which has periodic atomic step-edges and terraces, is simply prepared by one-step solidification of liquid Au. The atomic step-edges provoke the anisotropic adsorption energy of the TMD cluster, eventually leading to the growth of coherently aligned TMD grains over the whole region. The aligned TMD grains are merged without producing grain boundaries and form the single-crystal TMD films. Furthermore, the growth of several TMD monolayer films, including WS_2, WSe_2, MoS_2, the $MoSe_2/WSe_2$ heterostructure, and $W_{1-x}Mo_xS_2$ alloys is demonstrated, indicating that the atomic sawtooth surface could be employed as a universal growth template. This strategy provides a general avenue for the single-crystal growth of diatomic van der Waals heterostructures on a wafer scale, to further facilitate the applications of TMDs in post-silicon technology.

NM06.08.04
Synthesis of High-Quality, Large Violet Phosphorus Crystals by Mixed Metal Flux Jiwon Kim, Soo Ho Choi, Junseong Song, Ki Kang Kim and Young Hee Lee; Sungkyunkwan University, Korea (the Republic of)

Among diverse phosphorus allotropes, black phosphorus has been attracting significant attention due to the van der Waals layered structure, anisotropic property, Si-like bandgap, and high carrier mobility. However, it is difficult to apply black phosphorus to practical applications due to its poor ambient stability. Recently, violet phosphorus (VP) has newly emerged as the most stable phosphorus allotropes with similar properties. However, current chemical vapor transport (CVT) technology has limitations of small crystal sizes up to 0.5 mm and low crystal quality. In addition, black phosphorus always exists as a side product in the CVT synthesis of VP. Therefore, the synthesis of pure VP is still challenging owing to the absence of a new synthesis method. Here, we report a mixed metal flux method to synthesize high-quality, large VP crystals. VP crystals up to 5 mm in lateral size are synthesized by mixed tin and bismuth flux at high temperatures, whereas tiny black phosphorus crystals are obtained at low temperatures. It implies that the growth temperature is a key parameter to determine the phase of phosphorus. The full width at half maximum of ~0.14° is observed in X-ray diffraction, indicating the high crystal quality of the VP crystal. Furthermore, the crystal size can be simply controlled by adjusting the cooling rate in the synthesis process.

Self-Wrinkling Insulating Nanosheets as Substrates for Wrinkling of Graphene, Graphene Oxide and Other 2D Materials Barbara Pacakova[1], Paulo H. Michels Brito[1], Josef Breu[2], Koiti Araki[3] and Jon Otto Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]University of Bayreuth, Germany; [3]USP Sao Paulo, Brazil

Material properties of graphene[1–3], such as mechanical, electronic, optical, and chemical, can be altered by changing its topography[4–6]. Many applications based on the capture of gases and molecules, such as graphene sensors[7], require enhancement of chemical reactivity and subsequent functionalization of graphene. However, planar structure of graphene is disadvantageous for this purpose as in general, graphene carbon atoms located within the plane are almost inert compared to C atoms on defects and edges that are more reactive.
Enhanced chemical reactivity can be achieved by increasing the curvature of topographical features [4,6] – by wrinkling, rippling and crumpling[8], as curved parts are more reactive than planar regions.
Here we report unique wide band gap insulating single layers of high aspect ratio, that wrinkle spontaneously after deposition on a substrate – 1 nm thin clay mineral sheets decorated with nanoparticles. As these nanosheets readily disperse in water, this approach of formation of self-wrinkled substrates allows creation of self-assembled wrinkled 2D heterostructures, including graphene.

Multifunctional Nanosheets for Electromagnetic Interference Shielding and Infrared Detection Emma J. Renteria[1], Grant D. Heileman[1], Sadhvikas J. Addamane[2], Thomas J. Rotter[1], Ganesh Balakrishnan[1,1], Christos Christodoulou[1] and Francesca Cavallo[1,1]; [1]University of New Mexico, United States; [2]Sandia National Laboratories, United States

We report our recent results on developing multi-functional materials for electromagnetic interference (EMI) shielding and infrared detection. The work is motivated by the increasing use of devices that saturate the environment with radio-frequency (RF) electromagnetic radiation. RF radiation can disrupt the operation of electronic components, including sources and detectors of infrared (IR) radiation that are widely used in communication systems and night-vision cameras. Our work focuses on integrating a front-end shield of radio waves with an optoelectronic IR detector in a sheet that can conform to non-planar surfaces, such as windows on an aircraft and domes in IR cameras. In our design, a single-crystalline and highly doped III-As nanomembrane (NM) serves as the IR-transparent shield of EMI. The optoelectronic IR detector is based on black phosphorous (bP). Here, we present our effort in the characterization of IR transmittance and shielding effectiveness of III-As NMs. In addition, we show preliminary results on the integration of bP IR absorbers with III-As NMs. We fabricate III-As NMs with a thickness of a few hundred nanometers and a nominal doping level ranging between 10^{19} and 10^{20} cm^{-3}. The NMs are grown by molecular beam epitaxy onto GaAs substrates coated with lattice-matched sacrificial layers or etch stop layers (e.g., AlAs or AlGaAs). Freestanding NMs are isolated either by selective etching of the sacrificial layer or by removal of the growth substrate and etch-stop layer. After transfer to a new host (e.g., Kapton film), we measure the optical transmittance of the NMs above 1 μm. We extract the shielding effectiveness of the NM from measured s-parameters of frequencies ranging from 60 to 90 GHz. The extracted shield effectiveness is benchmarked against theoretical calculations to identify shielding mechanisms in the NM. Theoretical calculations use measured DC conductivities of the released NMs. We identify primary reflection (i.e., reflection of the RF radiation by the front surface of the NMs) as the dominant shielding mechanism in NMs. In addition, we quantify the effect of multiple internal reflections on shielding effectiveness.

Ultrafast Carrier Dynamics In 2D GeS—Role of Valley Polarization Sepideh Khanmohammadi[1], Catherine Tran[2], Erika Colin-Ulloa[3], Kateryna Kushnir[1], Kristie Koski[2] and Lyubov Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]University of California, Davis, United States; [3]worcester polytechnic institute, United States

Germanium sulfide (GeS) is a 2D semiconductor with high carrier mobility, a moderate band gap of about 1.5 eV, and highly anisotropic optical properties. In-plane anisotropy and a large in-plane spontaneous electric polarization in GeS have been predicted to result in a shift current in response to above-the-gap excitation. In our recent work, we have demonstrated shift current generation in GeS using THz emission spectroscopy. Here, we use time-resolved THz spectroscopy to investigate the dynamics and lifetimes of photoexcited carriers. We find that excitation with 1.55 eV vs 3.1 eV optical pulses results in drastically different photoconductivity response. Photoconductivity builds up slowly, over ~ ten picoseconds and persists for nanoseconds when excited with 1.55 eV. On the other hand, photoconductivity rise time is short and photoexcited carrier lifetime is on the order of hundreds of picoseconds for 3.1 eV excitation. We discuss these differences in terms of intervalley scattering effects. We also investigate in-plane anisotropy of photoconductivity.

NM06.08.10
Single-Crystal WS_2 Growth on High Miscut Angle Substrate Hyun Je Cho[1,2], Jong Yun Choi[1,2], Heonsu Ahn[1,2], Geonho Mun[1,2], Jaeyoung Kim[2], Hyunjin Jung[2] and Moon-Ho Jo[1,2]; [1]POSTECH, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

We report single crystalline monolayer tungsten disulfide (WS_2) growth on high miscut angle c-plane sapphire substrate. Unlike other step-edge-guided growth, we use high miscut angle substrate to initiate uni-directional nucleation. Since the high miscut angle substrate containing high portion of step-edge, terrace nucleation had succesively suppressed, leading to high quality single crystalline monolayer film can be acquired. Single crystalline texture is verified by microscopies and transmission electron microscope studies. Moreover, low energy electron diffraction measurements at different points perfectly exhibit 3-fold symmetry without any angle deviation. We also synthesize monolayer WS_2 nanoribbon by controlling the anisotropic growth. Finally, we show electronic and optoelectronic properties of our single crystal WS_2 film and WS_2 nanoribbon. Our method not only offers a universal and scalable growth strategy to produce TMDC single crystals for future electronics, but also gives perfect platform for studying large scale moiré physics.

Superior Mechanical Properties of Multi-Layer Covalent-Organic-Frameworks Enabled by Rationally Tuning Molecular Interlayer Interactions Qiyi Fang[1], Zhengqian Pang[2], Qing Ai[1], Yifeng Liu[1], Tianshu Zhai[1], Guanhui Gao[1], Yifan Zhu[1], Teng Li[2] and Jun Lou[1]; [1]Rice University, United States; [2]University of Maryland College Park, United States

Two-dimensional covalent-organic-frameworks (2D COFs) is a class of porous 2D polymer with periodic structure and ordered skeleton assembled from covalent bonds. 2D COFs distinct from 2D inorganic analogue by their high designability, which make them potential platform for mechanistic studies of mechanical behavior at 2D limit. In this talk, we will present the systematical study of the structure-mechanical properties relation by designing the structure of 2D COFs. With optimized Langmuir-Blodgett method, we successfully prepared layer-controlled 2D COFs, and measured their mechanical properties by nanoindentation. Our result showed that the interlayer hydrogen bonds in COFs provide enhanced interlayer interaction, leading to layer-independent mechanical properties, in sharp contract with 2D COFs without interlayer hydrogen bonds, in which the mechanical properties significantly

decreased as layer number increased. DFT calculation showed that the layer-independent mechanical properties are attributed to higher energy barriers against interlayer sliding due to the presence of interlayer hydrogen bonds. These results indicate that COFs can be a very promising platform for the preparation high-performance 2D polymeric materials by precise molecular design.

MoS2—Carbon Materials Composite with Dual Phase of MoS2 and Their Application for Energy Storage System Kyu Yeon Jang[1,2], Yeong A. Lee[1,3] and Hana Yoon[1]; [1]Korea Institute of Energy Research (KIER), Korea (the Republic of); [2]University of Science and Technology (UST), Korea (the Republic of); [3]Chungnam National University, Korea (the Republic of)

Graphite and graphene are known to be very good anode materials for lithium ion batteries due to their excellent stability, but have a low theoretical capacity of 372 mAh/g.[1] Electric vehicles and various electronic devices require a battery with a higher capacity than the current capacity, and it is essential to develop an anode material with a higher capacity.[2] Therefore, anode materials using Si are in the spotlight, but Si has a higher capacity (~4200mAh/g) than conventional graphite materials, but there is a problem of volume expansion when the cycle is performed, so it has a bottleneck in terms of stability.[3] Transition metal dichalgogenides (TMD) materials are attracting a lot of attention because of their structural properties, excellent stability, low cost and high storage capacity.[4] The theoretical capacity of MoS_2, one of the TMD materials, is known to be 670 mAh/g, making it a promising material for a new LIB anode material.[5] In particular, it is very advantageous to make a single layer of MoS_2 because their layered structure is combined with a weak van der walls force.[6] It is typically known to have 1T and 2H structures. The 1T phase of MoS_2 has the properties of a conductor and therefore has excellent conductivity as a LIB anode material. 1T structures can be produced when a single layer is made through exfoliation. However, due to its metastable structure, it is easily converted to the 2H phase as the most stable phase.[7]
In this study, a composite of MoS_2 and graphene was prepared by a chemical exfoliation method, and through this, a stable and high-capacity anode material was realized using the high energy storage capacity of MoS_2 and the stability of graphene. In addition, a mixed phase of 1T and 2H structures was generated through the post-treatment process, and it was confirmed that the 1T phase was stably present. Through this, the diffusion of Li^+ was facilitated by securing wide interface spacing and high conductivity of the 1T structure, and as a result, superior conductivity and high capacity were stably maintained compared to the single-phase material of the 2H structure.

Direct Patterning of Multi-Functional Photo-Reduced Graphene Oxide Fabrics (rGOf) on the Liquid Surface HaoTian H. Shi[1,2,3], Sung Hwa Hong[2] and Hani E. Naguib[2,2]; [1]Western University, Canada; [2]University of Toronto, Canada; [3]University of Cambridge, United Kingdom

A multi-functional photo-reduced graphene oxide fabric (rGOf) has been successfully created through an accessible laser direct-write technique at the liquid-air interface. Without the need for any substrate, patternable and porous rGOf can be readily created at the liquid surface through the photoreduction of self-assembled surface graphene oxides (GO). Processing parameters, such as the laser power, printing speed, laser focus, and inclusion of post-processing steps, can lead to tailorable rGOf morphologies. rGOf layering can also lead to the creation of 3-dimensional rGO stacking, further enhancing its functional performance. The as-printed rGOf can be transfer-printed onto any desirable substrates and has demonstrated tremendous potential in energy storage, Joule heating, temperature sensing, humidity sensing, tactile sensing, and ammonia sensing applications.

Laser-Assisted Zone Crystallization in Superscalable, Contactless Wet Coating of Ultrathin Films for Flexible Piezoelectrics and Electronics Adam Kiersnowski, Paulina Budzicka, Maciej Frankowski, Michal Wyskiel and Krzysztof Janus; Wroclaw University of Science and Technology, Poland

Fabrication of elastic piezoelectric generators, polymer-based pressure or vibration sensors, as well as flexible thin-film-based electronic devices, represent examples of a growing number of material technologies that require large-scale thin functional films deposition. There are several technologically-proven deposition solutions available such as roll-to-roll (roto)gravure/doctor blade coating, spray coating, or inkjet printing. Application of a particular deposition method depends on surface properties and deposited material. Quite often, however, implementation of a particular thin film technology is limited by scalability of the deposition method. The scalability is important, since deposition method have a key influence on e.g. wetting dynamics, solidification, crystallization and other factors critically affecting e.g. crystal size and orientation. The other challenge today is coating films on wavy, dimpled or other non-flat surfaces. Contact methods, such as listed above, typically fail in film deposition on non-flat surfaces.
In our report, we demonstrate a contactless wet film deposition method that addresses the scalability issues and enables wet, ink-based fabrication of films on flat and curved surfaces. In our approach we used specifically tuned laser beam to induce thermal gradients of substrate surface free energy and ink viscosity. The gradients induce local, internal flow in the ink causing formation of an ink bulge close to the laser spot. The bulge can be moved on the surface by moving the laser-heated spot over the substrate. The moving ink bulge is followed by a local solvent evaporation that causes deposition of a film. The footprint profile of the liquid bulge can be controlled by the laser focus. Using the line-focused laser enables deposition of the solid film in the way analogical to the doctor blade, but without any physical contact of the coating tool with the solution – the laser beam acts as a coating blade. The length of the focal line defines the coated area. Because of the working principle, we call the method laser-assisted zone crystallization (LAZEC).
We tested the LAZEC in fabrication of polymer and molecular films with thickness ranging from 3 to 100 nm and specific electronic properties. X-ray diffraction revealed high degrees of structural order and spatial orientation of the films. The ordered nature of the sample stems from, inter alia, controlled thermal conditions of the solidification process. Structure control in the LAZEC permits e.g. fabrication of organic semiconductor films revealing highly anisotropic charge transport properties. In our study we have also tested fabrication of piezoelectric polymer films. Imparting piezoelectricity to a polymer requires uniaxially, homogeneously and permanently oriented dipole moments in specific crystal polymorphs. Since the LAZEC inherently enables control over crystallization thermal conditions, it also permits a wide range control over a polymorphism. A control over the orientation of dipole moments was achieved by using external electric field. Using poly(vinylidene fluoride) (PVDF) and its copolymers as examples we demonstrate deposition of 100-nm thin piezoelectric films revealing d_{33} piezoelectric moduli comparable to their conventionally fabricated free standing film counterparts. During the

fabrication of the piezoelectric films we used external electric films to pole the samples. Noteworthy, the poling in LAZEC deposition required electric field several orders of magnitude weaker than the field used in conventional techniques (e.g. corona poling) and films required no mechanical treatment after the deposition. Voltages lower than 1 kV were enough to render PVDF film piezoelectric. In addition to the above experiments the presentation is aimed at showcasing deposition of functional organic films on curved parts of optical lenses.

The work was supported by National Science Centre Poland (NCN) through the grant UMO-2017/25/B/ST5/02869

NM06.08.17
2D Amorphous Carbon Dielectric for Nanoelectronics Congjun Wang; National Energy Technology Laboratory, United States

Two-dimensional (2D) semiconductors and semimetals could enable performance and scaling of solid-state electronic devices beyond the limits of those built on their conventional bulk counterparts. However, their suitable accompanying 2D dielectric, ideally in the highly disordered amorphous form similar to SiO_2 for silicon, has not been identified, which prevents nanoelectronic devices based on low-dimensional nanomaterials from fulfilling their potential. The synthesis of 2D amorphous dielectrics and their integration into electronic devices are challenging due to the metastable nature of amorphous phases. Here we discuss the synthesis of a solution processible precursor to enable a scalable and solution-based strategy to prepare large-area and freestanding 2D amorphous carbon monolayers and multilayers as novel dielectrics. The synthesis and characterization of the carbon precursor and the 2D amorphous carbon film will be described. To demonstrate the effectiveness of the 2D amorphous carbon as dielectric materials, carbon nanoelectronic devices are fabricated and evaluated.

NM06.08.18
Remote Epitaxy of Electrodeposited Zn and Cu on Graphene Salem C. Wright, Sonakshi Saini, Tejas Raman, Mengkun Tian, Pralav P. Shetty and Matthew T. McDowell; Georgia Institute of Technology, United States

Control over the growth of metals on 2D materials is important for creating electrical contacts to 2D-material-based electronic devices, as well as for energy storage devices such as batteries in which 2D materials are used. Recently, it has been shown that graphene and other 2D materials allow for an underlying substrate to exert a structural influence on semiconductors grown onto the 2D material through “remote epitaxy.”[1] Remote epitaxy has been observed primarily for semiconductors grown by vacuum deposition methods, and it represents an appealing method for versatile control over the orientation of deposited materials. However, it is unclear if remote epitaxy plays a role in the deposition of metals through methods such as electrodeposition. Here, we show that remote epitaxy acts to determine the growth characteristics of Zn and Cu electrodeposited on graphene/Cu substrates. Through a combination of three-electrode electrochemical experiments and extensive electron backscattered diffraction (EBSD) analysis, we show that the crystallographic orientation of the Cu grain below graphene determines the orientation of the electrodeposited metal, with the close-packed planes of the varying materials exhibiting epitaxial relationships. Transmission electron microscopy (TEM) is used to confirm the orientation relationship between the Cu substrate and the deposit through the graphene layer, providing atomic-scale information regarding the interface revealing that misfit strain is accommodated through edge dislocations. The graphene not only acts as a window layer, but also protects the underlying metal from oxidation to enable structurally continuous growth of the electrodeposit. These findings are important since they show that remote epitaxy can be achieved without vacuum methods using aqueous electrodeposition. Our results suggest that graphene coatings could be an effective way to enable controlled electrodeposition of a variety of metals, including those relevant to high-energy batteries (lithium, sodium).

Biotene—A New 2D Natural Oxide from Biotite Preeti L. Mahapatra[1], Raphael Tromer[2], Prafull Pandey[3], Gelu Costin[4], Basudev lahiri[1], Kamanio Chattopadhyay[3], Pulickel Ajayan[4], Ajit K. Roy[5], Douglas S. Galvao[2], Partha Kumbhakar[1] and Chandra Sekhar Tiwary[1]; [1]IIT Kharagpur, India; [2]State University of Campinas, Brazil; [3]Indian Institute of Science, India; [4]Rice University, United States; [5]Air Force Research Laboratory, United States

In this work, we employed liquid-phase exfoliation from naturally abundant biotite to demonstrate the synthesis and characterization of ultrathin metal oxide termed biotene. To gather energy, the flexoelectric response of the atomically thin biotene during sequential bending has been used. The effective flexoelectric response was improved due to the presence of surface charges, and the voltage increased up to 8 V, with a high mechano-sensitivity of 0.79 VN^{-1} for force applied. The flexoelectric response was verified using density functional theory (DFT) simulations. In the atomically thin biotene, the magnetic field and thermal heating suggest increased sensitivity. The development of two-dimensional (2D) metal-oxide biotene for energy generation and harvesting indicates to a multitude of potential 2D-oxide materials for energy generation and harvesting.

NM06.08.22
Formation of Monolayer Metal Oxides via Room Temperature Conversion from Two-Dimensional Transitional Metal Dichalcogenides Xudong Zheng[1], Zhien Wang[1], Tianyi Zhang[1], Benjia Dou[1], Jiangtao Wang[1], Ji-Hoon Park[1], Saien Xie[2], Darrell Schlom[3] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]Princeton University, United States; [3]Cornell University, United States

Two-dimensional (2D) materials have attracted significant interest due to their ultra-thin thickness and quantum confinement effect. Despite the rich and diverse library of discovered 2D materials, the study of metal oxides as atomically thin films have been limited. Here, by using 2D transitional metal dichalcogenides (TMDs) as starting templates for conversion, we show that monolayer metal oxides can be directly formed at room temperature. In this work we characterized the structural, optical and electrical properties of as-synthesized monolayer metal oxides and compared with their original template material. This strategy should be easily extended to a variety of metal oxides, enabling the study of monolayer metal oxides for the furture.

NM06.08.23
Solution-Gated Ultrathin Channel Indium Tin Oxide-Based Field-Effect Transistor Fabricated by a One-Step Procedure and Effect of Surface Modification on SARS-CoV-2 Detection Ritsu Katayama and Toshiya Sakata; The University of Tokyo, Japan

Introduction
Recently, indium tin oxide (ITO) has been widely used as an electrode material for flat panel displays owing to its transparency and conductivity. In our laboratory, we have found that a solution-gated ultrathin channel ITO-based field-effect transistor (FET) can be fabricated for biosensing in a single step by sputtering ITO using a shadow mask with controlled thickness, thus providing an ″all-by-ITO″ technology [1].
Solution-gated FETs with silicon or other semiconductive materials as channels can specifically and selectively detect ions and biomolecules related to biological functions by chemically modifying the gate electrode surface, and these are known as biologically coupled FETs (Bio-FETs) [2]. Since Bio-FETs can directly detect the charges of ions and biomolecules, they do not require to label fluorescent dyes and to induce redox reactions based on

enzymes. Therefore, Bio-FETs are expected to be used as *in vitro* diagnostic devices for a label-free monitoring of health conditions in daily life.
In this study, we investigated the electrical properties of the solution-gated ultrathin channel ITO-based FET (ultrathin channel ITO-based FET), which was fabricated in a single step, with a thin ITO channel (<30–40 nm) and thick ITO source/drain electrodes (ca. 100 nm), and performed the chemical modification of the thin ITO channel for its application in biosensors.
2. Methods
First, the ultrathin channel ITO-based FET was fabricated on a glass substrate by sputtering using a shadow mask with controlled thickness. The ultrathin channel ITO-based FET were then modified with 4-Nitrobenzenediazonium tetrafluoroborate (NBD). NBD thin film was electrochemically deposited on the channel surface using a cyclic voltammetry (CV) method with 1 mM of NBD, 25 mM of tetrabutylammonium hexafluorophosphate, and 2mM of 2,2-diphenyl-1-picrylhydrazil. Furthermore, nitro groups in the NBD thin film were reduced to amino groups by the CV method. The channel surface was then immersed in a solvent containing 1 mM N-succinimidyl 3-maleimidobenzonate for 1 hour, washed with deionized water, and reacted with 5 M thiolated SARS-CoV-2 aptamer overnight to chemically modify the channel surface. A semiconductor parameter analyzer was used to measure the fundamental properties such as drain current (I_d) – gate voltage (V_g) transfer characteristics and to detect inactivated SARS-CoV-2 viruses in real time. An elemental analysis of the channel surface before and after the surface modifications was performed by Auger electron spectrometer (AES).
3. Results and Discussion
Even after the NBD modification onto the ITO channel by the CV method, not only was the pH responsivity of the ultrathin channel ITO-based FET maintained, showing the Nernstian response, but the fundamental characteristics such as subthreshold slope (SS) in the V_g-I_d transfer characteristic were also hardly deteriorated. Thus, we confirmed that the surface modification of the ITO channel by the CV method is useful for the immobilization of aptamer molecules to recognize targets such as viruses using the ultrathin channel ITO-based FET.
Furthermore, we demonstrated the detection of inactivated SARS-CoV-2 viruses with high sensitivity using the ultrathin channel ITO-based FET chemically modified with the SARS-CoV-2 aptamer. The elemental analysis of the ITO channel surface by AES before and after the surface modification showed the presence of N from the NBD, O and P from phosphate backbone of the aptamer molecule. It also indicated the validity of the surface modification for the SARS-CoV-2 measurements.

CVD-Synthesized 2D Graphdiyne-Based Nanofilms for Ultrathin Compliant on-Skin Sensors Yichen Cai and Vincent Tung; King Abdullah University of Science and Technology (KAUST), Saudi Arabia

Thin-film electronics pliably laminated onto epidermis for noninvasive, specific, and multifunctional sensing are ideal wearable systems for health-monitoring and information technologies.[1-3] However, it remains a critical challenge to fabricate ultrathin and compliant skin-like sensors with high imperceptibility and sensitivities.[4] Graphdiyne (GDY) and its derivatives are emerging two-dimensional (2D) materials comprised of sp- and sp^2-hybridized carbon atoms with excellent chemical, mechanical, thermal properties, and electrical conductivity, making them attractive candidates for ultrathin e-skin. Especially, compared with other common 2D materials, such as graphene, MoS_2, and MXene, hydrogen substituted graphdiyne (HsGDY) that we will show in this work, shows inherent softness to better match the skin interface. However, the implementation of HsGDY into e-skin, while promising and has long been touted by theorists, has yet to be experimentally demonstrated.
In this work, we present a multifunctional on-sin sensing system with high imperceptibility that couples a rationally designed conductive 2D HsGDY nanofilms with transparent flexible polyethylene terephthalate (PET) substrates. The large-area uniform HsGDY ultrathin films (thickness ~18 nm) are accomplished by a facile chemical vapor deposition (CVD) approach using ultra-flat (Cu 111) as substrates and 1,3,5-triethynyl benzene (TEB) as the building blocks, currently unachievable by solution-phase synthetic chemistry. Importantly, it demonstrates uniformly distributed in-plane pores and inherent softness for on-skin sensing can better match the curved skin interface with improved mechanical compliance when compared with other rigid 2D materials. Then, dominated by the subtle deformation-induced changes in the inter-domain tunneling conductance, the engineered HsGDY based on-skin sensors can show continuous, accurate, and real-time non-invasive spatial mapping of dynamic/static strains in both tensile/compressive directions, monitor various body motions with high sensitivity (GF~22.6, under 2% strain), fast response (~60 ms), and long-term durability (~5000 cycles). Moreover, such devices can dynamically distinguish between the temperature difference (extremely tiny deformation) and frequency of air inhaled and exhaled through the nostril, revealing quantitative assessment on the movement/health of the human body. The proof-of-concept strategy provides a new general route for the design of next-generation wearable organic bioelectronics with multiple electronic functionalities.

The Metastable Pressure-Induced Transformation of Raman Scattering Spectrum of Bulk HfS_2 Igor Antoniazzi[1], Magda Grzeszczyk[2], Jakub Gawraczynski[1], Tomasz Wozniak[3], Jordi Ibanez[4], Zahir Muhammad[5], Weisheng Zhao[5], Maciej R. Molas[1] and Adam Babinski[1]; [1]University of Warsaw, Poland; [2]National University of Singapore, Singapore; [3]Wroclaw University of Science and Technology, Poland; [4]Geosciences Barcelona (GEO3BCN), CSIC, Spain; [5]Hefei Innovation Research Institute, China

The effect of hydrostatic pressure on the lattice dynamics of bulk hafnium disulphide (HfS_2) grown by chemical vapour transport method is investigated.
The pattern of powder X-Ray diffraction of the investigated material was found to be in perfect agreement with that of the octahedral 1T phase of HfS_2.
The Raman scattering has been studied at room temperature in diamond anvil cells in hydrostatic pressure up to 13.7 GaP.
There are four Raman modes observed at ambient pressure, which is consistent with previous studies.
There is an agreement in literature on the attribution of peaks at 266 cm^{-1} and 344 cm^{-1} to in-plane E_g and out-of-plane A_{1g} Raman-active modes, respectively. The peak at 325 cm^{-1} is attributed to the infrared-active E_u (LO) or A_{2u}(LO) alike mode.
Not clear is also the assignment of the weak feature at 141 cm^{-1}.Its attribution to a second-order difference processes was suggested, as such peaks can be observed in Raman scattering spectra of some transition metal dichalchogenides (TMDs) however the E_u (TO) was also suggested as the signature of the mode.
The Raman scattering modes blueshift with increasing hydrostatic pressure with the pressure rates from 1.6 cm^{-1}/GPa to 4.4 cm^{-1}/GPa, which is similar to the values reported before.
The lineshape of the Raman scattering spectrum does not significantly change with increasing hydrostatic pressure up to 5.7 GPa, however a substantial enhancement of the A_{1g} peak intensity can be noticed under the highest pressure.
A change in the Raman scattering spectrum is observed in hydrostatic pressure between 6.2 GPa and 7.2 GPa.

Seven vibrational modes can be observed in the spectrum above the transformation, as compared to four modes before the transformation.
The frequencies of the Raman scattering modes observed change linearly with pressure coefficients up to 2.6 cm^{-1}/GPa.
A negative pressure coefficinet (-0.13 cm^{-1}/GPa) of the Raman peak observed at the lowest enegy (approx 95 cm^{-1}) can also be noticed.
The overall lineshape of spectrum above the transformation does not change under pressure up to 13.7 GPa during compression.
Surprisingly, the seven Raman modes can be observed under hydrostatic pressure down to 1.5 GPa during decompression.
The apparent hysteresis of the Raman spectrum must reflect a metastable change in the sample structure.
We analyse the effect in the context of iodine (I_2) molecules, which are found to be present in van der Waals gaps between the HfS_2 layersin the investigated structure. Possible scenarios leading to the observed metastabilty are proposed.

Activate N_2-Selective Pathways for Electrochemical Ammonia Oxidation—Dual Active Site Tandem Catalysis in 2D Layered Nanospace Asuka Morinaga[1,2], Keisuke Shirai[1], Hiromori Tsutsumi[1], Masaharu Nakayama[1] and Yu Katayama[2]; [1]Yamaguchi University, Japan; [2]Osaka University, Japan

Ammonia oxidation reaction (AOR) plays a vital role in various applications including hydrogen production, direct ammonia fuel cell, and removal of ammonia-containing wastewater. During ideal AOR in an aqueous electrolyte, NH_3 undergoes dehydrogenation to form NH_x (x = 1 or 2), followed by the catalytical dimerization and electrochemical dehydrogenation to produce N_2.[1] However, most of the reported AOR catalysts, such as Pt[2] and NiCu alloys[3], suffer from its low N_2 selectivity (undesired nitrogen oxides (NO_x) formation) and/or low long-term stability (catalyst poisoning from N_{ad} species).
In this study, we introduce 2D layered MnO_2 composites co-intercalated with a dual active site, that is, hydrated Ni^{II} and Cu^{II} ions, for N_2-selective and stable AOR catalyst. Co-intercalated hydrated Ni^{II} and Cu^{II} ions are expected to accelerate the key (electro)chemical process, dehydrogenation and dimerization process, respectively, to achieve high N_2 selectivity.
Various spectroscopic methods such as X-ray diffraction, X-ray photoelectron spectroscopy, and high-energy X-ray total scattering were performed to clarify the electron and structural states of Ni^{II} and Cu^{II} within the layers. The result confirms that co-intercalated Ni^{II} and Cu^{II} coexist closely with a single ion state with negligible interaction, which is ideal for dual active site catalysis. Linear sweep voltammogram and gas chromatography analysis confirm the significant improvement in N_2-selectivity for Ni^{II}-Cu^{II} co-intercalated catalyst compared with single active site (Ni^{II} and Cu^{II}) counterparts. Furthermore, the role of Ni^{II} and Cu^{II} active sites for N_2-selective AOR was revealed by *operando* surface-enhanced infrared absorption spectroscopy. The result confirms that NH_3 was dehydrogenated in the vicinity of Ni^{II} site, and subsequent oxidation of Ni^{II} triggers the hand-over process of NH_x to Cu^{II} site, followed by the dimerization/dehydrogenation process in the vicinity of Cu^{II} to selectively produce N_2. This work revealed that the unique catalytic activity can be evoked by introducing multiple isolated metal complexes into 2D nano-spaces, providing a novel strategy for designing electrocatalysts with ideal efficiency and selectivity.

Optimization of 2D Transition Metal Dichalcogenides Using Electronic Structure and Thermoelectric Coefficient Calculations Isaiah Chen and Paulette Clancy; Johns Hopkins University, United States

Transition metal dichalcogenides (TMDs) and doped layered compounds are emerging classes of two-dimensional (2D) materials with technological potential for their use in photovoltaic devices. These materials exhibit useful electronic, optical, and thermal properties with tunable direct bandgaps. However, there is a need to develop novel nanostructure design strategies to improve the thermoelectric performance and *p*-type characteristics of these materials. Computational materials design can assist in these efforts and accelerate materials development. To address this need, we have performed plane-wave density functional theory (DFT) calculations for a series of transition metal dichalcogenide thin films ($MoTe_2$, WTe_2) and bismuth-antimony alloys (BiSb, BiTe). In particular, we are focusing on TMDs that contain telluride, given their particular importance for device studies. We used DFT to focus on the tolerance of the properties of these materials to variations in polymorph, composition, and defect type. We have validated the DFT predictions against experimental and published computational work. We will also present the predictions of DFT-generated thermoelectric coefficients using the open-source BoltzTraP2 codebase, based on the Boltzmann transport equation. These coefficients include electrical conductivity, thermal conductivity, Seebeck coefficient, power factor, and figure of merit. We will show how variation of the band gap and density of states (DOS) in all structures will cover both semiconductors and metals with thermoelectric properties in the expected ranges of previous observations. Our goal is to use these calculated thermoelectric properties to gauge which materials are preferable for use in device fabrication and assist with optimizing the performance of these 2D materials. We will use a Bayesian optimization machine learning algorithm (Physical Analytics Pipeline) to search the large combinatorial space comprised of different compositional alloys and determine which combinations yield particularly noteworthy *p*-type characteristics.

NM06.08.31
Mo/$MoSe_2$/Ag Memories with *In Situ* Formation of Mo/$MoSe_2$ Heterostructures via Selective Diffusion of Se in Mo So ByungJun; SungKyunKwan university, Korea (the Republic of)

Two-dimensional metal chalcogenides (TMDCs) are favorable candidates for high-density memristor crossbar arrays due to their ultrathin scaling limit, controllable interfacial properties, and potentiality in fabricating large-area electronics. However, the fabrication of large area crossbar arrays applied TMDCs has limitations by their high synthesize temperature and difficulty of mechanical transferring on the bottom electrode. The mechanical transfer can induce damages, such as cracks, wrinkles, and impurity residues between the electrode and active layer interface, which could degrade the device performance and uniformity over a large area. In this perspective, the present research involves the fabrication of crossbar array memristor using selectively diffusing selenium (Se) in pre-deposited molybdenum (Mo) to form Mo/$MoSe_2$ stack in-situ. This effortless way of forming the heterostructures of metal/TMDCs is not limited to Mo/$MoSe_2$ but can be generalized to a large spectrum of known TMDCs. This in-situ technique introduces an innovative way of forming a continuous mass of Mo/$MoSe_2$ with good quality interface leading to enhanced performance. Additionally, one-processing step reduction in a large number of sub-processes is introduced in this technique for the first time resulting in a fast and economical way of fabrication of two-terminal resistive memories. The present memories have been operated with small switching voltage (~ 1.1 V), high endurance (> 250 cycles), excellent retention (> 15000 s), minimum cycle-to-cycle and device-to-device variation. This implies that the present technique suggests the way toward non-destructive and easy fabrication of high-performance memristors.

NM06.08.32
Multi-Biomarker Thread-Based Biosensors for Monitoring Acute Compartment Syndrome Atul Sharma[1], Mossab K. Alsaedi[1], Junfei Xia[1], Giorgio Giatsidis[2] and Sameer R. Sonkusale[1]; [1]Tufts University, United States; [2]University of Massachusetts Chan Medical School, United States

Acute compartment syndrome (ACS) is a serious condition arising from pressure buildup due to swelling or internal bleeding of tissue, mostly as a result of

trauma [1]. ACS is prevalent in combat settings in military personnel as it could result from polytraumatic, blunt, or crushing accidents from explosions and the application of tourniquets [2]. Extreme trauma frequently results in ischemia, which can have long-term consequences like limb loss and death. Our overarching hypothesis is that early diagnosis of ACS may be possible through continuous and real-time assessment of physiological indicators, such as intramuscular oxygen, lactate, pH, and glucose [1,3]. Towards that goal, we propose the design of label-free thread-based electrochemical sensors for in-vivo measurement of these biomarkers inside the muscle tissue to capture physiological indicators for compartment syndrome detection. Compared to other flexible platforms, threads provide the most flexibility for tissue-embedded sensors, microfluidics, and bioelectronics [4-5]. For the enzymatic sensor (glucose and lactate), an amperometric method uses a two-electrode electrochemical set-up. The working electrode (WE) is composed of a composite Glutaraldehyde- Bovine Serum Albumin- Glucose Oxidase- Prussian Blue- carbon coated-suture (GA/BSA/GOx/PB/C) for glucose and GA/BSA/LOx/PB/C-coated suture for lactate sensing. An Ag/AgCl-coated suture as reference (RE) and counter electrodes (CE) is used. To measure pH, a composite silver/silver chloride (Ag/AgCl)-coated suture was utilized as the RE to determine the open-circuit potential of a polyaniline-carbon (PANI-C) coated suture. Fabrication on sensors starts with the cleaning of the suture (5/0 Polysorb^{TM} by COVIDIEN) in isopropyl alcohol (sonication 15 min), followed by plasma treatment (5 min) and carbon-ink deposition [4-5]. To create enzymatic (glucose and lactate) sensors, PB was electrochemically deposited on a carbon-coated suture in an electrolyte solution (0.10 M HCl and 0.10 M KCl) containing potassium ferricyanide and iron chloride for 90 seconds, followed by a cyclic voltammetric scan from -0.20 to 1.0 V at 0.10 V/sec vs Ag/AgCl electrode and washed with distilled water. To restrict the sensing region, a polyurethane (PU 5% w/v) layer is coated on the sensor leaving both ends of the sensor exposed. One end (carbon coated) is for the potentiostat connections and the other end is for further deposition of the enzyme matrix, which makes up the sensing region. PU/PB/C-suture was incubated in an enzyme solution containing BSA, and GA in 0.10 M phosphate-buffered saline (PBS, pH 7.4) then washed with PBS and dried. To fabricate the pH sensor, pH-sensitive dye polyaniline was electrochemically deposited at 0.80 V for 900 sec and washed with distilled water. The RE was fabricated by dip-coating a cleaned suture in conductive Ag/AgCl paste [5] and then baking at 60°C for 30 min. An amperometric response was noted on an Ag suture (as a cathode) for the oxygen sensor. To protect the enzyme layer from biofouling, an alginate-calcium hydrogel was drop cast on the sensing region, dried, then washed with PBS. For a demonstration of sensor performance, the electrochemical measurements were performed with cannulated sensors submerged in a phantom skin-gel environment (2.0 % agarose solution in 0.10 M PBS, pH 7.4). Under optimal experimental conditions, the devised pH sensor showed an excellent sensitivity of ~28 ± 3 mV/pH. Dissolved oxygen exhibited a linear relationship with change in current and a sensitivity of 0.66 μA/mgL^{-1}, whereas the glucose and lactate sensor sensitivity was considered adequate at 18.53 μA/mM and 30 μA/mM, respectively. Our results demonstrate that the thread-based flexible platform is capable of detecting physiological biomarkers in skin-mimicking models and could be particularly useful for continuous and real-time monitoring of several key metabolites such as glucose, lactate, pH, and oxygen in tissue.

NM06.08.34
Flexible Tellurium Nanowires and Tellurium Dual-Channel Field-Effect Phototransistor Array with High Linear Photoresponsivity Rho H. Yeol, Muhammad Naqi, Yongin Cho, Hae Won Cho, Pavan Pujar, Uisik Jung and Sunkook Kim; SKKU, Korea (the Republic of)

By introducing the method of uniformly synthesizing the tellurium nanowire (TeNWs) and the Tellurium hybrid structure to a flexible field effect transistor array, excellent electrical, mechanical and optical properties were achieved. All fabrication processes are carried out in a simple manner with low thermal budget (< 100 °C). Scanning electron microscopy (SEM) and Raman spectroscopy are performed to compare the uniform hybrid channel structure with bare Te related film. The hybrid structure of TeNWs/Te-film FET showed high mobility of 5.35 cm^2/Vs as with ~ 10^4 *on/off* ratio, and all array devices have uniform electrical properties. Stability tests such as positive bias stress, negative bias stress, long term stability response, mechanical bending stress test can confirm the good reliability of the suggested device performance. High-performance phototransistor array is proved by verifying threshold voltage shift, response, sensitivity, photocurrent, and detectivity as the optical properties. It is expected that the stable operation and excellent optical properties of the flexible hybrid channel FET array can be attributed to enabling a wide range of applications in the next generation.

NM06.08.35
Digital Light Processing (DLP) Printing of Polymer-Based Graphene Oxide Nanocomposite as an Efficient Antibacterial Coating for Surgical Implants Justin P. Edaugal[1,1,2], Emily Buckner[1,1,2], Mary K. Mitchell[3], Erick L. Ribeiro[1,1,2], Melissa Ellermann[3] and Rigoberto C. Advincula[1,1,2]; [1]The University of Tennessee, Knoxville, United States; [2]Oak Ridge National Laboratory, United States; [3]University of South Carolina, United States

Bacterial infections are one of the major causes of surgical implant inefficiency and failure. In fact, such infections can lead to post-surgical complications, requiring antibiotic treatment and, in some cases, full surgical removal, increasing cost, recovery time, and risks to the patient's health. Up to date, various antibacterial wet coatings have been developed as an attempt to suppress bacterial growth, however, the implementation of these coatings on implant surfaces has been limited, owing to their poor mechanical integrity, along with their intrinsic low chemical and thermal stability. The precise patterning ability of three-dimensional (3D) printing technologies can be employed to accurately coat implants, avoid potential post-surgical complications arising from infections, and maintain high thermomechanical stability. Graphene Oxide (GO) has been reported as a biocompatible material with high toxicity to microorganisms and low mammalian cytotoxicity. Herein, we present a Nanocomposite (NC) produced by the addition of Poly(N-vinylcarbazole) – GO dispersion (PVK-GO), as a nanofiller to a commercial photopolymer acrylate resin (Elegoo translucent resin). More specifically, a series of NCs with different PVK-GO compositions were obtained by varying the ratios of GO from 0 to 0.5 wt% in the PVK-GO dispersion. The resulting NCs were printed as coatings *via* Digital Light Processing (DLP) technique and subsequently subjected to two distinct thermal annealing processes. Several characterizations of the final NC-based coatings, including Raman Spectroscopy, Fourier Transform Infrared Spectroscopy (FTIR), Tensile Strength (UTM), Thermogravimetric Analysis (TGA), X-Ray Diffraction (XRD), and Scanning Electron Microscopy (SEM) revealed the effects arising from the addition of different compositions of PVK-GO nanofillers to the resin. Moreover, results from various bioassays, including disk diffusion test, biofilm growth assay, and fluorescent imaging using gram-positive and gram-negative bacteria, confirmed the efficient antibacterial activity of the printed NC-based coatings. To that end, the present study demonstrates the fabrication and optimization of a PVK-GO-based NC with enhanced thermomechanical properties as well as elevated antibacterial activity and its potential utilization as a 3D-printable coating for biomedical applications.

Identification of Proteinogenic Amino Acids Using MoS_2 Solid-State Nanopores Assisted by Machine Learning Andreina Urquiola Hernandez, Adrien Nicolai, Guyeux Christophe and Senet Patrick; Université de Bourgogne Franche Comté, France

Solid-State Nanopores (SSN) made of 2-D materials such as molybdenum disulfide (MoS_2) have emerged as one of the most versatile sensors for single-biomolecule detection, which is essential for early disease diagnosis (biomarker detection). One of the most promising applications of SSN is DNA and protein sequencing, at a low cost and faster than the current standard methods. The detection principle relies on measuring the relatively small variations of ionic current as charged biomolecules immersed in an electrolyte traverse the nanopore, in response to an external voltage applied across the membrane. The passage of a biomolecule through the pore yields information about its structure and chemical properties, as demonstrated experimentally particularly for DNA molecules. Indeed, protein sequencing using SSN remains highly challenging since the protein ensemble is far more complex than the DNA ensemble [1].
In this work, we performed extensive unbiased all-atom classical Molecular Dynamics simulations to produce data of translocation of biological peptides through single-layer MoS_2 nanopores (D = 1.5 nm). Peptide made of the 20 different amino acids from the different families (non polar/hydrophobic, polar/neutral, basic and acidic) were chemically linked to a short polycationic charge carrier [2]. First, ionic current time series were computed from MD and peptide-induced blockade events were extracted and characterized using structural break detection. Second, clustering (unsupervised learning) of ionic current drops and duration using Gaussian Mixture Model was applied. Using this technique, we demonstrate that each amino acid presents a large diversity of ionic current characteristics, however, charged amino acids were distinguished from the others. Finally, classification (supervised learning) was also implemented to identify residue motifs inside the pore, using XGBoost classifiers. We show that the addition of ionic current drops and duration to time series as input variables of the model greatly improve its performance, leading to the identification of the twentyproteinogenic amino acid. These promising findings may offer a route toward protein sequencing using MoS_2 solid-state nanopores.

Cation Driven Assembly of Two-Dimensional Reduced Graphene Oxide/Bilayered Vanadium Oxide Heterostructures for Li-Ion Batteries Ryan Andris, Timofey Averianov and Ekaterina Pomerantseva; Drexel University, United States

Inorganic two-dimensional (2D) materials can be advantageous for applications that require efficient ionic conductivity and high redox activity. They offer open diffusion pathways for ion intercalation as well as strategies to potentially mitigate structural damage that can occur from the repeated expansion and contraction processes due to the reversible Li^+ ion intercalation during extended Li^+ ion battery cycling. 2D bilayered vanadium oxide (BVO or δ-V_2O_5●nH_2O) is an especially promising material for electrochemical applications because it has an open structure with large interlayer spacing and vanadium's high oxidation state. These properties allow BVO to host a large number of charge carrying ions and undergo several reduction steps. However, the electrochemical performance of this bilayered phase is limited by its poor electronic conductivity and structural instability. In this work, we improved the cyclability and rate performance of BVO through an exfoliation process, the subsequent cation-driven assembly of exfoliated BVO and single-layer graphene oxide (GO) nanoflakes, and heat treatment processing to simultaneously reduce GO and partially dehydrate BVO.

Exfoliation followed by cation-driven assembly is a versatile technique that can be utilized for a variety of metal oxides and different conductive carbon precursors. The cations are used to maximize and stabilize the heterointerface formation between the BVO and GO by pulling these negatively charged nanoflakes together. As a proof of principle, exfoliated BVO and GO nanoflakes were assembled using a concentrated lithium chloride solution. The resulting flocculates were filtered, dried, and heat treated under vacuum at 210 °C to form a 2D heterostructure comprised of δ-V_2O_5●nH_2O and partially reduced graphene oxide as evidenced by cross-sectional scanning electron microscopy images, energy dispersive X-ray spectroscopy, X-ray photoelectron spectroscopy, Raman spectroscopy, and thermogravimetric analysis. The heat treatment is used to reduce the interlayer water content of BVO for better long-term stability and obtain reduced GO (rGO) to increase its electronic conductivity. The characterization techniques were also used to determine that the graphitic content of the heterostructure could be controlled by changing the initial GO concentration prior to assembly. Moreover, we found that the amount of GO present affected the BVO phase stability and electrochemical behavior.

The electrochemical charge storage properties of heterostructures with 0, 10, 20, and 35 wt% rGO were evaluated in Li^+ ions cells with non-aqueous electrolyte and exhibited initial capacities of 245, 260, 180, and 150 mAh g^{-1}, respectively. However, BVO/rGO-0wt% retained only 10% of its initial capacity after 20 cycles at a 20 mA g^{-1} specific current. In contrast, the BVO/rGO-10wt%, BVO/rGO-20wt%, and BVO/rGO-35wt% materials retained 80%, 97%, and 100% of their initial capacities after 20 cycles at the same specific current. Further, the BVO/rGO-35% heterostructure retained 75% of its initial capacity (110 mAh g^{-1}) after increasing the specific current from 20 mA g^{-1} to 200 mA g^{-1}, while the BVO/rGO-10 wt% and BVO/rGO-20 wt% samples retained only 18% (50 mAh g^{-1}) and 67% (120 mAh g^{-1}) of their initial capacities under the same cycling conditions. The improved capacity retention and rate performance of the materials with higher GO content indicates that the presence of GO inhibits the structural degradation of BVO during cycling as well as improves the overall electronic conductivity of the heterostructure. In summary, the cation driven assembly approach uses Li^+ ions to induce and stabilize the formation of stacked 2D layers of GO and exfoliated BVO for applications in energy storage devices, and it can be applied in a variety of systems utilizing 2D materials with complementary properties.

8:30 AM NM06.09.03
Tuning the Properties of 2D Materials Using Organic Molecules Natalie Williams[1,2], Serrae Reed[1], Haotian Huang[1], Nilay Hazari[1], Judy Cha[1,2] and James L. Hart[2]; [1]Yale University, United States; [2]Cornell University, United States

Surface functionalization using organic molecules is an effective method to dope two-dimensional (2D) materials due to their high surface areas. Furthermore, by tuning the properties of the molecule on ordered 2D crystals, surface functionalization can be used to precisely control the electronic properties of 2D materials.[1] In previous studies, we investigated the doping power of novel organic electron donors (OEDs) based on 4,4'-bipyridine on monolayer MoS_2 using field effect transistor (FET) measurements before and after surface functionalization, as well as various spectroscopic characterizations. For example, using the reductant DMAP-OED, we demonstrated that both the surface coverage and reduction potential of the molecule are critically important for controlling the carrier concentration in MoS_2. We experimentally estimated the doping power of DMAP-OED to be between 0.6 – 1.3 electrons per molecule, with good agreement with DFT results.[1] Our more recent study showed that a more compact reductant, Me-OED, is an even greater dopant, achieving record levels of electron donation on MoS_2 FETs.[2]

Here, I discuss the organic reductant tetrakis(dimethylamino)ethyelene (TDAE), a molecular dopant which has never been studied before for 2D functionalization but could greatly impact the electrical properties of 2D FET devices based on criteria developed in our previous research. The relative position of the Fermi level of many 2D transition medal dichalcogenides (TMDCs), like MoS_2, falls below the reduction potential of TDAE, resulting in

facile n-type doping to the 2D surface. More importantly, the small size and planar structure of TDAE molecules should allow for greater molecular surface coverage, and thus more electronic charge doping to surfaces. Our research is aided by spectroscopic and atomic force microscopic characterization. This project is conducted on MoS_2, but it can be expanded to other 2D TMCDs and materials. Our results highlight how the physical characteristics of a molecule are at least as important as their chemical affinity for charge donation, allowing us to realize unprecedented levels of doping to MoS_2.

Polymer Grafted Layered Transition Metal Dichalcogenide Hybrids and NanoComposites Ali Jawaid[1], Nikolaos Chalmpes[2], Emmanuel Giannelis[2] and Richard A. Vaia[1]; [1]Air Force Research Laboratory, United States; [2]Cornell University, United States

Molecular-level hybridization between polymers and layered transition metal dichalcogenides (LTMDs) result in emergent opto-electronic properties that are spurring development of low-cost, large-area technologies, from multi-functional sensors to optical coatings. The semi-conductive and semi-metallic character of few-to-monolayer LTMDs are tuned with surface-bound species, such as polymers, via orbital coupling and charge injection. However, balancing the requisite stoichiometric surface control with dispersability, processibility, and subsequent mechanical robustness is challenging. To meet these challenges, we utilize the redox exfoliation method to generate anhydrous LTMD dispersions, which enables direct functionalization of the LTMD surface, such as via Grignard coupling, derivitization with polymers, such as via RAFT / ATRP growth techniques, and nanometer control of morphology, such as via stoichiometric blending with polymers. The expanded formulation space supports design of opto-electronic performance via specific polymer-LTMD interactions, as well as bottom-up assembly of single-component mesostructured nanocomposites with improved mechanical toughness, for integration into a wide range of coatings, films, and monoliths.

Stabilization and Manipulation of Silicene via Interface Engineering Daya Sagar Dhungana[1], Chiara Massetti[1,2], Eleonora Bonaventura[1,2], Carlo Grazianetti[1], Christian Martella[1] and Alessandro Molle[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Milano-Bicocca, Italy

Silicene is the thinnest form of silicon, a two-dimensional (2D) layer with a quasi-planar (buckled) structure [1]. It is produced by epitaxy on substrates like (111)-terminated Ag in ultra-high vacuum conditions. Silicene has a chemically fragile nature for it is unstable on both of its faces. It undergoes quick environmental degradation on its top face if not encapsulated, and on its bottom face when stripped off from its epitaxial substrate. To address these issues, here we will report on stabilization schemes based on dry or wet chemical delamination starting from a both-side encapsulated silicene and ending up with a stable and durable silicene foil on a tested timescale of weeks [2]. We show that both-side encapsulation is made possible by Al_2O_3 capping of the top face [3] and interface engineering through the realization of a silicene-on-stanene heterostructure (with stanene being the 2D counterpart of tin) [4]. The silicene-stanene heterostructure proves to be a suitable layout where to capture unprecedented silicene-related features like local heat dispersion in silicene and its contribution to the optical reflectance of silver [5]. Finally, we show how the silicene foils can manipulated (e.g. streteched, bent, and transferred to secondary substrates) as desired therein displaying high mechanical flexibility and structural stability thus paving the way to their facile integration into diverse nanotechnology device platforms.

3D Printing of Hydrothermal Vanadium Disulfide Electrodes for Zinc-Ion Batteries Stefano Tagliaferri, Maria S. Sokolikova, Nagaraju Goli, Mauro Och, Haoyu Bai and Cecilia Mattevi; Imperial College London, United Kingdom

Aqueous Zinc Ion Batteries are receiving growing attention as beyond-lithium power sources for wearable electronics and sensors, owing to their high theoretical capacity, environmental friendliness and low cost. Vanadium disulfide is a layered Transition Metal Dichalcogenide (TMD) with great potential for zinc ion battery cathodes, owing to its large interlayer spacing, fast ionic diffusion and high conductivity. Despite these beneficial features, vanadium disulfide has mainly been investigated in coin-cell batteries, which are difficult to directly integrate in wearable electronics.

Here, we demonstrated the combination of an easily-scalable hydrothermal synthesis with a room-temperature 3D Printing process to fabricate vanadium disulfide electrodes with customized geometry. The hydrothermal vanadium disulfide was mixed with a polymeric binder and conductive additives to obtain a stable ink with optimal printability. The architecture of the VS_2 electrodes was rationally tailored *via* the printing process to facilitate the electrolyte penetration and promote fast charge transfer. Finally, the printed vanadium disulfide electrodes were coupled with zinc anodes to assemble aqueous zinc-ion batteries.

Mechanisms of Selective Ion Transport in Layered MoS_2 and Graphene Oxide Membranes Eli V. Hoenig, Mingzhan Wang and Chong Liu; University of Chicago, United States

Two dimensional materials such as MoS_2 and graphene are excellent scaffolds for nanometer and even angstrom scale fluidic channels. Unique chemical and physical phenomena arise in channels for which the size of the confined species has the same order as the confining dimensions. Here, we exploit the interlayer gallery of functionalized MoS_2 and graphene oxide to study the selective transport of ions through < 1 nm quasi two dimensional channels. In graphene oxide, we find that the permeance of Cu^{2+} is high relative to that of other divalent ions (Mg^{2+}/Ca^{2+}/Co^{2+}). From the X-ray absorption spectra and pair distribution functions of saturated graphene oxide membranes, we determine that the enhanced flux of Cu^{2+} is a result of its strong coordination with carboxylic acid functional groups[1]. In MoS_2, we find, surprisingly, that the relative adsorption of Pb^{2+} and Cu^{2+} reverses when MoS_2 is functionalized with

carboxylic acid groups (the membrane uptake of Pb^{2+} is higher when functionalized)[2]. Infrared spectroscopy reveals that this reversal is a result of the unique bidentate binding of Pb^{2+} in the functionalized MoS_2 channels. Here, we also discuss our recent investigation of the ion transport through pores in few-layer MoS_2.

Unusual Effects of Thermal Conduction in Twisted 2D Materials Sorren Warkander[1,2], Yin Liu[1], Lei Jin[1], Jie Yao[1] and Junqiao Wu[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

2D materials offer opportunities to tune the lattice and phonon structures, some of which are not possible in bulk materials. The moire superlattices formed in twisted bilayers are found to host rich and new electronic effects; they are expected to also have strong influence on phonon dispersion and thermal conduction that is twist angle dependent. In this work, we measure and strive to understand thermal conduction physics in these twisted stacked 2D materials, including in-plane thermal conduction moire superlattices of transition metal dichalcogenides, and cross-plane thermal conduction in GeS nanowires with a single screw dislocation in the core.

Tunable Adsorption and Catalysis on Two Dimensional Ferroelectric Materials and Heterostructures Joshua Young and Mo Li; New Jersey Institute of Technology, United States

Two dimensional ferroelectric materials display a switchable spontaneous electric polarization in one or few monolayers. While they have been primarily proposed as components for ultrathin electronic devices, switching the polarization can change the surface properties, providing a route to overcoming the Sabatier principle on one material. We first show that the surface of the ferroelectric MXene Y_2CO_2 [1] with an O vacancy can preferentially adsorb CO_2 or CO depending on if the surface is poled up or poled down. We then extend that by investigating the reduction of CO_2 to CO, formic acid, and methane, and find that the stability of various intermediates as well as the final product can be also changed by switching the direction of the polarization. Second, we interface singe transition metal atom and dimer (Cu and Fe) doped graphene with ferroelectric In_2Se_3; by switching the In_2Se_3 layer, the adsorptive properties of the metal-doped graphene layer can also be altered, leading to selective adsorption and catalysis. This is a unique route to preferential adsorption and product selectivity in catalysis.

Transient Laser Photothermal Generation of 3D Graphene for Sensing and Energy Applications Pilgyu Kang[1,1], Byoung Gak Kim[2,3], Minsu Kim[2], Seung Min Lee[1,1] and Shirin Movaghgharnezhad[1]; [1]George Mason University, United States; [2]Korea Research Institute of Chemical Technology, Korea (the Republic of); [3]University of Science and Technology, Korea (the Republic of)

Nanomaterials have shown potential for high-performance functional materials especially in sensing and energy applications. Structuring of nanomaterials, including atomically-thin two-dimensional (2D) materials (e.g. graphene) and combining 2D materials with conventional materials such as metals and polymers can enable new functionalities and high performance by engineering exceptional and outstanding mechanical, electrical, and optical properties. We present a facile and rapid laser photothermochemical processing method to produce 3D porous graphene as well as a nanoassembly of 3D porous graphene and PdNPs from polymer films. Multi-dimensional hybrid nanomaterials combining 3D graphene and 1D metallic nanoparticles are produced in large scale with low production cost by transient laser photothermal processing. The films are photothermally processed using a laser to generate a nanohybrid via photo-induced thermal and chemical processes. The nanohybrid exhibits four-times-enhanced electrical conductivity compared to plain porous graphene, high crystallinity, and coherent covalent metal bonds with a homogeneous size and distribution of PdNPs in the hierarchical micro/meso/macro porous graphene structures, allowing high-performance hydrogen sensing (1 ppm) with outstanding mechanical reliability, flexibility, and durability upon bending and twisting. The nanoassembly is integrated with a wireless sensing platform and hydrogen leakage (1 ppm) is detected by a smartphone. This laser-based nanomanufacturing of the nanoassembly can potentially be applied to wearable detector production platforms in the military and industry. A facile, fast, and scalable laser-induced photothermal method was also used to achieve flexible monolithic bilayer sheets (MBS) of hierarchically porous graphitic carbon (HPGC) and polymeric foam for use in salt-resistant and flexible solar steam generators. The MBS-based self-floating solar steam generator shows outstanding solar desalination performance with a solar thermal efficiency of 83.2% under 1-sun illumination and a high salt-rejection ratio (99.9%). The all-in-one multi-functionalities of the MBS, including broad-spectrum solar light absorption, heat localization, and capillary action enabled efficient solar thermal energy transformation. Our laser-based photothermal method holds promise to achieve high-performance solar thermal systems with substantial cost reduction by scalable production of multiscale hierarchically structured materials from micro-structured polymers.

SESSION NM06.10: Theory and Simulation-Driven Studies in 2D Materials

Designing New 2D Nanomaterials with an Environmentally Friendly Synthesis Route—A DFT + Solvent-Ion-Model-Driven Study Mona Layegh and Joseph W. Bennett; University of Maryland Baltimore County, United States

The growing demand for designing and synthesis of stable new classes of layered and non-layered 2D nanomaterials with novel properties to open up new avenues toward a wide range of applications is not deniable. This is mainly due to their unique electronic, optical, chemical, and magnetic properties associated with size, structure and shape which originates from the quantum confinement effects in these materials. Having said that, we are developing a model to chemically manipulate known 3D bulk materials and their surfaces to create new functional nanomaterials by the chemical manipulation with a high stability using Density Functional Method (DFT) plus Thermodynamic analysis. As one of the main points of this model, using water as the aqueous

media to create this new 2D materials yields an ecofriendly synthesis approach. The study starts with narrowing down the choice of known *ABX* compounds on the basis of their valence electrons and magnetic interactions and cell crystalline structure. Then, the classes of collected compounds will be filtered through the Pourbaix diagram characteristics of their *A* element so that they can be exfoliated in environmentally friendly aqueous media like water. The final obtained results of bulk compounds are ready to be the subject of DFT calculations in terms of structural, electronic and band gap properties. Following that, we apply the surface slab model and the subsequent surface transformation thermodynamics to design 2D materials. The last step will be bridging between the dissolution and hydration in an atomistic level and the changes in the electronic structure, stability, and surface reactivities of the obtained 2D nanomaterials.

1:45 PM NM06.10.02
The Role of Interlayer Charge Compression Effects in the van der Waals Heterointerfaces of $ReSe_2$/graphene and $ReSe_2$/h-BN Demystified Jae-Hyeok Ko[1], Woosun Jang[2] and Aloysius Soon[1]; [1]Yonsei University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Heterointerfaces of two-dimensional (2D) van der Waals (vdW) nanomaterials often exhibit unusual, "*non-textbook*" bonding mechanism that involves distinct (i.e., weak but non-negligible) orbital coupling within the compressed vdW gap [1]. This unique bonding mechanism is speculated to be quite different from the previously reported charge compression effect in ultrathin oxide films on metals [2]. To unravel this atypical bonding mechanism for 2D heterointerfaces, using vdW-corrected density-functional theory calculations, we examine the compressed charge redistribution in the heterostructures of $ReSe_2$/graphene and $ReSe_2$/h-BN. Here, we report the optimized atomic structures, electronic density-of-states, (integrated) planar-averaged electron density differences for these heterostructures, while focusing on the explicit contributions of the conductive graphene and insulating h-BN substrates to the interlayer confined charges. We demonstrate that this charge compression effect in the vdW gap is ubiquitous regardless of the nature of the substrates, and the magnitude of the confined charges can be modulated by atomic strain engineering. This study highlights the importance of understanding the interlayer charge compression effects by tailoring work function design for low-dimensional device applications [3].

2:00 PM NM06.10.03
Theory of the Near-Field Electrostatic Effects in 2D Materials and van der Waals Heterostructures Qunfei Zhou[1], Michele Kotiuga[2] and Pierre Darancet[3]; [1]Northwestern University, United States; [2]EPFL, Switzerland; [3]Argonne National Laboratory, United States

Two-dimensional (2D) materials have demonstrated a wealth of intrinsic as well as exotic electronic properties arising from near-field electrostatic interactions between layers and from surface organic absorbates, such as emergent ferroelectric order, excitonic energy landscape, and moiré superlattices. In this work, we derive an analytical theory for such near-field electrostatic effects, and validate it through first-principles calculations[1-2]. We demonstrate that superlattice potentials can be obtained in both 2D-2D and mixed-dimensional organic-2D heterostructures. We develop a classical electrostatic model of the superlattice potentials beyond the multipole expansion. Our theory quantitatively captures the out-of-plane decay and in-plane modulation, as well as elucidates the impacts of geometric effects, structural distortions, and material polarity on the electrostatic potentials.
Finally, we demonstrate the applicability of this theory on efficient prediction of the material-/angle-specific moiré potentials with periodicities challenging for DFT calculations, and band structure engineering for 2D materials by the near-field electrostatic effects.

Designing 2D Chalcogenide Piezoelectrics Jonathan Chin[1], Maria Hilse[2], Derrick Shao Heng Liu[2], Sebastian Marini[1], Roman Engel-Herbert[2] and Lauren M. Garten[1]; [1]Georgia Institute of Technology, United States; [2]The Pennsylvania State University, United States

Tin selenide (SnSe) is centrosymmetric in bulk but can become piezoelectric when reduced to an odd number of layers near the monolayer limit. However, synthesizing a monolayer of SnSe is challenging because the interlayer bonding is stronger than most 2D materials, making controllable exfoliation difficult. This work focuses on developing routes to stabilize monolayer films of SnSe by molecular beam epitaxy (MBE).

The processing window for SnSe on MgO substrates fell between 250 – 300 °C for flux ratios of 1:3 – 1:5 (Sn:Se). The Raman modes present in thick films are consistent with the *Pnma* phase of SnSe with the mode at 185 cm^{-1} appearing first. Once the phase formation conditions were identified then changes in the Raman spectroscopy with processing time were used to identify the onset of crystallization. These results were then used to estimate the timing necessary to grow a monolayer film. The thickness of the MBE films was directly measured by atomic force microscopy corroborating the layer timing determined from the Raman results. Then X-ray photoelectric spectroscopy was used to determine the surface stability of these 2D films against oxidation and degradation. The timing and processing conditions necessary to achieve 2D SnSe will be discussed in this talk. These results will provide insight into routes to control the layering and surface stability of SnSe that will be necessary for the development of 2D piezoelectric and electronic devices.

3:00 PM NM06.10.05
Machine Learning Aided Understanding of the Interaction in Borophene-Boride Hetero-Structures Luqing Wang[1,2], Qunfei Zhou[1,2], Qiucheng Li[1], Joshua T. Paul[2], Mark C. Hersam[1], Pierre Darancet[2,1] and Maria K. Chan[2,1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

Borophene is unusual among two-dimensional (2D) materials for the lack of a bulk layered counterpart, resulting in novel properties which are not inherited and cannot be predicted from bulk boron, as well as polymorphic phases which enrich its properties. Also, its metallicity is unusual within the 2D materials family and enriches the diversity of available materials properties. However, the application of borophene is limited by the lack of achievement of freestanding borophene. It's difficult to lift borophene from the substrates due to the strong interaction between them. Thus it is important to search for optimal substrates for borophene synthesis and separation. Recently, it was reported that boride is formed through the reconstruction of the top metal layer mixed with boron during borophene synthesis on Al(111) [1]. Metal borides have the potential to be superior substrates, compared to metals, for borophene synthesis and separation. The understanding of the interaction in borophene-boride hetero-structures would assist the search of optimal substrates as well as reveal the synthesis mechanism. What borides surfaces are optimal substrates for borophene synthesis? What intrinsic properties of borides dominantly affect the interaction in borophene-boride hetero-structures? How does the charge transfer between borophene and borides affect the interaction? Here we

explore these questions through machine learning and density functional theory calculations of their structures, binding energies, and charge transfer. This work allows us to explore alternative routes of borophene synthesis.

3:45 PM NM06.11.01
Impact of Metal Solvent Composition on the Properties of hBN Crystals Grown from Molten Metal Solutions Eli Janzen[1], Bernard Gil[2], Guillaume Cassabois[2], Adrien Rousseau[2] and James H. Edgar[1]; [1]Kansas State University, United States; [2]CNRS-Université de Montpellier, France

Hexagonal boron nitride (hBN) is a wide energy bandgap (>6.0 eV) semiconductor with a layered graphite-like structure and a high internal quantum yield for deep ultraviolet luminescence. These properties make it a good candidate deep UV light emitters and detectors, single photon emitters, and in nanophotonics by forming strong phonon polaritons. [1] While many researchers have focused on the heteroepitaxy deposition of hBN, there are many advantages to its bulk crystal growth via the solution growth method. Atmospheric pressure solution growth of hBN crystals using molten metals as solvents can produce material with crystal quality (Raman E_{2g} FWHM < 8 cm^{-1} [2]) that is as good or better than material produced by high temperature high pressure solution growth. Furthermore, it is a scalable process that is more capable at growing much larger crystals (up to 4 cm^2 [3]) than the high pressure process.

Here we report on the effects of the metal solvent composition on the crystal growth process and the quality of crystals produced. We analyzed how the process is affected using four different solvents: iron, iron-vanadium, nickel-chromium, and cobalt-chromium. These solvents represent a large range of nitrogen solubilities, with Fe and Fe-V having low solubility (0.04-0.1 mass% N) and Co-Cr and Ni-Cr having high solubility (0.15-0.3 mass% N). Crystal growth experiments were conducted with each of these solvents with varying compositions, the results of which were analyzed with optical microscopy, surface profilometry, and photoluminescence spectroscopy.

Based these results, the solvent appears to primarily affect three different characteristics: crystal thickness, the prevalence of certain defects, and the morphology of the bulk crystals. Crystals grown from Ni-Cr and Co-Cr solvents were hexagonal shaped with large steps and thicker (10-100 µm as-grown) than those grown from other solvents. In contrast, crystals grown from Fe and Fe-V were triangular-shaped with many wrinkles and thinner (5-30 µm as-grown). Comparisons between the photoluminescence spectra are also made, but the trends are less clear, though most spectra showed a strong peak at 5.75 eV, indicating high quality crystals can be grown with any of these solvents. To better understand these effects, the properties of the solvent such as nitrogen solubility are correlated with these observations and a model for their cause is proposed.

These results demonstrate that solvent choice is an important factor for optimizing atmospheric pressure solution growth of hBN and suggests a potential avenue to tailor crystals for specific applications. For example, in devices where a thicker crystal would improve efficiency, the crystals could be grown from a Ni-Cr solvent, while for devices that function better with thin crystals, they could be grown from an Fe solvent instead. Furthermore, these results provide insights into the mechanisms that guide hBN solution growth that can be used to optimize the process in general.

In-Plane TMDs Heterostructure Mesh Grown by Gap-Filling Chemical Vapor Deposition Hongwei Liu[1,2], Jing Kong[2] and Zhengtang Luo[1]; [1]Hong Kong University of Science and Technology, Hong Kong; [2]Massachusetts Institute of Technology, United States

Lateral superlattices have been a research focus due to the strain induced in their coherent structure, while the growth of large size heterostructure with high density of heterointerfaces remains challenging. In this work, we report a gap-filling approach to synthesize large scale lateral mesh heterostructures of WS_2 embedded in MoS_2 matrix. This synthesis method utilizes the uniformly distributed gaps in single crystalline MoS_2 made from by sulfur substitution-induced transformation of metastable-$MoTe_2$ as the growth pattern, for the second material growth. By finely controlling the growth kinetics, highly crystalline WS_2/MoS_2 lateral heterostructure mesh is successfully grown. Optical images and Raman mapping show a clear spatial distribution of WS_2 channels embedded in MoS_2.The coherent epitaxial nature is further confirmed by scanning transmission electron microscopy, showing insignificant dislocation at the interfaces. Density function theory simulation suggests that growth of WS_2 starts from the edges of cracked MoS_2.

4:15 PM NM06.11.03
Stable Black Phosphorus Nanoassembly Achieved Through Heterogeneous Hydrophobic Functionalization Yan-Lin Wang, Ying-Hao Pai, Karan Giri, I-Jung Wang, Yi-Chen Chen, Cheng-Ju Yang, Pei-Hsuan Cho, Yu-Chieh Shih, Chuan-Wen Wang, Ling-Chun Chao and Chun-Hua Chen; National Yang Ming Chiao Tung University, Taiwan

Black phosphorus (BP), a promising two-dimensional material, has sparked a research boom in various fields. BP possesses a tunable direct bandgap varying from 0.3 eV of bulk to 2.2 eV of the monolayer, which perfectly bridges the energy gap between graphene and transition metal dichalcogenides. Besides this, numerous extraordinary characteristics, including ultrahigh hole mobility of ~10^3 cm^2/V s, current on-off ratios of ~10^5, current density, and high in-plane anisotropy of the optical, electrical, and vibrational properties, further expand the scope and possibilities in a variety of applications. However, its fatal atmospheric instability, which mainly originates from the continuous oxidation and hydration spontaneously beginning from the surface phosphorene atoms under the ambient atmosphere, seriously obstructs the progress of most practical applications.
In this work, the selective deposition of Al_2O_3 capping layers with either hydrophobic or hydrophilic surfaces has been successfully achieved on the top surface of the BP flake assemblies via tuning the layer structure and porosity. Dielectric Al_2O_3 is the best candidate, mainly due to its chemical stability and weaker response to most gases. The moisture resistance, lifetime, and the humidity sensing potential of the BP flakes assembled devices capped with hydrophilic dense Al_2O_3 layers, and hydrophobic porous Al_2O_3 nanoassemblies were evaluated by monitoring the overall resistance change under periodical exposure to high-humidity environments (RH = 85%). It was found that the pristine BP flake assembly completely loses its humidity sensing ability at RH = 85% after being stored at RH = 70% for three weeks. Remarkably, with the presence of hydrophobic Al_2O_3 capping layers, a 75% residual humidity sensing response is maintained after five weeks. In other words, the Al_2O_3 capping layers provide complete protection against severe and rapid degradation of the original BP, even in high humidity environments. The proposed functionalization strategy for the BP assemblies further opens the possibility of creating novel BP devices.

Target-Specific Synthesis of Monolayer Molybdenum Disulfide via Adaptive Experimental Design with Batch Bayesian Optimization Yujia Wang, Guoyan Li, Xiaoning Jin and Swastik Kar; Northeastern University, United States

Abstract
When it comes to the predictable synthesis of 2D transition metal dichalcogenides using chemical vapor deposition, the large number of design of experiments (DoE) parameters (such as temperature, pressure, flowrate, quantity and initial positioning of precursors, pressure etc.) and their and complex interdependencies is a well-recognized experimental challenge. Often, small changes in one of these parameters can lead to large variabilities in size, yield, and quality. Although literature is replete with information regarding growth conditions, they vary from system to system. Hence, a method that can reduce the inevitable risk of "trial and error" approaches and guide experimentalists systematically towards the most suitable outcome is important for accelerating research. Here, in order to increase the efficacy and accelerate development, we present a machine learning approach to experiment design providing an alternative data-enabled materials synthesis design to establish desired process-and-quality linkage within the target material quality space. The proposed approach uses a batch Bayesian optimization-based method that employs a batch acquisition strategy to adaptively guide the selection of the experimental parameters and iteratively find the most rapid path for reaching the optimized design of experiments for a target material quality. Using the synthesis of molybdenum disulfide (MoS2) by thermal chemical vapor deposition as an example, we extracted five physically correlated experimental parameters (position of the sulfur precursor, position of MO2 precursor, Ar gas flow rate, temperature ramp-up rate, maximum temperature holding time) and three physically correlated observational parameters (Raman peak height, Excitonic linewidth, Shape). We combine an efficient and predictive surrogate model for monolayer prediction with a batch Bayesian Optimization algorithm to adaptively explore and exploit the design space. We show the success of implementing this method in MoS2 synthesis in which MoS2 with target observational parameters is achieved within 3 batches of experiments (46 samples) and the optimal region of synthesis parameters need to make targeted materials are identified.

SESSION NM06.12: Advanced Characterization and Unique Phenomena in 2D Layered Materials
Session Chairs: Nicholas Glavin and Won Il Park
Friday Morning, December 2, 2022
Hynes, Level 2, Room 207

8:00 AM NM06.12.01
^{60}Co Gamma-Ray Irradiation Effects in Aerosol Jet Printed Two-Dimensional Multilayered Materials Twinkle Pandhi[1], Gregory P. Horne[2], Fahima Ouchen[3], Timothy A. Prusnick[3], Roberto S. Aga[3] and Emily M. Heckman[1]; [1]Sensors Directorate, Air Force Research Lab, United States; [2]Idaho National Laboratory, United States; [3]KBRwyle, United States

Recent advances in nuclear applications and the development of the US Space Force has led to an increased interest in radiation-detection and radiation hardness technologies.[1–3] Novel ionizing radiation-tolerant (X-rays, γ-rays, neutrons) materials and fabrication processes are needed to develop next-generation radiation-detection systems that meet size, weight, power consumption, and cost (SWaP-C) considerations.[4–6]
Inorganic semiconductor materials, such as silicon, cadmium, zinc telluride, or mercury iodide-based radiation detection systems are currently fabricated using a standard silicon-based lithography process.[5] While this silicon-based electronic system enables high performance, it does have several drawbacks: its inability to conform to various structures, limited large-area processing, and relatively high cost.[7]
Two-dimensional (2D) materials offer unique electrical, optical, and mechanical properties that may make them advantageous for use in harsh nuclear or space environments.[8,9] Mono to few layers of 2D materials such as graphene, hexagonal boron nitride, black phosphorus, and metal dichalcogenides have shown negligible change in performance after irradiation and are reported to exhibit high degrees of radiation hardness.[10,11] Solution-based deposition techniques allow for a cost-effective approach for rapid prototyping of devices. Additive manufacturing technologies (direct-write, aerosol jet printing, inkjet printing, etc.) offer low-cost, high-throughput production of flexible electronics, with little material waste and a high degree of compatibility to most substrates of interest.[12–14]
Previous studies have reported on gamma irradiation for mechanically exfoliated, chemical vapor deposition (CVD), and epitaxial grown graphene-based devices. [15–19] However, irradiation effects on printed 2D materials have yet to be reported. This work investigates the roles of microstructure and the substrate properties affected by gamma irradiation in aerosol-jet printed (AJP) 2D materials. The information gained from this study is expected to provide new fundamental insights that can guide the development of nuclear and space applications of printed 2D material devices.
Radiation effects from ^{60}Co gamma-ray radiation are reported for aerosol-jet printed 2D-materials (graphene, MoS_2, WS_2, and h-BN) on various substrates (Si/SiO_2, glass, sapphire, and kapton). Irradiated samples were characterized through Raman spectroscopy, SEM/EDX, XPS, and stylus profilometer.

Furthermore, we fabricated AJP h-BN capacitors to study the effects of gamma radiation on its electrical properties. The information gained from this study is expected to provide new fundamental insights that can guide the development of nuclear and space applications of printed 2D material devices.

A Path Toward Achieving Perfect Absorption in 2D Heterostructures Dongjea Seo[1], Seungjun Lee[1], Nezhueyotl Izquierdo[1], Sang Hyun Park[1], Eng Hock Lee[1], Rehan Younas[2], Guanyu Zhou[2], Christopher Hinkle[2], Tony Low[1] and Steven Koester[1]; [1]University of Minnesota, United States; [2]University of Notre Dame, United States

MoS_2 is a promising material for atomically thin perfect absorbers due to the high oscillator strength of its excitonic transitions and excellent band nesting. As MoS_2 is thinned from multilayer to monolayer, the magnitude and energy of its optical conductivity were exponential attenuation in magnitude and manifested by a gradual blueshift in energy with decreasing layer number due to interlayer orbital hybridization. The intrinsically poor light absorption of monolayer MoS_2, which varies by about 12 % in visible spectral range, induces the weak light-matter interaction. Although this absorption is surprising for the atomic thickness of MoS_2, these values must be increased to design MoS_2-based absorbers. Most approaches to improving the light-matter interaction of MoS_2 have been devoted to plasmonic nanostructure and photonic crystal. The photonic crystal slab with a perfect conductor mirror achieves near-unity absorption at 450 nm and average absorption of 51 % over the spectrum from 400 to 700 nm in the MoS_2 [1].
Here, we demonstrate a new approach to achieving perfect light absorption in MoS_2/graphene/MoS_2 (MGM) heterostructure. By putting graphene in the intermediate layer to reduce the interlayer interaction of MoS_2 with each other, the doubling effect of light absorption can be obtained. As a demonstration of the concept, we experimentally show the optical contrast of MGM heterostructure can be improved by ~28 % compared to the bilayer MoS_2 at λ = 442 nm near the band nesting region. This result is in excellent agreement with the density functional theory of absorbance of a freestanding MGM heterostructure. Based on this structure, we also demonstrate a method based on the insertion of a silver (Ag) mirror layer between the dielectric layer and the substrate to enhance the optical absorption, resulting from Fabry-Perot cavity reflection. The interband absorption of MGM heterostructure is maximized by the cavity resonance and can reach the near-perfect absorption for frequencies satisfying the cavity resonance condition. With various 2D materials and optimization strategies, we can realize ideal absorption over the wide frequency range from UV to IR. Our study points to a new opportunity to combine 2D heterostructure with cavity optics to enable novel device applications such as high-efficiency solar cells with nanometer-scale thickness.

Two-Dimensional Janus GePAs Monolayer: Direct Band Gap Semiconductor with High and Anisotropic Mobility for Efficient Photocatalytic Water Splitting Dogukan Hazar Ozbey[1], Mehmet E. Kilic[2] and Engin Durgun[1]; [1]Bilkent University, Turkey; [2]Korea Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) materials with suitable electronic and optical properties offer different possibilities for photocatalytic applications. Although various 2D materials have hitherto been specified as adequate candidates, materials with high photocatalytic efficiency for water splitting are still minimal. In this study, we predict a 2D Janus GePAs monolayer and examine its capability for photocatalytic water splitting by performing first-principles calculations. The GePAs monolayer is shown to possess robust dynamic and thermal stability. The direct electronic band gap in the visible region and band edge positions of the strain-free and strained monolayers are revealed to be convenient for redox reactions in wide pH ranges. The low recombination probability of charge carriers ensured by high and anisotropic carrier mobility enhances the material's photocatalytic potential. Optical response calculations, including many-body interactions, exhibit significant optical absorption capacity in the UV–visible range. Furthermore, low exciton binding energy facilitates dissociation into free electrons and holes, promoting photocatalytic reactions. Our study suggests GePAs monolayer is an ideal and remarkably promising material to be utilized in visible-light-driven photocatalytic applications.

Probing Sulfur Vacancies in MoS_2 by Photoluminescence Yiru Zhu[1], Yan Wang[1], Soumya Sarkar[1], Juhwan Lim[1], Zhepeng Zhang[2], Goki Eda[2], Robert Hoye[3] and Manish Chhowalla[1]; [1]University of Cambridge, United Kingdom; [2]National University of Singapore, Singapore; [3]Imperial College London, United Kingdom

Chalcogen vacancies can influence the electronic structure of 2D transition metal dichalcogenides (TMDs) by introducing mid-gap defect states. A relatively simple way to create chalcogen vacancies is by thermal annealing. The vacancy defects are optically active and can be probed by photoluminescence (PL) spectroscopy. In this study, we annealed mechanically exfoliated monolayer MoS_2 in different atmospheres and probed the sulfur vacancy states by PL. In nitrogen or argon atmosphere, room temperature defect emission is absent. However, annealing in hydrogen/argon (5% H_2) gives rise to room-temperature defect PL peak at 1.72 eV. Stronger defect PL signal at 10K is observed when annealing time is increased. We show that sulfur vacancies can be passivated by annealing in sulfur vapor. X-ray photoemission spectroscopy is used to confirm the creation and passivation of sulfur

vacancies. Our results suggest that defect states introduced by sulfur vacancies act as trapping centres for radiative recombination and can be passivated by annealing in sulfur vapor environment.

Direct Write, Read and Erase of a Graphene/Monolayer Electrolyte/h-BN Heterostructure via Electric Force Microscopy Huiran Wang[1], Shubham S. Awate[1], Ke Xu[2,2] and Susan Fullerton[1,1]; [1]University of Pittsburgh, United States; [2]Rochester Institute of Technology, United States

A solid-state, non-volatile memory based on electric-double-layer (EDL) gating using a monolayer electrolyte (ME) has been developed in our lab. This ME consists of cobalt crown ether phthalocyanine (CoCrPc) and a lithium salt that forms an ordered array on the surface of 2D materials. Each crown ether solvates one cation that is stable in two states in the crown – one near the 2D material creating a low-resistance state and the other further away creating a high-resistance state. The location is set by an electric field via a backgated transistor architecture. Here, we investigate an approach to locally toggle the ions through the crown using an atomic-force microscopy (AFM) tip. Instead of a three-terminal transistor, here we use a two-terminal stack of graphene/ME/hexagonal boron-nitride (h-BN) on p-doped Si prepared by dry flake transfer. P-doped Si serves as one terminal, and the AFM tip/graphene as the second. AFM is used in electric force microscopy (EFM) mode to write, read, and erase the stacks. The AFM tip is brought into contact with the graphene surface to perform the local switching on the stack wherein the AFM tip acts like a charge source to locally inject charges to the graphene surface while the p-doped Si is grounded. The resulting electric field toggles the ion back and forth through the crown. By switching the location of the ions using a "write" voltage > 9 V, the differences of the electrostatic interaction between the tip and the written regions can be detected using a "read" voltage. In this non-contact reading mode, the tip is raised to lift height and biased (V_{read} = ± 3V) to sense the local electric field of the sample surface. The read voltage is chosen so as not to disturb the state of the ions. These differences of tip-sample interaction appear as a change in the phase, indicating the tip is experiencing a repulsive or attractive force during the scan. When the ions are positioned closer to the graphene surface, graphene will be n-doped and the repulsion between the tip and the sample surface is increased. Our results show a continuously increasing phase shift (total ~ 0.7 degree) with increasing write voltages from 5 to 10 V, detected by a read voltage of 3 V (45 nm lift height). This trend suggests that lithium ions are switching through the crown, and that more of them are switching with increasing write voltage. A reverse "erase" bias is applied to the same region to push the ions away from the graphene, and the region is read with the same read voltage. The results show no increasing phase shift, suggesting a successful erase. The same procedure was also performed on control samples without the ME (i.e., graphene/h-BN), confirming that the origin of the phase shift is ME. We also confirm that the polymer residue from the dry flake transfer is not the origin of the phase shift. In addition, the magnitude of the phase shift as a function of tip bias provides a means to quantify the surface charge. We estimate the surface charge to be 5.44 x 10^{12} cm^{-2} for graphene alone (without the monolayer electrolyte), and the value for the monolayer electrolyte stack will be reported. This work is supported by the NSF under Grant # NSF-DMR-EPM CAREER: 1847808.

Defect Engineering Graphene for Dynamic Reliability Boran Kumral[1], Teng Cui[1,2], Pedro Guerro Demingos[1], Nima Barri[1], Chandra V. Singh[1] and Tobin Filleter[1]; [1]University of Toronto, Canada; [2]Stanford University, United States

The ability to withstand high tensile strain as a result of strong in-plane sp^2 covalent bonding, low bending stiffness, and a wide variety of tunable electrical properties has led to wide interest in the development of 2D materials-based flexible devices such as flexible electronics, nanocomposites, and multifunctional coatings. Despite exceptional intrinsic mechanical, electrical, and optical properties, challenges remain in the realization of 2D materials in their functional device applications. The interface between 2D materials and soft stretchable substrates is a governing parameter in proposed 2D materials-based flexible devices. However, the same interface is dominated by van der Waals (vdW) forces and the mismatch in elastic constants between the contact materials leads to very low adhesion energy (also referred as interface toughness, work of separation, or work of adhesion). For example, the adhesion energy between monolayer graphene and silicon oxide is estimated to be ~450 $mJ.m^{-2}$ (*1*), while the adhesion energy between monolayer graphene and polydimethylsiloxane (PDMS), a soft and stretchable elastomeric substrate, is estimated to be only ~7 $mJ.m^{-2}$ (*2*). When the 2D material/stretchable substrate system is subjected to cyclic loading by applying continuous tension and compression, the low adhesion leads to decoupling, slippage, and extensive damage propagation in the 2D lattice (*3*). With only 10 cycles of cyclic loading of graphene on PDMS at ε = 20% strain range, ~30% of a graphene flake's area is catastrophically damaged (*3*).

We reveal that through careful defect engineering of graphene, the contact interface between graphene and PDMS can be modified to increase the adhesion energy to ~40 $mJ.m^{-2}$, which is characterized with an atomic force microscope (AFM) by employing buckling-based metrology (*4*). The defect engineering consists of exposing a single side of a graphene flake to controlled and mild oxygen plasma, and then placing the flake's functionalized side in direct contact with PDMS. The type and density of defects are characterized using X-ray photoelectron spectroscopy (XPS) and Raman spectroscopy. The defects present are revealed to be a low density of sp^3-type defects, mainly oxygen functional groups. In situ micro tensile testing under an optical microscope and optical image processing reveals that the increased adhesion in defect engineered graphene/PDMS systems drastically inhibits damage propagation and improves fatigue life. Additionally, insight into the role of each functional group in relation to the change in adhesion is investigated using molecular dynamics (MD) simulations. This work could be extended to other 2D material/stretchable substrate systems and offers insight into achieving dynamically reliable contacts, which could facilitate the development of 2D materials-based flexible devices.

***In Situ* TEM Imaging of Novel Edge Reconstruction in Bilayer Phosphorene** Sol Lee[1,2], Yangjin Lee[1,2], Li Ping Ding[2,3], Kihyun Lee[1], Feng Ding[2,4] and Kwanpyo Kim[1,2]; [1]Yonsei University, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of); [3]Shaanxi University of Science & Technology, China; [4]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Atomic-scale characterization of two-dimensional (2D) materials and their heterostructure is indispensable to understanding their physical, electrical, and chemical properties. In particular, atomic-scale configurations and morphology of 2D crystals' edges strongly influence properties including electronic, transport, and optical properties. Transmission electron microscopy (TEM) has been employed to observe the atomic-scale edge structure of various 2D materials. Moreover, via in-situ TEM capabilities, the controlled edge formation under various environments and stimuli has been achieved. On the other

hand, atomic-scale TEM imaging of crystalline edges of phosphorene has been quite challenging compared to other 2D crystals. The main obstacle is the sample's vulnerability to ambient exposure and the characterization process.

Here, we report the atomic scale TEM observation of ultra-stable self-passivated phosphorene edges in bilayer phosphorene. We use graphene as a supporting layer for phosphorene to suppress the electron-beam-induced radiolysis effect during TEM measurement. We prepare phosphorene/graphene vertical heterostructure samples on an in-situ heating chip by dry-transfer technique. Using in situ heating, the prepared phosphorene/graphene samples suffer from little residues and adsorbates. At elevated temperatures, the layer-by-layer etching of black phosphorus has been observed, which leads to the formation of monolayer and bilayer phosphorene. While etching of monolayer phosphorene under e-beam is pronounced, we observe that the edge of bilayer phosphorene with zigzag edge configuration shows high stability under the electron beam.

To investigate the detailed edge configuration of stable bilayer ZZ phosphorene edge, we perform TEM imaging at various defocus values as well as tilting configurations. Based on first-principles calculations and TEM image simulations, we confirm that the bilayer ZZ edge shows the reconstruction with the interlayer self-passivating covalent bonds. Our theoretical calculations also confirm the low formation energy of the observed edge configuration compared to other possible configurations. Our study demonstrates that atomic-scale reconstruction of phosphorus can be harnessed to fabricate stable phosphorene nanostructures with precisely controlled thickness and edge configuration.

Strain Fields at the Micro-Scale in Two-Dimensional Materials Elena Blundo[1], Cinzia Di Giorgio[2], Giorgio Pettinari[3], Tanju Yildirim[4], Alessandro Surrente[5], Paulo Eduardo Faria Junior[6], Mikhail Prosnikov[7], Katarzyna Olkowska Pucko[8], Maciej R. Molas[8], Marco Felici[1], Adam Babinski[8], Peter Christianen[9], Fabrizio Bobba[2], Jaroslav Fabian[6] and Antonio Polimeni[1]; [1]Sapienza, University of Rome, Italy; [2]Università di Salerno, Italy; [3]Centro Nazionale Ricerche, Italy; [4]National Institute for Materials Science, Japan; [5]University of Wroclaw, Poland; [6]Universität Regensburg, Germany; [7]Ioffe Institute, Russian Federation; [8]University of Warsaw, Poland; [9]High Field Magnet Laboratory, Netherlands

The variegated family of two-dimensional (2D) materials comprises crystals that have attracted great interest for their exceptional characteristics. Among them, hBN is a thermally stable and mechanically robust insulator, and semiconducting transition-metal dichalcogenides (TMDs) possess alluring optoelectronic and spin properties when reduced to the single layer. In particular, TMD monolayers are characterised by a direct bandgap, resulting in an efficient light emission in the visible/infrared range, which renders them appealing for optoelectronic devices. Furthermore, a strong spin-orbit coupling makes them interesting candidates for valley- and spin-tronics. Indeed, the inherent plane-confined nature of these materials -coupled to their exceptional mechanical flexibility and robustness- makes them highly sensitive to external stimuli. Methods to tailor their unique properties on demand have been thus sought after, and protocols based on controllable external perturbations such as mechanical deformations have shown promise in this respect.

Here, we explore new strategies to tune the peculiar properties of 2D TMDs and hBN by mechanical deformations.

We show how low-energy hydrogen-ion irradiation of bulk flakes can be exploited to engender localised strains. More specifically, the hydrogen ions penetrate through one or a few layers, leading to the production and accumulation of molecular hydrogen in the first interlayer region. The trapped gas coalesces, leading to a local blistering of the material, and thus to the formation of few-layer-thick micro/nano-bubbles [1,2].

The bubbles host complex strain fields that reach high values. Raman measurements allowed us to characterise experimentally the strain and its effect on the vibrational properties of the materials [2,3]. An analytical model allows us to calculate the strain distribution, in agreement with the experiments. The model further allows us to obtain precious information on the adhesion energy between the bubble and the substrate, and the bubbles can thus be exploited to measure the adhesion energy of a variety of van der Waals materials [3]. Furthermore, nano-indentation measurements permitted us to probe the elastic properties of the material and highlight their exceptional flexibility [4].

These bubbles are durable and incredibly robust, and in TMDs the bubble thickness is just one layer. In turn, TMD bubbles behave as efficient light emitters. The high fields they host cause dramatic changes in the TMD opto-electronic properties, and photoluminescence steady-state and time-resolved studies enabled the characterisation of the strain-induced band-structure modifications and revealed intriguing phenomena, such as a strain-induced direct-to-indirect bandgap crossover [5]. Our optical characterisation further allowed to pinpoint hybridization phenomena between direct and indirect excitons [6].

Our results unveil unprecedented information on the strain effects on TMDs and hBN, the understanding of which represents an essential step towards their integration into flexible electronic devices.

10:30 AM NM06.12.09
***In Situ* Monitoring of Phase Transition of MoS_2 During Chemical Lithiation** Juhwan Lim, Jung-In Lee, Christoph Schnedermann, Manish Chhowalla and Akshay Rao; University of Cambridge, United Kingdom

Phase engineering of MoS_2, mainly between two crystallographic phases of octahedral (1T) phase and trigonal prismatic (2H) phase, has attracted attention for its ability to tailor different phases within a single flake and enhance the materials and device performances, such as higher hydrogen evolution efficiency and lower contact resistance. Many studies have used lithiation, both chemically and electrochemically, to change the phase of MoS_2, from the semiconducting 2H- to metalic 1T phase. It is understood that the intercalation of Li cations into the van der Waals gap of 2H-MoS_2 promotes the 2H/1T phase transition by electron donation. n-butyllithium (n-BuLi) is the most widely used organolithium reagent for chemical lithiation of transition metal dichalcogenides (TMDs). However, a better understanding of this chemical lithiation reaction is required, not only to provide mechanistic insight, but also to enable more efficient phase engineering of transition metal dichalcogenides for electronic, optoelectronic, and energy applications. Recently, in-situ characterization techniques (ex, in-situ Raman, STEM/TEM, LCM–DIM) have been applied to monitor the phase transition of bulk or multilayer MoS_2 using electrochemical lithiation or direct contact of lithium metal. However, practical limitations on handling the highly pyrophoric n-BuLi, as well as the lack of optimized operando characterization techniques have curtailed the microscopic understanding of the lithiation and structural transition.
Here, we captured in real-time the chemically-induced 2H to 1T phase transition of mechanically exfoliated mono-, bi-, and multilayer MoS_2 flakes in n-BuLi using in-situ optical reflectance interferometric contrast microscopy (RICM). By exploiting the different dielectric properties of 2H-MoS_2 and 1T-MoS_2, we directly quantified the phase transition dynamics in micrometer-sized MoS_2 flakes with diffraction-limited resolution (~200 nm) and

complemented the results with ex-situ Raman and Photoluminescence (PL) measurement to obtain detailed structural insights into this process. We reveal that the phase transition is charge-transfer limited in few-layer MoS_2, which gives rise to sharp phase fronts propagating from the edges of the flake inwards with constant velocity. Comparison to monolayer MoS_2 further highlights the importance of surface reactivity. Incorporating the result from the ex-situ measurement of flakes of the different number of layers, such as ground state A-exciton and low-energy PL emission, shifts or broadening of E_{2g} and A_{1g} Raman peaks, and arising of Raman J peaks, we suggest a systematic interpretation for this behavior. Critically, the phase transition dynamics appeared highly dependent on the illumination conditions, with mild above-bandgap illumination accelerating the transition and changing the underlying mechanism. We suggest possible applications to harness this effect open up new possibilities in phase engineering of MoS_2 and other TMDs.

10:45 AM NM06.12.11
Studies of 2D Materials by Scanning Tunneling Microscopy Associated with a Light Detector Ricardo Peña Román[1], Fábio J. Costa[1], Thiago G. Brito[1], Ingrid D. Barcelos[2] and Luiz F. Zagonel[1]; [1]Campinas University, Brazil; [2]Centro Nacional de Pesquisa em Energia e Materiais, Brazil

2D materials are been considered for several applications due to their new and promising mechanical, electronic and optical properties. Scanning Tunneling Microscopy (STM) is a great tool to investigate their morphology and electronic structure by means of imaging (which reaches atomic resolution) and spectroscopy. Adding a light detector to the STM provides access to the light emission that is triggered by the very local tunnel current (usually called STM induced light emission or luminescence, STML). We have developed a new light collection device compatible with an adapted low temperature UHV STM. [1] This device is based on an off axis parabolic mirror and it is designed to have high collection efficiency while keeping high spectral resolution. Using our STM equipped with such device, we studied WSe2 mechanically transferred to gold, to HOPG, and to ITO. These conducting substrates affect this transition metal dichalcogenide (TMD) in different ways.[2] After the mechanical transfer, a water interlayer isolates the TMD from gold and from ITO, but such interfacial layer was not observed for HOPG. After an annealing, light is severally quenched on the TMD over gold while on ITO the TMD preserves its emission and becomes highly doped. The TMD on HOPG was not significantly doped but was also quenched. Another study used HOPG as a support to epitaxial growth of hexagonal boron nitride (h-BN). This substrate preserved h-BN properties and both the electronic gap and light emission from defects could be determined.[3]

Colossal Photocurrents in Topological Janus Transition Metal Dichalcogenides Haowei Xu, Hua Wang, Yunfan Guo, Jing Kong and Ju Li; Massachusetts Institute of Technology, United States

Nonlinear optical properties such as bulk photovoltaic effects possess great potentials in energy harvesting, photodetection, rectification, etc. To enable efficient light-current conversion, materials with strong photo-responsivity are highly desirable. In this work, we predict that monolayer Janus transition metal dichalcogenides (JTMDs) in the 1T' phase possess colossal nonlinear photoconductivity owing to their topological band mixing, strong inversion symmetry breaking, and small electronic bandgap. 1T' JTMDs have inverted bandgaps on the order of 10 meV and are exceptionally responsive to light in the terahertz (THz) range. By first-principles calculations, we reveal that 1T' JTMDs possess shift current (SC) conductivity as large as 2300 nm μA V^{-2}, equivalent to a photo-responsivity of 2800 mA/W. The circular current (CC) conductivity of 1T' JTMDs is as large as 10^4 nm μA V^{-2}. These remarkable photo-responsivities indicate that the 1T' JTMDs can serve as efficient photodetectors in the THz range. We also find that external stimuli such as the in-plane strain and out-of-plane electric field can induce topological phase transitions in 1T' JTMDs, and that the SC can abruptly flip their directions. The abrupt change of the nonlinear photocurrent can be used to characterize the topological transition, that has potential use in 2D optomechanics and nonlinear optoelectronics.

1:45 PM NM06.13.02
Effects of Electrostatic Interactions and Charge Transfer Mechanisms on Interlayer Excitons in van der Waals Heterostructures Jaehoon Ji and Jong Hyun Choi; Purdue University, United States

Atomically thin heterostructures from transition metal dichalcogenides (e.g., MoS_2/WSe_2) may exhibit interlayer excitons (IXs) due to strong light-matter interaction.[1] IXs are bound states of spatially separate electrons and holes in opposite 2D semiconducting heterolayers. The IXs show various unique properties, including large binding energy, long lifetime, diffusion length, and substantial dipolar interaction.[2] These characteristics may be exploited to develop diverse optoelectronics, including light emitting diodes, photodetectors, photovoltaics, and excitonic devices. Given the importance, several mechanisms have been explored for tailoring the formation and behavior of IXs such as external electrical field and doping.[2]

Despite the extensive studies, the effects of electrostatic interactions (e.g., dielectric screening and dipolar interaction of charges) and charge transfer pathways on the IX formation have not been fully understood. To elucidate them in this work, we have introduced a new approach of inserting an organic layer between MoS_2 and WSe_2 heterobilayers.[3] The sandwiched organics, 1,3-bis(3,5-dipyrid-3-ylphenyl)benzene (B3PyPB) and eosin Y (EY), were chosen for their properties that may reduce the dielectric screening on the charges of IXs due to the smaller dielectric constants of the organic layers than those of TMDs. Additionally, the inserted layer may expand the separation distance of IXs. Given the reduced screening and the increased distance, the binding energy of IXs will be reduced. We estimated the change of the exciton binding energy by using a simple hydrogen-like particle model.[4] The organic-inserted hybrid heterostructure had a smaller binding energy than the control, MoS_2/WSe_2 heterostructure by ~40 meV. This was confirmed by PL spectroscopy of the hetero-samples with and without organic layers. The B3PyPB-inserted MoS_2/WSe_2 sample showed a blueshifted IX emission compared to the TMD-only heterojunction, consistent with the binding energy theory.

Furthermore, we found that the charge transfer pathways can modulate the IX energy. The EY may develop type II energy level alignments that facilitate energetically favorable charge transfer. In contrast, B3PyPB creates a substantial energy barrier at the TMD/organic interface that only allows a tunneling

of charges. The PL measurements show that MoS_2/EY/WSe_2 exhibits an IX emission at ~1.62 eV, which is higher than the emission energy (~1.60 eV) from the B3PyPB-embedded heterojunction. Due to the energetically favorable transport, the EY-inserted hybrid may accommodate a greater extent of IXs than the other. Since the IXs are aligned in an out-of-plane direction within the ultrathin structure, they may behave as repulsive dipoles, leading to the further increase of IX energy. By adopting a model that correlates the emission energy and the dipole density, we found that MoS_2/EY/WSe_2 has a higher dipole density than the B3PyPB-inserted sample (by ~$2.5x10^{12}$ cm^{-2}). The results strongly suggest that the IX properties can be tuned by varying the dielectric environments, the electrostatic interaction, and the charge transfer pathways. This work may pave a new way to control the IXs for future optoelectronics.

Controlled Synthesis of Large-Sized 2D Ultrathin SnSe Crystals with In-Plane Ferroelectricity Tianyi Zhang[1], Ming-Hui Chiu[1,2], Xiang Ji[1], Nannan Mao[1], Yue Luo[3], Chuqiao Shi[4], Yimo Han[4], William L. Wilson[3], Vincent Tung[2] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]Harvard University, United States; [4]Rice University, United States

Tin (II) selenide (SnSe) is an emerging member of two-dimensional (2D) materials with many intriguing properties, such as record-high thermoelectric figure of merit (ZT), purely in-plane ferroelectricity, and excellent nonlinear optical properties. Moreover, as a semiconducting material that is structurally analogous to layered black phosphorus, a rising star for next-generation nanoelectronics, 2D SnSe is anticipated to possess attractive electronic and optoelectronic properties, such as thickness-dependent bandgap and high photoresponse. To facilitate the exploration of these functional properties and applications, it is important to develop controllable routes to synthesize ultrathin crystals of SnSe with large area and high quality. Physical vapor deposition (PVD) constitutes a reliable method to synthesize 2D SnSe with the scaling-up potential. Nevertheless, effects of various growth parameters have not yet been systematically investigated, and current PVD-synthesized SnSe flakes are often thick (> 10 nm) with small lateral sizes (< 10 μm). In this work, we demonstrate the growth of high-quality 2D SnSe crystals *via* a low-pressure PVD method, which display in-plane ferroelectric domains observed by polarization-dependent reflectivity spectroscopy. We further comprehensively studied roles of various parameters, including substrate pre-annealing, growth duration, temperature, and growth pressure, which enables us to rationally optimize the growth and obtain 2D SnSe crystals with lateral size up to ~23.0 μm and controllable thicknesses down to ~2.0 nm (3-4 layers). Our work takes an important step forward on the controlled growth of large-area 2D SnSe, facilitating the future exploration of its interesting multiferroic properties and applications with atomic thickness.

Continuous Liquid Metal Printed 2D TCO Superlattices Youxiong Ye, Andrew B. Hamlin, Md Saifur Rahman, Julia Huddy and William J. Scheideler; Dartmouth College, United States

Two-dimensional (2D) conducting metal oxides offer unprecedented control of thin film electrostatics at the nanoscale. We present a scalable, roller-based continuous liquid metal printing (CLMP) approach for fabricating large area (100 cm^2) layered transparent conductive oxides (TCOs) via rapid low-temperature Cabrera-Mott oxidation of compliant liquid metals (Ga, In). We exploit repeating heterostructures of these 2D oxides (3 nm per layer) to produce TCOs at 180 °C with record conductivity while simultaneously raising visible range transmittance above 98%. HRTEM and XRD characterization reveal the unique 2D film morphology consisting of large grained cubic InO_x layered with amorphous GaO_x. To investigate the impact of modulation doping at the type I heterojunction between InO_x / GaO_x, we also present XPS, UV-Vis, and Hall characterization. Our rapid (6 m / min) low-temperature CLMP approach yields flexible TCOs that demonstrate 20X enhanced strain tolerance while requiring zero post-annealing and offering greater conductivity than low-temperature ITO, which is limited by poor dopant activation. These capabilities establish CLMP 2D TCOs as a promising set of transparent electrode materials for flexible optoelectronic devices such as photodetectors and displays.

2:30 PM NM06.13.05

Photoresist-Free and Large-Area Patterning Method for van der Waals Materials via Direct Optical Lithography Seong Rae Cho[1], Seonghun Ahn[1], Seung Hyung Lee[1], Heonhak Ha[1], Tae Soo Kim[1], Min-kyung Jo[1,2], Chanwoo Song[1], Tae Hong Im[1], Pragya Rani[1], Minseung Gyeon[1], Kiwon Cho[1], Seungwoo Song[2], Min Seok Jang[1], Yong-Hoon Cho[1], Keon Jae Lee[1] and Kibum Kang[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of)

Van der Waals (vdW) materials have attracted significant interest as new research platforms of next-era research since they exhibit novel properties with surface-dominant geometry. However, the properties of vdW materials are highly affected by the surface state of the materials owing to the geometrical feature of the materials and, therefore, the conventional photolithography technique accompanying undesired photoresist residues and solution process has negative effects on vdW materials. Several alternative patterning techniques have been reported to avoid the issue, but they suffer from low resolution, scalability, and low throughput.
In this work, we report a new patterning technique, the direct optical lithography technique, specialized for vdW materials. The direct optical lithography uses highly intensive photo illumination in a short pulse with a special photomask to follow the advantage of conventional photolithography without photoresists and solvents. We patterned various vdW materials (monolayer MoS_2, bilayer MoS_2, monolayer graphene, monolayer WSe_2, and two-dimensional metal-organic framework) in multiscale and desired shapes. Morphological characterization revealed that direct optical lithography did not cause photoresist residues unlike conventional photolithography and optical characterization exhibited critical differences between direct optical lithography and conventional photolithography. The finite element method (FEM) simulation results demonstrated that the photo source used in this work, the highly intensive light with a short pulse, was suitable for high-resolution patterning of vdW materials without degradation of patterned materials.

2:45 PM NM06.13.06

Humidity Controlled Composition and Morphology of 2D Material Nanobubbles Daniel Sanchez[1], Andrei Dolocan[2], Jinlong He[3], Santiago Diaz-Arauzo[2], Eunbin Kim[2], Melanie Murillo[2], Jiaming He[2], Zhaohe Dai[4], Ying Li[3] and Nanshu Lu[2]; [1]University of Pennsylvania, United States; [2]The University of Texas at Austin, United States; [3]University of Connecticut, United States; [4]Peking University, China

When two-dimensional (2D) materials are transferred onto a supporting substrate, matter trapped at the interface can spontaneously coalesce to form nanobubbles. These bubbles are emerging for novel nanoscale applications to strain engineer 2D materials and to explore chemical reactions under nanoscale confinement. Strategies to deterministically control the chemical content of these bubbles remain unclear, and current analyses of the contents of spontaneously formed bubbles offer limited chemical information about the trapped matter. We therefore develop a three-dimensional chemical analysis methodology combining cryo-ToF-SIMS (time-of-flight secondary ion mass spectrometry), atomic force microscopy (AFM), and computational modeling

to study the intricate structural chemical composition and the morphology of nanobubbles formed in various environments. By applying this methodology to nanobubbles produced in different relative humidities (RHs), we discover their rich chemical composition, consisting of phase-separated water, hydrocarbons, and substrate materials. Our technique can identify, locate and relatively quantify, with an unprecedented level of detail, the composing species of these nanobubbles, unambiguously proving their chemical inhomogeneity, which settles the long-standing debate concerning the co-existence of multiple chemical species within spontaneously formed nanobubbles under 2D materials. Importantly, we find that both the phase separation and the individual concentrations of the trapped chemicals vary with the RH of the fabrication environment. This methodology is generally applicable to stacked 2D materials to fundamentally understand their material properties and matter confined to their interfaces. Our work significantly deepens the current understanding of spontaneously formed nanobubbles and unveils new design avenues for their chemical tunability.

3:30 PM NM06.14.01
Crystal Anisotropy Implications on the Intrinsic Magnetism in van der Waals $FePS_3$ Ellenor Geraffy; Technion Institute of Technology, Israel

Ultrathin 2-D van der Waals (vdW) semiconductor materials have procured scientific and technological interest since the discovery of single layered graphene in 2004. Similar to graphene, transition metal trichalcogenides, with the general chemical formula MPX_3 (M= 1st row transition metals, X = chalcogenides), possess fast electron transport and strong spin orbit coupling without the drawback of no bandgap. These vdW inorganic lamellar compounds are characterized by strong intralayer covalent bonding and weak vdW interaction between adjacent layers. Transition metal atoms endow these materials with magnetic (either ferromagnetic or antiferromagnetic Neel, zigzag or stripy) and magneto-optical properties which can be utilized for new generation 2D magnets and opto-spintronic devices. Yet, the fundamental understanding of these materials as well as the manipulation of their intrinsic magnetism via external stimuli remains to be an unexplored endeavor.
$FePS_3$ exhibits an overall zigzag antiferromagnetic ordering owing to its ferromagnetic Fe zigzag chains which are antiferromagnetically coupled to eachother, resulting in a high linear dichroism dependency which is direction depdenent. Additionally, the presence of crystallographic anisotropy is expected to yield significant impacts on its intrinsic magnetism and optical properties, particularly in the presence of external factors such as increasing temperature and external magnetic fields.
In this talk,the correlation between the crytallographic anisiotropy and the optical and intrisic magnetic properties in $FePS_3$ is shown using temperature dependent photoluminescence (PL) and magneto-PL measurements. Additioanally, the presence of a metamagnetic phase transitions in $FePS_3$ upon inducing thermal and magnetic fluctuations using temperature dependent PL and linearly and circularly polarized magneto-PL.

3:45 PM NM06.14.02
Magnetic and Catalytic Properties of Two-Dimensional Cobalt Tellurides Raphael M. Tromer[1], Solomon D. Negedu[2], Saif Siddique[2], Femi E. Olu[2], Mithun Palit[3], Ajit K. Roy[4], Cristiano F. Woellner[5], Prafull Pandey[6], Douglas S. Galvao[1], Partha Kumbhakar[2] and Chandra Tiwar[2]; [1]universidade estadual de campinas, Brazil; [2]Metallurgical and Materials Engineering, India; [3]Defence Metallurgical Research Laboratory, India; [4]Materials and Manufacturing Directorate, Air Force Research Laboratory,, United States; [5]Universidade Federal do Paraná, Brazil; [6]Department of Materials Engineering, Indian Institute of Science, India

Recently, 2D cobalt telluride materials have attracted much attention due to their potential applications in memory devices, sensors, spintronics, and biomedical areas. [1-4]. In this work we investigated the magnetic and catalytic properties of synthesized 2D cobalt telluride (CoTe) from its bulk crystals using a simple liquid exfoliation method[1,4]. The results from the hysteresis curves show that the magnetic saturation value for 2D CoTe is ~400 times the corresponding values of their bulk counterpart. They exhibit good absorption in the high-energy region corresponding to the ultraviolet range. We also carried out density functional theory (DFT) [5] simulations to gain further insights on their structural and electronic properties. Our results suggest that the reduced coordination number of the surface atoms, anisotropy, and surface charge effects are responsible for the larger magnetism presented by 2D CoTe in comparison to their bulk structures. Moreover, the semiconducting nature and surface charges of 2D CoTe lead to a significant photocatalytic behavior. These results strongly support that 2D CoTe are promising materials for magnetic and catalytic applications.

4:00 PM NM06.14.03
Synthesis, Fabrication and Characterization of a Fe:MoS_2-Based Magnetic Tunneling Junction Siwei Chen, Zitao Tang, Mengqi Fang, Kyungnam Kang, Abdus Salam Sarkar, Na Liu, Yuze Zhang, Stefan Strauf, Grzegorz Hader and Eui-Hyeok Yang; Stevens Institute of Technology, United States

The discovery of ferromagnetism in 2D atomic layers, including chromium triiodide (CrI_3), chromium germanium telluride, and other van der Waals (vdW) materials, has enabled the exploration of vdW magnetism, opening new avenues for the next-generation spintronic. For example, 2D van der Waals magnets can be used to construct magnetic tunnel junctions (MTJs) toward spintronic memory systems such as magnetic random access memories (MRAM). A rapid current-induced magnetization switching (CIMS) is essential for high-speed and low-power next-generation spintronics [1-4], which may be achieved using 2D magnets. Recently, room temperature ferromagnetism was demonstrated in *in-situ* Fe-doped MoS_2 (Fe:MoS_2) and V-doped WSe_2 (V:WSe_2) *via* chemical vapor deposition (CVD) [5-7]. These 2D magnets can be used as electrodes or barriers in vdW MTJs.

Here, we present the synthesis, layer transfer, and characterization of a 2D magnet (*i.e.,* Fe:MoS_2 monolayer)-based MTJ, consisting of a thin film Fe, multilayered hBN and a Fe:MoS_2 monolayer.
The Fe:MoS_2 monolayers were synthesized *via* low-pressure chemical vapor deposition. The Fe:MoS_2/graphene was fabricated by directly transferring an exfoliated multilayer graphene onto CVD-grown Fe:MoS_2 via PDMS stamping. A Fe layer connected to Au/Cr electrodes as the bottom electrodes and a

multilayer hBN was transferred onto the Fe thin film via PDMS-stamping, followed by another transfer of the Fe:MoS_2/graphene junction onto Fe/hBN via a PMMA-based wet transfer. Here, hBN was used as the tunneling barrier, Fe:MoS_2 as the free layer, and Fe thin film as the fixed layer of the 2D MTJ. A probe station with Keithley 6487 pico amperometry was used to test the IV characteristics of the fabricated MTJ at room temperature. The MTJ junction showed a parabolic tunneling behavior under 0.3V source-drain voltage.
We will measure the tunneling magnetoresistance (TMR) inside an ultra-low vibration cryogen-free cooling closed-cycle cryostat at 4 K to measure the CIMS by applying short current pulses over the junction. (We will add these data in a week.)
KEYWORDS: magnetic tunnel junction, spin valve, van der Waals heterostructure

Ferromagnetic Properties of Fe-Doped Tungsten Diselenide Monolayers Toward Diluted Magnetic Semiconductors Mengqi Fang[1], Siwei Chen[1], Kyungnam Kang[1], Arunabh Mukherjee[2], A. Nick Vamivakas[2] and Eui-Hyeok Yang[1]; [1]Stevens Institute of Technology, United States; [2]University of Rochester, United States

Two-dimensional (2D) transition metal dichalcogenides (TMDs) possess interesting electronic, optical, and structural features, including a direct band gap in monolayers with a photoluminescence emission in the visible and near-infrared spectral range [1-2], which due to transition metal atoms fill non-bonded d-bands to a variety of levels [3]. With the superior 2D atomic thickness and tunable electronic band structure, TMDs, have become suitable candidates for studying high nonlinear optical susceptibilities, spin-orbit interactions, and novel valleytronics properties [4]. Doping is an efficient way to tune the properties of TMDs. These 2D TMD semiconductors doped with transition metal atoms (such as vanadium (V), Rhenium (Re), and iron (Fe)) link the properties of semiconductors and ferromagnets, creating new known as dilute magnetic semiconductors (DMS) [5]. These 2D DMS were synthesized via chemical vapor deposition (CVD), thereby opening the door toward utilizing novel modes of magneto-electronic and magneto-optical responses of 2D heterostructures [6-8].

Here we demonstrate an in situ substitutional doping of iron atoms into WSe_2 monolayers via low-pressure chemical vapor deposition (LPCVD). Fe_3O_4 particles as iron sources were cast onto the SiO_2/Si substrate, and a MoO_3-deposited substrate contacted the source substrate face-to-face. The furnace was then heated to 850 °C and held for 15 mins. During the heating process, selenium (Se) is provided via vaporizing Se powder placed in crucibles outside the central furnace area as the furnace temperature rises to 640 °C. Argon (Ar) gas was flown to the furnace at 200 °C, and hydrogen (H_2) gas was supplied at 660 °C. To verify the growth of monolayer Fe: WSe_2 domains, we first characterized the samples via Raman/PL spectroscopy and atomic force microscopy (AFM), confirming that the grown materials are Fe-doped WSe_2 monolayers. We plan to characterize the ferromagnetic domains of the grown materials using magnetic force microscopy (MFM) at our facility (new MFM equipment has been recently installed). Finally, the ferromagnetic nature of the grown Fe-doped WSe_2 monolayers will be confirmed using spatially resolving nitrogen-vacancy (NV^-) center magnetometry (this characterization has been routinely performed by the authors' group [9]).

Giant Nonlinear Optical Response via Coherent Stacking of In-Plane Ferroelectric Layers Nannan Mao[1], Yue Luo[2], Ming-Hui Chiu[1], Chuqiao Shi[3], William L. Wilson[2], Yimo Han[3], William Tisdale[1] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard University, United States; [3]Rice University, United States

Ferroelectric materials are essential components for various applications such as high-density non-volatile memories, nonlinear optics, electro-optical switches and sensors. Thin-film ferroelectric materials hold great promise on miniaturization and on-chip integration of related functional devices. Recently, a class of 2D materials called group-IV monochalcogenides have attracted extensive attentions due to robust in-plane ferroelectricity in atomically-thin layer (1-5). Besides ferroelectric property at room temperature, these materials were predicted with a range of fascinating properties, such as giant nonlinear optical effect (6, 7), large piezoelectric (8, 9) and thermoelectric coefficient (10), multiferroic (6, 11), spintronic properties (12) and promising bulk photovoltaic effect (13). Herein we demonstrate the in-plane ferroelectricity in thin flake of tin monoselenide. Giant second harmonic generation was observed due to parallel ferroelectric stacking structure. The measured nonlinear optical susceptibility is more than one order-of-magnitude larger than that of monolayer TMDs such MoS2. Our findings open up exciting opportunities of the applications of group-IV monochalcogenides in ultrathin non-volatile memory and miniaturized nonlinear optical devices.

Engineering Interlayer Electron-Phonon Coupling in WS_2/h-BN Heterostructures Yi F. Li[1], Xiaowei Zhang[1], Jinhuan Wang[1], Xiaoli Ma[2], Jin-An Shi[3], Xiangdong Guo[4], Yonggang Zuo[5], Ruijie Li[1], Hao Hong[6], Ning Li[6], Kai Xu[3], Xinyu Huang[7], Huifeng Tian[1], Ying Yang[8], Zhixin Yao[1,9], Xiao Li[8], Junjie Guo[9], Yuang Huang[7], Peng Gao[1], Lifen Wang[2], Xiaoxia Yang[4], Qing Dai[4], EnGe Wang[1], Kaihui Liu[1], Wu Zhou[3], Xiaohui Yu[2], Liangbo Liang[10], Ying Jiang[1], Xin-Zheng Li[1] and Lei Liu[1]; [1]Peking University, China; [2]Institute of Physics, Chinese Academy of Sciences, China; [3]University of Chinese Academy of Sciences, China; [4]National Center for Nanoscience and Technology, China; [5]Kunming University of Science and Technology, China; [6]School of Physics, Peking University, China; [7]Beijing Institute of Technology, China; [8]School of Physics and Technology, Nanjing Normal University, China; [9]Taiyuan University of Technology, China; [10]Oak Ridge National Laboratory, United States

The nonadiabatic electron-phonon coupling (EPC) is ubiquitous in condensed matter physics and materials science, and plays a critical role in areas of transport scattering, conventional superconductivity, optical properties, spintronics, and quantum information. Particularly in van der Waals (vdW) heterostructures, the non-local interlayer EPC, which bridges electrons and phonons belonging to different layers, provides one unique channel to engineer these elementary particles, realizing emergent quantum behaviors. However, in-depth exploration of interlayer EPC effects is limited by stringent conditions for occurrence, and the efficient engineering of the interlayer EPC strength has remained elusive. Here we report a multi-tier engineering approach of studying the interlayer EPC in WS_2/hexagonal boron nitride (h-BN) heterostructures, including the isotope enrichment of h-BN substrates (h-^{10}BN and h-^{11}BN), temperature tuning, and application of high pressures. The hyperfine, robust isotope dependence of Raman intensities was unambiguously revealed in isotopically-engineered heterostructures. Combined with theoretical calculations, we anticipate that the WS_2/h-BN supercell could induce Brillouin-zone-folded phonons which contribute to the interlayer coupling, leading to complex nature of the broad Raman peaks at ~800 cm^{-1}. We further demonstrate the significance of a previously unexplored parameter, the interlayer spacing between WS_2 and h-BN. By varying temperature and applying high pressure, we can effectively manipulate the strength of the interlayer coupling with turn-on/off capabilities, indicating the critical thresholds of the layer-layer spacing for activating and strengthening the interlayer EPC. Our findings provide new opportunities to engineer van der Waals heterostructures with controlled interlayer coupling.

9:05 PM NM06.15.03
Additives and Post Treatments to Enhance Graphene Oxide Membrane Desalination Aaron Morelos-Gomez[1], Souya Terashima[1], Roque Sánchez-Salas[2], Rodolfo Cruz-Silva[1] and Morinobu Endo[1]; [1]Shinshu University, Japan; [2]University of Sussex, United Kingdom

Water is a natural source vital for a sustainable society. However, given climate change and population growth natural water source are being depleted. Therefore, seawater desalination may provide potable water. This can be performed by using membrane technology. Traditionally, these membranes are polymer-based. Unfortunately, they are prone to fouling and can exhibit low chemical stability, therefore, alternative membranes are needed. Graphene oxide (GO) is 2d-material that can be produced in large quantities and is easy to handle. We have developed an original method to make GO membranes by spray-coating. Over the course of six years, we have modified graphene oxide membranes by adding nanomaterials and surfactants, and with post treatments such as heating, plasma, divalent ion cross linking and solvent hydration. The data consists of a wide range of desalination performance from 40% to 90% NaCl rejection and permeate flux between 0.2 and 1 $m^3m^{-2}day^{-1}$, therefore GO membrane desalination is highly sensitive to the preparation method. In this work, we performed a statistical analysis on the obtained results to determine the most relevant factors for GO membrane desalination. For flux, the added nanomaterials and concentration exhibit the highest impact; and for salt rejection the GO concentration, number of coats and post treatment have the highest correlation. The identification of the most relevant parameters may serve as a guide to design GO membranes with higher desalination performance.

9:20 PM NM06.15.04
Room Temperature H_2S Gas Sensor Using One-Step CVD Grown MoS_2 and 2H - MoS_2/1T@ 2H - MoS_2 Heterostructure Swathy B. Saseendran[1], Anamika Ashok[1] and Asha A S[1,2]; [1]Cochin University of Science and Technology, India; [2]cochin university of science and technology, India

MoS_2; a 2D TMDC (Transition Metal Dichalcogenides) has attracted immense attention in energy storage devices, optoelectronic devices, optical switching devices, and gas sensors due to its unique physical and chemical properties. MoS_2 thin films and nanostructures can be synthesized by different physical and chemical growth mechanisms. CVD is one of the most effective methods to achieve large-area growth of atomically thin horizontal and vertical 2D TMDCs for device applications. The vertically aligned MoS_2 nanostructures are reported to have maximum edge sites, reactive dangling bonds, and high adsorption-desorption capacity, making them an attractive candidate for gas sensing. In CVD the growth conditions such as the temperature of the heating zone, growth duration, the pressure inside the tube, and the carrier gas flow rate can be tuned to change the alignment and number of layers of MoS_2 thin films. In this work growth parameters such as temperature, Mo:S ratio, sulfur-source to substrate position, and growth time have been optimized for synthesizing few-layered vertically aligned MoS_2 thin films through a one-step CVD process. The formation of MoS_2 thin film was confirmed by the presence of and peaks in the Raman spectra. The presence of an intense (002) peak in the XRD pattern further indicates the formation of c- axis oriented MoS_2 thin film. FESEM and TEM images show an obvious evolution from horizontal to vertical morphology of MoS_2 nanoflakes with the variation in growth condition. The vertical morphology, provides a high rate of adsorption and desorption processes and outstanding gas sensing properties due to the presence of dangling bonds and higher aspect ratio. Herein, few-layered vertically aligned MoS_2 nanoflakes were obtained directly on Si/SiO_2 substrate

supported with interdigital Au electrodes and were used for gas sensing measurement. The fabricated MoS_2 sensor shows response towards H_2S at room temperature. However, sensors fabricated from 2D TMDCs suffered sluggish response and recovery time. Therefore to prevent homogeneous restacking and to enlarge the active surface area 2D/2D heterostructure was developed by decorating MoS_2 thin films on Si/SiO_2 substrate with the hydrothermally synthesized 1T/2H MoS_2 nanostructures. These 2D / 2D heterostructure-based gas sensors showed enhanced response and sensitivity towards H_2S sensing at room temperature and the architecture can be considered for developing efficient gas sensors.

9:35 PM NM06.15.05
Argon Plasma Thinning of Bi_2O_2Se and the Impacts on Transistor Performance Ming Gao, Wei Wei, Zhe Zeng and Chunxiang Zhu; National University of Singapore, Singapore

The argon plasma etching is used to uniformly thin thickness of as-exfoliated 2D Bi_2O_2Se nanoflake, because the interlayer binding energy of Bi_2O_2Se (76.8 meV/Å^2) is much larger than that of graphene (21.1 meV/Å^2) or MoS_2 (26.3 meV/Å^2) which makes it difficult to obtain ultra thin film. The clean surface morphology and good crystalline quality of Bi_2O_2Se nanoflakes after etching are obtained and characterized. The X-ray photoelectron spectroscopy results show that the O and Se vacancies on the top surface of Bi_2O_2Se nanoflakes are created during etching, which can be passivated by forming an ultrathin oxide layer with UV ozone treatment. The on-current/off-current (I_{on}/I_{off}) ratio of bottom gate Bi_2O_2Se FET increases with argon etching time, and is further improved by UV ozone treatment. Eventually the thickness-controlled Bi_2O_2Se FET obtains a high I_{on}/I_{off} ratio of $>5.0\times10^4$. Importantly, the variation trend of I_{on}/I_{off} ratio and the electronic transport properties for Bi_2O_2Se FETs are well described by parallel resistor model and corresponding energy band diagram. Moreover, the I_{ds}-V_{gs} hysteresis and its inversion with UV irradiation are interpreted by charges trapping/detrapping and tunneling mechanism, respectively.

9:50 PM NM06.15.06
Novel Two-Dimensional-Based Materials as Effective Electrothermal Agents for Advanced-Imaging-Enhanced Combination Cancer Therapy Maria P. Meivita[1], Denise Lee[1], Natasa Bajalovic[1] and Desmond K. Loke[1,2]; [1]Singapore University of Technology and Design, Singapore; [2]Office of Innovation, Changi General Hospital, Singapore

In clinical studies, the utilization of electrothermal agent (ETA) in cancer electrothermal therapy has shown promising results. The safety concerns are addressed by the rapid degradation of ETAs, but the electrothermal stability required for efficacious treatment is limited. On the other hand, slow degradation occurs in ETAs with high electrothermal stability. Limited solutions exist to address the balance between the high electrothermal stability and rapid degradation of ETAs. Herein, we report that the assembly of novel two-dimensional (2D) material types can accelerate the degradation of 2D materials, while also maintaining high electrothermal stability. Moreover, by utilizing specified 2D materials archetypes, advanced imaging can be achieved for cancer monitoring. Thus, this work not only introduces an 'ideal' ETA that avoids the limitations of ETAs, but also provides the proof-of-concept application of 2D-based materials in advanced-imaging-facilitated combination cancer therapy.

A GO/$CoMo_3S_{13}$ Chalcogel Heterostructure with Rich Catalytic Mo–S–Co Bridge Sites for the Hydrogen Evolution Reaction Thanh Duy C. Ha[1], Huu Ha Do[2], Heehyeon Lee[3], Thi Thu Ha Nguyen[4], Youngtak Oh[3], Soo Young Kim[5] and Myung-Gil Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Chung-Ang University, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of); [4]Hanoi National University of Education, Viet Nam; [5]Korea University, Korea (the Republic of)

Molybdenum disulfide (MoS_2)-based materials are extensively studied as promising hydrogen evolution reaction (HER) catalysts. In order to bring out the full potential of chalcogenide chemistry, precise control over the active sulfur sites and enhancement of electronic conductivity need to be achieved. This study develops a highly active HER catalyst with an optimized active site-controlled cobalt molybdenum sulfide ($CoMo_3S_{13}$) chalcogel/graphene oxide aerogel heterostructure. The highly active $CoMo_3S_{13}$ chalcogel catalyst was achieved by the synergetic catalytic sites of $[Mo_3S_{13}]^{2-}$ and the Mo–S–Co bridge. The optimized GO/$CoMo_3S_{13}$ chalcogel heterostructure catalyst exhibited high catalytic HER performance with an overvoltage of 130 mV, a current density of 10 mA cm^{-2}, a small Tafel slope of 40.1 mV dec^{-1}, and remarkable stability after 12 h of testing. This study presents a successful example of a synergistic heterostructure exploiting both the appealing electrical functionality of GO and catalytically active $[Mo_3S_{13}]^{2-}$ sites.

10:10 PM NM06.15.08
Threshold Voltage and On-Off Current Ratio Tuning of MoS_2 Transistor Fatemeh Khorramshahi; VTT Technical Research Center of Finland, Finland

Immunity to short channel effects and abrupt switching along with transparency and flexibility have made 2D molybdenum disulfide (MoS_2) transistors compelling to be used in digital logic circuits. However, difficulties in obtaining a positive threshold voltage (V_{th}) have hindered its application as in digital logics, an incorrect V_{th} can lead to large short-circuit power consumption during switching. Similarly, a poor ON/OFF current ratio (I_{on}/I_{off}) can cause impractically low output swings and high leakage.
In this work, we employed the strategy of tuning the work function of gate metal using an ALD-grown metal plus thinning the gate oxide dielectric in order to reduce the trap states to shift the threshold voltage towards the positive direction and increase I_{on}/I_{off}. To achieve that, two series of transistors were fabricated using a bottom gate structure on silicon substrates. The transistor's channel lengths varied from 1.5 um to 40 um and the channel widths varied from 10 um to 160 um. In one series of transistors, niobium was deposited as the gate metal and 35 nm aluminum oxide (Al_2O_3) was used as the gate dielectric. In the second series of transistors, titanium nitride (TiN) and 12 nm Al_2O_3 were used as the gate metal and the gate dielectric respectively. A CVD-grown multilayer MoS2 was wet transferred to the structure and used as the gate channel.
The electrical characteristics of the transistors were measured in the ambient environment and under dark conditions. A virtual source (VS) model was used to fit a curve on the measured data. The extracted transistors parameters from the fitted curves for the two series of transistors were compared. It was observed that the device performance enhanced significantly when TiN and thinner Al_2O_3 were deposited as the gate metal and the gate dielectric. While as-fabricated devices with Nb and 35 nm Al_2O_3 showed a negative threshold voltage of ~ -3 V, the device threshold voltage shifted toward the negative direction over time and by keeping the sample in the ambient environment. The I_{on}/I_{off} of these devices did not exceed 10^4.
The transistors using TiN gate metal and 12 nm Al_2O_3 with the W/L ratio of 160/10 showed the ON-OFF current ratio of 10^6 with the ON current of 11.4 uA at V_{ds} of 1 V and V_{gs} of 5 V and the threshold voltage of 1.1 V. The average threshold voltage of the transistors fabricated using TiN gate metal and thin Al_2O_3 dielectric layer for different W/L ratios was 1.3 V. We were able to adjust the threshold voltage to the positive values and tune the on-off current ratio across 10^4 to 10^6. This study shows a comparably simple strategy for the fabrication of MoS_2 transistor for low power consumption logic circuits for industrial applications.

10:15 PM NM06.15.09
pH Sensing Performances of CVD Graphene-Based ISFETs with High Stability Zhe Zeng, Wei Wei, Ming Gao and Chunxiang Zhu; National University of Singapore, Singapore

This work aims to investigate the pH sensing performances of CVD graphene, develop highly stable graphene-based ISFETs with reduced drift and hysteresis effects and further improve the sensing performance by applying plasma treatments on graphene. The advantage of graphene is its robust honeycomb ring structure formed by tightly bonded sp^2 carbons, which makes it a super barrier against diffusion species like water. This property addresses the stability issues of ISFETs, which are mainly caused by the slow penetration of water and water-related species into the gate sensing oxide in traditional ISFET structures. As a result, graphene-based ISFETs exhibit low drift rates, normally below 1 mV/hr, and small hysteresis widths within 3 mV, which is competitive among most metal oxides. Besides, a fresh polycrystalline CVD-grown graphene with minor oxidation is less sensitive to pH with about 5 mV/pH, however, we could tune up the sensitivity by surface oxygen plasma treatments, resulting in as high as 40 mV/pH with high stability and reliability. Lastly, we have also demonstrated a reference-electrode-free ISFET that comprises two graphene sensing films with different sensitivities, exhibiting a drift rate as low as 0.38mV/hr, which can be an example of future development of graphene-based ISFETs.

10:20 PM NM06.15.10
Signatures of Rashba Effect in Angle Dependent Magnetoresistance Anshu Gupta and Suvankar Chakraverty; INST mohali, India

We have studied the angular dependence of the longitudinal and planar magnetoresistance at the conducting interface of $LaVO_3$-$KTaO_3$ having strong spin-orbit coupling strength. The system exhibited negative longitudinal magnetoresistance, planar Hall effect and anisotropic magnetoresistance which are the signature of chiral anomaly. The observance of negative magnetoresistance for all in-plane angles is unusual feature. These features are of quantum origin arises from strong spin-orbit coupling and pave a path to engineer non-magnetic materials as sensors for vector magnetic fields.

10:25 PM NM06.15.11
Enhanced Photoresponsivity by Photovoltaic Effect in MoS_2/WSe_2 Heterostructure Seokwon Choi; Department of Electrical and Computer Engineering, Sungkyunkwan University, Korea (the Republic of)

There are various types of photosensors that can be classified according to sensing mechanisms such as photoelectric or photochemical effects, or various performance metrics such as spectral responses. Two-dimensional transition metal dichalcogenides (2D TMDs), such as MoS2 and WS2, are widely known as photoabsorbent material in photodetectors. Most of the reported MoS2 photodetectors has disadvantages of quantitative control due to their photo gating effect. These devices typically suffer from poor responsivity and response speed and low on/off ratio. To solve these shortcomings, van der Waals (vdW) heterostructures can be utilized. Van der Waals heterostructures provide a unique platform for next-generation optoelectronics with unique flexibility and high performance with two-dimensional materials integrated with a variety of functional materials

In our study, we demonstrated a high-response photodetector with MoS_2/WSe_2 heterostructure on Al_2O_3 insulator. While using single layer MoS_2 as a channel, a photodetector is fabricated by covering MoS_2/WSe_2 van der Waals (vdW) heterostructure, which facilitates efficient separation and transportation of photogenerated carriers based on photovoltaic effect. By fabricating MoS_2/WSe_2 heterostructure on top of Al_2O_3 insulator, the photodetector can get higher on-off ratio and high responsivity. It shows a high responsivity of 80 mA/W and 30 mA/W with a 638 nm laser, which is 20-times higher than traditional MoS_2 photodetectors, and it also demonstrates the advantage of an improvement in photocurrent ratio resulting from the enhancement of on-current by more than 10-times. This mechanism is expected to be applied to increase the efficiency of photodetectors as well as electric devices such as solar cells

10:30 PM NM06.15.12
Defect Engineed 2D Layered Double Hydroxide Electrocatalysts for Improved Water and Biomass Electro-Oxidation Muhammad Zubair and Nicholas Bedford; University of New South Wales, Australia

Layered double hydroxides (LDHs) are promising materials due to their ability to modulate metal chemistries within 2D lattice that allows an optimized structure and electronics for the limiting oxygen evolution reaction (OER) and alternative biomass electro-oxidation. Substantial efforts have been devoted in developing transition metal (double) hydroxide based electrocatalysts for oxygen evolution reaction (OER) in alkaline electrolyte. Still, the fundamental understanding of electrocatalytic structure and its influence on reactivity is limited, particularly in electrochemical biomass conversion reactions. The most common LDHs for electrochemical conversions employ a base structure of M^{2+}/M^{3+} hydroxides using Co, Fe, and/or Ni, where reaction performance can be improved with the inclusion of high valency metal dopants, modulation of the interlayer spacing/anion chemistry and heterostructuring onto various substrates (e.g., graphene, carbon nanotubes). Though relatively understudied, the incorporation of oxygen vacancies (V_O) have also shown the ability to greatly improve the electrochemical performance. From a fundamental prospective, the precise role of V_O is not well elucidated, leading to lack of atomic-scale insights needed for further electrocatalyst development for OER and biomass electro-oxidation. Here we report, an alternative approach to elucidate electrocatalytic structure and activity relationships in Cerium and lanthanum doped transition metal (such as Co, Ni, Fe) based layered (double) hydroxide electrocatalyts. High resolution TEM, EDX mapping and AFM revealed layered structure with uniform incorporation of Cerium/Lanthanum in layered structure. High Energy XRD derived pair distribution function (PDF) analysis described the long range crystalline nature of as synthesized LDH materials. The electrochemical performance tests revealed Cerium/Lanthanum doping is not only beneficial for OER but also synergetic to biomass conversion. The atomic level structural insights through in-situ X-ray absorption spectroscopy allows density functional theory (DFT) to predict synergetic role of Cerium. These atomic level structural atrributes correlated with electrocatalyst activity are essential for rationally design low cost, able to generate high current density with low overpotential and long term stable electrocatalysts to meet practical requirements. Taken together, our work not only demonstrates the ease of V_O generation through Ce doping but provides further atomic scale insights needed to guide future LDH development for OER and other potential electrooxidation reactions.

Two-Dimensional Materials Based On-Skin-Wearable Electronics Shideh Kabiri; Queen's University, Canada

In the last two years we have witnessed the quick transition to remote and virtual life in various aspects such as education, work, healthcare and even entertainment. We have realized how reliable and high-performance wearables can influence the quality and accessibility of health care.
Ideal and practical wearables can be imagined as accurate, multifunctional, low weight, comfortable to wear, affordable and even visually imperceptible to

offer privacy and mental comfort to users.
Conventional electronics made of rigid metal and semiconductors are performant and well-established but when it comes to sensing and functioning at the interface with soft tissues and body, they lack the mechanical compatibility results in poor sensing and electrical performance, irritation and in the case implantable devices creating scar tissue and triggering foreign body reaction.
Two-dimensional materials are a group of atomically thin materials with a wide range of electrical, optical and mechanical properties that make them excellent candidates for making on-skin wearable electronics and sensors.
Here, we present: 1) a group of skin-soft, ultrathin, stretchable and visually imperceptible on-skin-wearable sensors for physiological sensing that can conform to the microscopic features of skin; and 2) a methodology for fabricating two dimensional based ultrathin and stretchable electronics circuits, mechanically compatible with such skin-soft wearable sensors. Minimizing local strain in the vicinity of the electronic circuit's active devices using our strategy, results in stable operation of the circuits under various forms of deformation during daily activities. This platform paves the way for the fabrication of fully integrated ultrathin stretchable and visually imperceptible wearable sensor-circuits.

8:30 AM *NM06.16.02
Low-Power Artificial Neural Networks and Logic-in-Memory Circuits with Monolayer MoS_2 Andras Kis; Ecole Polytechnique Federale de Lausanne, Switzerland

Machine learning and signal processing on the edge are poised to influence our everyday lives with devices that will learn and infer from data generated by smart sensors and other devices for the Internet of Things. The next leap towards ubiquitous electronics requires increased energy-efficiency of processors for specialized data-driven applications. I will present here how we realised an in-memory processor fabricated using a two-dimensional materials platform can potentially outperform its silicon counterparts in both standard and non-traditional Von Neumann architectures for artificial neural networks. The circuits are based on a flash memory array with a two-dimensional channel using wafer-scale MoS_2. Simulations and experiments show that the device can be scaled down to sub-µm channel length without any significant impact on its memory performance.

9:00 AM NM06.16.03
Large Area Growth of Single Phase Transition Metal Tellurides Nanosheets Through Simulation Guided AP-CVD Tellurization Alessio Lamperti[1], Pinaka Pani Tummala[1,2,3], Sara Ghomi[1,4], Carlo S. Casari[4], Christian Martella[1] and Alessandro Molle[1]; [1]IMM-CNR Agrate Brianza, Italy; [2]Università Cattolica del Sacro Cuore, Italy; [3]KU Leuven, Belgium; [4]Politecnico di Milano, Italy

Among transition metal dichalcogenides, transition metal mono- and di-tellurides (TMTs) are the subject of a significant attention due to their intriguing polymorphic nature from semiconductor to metal and topological Weyl semimetal. To date, considerable efforts have been devoted to synthesizing single phase TMTs nanosheets with superior quality and lateral extension suitable for device integration in nanotechnologies and fundamental investigations. Ambient pressure chemical vapor deposition (AP-CVD) is an easy and cost effective method for synthesizing TMTs nanosheets up to the centimeter scale, due to its high flexibility. Here we report on AP-CVD large area growth and
selective phase tuning strategies combined with finite element simulations for obtaining single phase TMTs nanosheets by design via tellurization of a predeposited metallic thin film by e-beam evaporation. In particular, we demonstrate the capability to obtain $MoTe_2$ in pure 1T' and 2H phase, $PtTe_2$ in 1T phase and $NiTe_2$ in 1T phase. In all cases, the AP-CVD tellurization makes use of Te solid powder as source for the generation of Te vapors and Me (Me: Mo, Pt, Ni) thin films of variable nominal thickness from 4 to 10 nm, on SiO_2/Si substrates.
Considering $MoTe_2$ case as an example, we also show a detailed study of the heterogeneous vapor-solid reaction between the pre-deposited Mo film and Te vapor optimizing the scalability and quality of the $MoTe_2$ nanosheets. Specifically, with simulation based on finite element method, for a given growth temperature, we show $MoTe_2$ structure and morphology are kinetically dictated by the distribution of the Te concentration gradient on the reaction site with varying geometric configurations inside the CVD reactor. Further, the role of temperature and Te concentration is elucidated for the other cases to achieve $PtTe_2$ and $NiTe_2$ growth. We characterize the so-grown nanosheets by using several techniques, such as Raman visible spectroscopy, atomic force microscopy, X-ray diffraction and transmission electron microscopy. By combining the results we could retrieve the structure of the different TMTs nanosheets in terms of their crystalline phase and crystallinity, thickness (number of layers), morphology, RMS roughness and domain (grain) size. In synthesis, we obtain nanosheets in pure single phase, with a polycrystalline character related to the pristine metallic thin film, with RMS roughness limited to few nm and a grain size in the tenth to the hundreds nm range.
Our study elucidates a methodological approach that could be considered as an efficient, scalable, and relatively simple solution to enable the controlled growth and optimize the characteristics of TMTs, and in extension TMDs, over large areas, whenever a tellurization (chalcogenization) CVD based process is considered. Furthermore, this concept provides a pivot scheme for enabling scalable integration of TMTs exhibiting single phase in potential applications for novel micro- and nano-electronics, spintronics, photonics, and thermoelectric devices.

9:15 AM NM06.16.04
Molecular Layer Deposition Approach for Hybrid Metalorganic-Inorganic Systems— Thin Film Oxides Functionalized with a Luminescent Europium Complex Monolayer Anna L. Pellegrino[1,2], Adolfo Speghini[3,4], Guglielmo G. Condorelli[1,2] and Graziella Malandrino[1,2]; [1]Università degli Studi di Catania, Italy; [2]INSTM UdR Catania, Italy; [3]Nanomaterials Research Group, Department of Biotechnology, Italy; [4]INSTM RU Verona, Italy

The organic-inorganic hybrid systems have attracted great attention because of their potential applications in several fields of material science such as sensors, dye sensitized solar cells (DSSCs), optoelectronic devices, and heterogeneous catalysis. In these systems, transition metal oxides thin films are the most promising inorganic materials, due to their wide spectrum of magnetic, electrical, and optical properties. Nickel oxide has been chosen as the inorganic component of the hybrid system due to its multifunctional properties such as high dielectric constant, low resistivity and UV optical transparency.
The most common functional organic moieties chosen for the hybrid approach are the molecules having silane, thiol and carboxylic functionalities as anchoring groups. Among these, the attention has been devoted to luminescent lanthanide complexes due to the exceptional photophysical properties such as high quantum yields and sharp emission profiles related to f–f electronic transitions. Eu(III) complexes have attracted growing interest as efficient downshifter and as a probe to sense the chemical environment.
For a variety of applications, the possibility of a fast, high efficiency and reproducible assembly method of molecules into nanostructured solid substrates is of great importance. Molecular layer deposition (MLD) is a solvent free method to create conformal coatings of organic molecules layers through self-limiting reactions on the surface and with an excellent molecular-level control of thickness and composition.
In the present work, we applied for the first time a full vapor phase approach based on the sequential steps of (i) Metal-Organic Chemical Vapor Deposition (MOCVD) of the inorganic NiO thin films, and (ii) MLD to link, in a covalent way, on the activated surface an Eu(β-diket)$_3$L complex, where β-diket is a β-diketone and L is a Lewis base. An accurate X-ray photoelectron characterization confirmed the optimal parameter conditions of the activation step and of the covalent anchoring of the luminescent europium(III) adduct on the NiO films. Emission spectroscopy of the hybrid NiO/Eu(III) system shows that an accurate control of the Eu(III) coordination sphere may tune the luminescence of the monolayers.

9:30 AM NM06.16.06

Schottky Barrier Variable Heterostructure Hydrogen Gas Detector through Electron Transfer between Pd NPs and Graphene Jihun Sim and Woojong Yu; Sungkyunkwan University, Korea (the Republic of)

Among future fuels that are in the spotlight, hydrogen has a dangerous side. The combustion rate and low flash point of hydrogen cause major explosion accidents. Therefore, leakage accidents are the most important issue in using hydrogen as a fuel. Therefore, a system that can detect hydrogen from very low concentrations is an essential problem.
Palladium (Pd) has the property of decomposing and bonding hydrogen molecules when exposed to hydrogen atmosphere. At this time, the volume changes at the same time as the bonding, and the energy structure of Pd also changes. Research on a system for sensing hydrogen using these properties of Pd has been conducted. In this study, we propose a hydrogen sensor attached to the surface of graphene by fabricating such Pd in the form of naoparticles (NPs).
In the case of Pd NPs, it has a larger surface area than that of Pd sheet, minimizing the effect of volume increase and maximizing the contact area with hydrogen molecules. Pd NPs were fabricated through the annealing process and were confirmed using electrical characterization and Scanning Electron Microscope (SEM). When Pd NPs are attached to graphene, electrons are moved between graphene and Pd NPs when the energy structure is changed as the Pd NPs adsorb hydrogen. This results in changes in the energy structure and surface conductivity of graphene. This change occurs with the concentration of hydrogen.
We fabricated a device using a heterogeneous structure of Silicon (Si) and Graphene. The two materials have the characteristics of a semiconductor and a metalloid, forming a Schottky barrier. Then, Pd NPs are attached to the graphene surface of the device. When the device is exposed to hydrogen, the Pd NPs adsorb hydrogen, which changes the energy structure of graphene. As a result, the Schottky barrier between Si and graphene changes and the current flowing through the device changes.
Using this principle, the reactivity to hydrogen is electrically detected with a Si/graphene heterostructure device. As a result of the detection, it was confirmed that it was possible to detect low-concentration hydrogen gas at a level of 250 ppm.

9:35 AM NM06.16.07
Conductivity Modulation of Solution-Processed Two-Dimensional Materials for Printed Electronics Development Songwei Liu[1], Xiaoyue Fan[2], Pengyu Liu[1], Jingfang Pei[1], Yang Liu[1], Lekai Song[1], Yingyi Wen[1], Gang Wang[2] and Guohua Hu[1]; [1]The Chinese University of Hong Kong, Hong Kong; [2]Beijing Institute of Technology, China

Printing of two-dimensional (2D) materials is emerging as a promising approach for scalable electronics manufacturing. The state-of-art advances, however, show inferior device performance due to poor electrical conductivity as a result of the discrete nature of the printed 2D material networks. Methods such as modifying the connections and alignments between the 2D material nanoflakes show limited enhancements. Here we introduce a ferroelectric polarization effect to overcome the conductivity limitation of printed 2D material networks and exploit this mechanism in printed electronics developments.

We start printed electronics fabrication with solution processing of 2D materials. The yield 2D materials are in an irregular, nanoscale dimension. Using MoS_2 as the example, we show that printed thin films from such nanoflakes give an extensively high electrical resistance due to the poor inter-flake contacts and the carrier transport of the nanoflakes. This makes it impractical to fabricate functional printed electronics. To address this issue, we couple the printed MoS_2 with ferroelectrics and show significant electrical resistance tunning from a high resistive state to a low resistive state, with a ratio of $>10^3$. We assume this arises from a complex mechanism of printed MoS_2 under the electric field. Our detailed density-functional theory calculations and spectroscopic characterisations suggest MoS_2 transition from a semiconducting state to a metallic state, driven by the localized electric field exerted by the nonlinear electric polarization of the ferroelectrics. The localized electric field can cause the electron cloud of MoS_2 to redistribute and form conductive electron gases on the surface or between the atomic planes. Such distortion in the electron cloud may deform the atomic structure of MoS_2, leading to a phase transition that can further promote the conductivity. Exploiting this transition, we demonstrate printed memristive electronics, for instance, ferroelectric tunnelling junctions, and show the possibility of implementing neuromorphic computing. Besides MoS_2, this transition mechanism may also be viable for other 2D materials (e.g. $MoTe_2$) and low-dimensional materials (e.g. CNTs).

Our approach to tune conductivity may serve as a universal strategy for modulating the properties of solution-processed low-dimensional material networks, and through printing, the approach can lead to scaled-up and even wafer-scale manufacturing of electronics that can find applications in, for instance, integrated and intelligent circuits, in-memory neuromorphic computing, and human-machine interfaces.

9:40 AM NM06.16.08
Bottom-up Assembly of Patterned Graphene/MoS_2 Heterostructures Xin Chen, Kathrin Knirsch and Andreas Hirsch; Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany

Combining two-dimensional materials into one vertical stack has evolved as an appealing strategy to modify the materials' properties and enable functional integrity and complexity. Among the heterostructures investigated so far, graphene/MoS_2 (G/MoS_2) heterostructures have drawn particular attention owing to their extraordinary properties and great potential for the use in high-performance devices.[1-2] The individual layers of such heterostructures are usually held together by van der Waals (vdW) forces. However, for most vdW interfaces, the structural disorders and contaminations induced by the integration steps are not rare, which are detrimental to the interface quality and would severely limit electronic communication and device efficacy. Here, we will present an efficient and facile approach to bottom-up construct covalently bridged G/MoS_2 heterostructures in a spatially defined manner. The formation of these patterned heterostructures was demonstrated by Raman and photoluminescence (PL) spectroscopies and Kelvin probe force microscopy (KPFM). Our approach enables the high throughput generation of covalent hetero-interfaces and precise transcription of spatial patterns from the bottom to the top layer of the heterostructures.[3] This covalent assembly concept has great potential to be extended to the construction of a broad array of two-layer or multi-layered covalent heterostructures, which is of great importance for future material design and engineering.

9:55 AM NM06.16.09
3D Printing of 0D-2D Material-Based Aerogels for High-Performance Room-Temperature Ammonia and Formaldehyde Sensing Zhuo Chen, Binghan Zhou and Tawfique Hasan; University of Cambridge, United Kingdom

Graphene-based aerogels are promising for gas sensing due to their high porosity, large surface area, and additive manufacturability of complex shapes through 3D printing. However, their performances are greatly hindered by graphene's intrinsically poor gas sensing capability and the lack of

understanding of the effect of aerogel morphology on mass transfer. We hybridize graphene with tin oxide quantum dots (QDs) and fabricate highly sensitive 3D-printed aerogel-based gas sensors. We quantitatively identify two factors that affect the gas sensing performance of the aerogels, namely cross-sectional area and surface porosity of the printed structures. Through Knudsen-diffusion-based modelling and empirical analysis, we show that filament-structured aerogel sensors with smaller cross-sectional area have response towards ammonia and formaldehyde which are significantly superior to widely demonstrated aerogel 'thin-film' sensors. Meanwhile, the gas sensing performance can be further improved by increasing the surface porosity of printed aerogels to enable more efficient gas diffusion. Our findings enable precise control of the morphology of printed aerogels for optimized gas diffusion and sensing. The proposed hybrid aerogel gas sensor shows ultrahigh response at room temperature to ammonia (14%, 1ppm) and formaldehyde (13.3%, 1ppm), the best for chemiresistive aerogel sensors. Our approach to hybridized QDs-graphene-based aerogels and printing-enabled morphological control provides a promising strategy to design high-performance room-temperature ammonia and volatile organic compounds (VOCs) gas sensors and beyond.

Boron Nitride on Sapphire a Scalable and Versatile van der Waals Template for Growth and Lift-Off of Thin Films and Devices Michael Snure[1] and Eric Blanton[2]; [1]Air Force Research Laboratory, United States; [2]KBR, United States

Van der Waals surfaces, such as graphene or hBN, offer a unique route to growth, lift-off, and transfer of a wide variety of thin film materials and devices. Specifically, sp^2 bonded BN is interesting due to its atomically flat and smooth surface, high temperature and chemical stability, excellent insulating and dielectric properties, and ability to be grown uniformly over large areas 4" by commercial techniques such as metal organic chemical vapor deposition. Here we will describe the use of boron nitride on sapphire templates for growth of a variety of electronic films including GaN, AlN, AlScN, and Ga_2O_3, Key challenges, including nucleation, template morphology, stability, and strain will be covered with the goal of achieving high quality films that can be easily lifted off and transferred. Mechanical lift-off techniques including both soft and spalling induced methods for transfer of full wafers, individual devices, and selectively defined areas will be discussed. Finally, we will cover bonding these thin layers to a variety of surfaces in order to create heterojunctions and integrate devices.

11:00 AM NM07.01.02
Graphene Nanopattern for Single-Crystal Film Growth, Defect Reduction and Layer Transfer Hyunseok Kim, Sangho Lee, Jiho Shin and Jeehwan Kim; Massachusetts Institute of Technology, United States

Thin film heterostructures are key building blocks for advanced electronic and optoelectronic devices. For this, direct heteroepitaxy has been pursued for decades, although it has been challenging to reduce crystal defects stemming from lattice mismatches and thermal mismatches between materials. The layer transfer method has been proposed as an alternative approach, wherein dissimilar materials are separately grown and then hetero-integrated. However, the applicability of layer transfer techniques is limited by several technical challenges, such as controllability, throughput, and damage to the substrate. Remote epitaxy, which is a recently developed method to produce single-crystalline membranes, is a promising approach but cannot be applied to elemental materials such as Si and Ge.
In this work, we report graphene nanopattern as a universal template for the growth of single-crystal thin films that can be exfoliated as a freestanding form. This is realized by the chemical inertness of graphene, which allows selective nucleation at the exposed region, followed by lateral overgrowth onto graphene to form a planarized thin film. By employing graphene nanopattern, both group IV and III-V materials are utilized as the substrate as well as the epilayer. The epilayer can be exfoliated at the graphene interface because partially covered graphene effectively weakens the interface, which is corroborated by theoretical analyses of spalling theory. We reveal that graphene nanopattern not only works as a weakened interface for exfoliation, but

also allows for dislocation reduction in heteroepitaxial films. This is because of the flexibility and the dangling-bond-free nature of graphene, which provides an additional path for strain relaxation. Therefore, these results represent a meaningful step toward production of high-quality single-crystal membranes that can be hetero-integrated.

11:15 AM NM07.01.03
Direct Writing of Graphene and Silicon Carbide Quantum Dots on an Elastomer by Laser-Induced Carbonization Shuichiro Hayashi and Mitsuhiro Terakawa; Keio University, Japan

Laser-induced carbonization has been emerging as a versatile method to simultaneously synthesize and pattern functional materials on polymers for the realization of bendable and stretchable devices. By simply irradiating a flexible polymer with a laser beam, the organic substrate can be modified into electrically conductive material, namely graphene, allowing for the rapid fabrication of flexible electronic devices. Recently, we have demonstrated the formation of fluorescent graphene quantum dots (GQDs) by the laser-induced carbonization of polydimethylsiloxane (PDMS), expanding the possibilities of laser-induced carbonization for the fabrication of, not just electronic, but optoelectronic devices. It has been well established that laser-induced carbonization of PDMS results in the formation of graphene and silicon carbide (SiC) crystals, and our results suggested that the formation mechanism of the GQDs was a top-down method based on the laser-induced pyrolysis of these materials. In this study, we demonstrate the selective formation of nanometer-sized SiC crystals by laser-induced carbonization of PDMS using a femtosecond laser. Laser pulses of varying energies were irradiated onto the PDMS surface to induce carbonization. Transmission electron microscopy (TEM) observations revealed that the fabricated structures were composed of few-layered graphene sheets containing SiC nanocrystals. The average size of the observed SiC nanocrystals varied depending on the energy per laser pulse used for fabrication, where larger SiC nanocrystals were observed for structures fabricated using higher energies. Moreover, photoluminescence (PL) spectra obtained from the structures indicated an emission peak distinctively different from that of GQDs, centered at ~450 nm (ex. 320 nm). Such emission peak has been commonly reported for SiC quantum dots. When electrical conductivity measurements were performed, the current increased linearly with applied voltage in the case of structures fabricated using relatively lower energies per laser pulse. Contrarily, the current increased exponentially with applied voltage in the case of structures fabricated using relatively higher energies per laser pulse, indicating semiconducting property. To the best of our knowledge, this is the first demonstration of the fabrication of structures exhibiting measurable semiconducting properties by laser-induced carbonization. For the ultrafast thermalization of materials due to ultrashort-pulse irradiation, the generated thermoacoustic stress waves can induce localized pressures in the MPa and GPa regime, particularly for shorter pulse durations and higher energies per laser pulse. Since high-pressure conditions are favorable for synthesizing SiC, it is inferred that SiC nanocrystals were more easily synthesized using femtosecond laser pulses with high energies per laser pulse.

SESSION NM07.02: Application of Various Dimensional Materials and Heterostructures I

Power Generation Using Non-Equilibrium Electron Gas Thermodynamic Cycle Mona Zebarjadi[1], Farjana F. Tonni[1], Kazuaki Yazawa[2] and Ali Shakouri[2]; [1]University of Virginia, United States; [2]Purdue University, United States

A thermal to electrical power generator is proposed recently that replicates the idea of the thermodynamic cycle of mechanical heat engines using an analogous electron gas.[1] The non-equilibrium electron gas is compressed using electrostatic gating, heated using a localized heat source, and released. The input heat power is converted to electrical power upon the electron gas expansion and cooling. The power is fully delivered to the load within a few picosecond time scales when electrons are relaxed and cooled down to the lattice temperature. The cycle is then repeated. We present a Monte Carlo simulation of power generation by such a non-equilibrium electron gas using GaAs-based heterostructures. Electrons are confined using an enforced one-dimensional potential well to form a 2D electron gas. The confined electrons' temperature is then raised to higher temperatures instantaneously, replicating a localized short heat pulse. The compressed hot electrons are then released and their positions are tracked via a Monte Carlo simulator coupled with a 1D Poisson solver. At room temperatures, we observe hot electrons are cooled to lattice temperature within 3 to 10 ps depending on the amount of their excess energy. A current-voltage pulse is delivered with about 0.4 ps delay (related to the device dimensions and drift velocity) to the load. The electrical energy delivered to the load increases quadratically with increasing temperature. The simulation results show that the proposed solid-state device is not limited by the Carnot efficiency due to its transient nature and can have more than 50% energy conversion efficiency.

2:00 PM NM07.02.02
Vertically Stacked Full Color Micro-LEDs via Two-Dimensional Material-Based Layer Transfer Jiho Shin[1], Hyunseok Kim[1], Junseok Jeong[1], Suresh Sundaram[2] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Georgia Tech Lorraine, France

Full color micro-light emitting diode (μLED) displays have been explored for augmented and virtual reality (AR/VR) applications that require extremely high pixels-per-inch (PPI). However, conventional manufacturing processes based on pick-and-place methods are slow and expensive, and their resolutions are insufficient to meet the required pixel densities. Recent demonstrations of vertical μLED displays attempt to address these issues by stacking freestanding red, green, and blue (RGB) LED membranes and fabricating top-down, but the absence of lift-off techniques to produce ultrathin, readily released, and low-cost layers of LEDs has delayed essential technological progress. Here, we report full color, vertically stacked μLED displays that achieve the highest pixel density (5100 PPI) and the smallest pixel size (4.5 μm) reported to date, which is uniquely enabled by two-dimensional material-based layer transfer (2DLT) techniques. 2DLT allows the growth of RGB LEDs with near-submicron thickness on 2D material-coated substrates via remote epitaxy or van der Waals epitaxy, mechanical release of LEDs from 2D materials, stacking of LEDs via adhesion layers, and top-down fabrication to yield vertical RGB pixels. The smallest ever pixel height of ~9 μm is the key enabler for μLED arrays with record high PPI. Facile mechanical release process allows high-throughput manufacturing of μLEDs, and the reusability of wafers reduces material cost. Wavelength-selective polyimide absorbers serve as adhesive interlayers as well as optical filters that prevent interference between LEDs, allowing further reduction in stack thicknesses. We also demonstrate a highly resolved transfer of μLED chips to illustrate the versatility of 2DLT for constructing large-scale μLED displays. These results not only establish routes to exceptionally high-pixel density full color μLED displays for AR/VR, but also offer a generalizable platform for broader classes of 3D-integrated systems.

2:15 PM NM07.02.03
Development of Mixed-Dimensional QDs/MoS_2/TiO_2 Heterostructured Resistive Random Access Memory with Interfacial Analog Switching Characteristics for Potential Neuromorphic Computing Shin-Yi Tang, Yu-Chuan Shih, Ying-Chun Shen, Ruei-Hong Cyu, Ling Lee and Yu-Lun Chueh; National Tsing Hua University, Taiwan

Resistive random access memory (RRAM) has been considered as one of the most promising candidates for next-generation nanoscale nonvolatile memory devices and neuromorphic computing applications. In this study, a novel mixed-dimensional design of heterostructured RRAM devices with the switching layer composed of 0D quantum-dots (QDs), 2D MoS_2 and TiO_2 is proposed and exhibited prominent interfacial switching behaviors. Continuous MoS_2 bilayer synthesized through the chemical vapor reduction (CVR) process is transferred on top of TiO_2/Pt, followed by the decoration of QDs and the deposition of ITO top electrodes, to realize the mixed-dimensional memory device. Compared to typical filamentary type RRAMs, the insertion of QDs/MoS_2 layer enables the bias-controllable interfacial resistive change during set and reset process without abrupt switching, resulting from the effective electron-hole pair separation upon excitation and the generation of a thin MoO_x layer due to the accumulation of oxygen ions at the interface between MoS_2 and TiO_2, which is also proven through HRTEM observations. In addition, the enhanced endurance, multilevel storage and analog synaptic characteristics with improved linearity in potentiation and depression are demonstrated to open up the opportunities of this heterostructured device for future neuromorphic applications.

InAs QD Layer Homojunction Combined with Zinc Oxynitride to Fabricate Phototransistors for Near-Infrared Sensing Applications Jong-Ho Kim, Byung Ku Jung, Su K. Kim, Kwang Ro Yun, Min-Gyu Jeon, Tae-Ju Lee, Soong Ju Oh and Tae-Yeon Seong; Korea University, Korea (the Republic of)

Amorphous metal-oxide semiconductor thin-film transistors (AOS-TFT) have been widely studied for applications in various fields, including display panel driving devices, biosensors, gas sensors, and optical sensors because of their scalability, low off-current, and high uniformity of performance. Recently, the integration of AOS-TFT with light-absorbing materials, such as colloidal quantum dots (CQDs), perovskite, and conjugated polymers, has been widely investigated to develop near-infrared (NIR) detection devices. CQDs are also actively studied for application in hybrid phototransistors because of their tunable bandgap and low exciton binding energy. However, the low mobility of QD layers and significant charge accumulation within the QD layer limit the performance of phototransistors. Further, AOS phototransistors have disadvantages such as limited detection wavelength (< 450 nm), modest field-effect mobility (~10 cm^{2}/Vs), and high persistent photocurrent (PPC) effect. The PPC effect is caused by the ionization of oxygen vacancy (V_O) under illumination, increasing the time to return to the initial state. Meanwhile, zinc oxynitride (ZnON) can be an alternative to solve most of the problems of AOS and QD layers. In ZnON, the PPC effect is suppressed because N 2p orbital covers V_O states. Further, since ZnON has high mobility (> 50 cm^2/Vs) owing to its low effective mass (0.19 m_e) and no potential fluctuations in conduction band minima, it can compensate for the low mobility of QD layers.
Thus, in this study, low toxicity and chemically stable InAs QD layers were combined with promising ZnON to fabricate a hybrid phototransistor. In particular, homojunction of InAs QD layers was for the first time applied to resolve the charge accumulation in QD layers. $InCl_{3}$ and 2-Mercaptoethanol (ME) were adopted as ligands for InAs QDs. To form the homojunction of QD layers, an InAs-$InCl_{3}$ layer was deposited over the InAs-ME layer. Three hybrid phototransistors (e.g., InAs-$InCl_3$/InAs-ME/ZnON, InAs-ME/ZnON, bare ZnON) were prepared and their performances were compared. The responsivity of InAs-$InCl_{3}$/InAs-ME/ZnON, InAs-ME/ZnON, and bare ZnON at the light intensity of 20 μW/cm^{2} was 2.59×10^{4}, 1.47×10^4, and 1.43×10^2 A/W, respectively. The detectivity of the InAs-$InCl_3$/InAs-ME/ZnON, InAs-ME/ZnON, and bare ZnON at 20 μW/cm^{2} was 4.86×10^{13}, 2.84×10^{13}, and 3.30×10^{11} jones, respectively. A comparison shows that the QD homojunction-based phototransistors exhibit much better performance than the other two samples. To understand the surface characteristics and hole blocking mechanism, the depth profile of ZnON was examined with time-of-flight secondary ion mass spectroscopy. Moreover, to confirm the formation of an InAs QD homojunction, the Fermi levels of InAs-$InCl_3$ and InAs-ME were measured and obtained to be 4.2 and 4.06 eV, respectively. They were found to have the same optical bandgap of 1.27 eV. Further, transmission electron microscope elemental mapping was used to confirm the uniform distribution and stacking of the InAs QD and ZnON layers. These results show that the integration of the InAs QD homojunction and ZnON could serve as an important component of phototransistors for the fabrication of high-performance NIR sensing devices.

3:15 PM NM07.02.06
Simultaneous Control of Nanowire Morphology and Doping in Mixed-Dimensional Heterostructures for Topological Quantum Computing Chunyi Huang[1], Didem Dede[2], Martin Friedl[3], Christopher E. Mead[1], Anna Fontcuberta i Morral[2,2] and Lincoln J. Lauhon[1]; [1]Northwestern University, United States; [2]EPFL, Switzerland; [3]Lumiphase Corporation, Switzerland

Templated networks of semiconductor nanowire networks[1,2] are a promising route to quantum computing through the manipulation of Majorana zero modes. These structures are inherently mixed dimensional; connected nanomembranes of GaAs are grown via selected area epitaxy in openings of lithographically patterned oxide masks, and one-dimensional InGaAs nanowires assemble atop the nanomembranes to define one-dimensional channels for electrons. The temperature and ratio of group III to group V elements are the primary variables used to tune the diffusivity of adatoms and control the faceting of the growth interface, directing the nanowire formation. In prior work, remote doping of the InGaAs nanowires was demonstrated, but control over the Si doping profile was limited by surface segregation,[2] and an ideal delta-doping profile was not achieved. In this talk, we report a new approach to the simultaneous control of nanowire morphology and dopant distribution using atom probe tomography to reconstruct buried growth interfaces and the distribution of dopants. InGaAs nanowires were again grown on GaAs membranes, but dilute Al marker layers were introduced at various stages to visualize buried growth interfaces, track the diffusion of dopants, design modified growth processes. After finding that Si segregates preferentially to different facets, we implemented a strategy in which dopants are trapped by dilute ternary layers ($In_xGa_{1-x}As$ and $Al_xGa_{1-x}As$) via increases in bulk solubility and/or modifications of the partition coefficient. Deposition of trapping layers was followed by the growth of GaAs spacer to separate the dopants (ionized impurities) from the channel. Si is incorporated at the onset of the trapping layer as intended, forming a narrow doping band several nanometers below the nanowire. A simple empirical model that assumes a linear dependence of the bulk solubility on Al concentration captures the resulting dopant profile, validating the principle of dopant trapping for controlled remote doping of nanowires grown on faceted supports. Such an approach can be generalized to other mixed-dimensional III-V heterostructures.

Nanostructured Manganese-Oxide/Reduced Graphene Oxide Hybrid Nanocomposites for Performance Enhancements of All-Printed Supercapacitor Devices Erick L. Ribeiro[1,2,3], Mahshid Mokhtarnejad[1], Dibyendu Mukherjee[1], Bamin Khomami[1] and Rigoberto C. Advincula[1,2,3]; [1]University of Tennessee,Knoxville, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Supercapacitor devices (SCs) have emerged as a promising energy-storage alternative that could enable the efficient utilization of electrical energy while fulfilling most of the technical specifications commonly encountered in the field of electronics. Additionally, SCs are essential for applications requiring high-power outputs and can be easily integrated into many complex electronic architectures, including small chips and flexible substrates. Nonetheless, alterations in the structural design of modern electronic devices to facilitate transportation and portability, especially inspired by the rapid expansion of the Internet of Things (IoT), have created strict requirements in dictating their operating conditions, consequently demanding engineers and scientists to explore novel functional materials and manufacturing approaches that go beyond the limits of the commonly-used power-source technologies. Herein, we present the synthesis of Hybrid Nanocomposites (HNCs) based on nanostructured Manganese Oxide species interfaced with reduced Graphene Oxide (rGO) for the fabrication of electrochemical active electrodes components in all-printed supercapacitor devices. Comprehensive structural characterizations demonstrate that the active material is composed of $MnOx/Mn_3O_4$ nanorods and nanoparticles embedded in rGO nanosheets. The development of such novel structures is facilitated by the extreme synthesis conditions (high temperatures and pressures) of the liquid-confined plasma plume present in the Laser Ablation Synthesis in Solution (LASiS) technique. Specifically, functional characterizations demonstrate that the performance of the active layer is highly correlated with the $MnOx/Mn_3O_4$ to rGO ratio and the morphology of $MnOx/Mn_3O_4$ nanostructures in HNCs. To that end, active layer inks comprising HNC samples prepared under optimal laser ablation conditions were dispersed into a percolated conductive network of electronic grade Graphene and Carbon Nanofibers (CNFs), which were subsequently applied to yield functional electrodes in an all-printed supercapacitor device. Electrochemical characterizations unequivocally reveal that the electrode composed of the LASiS-synthesized $MnOx/Mn_3O_4$-rGO HNCs exhibits a significantly higher charge storage capacity (325 F/g) when compared to the devices composed of electrodes containing commercially available nanostructured Mn_3O_4 -Graphene Nanocomposites (NCs) (189 F/g). Overall, the results presented here pave the way for use of LASiS as a facile methodology for the synthesis of functional nanostructured materials for applications in the additive manufacturing of next-generation energy-storage devices

Heterostructural Metal-Halide Perovskites for Optoelectronic Applications Hobeom Kim; Gwangju Institute of Science and Technology (GIST), Korea (the Republic of)

Metal-halide perovskites are interesting optoelectronic material as their dimensionality can be tuned by a facile chemical synthetic process to build a hybrid dimensional heterostructure. Plus, optoelectronic devices such as solar cells and light-emitting diodes (LEDs) using 3D perovskites as a photo-active material have shown great achievement in terms of their device performance. However, the 3D perovskites fundamentally suffer from their internal defects in the bulk and at the surface. For example, the presence of defects can cause quenching of charge carriers via non-radiative recombination channels to degrade the optoelectronic performance of the devices. In addition, the defects migrate to lead to peculiar electronic and optical behavior of the devices such as current-voltage hysteresis and luminance overshooting, which can seriously impact the stability of the perovskite optoelectronic devices accelerating their degradation. Thus, various strategies for defect passivation by using different classes of materials have been presented. Among them, here, we demonstrate the incorporation of 2D perovskites into the 3D perovskites to build 3D-2D hybrid or 3D/2D heterostructural perovskites. The mixed-dimensional perovskites prove to be effective in terms of suppression of defect or trap formation, and ion migration. Thus, LEDs and solar cells employing the mixed-dimensional perovskites exhibit improved optoelectronic characteristics and operational stability.

NM07.03.01
Versatile and Cost-Effective High-Resolution Patterning of Carbon Nanotube Composite via Intaglio Contact Printing Seokwon Joo[1], Ju-Hyung Kim[2,2] and Yoon-Kyu Song[1]; [1]Seoul National University, Korea (the Republic of); [2]Ajou University, Korea (the Republic of)

CNT is a promising material for next-generation electronics due to its unique properties such as mechanical strength, chemical stability, and environmental friendliness. Despite those superior characteristics, CNTs has been used to some limited applications due to a number of reasons – difficulty of patterning being the most critical among those. The traditional method for patterning CNT layers through photolithography provides high-quality CNT patterns, but has limitations in substrate, time, and cost. The solution process, which is a simple and cost-effective alternative, solves the limitation of the substrate as well, but has a disadvantage in dispersing CNTs in the solution that leads to films with non-uniform characteristics. In this work, we introduce a new method for printing high-resolution carbon nanotube (CNT) patterns on almost any type of substrates quickly and inexpensively.
To solve this CNT patterning problem, we employed paraffin, an oligomer, in CNT films. Molten paraffin as a solvent facilitates dispersion of CNTs than

other solvents because the chains of paraffin molecules surround the CNTs and weaken the van der Waals force, thus forms a well-dispersed CNT in CNT/paraffin composites. Since this method does not require mono-disperse CNTs, mixing takes only a few seconds of simple stirring. The CNT/paraffin composite slurry is filled in the intaglio of the PDMS stamp (≥56 °C, which is the paraffin melting point) and then transferred to the substrate. In this case, as the composite slurry is hardened while being attached to the surface of the substrate(≤56 °C), the adhesive force between the composite and the substrate increases. Through this, we enable printing of the CNT composites on various substrates, such as leaves, clothes, and skin, as well as glasses and metals. The use of paraffin also provides improved physical properties, fast processing time, and low cost. We also measure various properties of the composite – e.g. electrical resistance of ~14.6 Ω cm, the minimum line width of 7 μm, bending stability up to 12,000 cycles, and self-healing properties by heating over 56 °C. Subsequently, high-resolution CNT composite patterns on various substrates have been applied to several applications. An interdigitated pattern of CNT composite is used to fabricate a capacitive touch sensor and a water drop energy harvesting device. As the line-width being decreased and the number of fingers increased, the performances of the two devices improve. In the capacitive touch sensor, the non-contact and contact sensing method are implemented, and the sensitivity is enhanced by reducing the line-width (50 μm). A noteworthy point in water drop harvesting device is the substrate. By printing on fluorinated ethylene propylene, a substrate that is difficult to coat due to its low surface energy, the polarization with water droplets is enhanced and the output value increases significantly. In addition, we print patterns on clothes and fabricated triboelectric nanogenerators in contact-separation mode, showing the potential for development into wearable energy harvesters or sensors.
In conclusion, we introduce a method for printing CNTs on various substrates by mixing CNTs with paraffin. Through this method, it is possible to overcome the disadvantages of patterning CNTs via conventional methods. That is, high-resolution CNT printing is possible within a few minutes regardless of the substrate. It is also shown that patterned CNTs with the new method can be utilized in various applications. We anticipate this method will contribute to the development of patterning CNTs/CNT composites as well as the application of CNTs/CNT composites in the commercial domain.

NM07.03.02
Tetrazole-Based Metal-Organic Frameworks for Energetic Materials with Excellent Properties in Sensitivity Hae-Wook Yoo and Kuktae Kwon; Agency for Defense Development, Korea (the Republic of)

Metal-organic frameworks (MOFs) are a material with a great diversity of properties from diverse three-dimensional structures that can be achieved through the combination of various metals and organic materials, and are expected to be useful in a wide range of fields. In this study, MOFs structures with energy properties (eMOFs) were developed using tetrazole as an organic framework; 5-methyltetrazole (mtz) and 5-aminotetrazole (atz). Through combinations attempts with various metals, the eMOF-1 [$Mn_5(mtz)_{6.1}(atz)_{2.9}(NO_3)$] and eMOF-2 [$Cu(mtz)_2$] were successfully synthesized. The heat of formation for these materials was obtained by measuring the heat of combustion through bomb calorimeter(BCA), and this was introduced into the Explo 5 program to calculate explosive properties such as detonation velocity and pressure. In addition, by directly measuring friction, impact, and electrostatic sensitivity, the characteristics as energy materials were confirmed in all directions. In case of eMOF-1, it represented higher detonation velocity than TNT, a representative explosive, and to show excellent insensitivity characteristics. In the development of energetic materials, improvement in sensitivity characteristics at similar performance is a very important factor, and it was expected that eMOF could develop into a new field of energetic material development through this study.

NM07.03.04
Multifunctional Electrospun Nanofiber Air Filters for Removing Particulate Matter and Sensing Formaldehyde Gas Simultaneously Jin Yeong Song and Sang Min Park; Pusan National University, Korea (the Republic of)

Particulate matter (PM) and volatile organic compounds (VOCs) in contaminated air have harmed human health and the global biosphere. PM is defined as particles smaller than 10 μm in size and composed of ionic, metal, and carbon components. VOCs are invisible gases made up of dangerous CO, NO_2, and HCHO (formaldehyde). Many filters for treating PMs and VOCs, which cause a variety of ailments, have been developed, but people are still becoming exposed to these contaminants.
Electrospinning has been explored with significant interest among many methods for fabricating air filters because of its unique ability to produce nanofibers with adjustable permeability and porosity. Various electrospun nanofiber filters with better PM removal performance and lower pressure drops than commercial filters have been developed. However, electrospun nanofiber filters were challenging to maintain their morphology due to weak mechanical properties and be uniformly deposited on non-conductive substrates by instability from the electrospinning process.
Removing VOCs with adsorption frameworks is generally ineffective compared to PM removal. Meanwhile, colorimetric nanofiber membranes have been demonstrated for their rapid color changes induced by VOC reactions without the need for expensive equipment or a controlled environment. Still, these nanofiber membranes or mats have been revealed in treating one type of air pollutants, such as PM or VOCs.
In this study, we proposed a fabrication process of electrospun nanofiber filters that remove PM while also detecting formaldehyde gas. By our methods, fabricated nanofiber filters were uniformly and directly deposited on non-conductive masks and showed self-assembled structures that could possess a high PM removal rate and moderate pressure drop compared to commercial filters. As a representative indoor VOC capable of causing underlying death even at low concentrations, formaldehyde was also colorimetrically detected by changing the color of nanofiber filters that can effectively remove PM. As a result, the fabrication of an electrospun nanofiber filter that can simultaneously perform PM capture and formaldehyde detection in complex air pollution was successfully demonstrated. We believed that this fabrication process is pioneering work for producing nanofiber filters for capturing PM and synchronously sensing VOCs and that it could provide new insight into the production of multifunctional electrospun nanofiber filters.
This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. 2020R1C1C100944311) and BK21 FOUR Program by Pusan National University Research Grant, 2021. NM07.03.05
Heterointerfaces of Carbon Incorporated Ni_2P-Fe_2P Hollow Nanorods as Superior Electrocatalysts for Oxygen Evolution Reaction Siva Kumar Ramesh[1], Jihye Son[1], Vinoth Ganesan[2] and Jinkwon Kim[1]; [1]Kongju National University, Korea (the Republic of); [2]Kumoh National Institute of Technology, Korea (the Republic of)

The rational design of transition metal-based hollow nanostructures is critical for improving hydrogen production efficiency through water electrolysis and rechargeable metal-air batteries. In this study, a self-templating approach is reported to synthesize carbon-incorporated Ni_2P-Fe_2P hollow nanorods ($(Ni,Fe)_2P$/C HNRs) as efficient oxygen evolution reaction (OER) in alkaline solutions. First, a $Ni_2(BDC)_2(DABCO)$-MOF (Ni-MOF) is converted to NiFe-PBA hollow nanorods (HNRs) by anion ion exchange, followed by a subsequent phosphidation process to construct $(Ni,Fe)_2P$/C HNRs. Benefiting from the synergetic effect of heterostructure phosphide composition and unique hollow rod morphology, $(Ni,Fe)_2P$/C HNRs have a high specific surface area and superior electrocatalytic OER performance. The as-prepared $(Ni,Fe)_2P$/C HNRs exhibit OER performance with a small overpotential of 258 mV to reach a current density of 10 mA cm^{-2}, a small Tafel slope of 45.5 mV dec^{-1}, and long-term stability for 40 h, which significantly outperforms the $(Ni,Fe)_2P$/C NPs and commercial RuO_2. Post-XPS and SEM measurement of $(Ni,Fe)_2P$/C NPs indicates the robust nature of the catalyst.

NM07.03.06

2D Halide Perovskite Growth within Interlayer Spacings of van der Waals Substrates Saloni Pendse and Jian Shi; Rensselaer Polytechnic Institute, United States

Two-dimensional hybrid organic-inorganic perovskites (2D-HOIPs) have been extensively researched for use in solar cells as well as optoelectronic devices over the past few years. While various solution-based techniques have been explored and established for growth of 2D-HOIPs in polycrystalline and bulk form, studies of their growth in single-crystalline thin film forms have been limited. Here, we report a solution-based method for growth of 2D-HOIPs using muscovite mica as a van der Waals substrate that yields millimeter scale perovskite flakes. Interestingly, the grown 2D-HOIP flakes lie embedded within interlayer spacings of muscovite mica. We find that such 2D-HOIP flakes buried in mica demonstrate enhanced photostability in comparison to conventional 2D-HOIP flakes. Such liquid phase growth in the interlayer spacings of van der Waals substrates opens a new avenue for developing novel materials structure for designing high-performance optoelectronic devices.

NM07.03.07
An Experimental and Computational Approach to the Effective PEC Water Oxidation of Rh Deposited α-Fe_2O_3 Young-Min Kim[1], Ye-Rin Hong[1,2] and Yun-Mo Sung[1]; [1]Korea University, Korea (the Republic of); [2]KIST, Korea (the Republic of)

Among water-splitting metal oxide materials, hematite (Fe_2O_3) has been well known for its facile synthesis, low toxicity, and significant chemical stability, while fast recombination rate and sluggish electron transfer kinetics highly limit the carrier transfer. Introducing noble metal catalysts on metal oxide photoelectrodes is a common strategy for enhancing various water-splitting materials' photoelectrochemical (PEC) performances. Although the effect of various noble metals such as Au, Ag and Pt on the performance of Fe_2O_3 has been extensively studied in the aspects of catalytic performances and electron injections, Rh has been less investigated for photocatalytic applications.
In this study, we propose Rh as a promising candidate for enhancing the PEC capability of Fe_2O_3 photoanodes. The PEC performances of the Rh/Fe_2O_3 photoanodes were analyzed in detail by both experimental and computational approaches. The Fe_2O_3 nanorods were first fabricated using a two-step hydrothermal synthesis and subsequently the 2 nm-sized Rh clusters were deposited onto the Fe_2O_3 nanorods using the facile UV-assisted solution casting method. The electrochemical analyses were done to discover distinct charge separation mechanisms of the Rh cluster catalysts. In detail, electronic circuits were constructed using EIS analysis and the donor densities were determined from Mott-Schottky plots. The resulting electronic properties of Rh/Fe_2O_3 revealed that the Rh cluster is highly responsible for charge separation and hole transport, leading to significantly enhanced PEC performance. Owing to enhanced carrier generation and hole transfer, the optimum Rh/Fe_2O_3 showed a photocurrent density of 0.81 mA/cm^{-2} at 1.23 V_{RHE}, which corresponds to the 100% increase compared to the pristine Fe_2O_3 nanorod electrode.
In addition, we confirmed the role of the Rh cluster on the OER process using DFT calculations. The bulk and surface slab models were constructed based on the fabricated Fe_2O_3, with a preferred growth orientation of (1 1 0). The calculated free energy changes on each reaction step of pristine Fe_2O_3 (1 1 0) well corresponded to previous studies, showing a high OER overpotential of 0.80 eV at the OH* → O* step. On the Rh/Fe_2O_3 (1 1 0), the rate-determining step moved to the O* → OOH* step, and the OER overpotential was significantly reduced to 0.58 eV, indicating the lowered energy barrier of the OER process due to the catalytic performance of the Rh clusters.

Next-Generation Passive Cooling Textile with Targeted Optical Performances Kyuin Park and Margaret Frey; Cornell University, United States

Smart thermal management is a key to conserving energy use. Ironically, high-tech, active methods to cool down are considered superior to passive solutions in the battle against climate change. In recent years, the studies of passive radiative cooling (RC) have generated notable results and contributed to a net-zero-energy future.[1,2] These RC materials have heterostructures with mid-IR (MIR) (λ=8um~14um) transparency that allow dissipation of heat from the surface. Another approach to cooling is to prevent heating by reflecting the NIR radiation (λ=0.8um~2.5um) which accounts for 52% of the total solar irradiance. Recently, researchers have successfully improved the NIR reflectance and achieved 12 degrees Celsius cooling performance by incorporating nanofibers.[3] Unlike coatings, films, and membranes in 0D or 2D structures for RC applications, 2D matrices composed of continuous 1D nanofiber highlighted intrinsic physical and optical properties and the potential to widen applications into wearables and other textile systems. Thus, in order to amplify the effectiveness of passive cooling and to utilize the intrinsic properties of textile, this study presents a fabrication method and quantitative results for a next-generation, passive cooling textile by creating a heterostructure that targets two different radiation spectrums, MIR and near-IR (NIR).

Combination of NIR and MIR optical optimizations into a textile structure is not only beneficial in performance, but also promising. First, this textile structure is ideal for wide applications, unlike a 2D non-breathable membrane or 0D particle coatings that require substrates. Though a textile and a porous membrane may have similar optical performance due to similar roughness and voids, a textile structure allows moisture and air to permeate through, which improves convection and evaporation. Secondly, the surface of fibers provides a dimension to introduce another hetero-interface. With the added dimension, we have incorporated porosity and nanoparticles on an electrospun bio-based polymer, polylactic acid (PLA). Fibers with uniform and non-uniform diameters, various average diameters, and varying porosities were successfully fabricated by electrospinning. Optical analysis of a 10g/m^2 electrospun fiber sample using UV-Vis-NIR with integrating spheres showed ~80% reflectance in NIR. Additionally, there was no significant change in NIR performances when highly porous fibers with a pore diameter of 0.1μm were tested. With optimization of pores and nanoparticles, such as TiO_2, SiO_2, and Ag, we expect to observe significant effects in the full spectrum of radiation from UV to MIR. After optical evaluations, real-time outdoor thermal testing can be conducted to monitor the result with respect to time and temperature.

Further advancements in optical properties across the full spectrum of radiation have important implications in improving passive cooling methods. This study will strengthen the capability of passive thermoregulation methods for the human body and outdoor objects, such as buildings. Demonstrating fabrication methods and resultant prototypes would allow discussions among researchers in advancing heat regulation techniques, and furthermore, affect a wider scope of research and applications, such as solar absorber and aerogel-like barrier.

NM07.03.09
Photoelectrochemical CO2 Reduction Toward Multicarbon Products with Silicon Nanowire Photocathodes Interfaced with Copper Nanoparticles Inwhan Roh[1,2] and Peidong Yang[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The development of photoelectrochemical systems for converting CO2 into chemical feedstocks offers an attractive strategy for clean energy storage by directly utilizing solar energy, but selectivity and stability for these systems have thus been limited. A promising approach is to use a multicomponent system in which each individual component is optimized for a different aspect of the photoelectrochemical process. Here, we fabricate high aspect ratio

silicon nanowire (SiNW) arrays on a wafer scale to use as photocathodes for its favorable light absorption and charge separation properties and form a radial n^+p junction for increased photovoltage and stability. We then interface these photocathodes with a copper nanoparticle (CuNP) ensemble through a facile dropcasting method to drive efficient photoelectrochemical CO2 conversion to multicarbon products. This integrated system enables CO2-to-C2H4 conversion with faradaic efficiency approaching 25% and partial current densities above 2.5 mA/cm^2 at −0.50 V vs RHE, while the nanowire photocathodes deliver 350 mV of photovoltage under 1 sun illumination. Under 50 h of continual bias and illumination, CuNP/SiNW can sustain stable photoelectrochemical CO2 reduction. These results demonstrate the nanowire/catalyst system as a powerful modular platform to achieve stable photoelectrochemical CO2 reduction and the feasibility to facilitate complex reactions toward multicarbons using generated photocarriers.

Single-Atom Pt Stabilized on One-Dimensional Nanostructure Support *via* Carbon Nitride/SnO_2 Heterojunction Trapping Hamin Shin and Il-Doo Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Catalysis with single-atom catalysts (SACs) exhibits outstanding reactivity and selectivity. However, fabrication of supports for the single atoms with structural versatility remains a challenge to be overcome, for further steps toward catalytic activity augmentation. Here, we demonstrate an effective synthetic approach for a Pt SAC stabilized on a controllable one-dimensional (1D) metal oxide nano-heterostructure support, by trapping the single atoms at heterojunctions of a carbon nitride/SnO_2 heterostructure. With the ultrahigh specific surface area (54.29 m^2 g^{-1}) of the nanostructure, we obtained maximized catalytic active sites, as well as further catalytic enhancement achieved with the heterojunction between carbon nitride and SnO_2. X-ray absorption fine structure analysis and HAADF-STEM analysis reveal a homogeneous atomic dispersion of Pt species between carbon nitride and SnO_2 nanograins. This Pt SAC system with the 1D nano-heterostructure support exhibits high sensitivity and selectivity toward detection of formaldehyde gas among state-of-the-art gas sensors. Further *ex situ* TEM analysis confirms excellent thermal stability and sinter resistance of the heterojunction-immobilized Pt single atoms.

NM07.03.11
Tuning Nanowire Lasers via Hybridization with Two-Dimensional Materials Edwin Eobaldt[1], Francesco Vitale[1], Maximilian Zapf[1], Margarita Lapteva[1], Tarlan Hamzayev[1], Christof Neumann[2], Ziyang Gan[2], Emad Najafidehaghani[2], Antony George[2], Andrey Turchanin[2,3], Giancarlo Soavi[1,3] and Carsten Ronning[1,3]; [1]Institute of Solid State Physics, University of Jena, Germany; [2]Institute of Physical Chemistry, University of Jena, Germany; [3]Abbe Center of Photonics, University of Jena, Germany

Semiconductor nanowires have attracted great scientific interest due to their remarkable waveguiding properties and their intrinsic capability to lase under sufficiently high excitation, thus, paving the way towards nanoscaled coherent light sources and the realization of all-optical circuits. The spectral and temporal characteristic of single nanowire lasers have been extensively studied in the past decade. Today's research focuses on their effective integration into functional and nanoscaled environments. In this regard, the hybridization of semiconductor nanowire lasers with two-dimensional materials could offer new knobs to control and modulate lasing at the nanoscale through carrier transport at the heterointerface. We focused on hybrid systems containing ZnO nanowires on top of MoS_2 monolayers. As a consequence of their high optical gain supplied by the formation of an electron hole plasma, ZnO nanowires provide robust ultraviolet lasing emission at room temperature. On the other hand, MoS_2 monolayers emit light in the visible range which, in turn, does not spectrally overlap with the nanowire lasing emission. Additionally, the lattice constants of these materials match almost perfectly, making them ideal candidates for hybrid 1D-2D heterostructures. Our findings show a significant blue-shift of the nanowire lasing modes after the hybridization. Supported by photoelectron spectroscopy measurements, this blue shift can be assigned to the formation of a type II band alignment at the heterointerface, leading to an effective separation and transfer of electrons from MoS_2 to ZnO. This results in an increase of the ZnO optical band gap induced by the carrier injection into the nanowire conduction band, known as the Moss-Burstein effect.

NM07.03.12
An Enhanced Gas Sensor Based on Zig-Zag TiO_2 Nanorods (1D)–$BiVO_4$ Nanosheet (2D) Heterojunction Yuk YeonJi and Sanghan Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

The detection of low-concentration gases and odors in fields such as healthcare, mobility, and indoor environment control is attracting tremendous attention. Among various gases, oxidizing gas can cause damage to the human respiratory tract even quite low concentration. At present, oxidizing gas can be tested by gas sensors of all types, including semiconductor metal oxide (SMO), electrochemical, organic compound, optical and carbon-based gas sensor. Within them, SMO gas sensor have been widely concerned due to their advantages, such as simple device structure and manufacturing process, easy integration and suitable for online measurement. Various nanostructures have been investigated for oxidizing gas sensing performance, primarily in single oxides, such ZnO, SnO, Fe_2O_3, TiO_2 and $BiVO_4$ combining with different modification skills including constructing of complex multi-dimensional structures, loading of noble metal catalysts and doping of MOSs, etc. However, there are still great challenges for constructing high-performance oxidizing gas sensors. Representatively, poor active surface area of nanostructure and large energy band gap of SMO resulting low detection limit.
Recently, many researchers have attempted to overcome these issues. There are some strategies such as increasing active sites for adsorption of target gas and design of novel nanostructure via formation of heterojunction. Zigzag structure is one of the most effective structures that can expand the surface to volume ratio compared to other one-dimensional (1D) nanostructure like nanowires and nanorods. In addition, n-n heterojunction structure leads to energy band bending and high potential barrier at material interface, which improving resistance changes.
Herein, we demonstrated a gas sensor enhanced by fabricating heterojunction between 1D TiO_2 zigzag nanorod and two-dimensional (2D) $BiVO_4$ nanosheet on Si wafer. The 1D TiO_2 zigzag nanorods were realized on 2D $BiVO_4$ nanosheet by glancing angle deposition (GLAD) method using e-beam evaporation. Compared to the single TiO_2 zigzag nanorods, the TiO_2-$BiVO_4$ n-n heterostructures can induce a large quantifiable variation in resistance when the oxidizing gas adsorbed at the surface even at room temperature. This improvement is induced by increased depletion layer width at the surface and energy band bending between TiO_2 and $BiVO_4$ interface. Additionally, we performed the analysis about sensing properties including stability and response time at the room temperature.
We believe that our study will be a cornerstone for the application of functional nanoscale heterostructures based on SMO to gas sensor.

NM07.03.13
Hematite-Based Photoanodes Realized on Flexible YSZ Substrate for Photoelectrochemical Sensing of Hydrogen Peroxide Hwang Junbeom and Sanghan Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

One of important chemical, hydrogen peroxide (H_2O_2) is broadly utilized in the various field and it also considered as a kind of toxic chemical for living organisms. When H_2O_2 remains in overdoes in living organism can cause serious diseases, the fast and accurate monitoring of H_2O_2 is of great importance. At present, many methods have been developed successfully for the detection of H_2O_2 with high reliability and selectivity. Among them, photoelectrochemical (PEC) detection is a promising protocol owing to its high sensitivity, low background signal, easy operation and simple equipment. Among various semiconductor materials, hematite (α-Fe_2O_3) has been generally used in PEC application, due to its favorable band-gap (~2.1 eV), wide light harvest range, excellent chemical stability, elemental abundance, and low-cost. Recently, many studies have been reported to improve the sensitivity

of PEC H_2O_2 sensors and verify the reaction mechanism of detection of H_2O_2 with PEC sensors. Even so, owing to its intrinsic properties, α-Fe_2O_3 based photoelectrodes still have great challenges to achieve high efficiency before practical application. In addition, the photoanodes, which are synthesized on rigid substrates, such as glass-based FTO or ITO are hardly applicable to human-body contact bio-sensor because of its physical property. However, due to the high synthesis temperature of hematite (800 ºC), it is difficult to form high-efficiency hematite on polyethylene terephthalate or polyimide substrates, which are conventional flexible substrates. In order to overcome limitations above for practical application, yttria-stabilized zirconia (YSZ) substrate was adopted due to its intrinsic properties, such as superior thermal stability (~1450 ºC) and flexibility.
Herein, we successfully synthesized the high-efficiency hematite nanostructure photoanodes on flexible yttria-stabilized zirconia (YSZ) substrate via simple hydrothermal method. For the growth of hematite nanostructure, first of all, platinum/titanium (Pt/Ti) layer was grown on YSZ substrate via electron-beam evaporator. Pt/Ti bottom electrode also performed as a function of growth buffer layer and metal ion doping. By using the novel Fe_2O_3/Pt/Ti/YSZ (FPTY) photoanode, state-of-the-art PEC response toward H_2O_2 detection was achieved and also we evaluated the H_2O_2 sensitivity when the FPTY photoanode was bent and it was maintained as it is.
We expect that our study will open the way for the development of flexible H_2O_2 PEC sensor and be applied for the fabrication of next-generation electronic devices through follow-up studies.

NM07.03.15
Application of g-C_3N_4/Sn_3O_4 Heterostructure for Photoelectrochemical H_2 Generation Fernanda d. Romeiro, João A. Perini, Marcelo O. Orlandi and Maria Valnice B. Zanoni; UNESP, Brazil

The hydrogen gas (H_2) has attracted attention due to its environmentally friendly burn with no emission of greenhouse gases [1]. Among the nanostructured materials studied for this purpose, the n-type Sn_3O_4 has been recently applied for H_2 generation. To avoid rapid rate of charge carrier recombination and improve photoelectrochemical performance in Sn_3O_4, the construction of heterojunctions can be generally employed to overcome charge recombination at the interfaces of two semiconductors.
Herein, Sn_3O_4 and g-C_3N_4/Sn_3O_4 heterostructures were synthesized via the microwave-assisted hydrothermal method, while g-C_3N_4 was obtained by the heating of melamine. The g-C_3N_4, Sn_3O_4 and g-C_3N_4/Sn_3O_4 films for the working electrodes were prepared by spin coating. The photoelectrochemical tests for H_2 generation was performed using a solar simulator (300 W Xenon lamp) and a sealed photoelectrochemical reactor containing two compartments and equipped with a quartz window (electrolyte: 0.1 mol L^{-1} Na_2SO_4). The H_2 gas was identified and quantified using gas chromatography with a *thermal conductivity detector*.
The characterization of g-C_3N_4 by X-ray diffraction revealed peaks at 2θ = 13.1° and 27.4° corresponding to (100) and (002) hexagonal structure planes (JCPDS 87-1526), respectively; for the Sn_3O_4 and the g-C_3N_4/Sn_3O_4 materials, the diffraction patterns matched the triclinic structure (JCPDS 16-0737). The FTIR and Raman spectrum of the nanocomposites confirmed the obtainment of g-C_3N_4/Sn_3O_4 heterostructure. SEM and TEM images showed that g-C_3N_4 presented a two-dimensional structure consisting of micrometer-long wrinkled sheets (2D material), while the Sn_3O_4 3D nanomaterial is formed by petals-like morphology with nanometric thickness. In comparison to pure materials, the nanocomposite presented Sn_3O_4 nanopetals distributed over the g-C_3N_4 sheets, suggesting the effective formation of the g-C_3N_4/Sn_3O_4 heterostructure. The Sn_3O_4 presented a E_{gap}= 2.9 eV, while both g-C_3N_4 and g-C_3N_4/Sn_3O_4 possessed E_{gap}= 2.7 eV, indicating that all the photoelectrocatalysts showed promising application in the visible light region.
During photoelectrochemical tests the g-C_3N_4/Sn_3O_4 composite presented the highest photocurrent density of (1.2 mA.cm^{-2}). Transient photocurrent curves showed that the g-C_3N_4/Sn_3O_4 nanocomposite showed a quick response in the presence of light and back to zero when the light was turned off, indicating that the nanomaterial is sensitive to the UV-vis irradiation and presents faster charge separation [2]. Constant potential electrolysis experiments were performed (at 0.8 V vs Ag/AgCl, under UV-vis irradiation) for all samples and indicated their high stability. Nyquist plots showed that g-C_3N_4/Sn_3O_4 has lower electron transport resistance than the g-C_3N_4 and Sn_3O_4, indicating that its charge transfer is faster. The cumulative H_2 formation using all electrodes showed a stable production of H_2 for pure g-C_3N_4 and Sn_3O_4 materials within the investigated time period of 3 h, while for the g-C_3N_4/Sn_3O_4 a crescent generation of H_2 was observed until reach the maximum of 0.487 mmol L^{-1}. The H_2 production rate was nearly 4.4 and 4.8 times higher than the H_2 production using of g-C_3N_4 and Sn_3O_4 photoanode, respectively. This observation can be explained by the synergistic effect between Sn_3O_4 nanostructures and g-C_3N_4 nanosheets, in which the heterostructure exhibited efficient separation of photoexcited electron–hole pairs, which decreased the recombination rate and therefore promoted higher H_2 generation. Therefore, this study offers a promising strategy to synthesize effective and low cost photocatalyst for energy conversion applications, especially for H_2 generation.

NM07.03.16
Tailoring the Dielectric Contrast of Hierarchically Structured Photoelectrodes via Sol-Gel Synthesis of Ternary Metal Oxides Joseph J. Muhanga and Robert H. Coridan; University of Arkansas, United States

A common problem in photoelectrochemistry is that attractive thin film semiconductors for use as light absorbing photoelectrodes often have long characteristic absorption length and short minority carrier diffusion length. This is a particularly common combination of properties for chemically synthesized, nanoparticulate films formed via chemical synthesis. Strategies for increasing the incident photon-to-electron conversion efficiency (IPCE) in photoelectrodes often involve the use of multiscale porosity. The optical advantage of hierarchical nanostructure in these electrodes is that it induces light scattering to increase the effective path length in thin film light absorbers. More complex schemes induce modes of resonant light trapping (via photonic crystals, for example) to confine and concentrate incident light to small volumes of the electrode. The transition from a weak scattering structure to a strong one depends on the refractive index contrast between the electrode material and the surrounding electrolyte. The optical properties of these structures are predictable by electromagnetic simulations such as finite element methods. However, the continuously definable parameters in simulations do not directly translate to experimental systems due to the limitations of physically realizable materials. Here, we describe the experimental synthesis of ternary metal oxide composites (Ta-Ti-O, for example) via sol-gel synthesis as an experimental approach to tailor the refractive index contrast in hierarchically structured photonic glass electrodes. The difference in refractive index between TiO_2 (n = 2.5) and Ta_2O_5 (n = 2.1) or Ga_2O_3 (n = 1.9) enables nearly continuous control over the *effective* refractive index in that range. Sol gel infiltration in colloid-templated structure allows this control to be integrated into a three-dimensional electrode structure. We will show how simulation and experimental results can elucidate the connection between the synthesis and optical properties of thin film and three-dimensional structures. These materials can then serve as hierarchically structured transparent conductive oxide current collectors for photoelectrochemical and optoelectronic applications.

NM07.03.17
Machine Learning Methods for the Prediction of Solution Synthesis Parameters Stefan Wuttke[1], Manuel Tsotsalas[2] and Pascal Friederich[2]; [1]BCMaterials, Spain; [2]Karlsruhe Institute of Technology, Germany

Despite rapid progress in predicting materials properties, the potential of using machine learning (ML) methods to predict optimal synthesis parameters is still untapped. In Luo et al. [1], we demonstrate how ML can be used for rationalization and acceleration of the discovery process of metal-organic frameworks (MOFs) by directly predicting the synthesis conditions of a MOF based on its crystal structure. Our approach is based on: i) establishing the first MOF synthesis database via automatic extraction of synthesis parameters from the literature, ii) training and optimizing ML models by employing the MOF database, and iii) predicting the synthesis conditions for new MOF structures. The ML models, even at an initial stage, exhibit a good prediction

performance, outperforming human expert predictions, obtained through a synthesis survey. The automated synthesis prediction is available via a web tool on https://mof-synthesis.aimat.science. The methods presented in this work are not application-specific, and thus can be transferred to other materials classes.

NM07.03.18

A Strategy to Enhance Humidity Robustness of P-Type Sensors for Breath Acetone Quantification Dina N. Oosthuizen[1], Ines C. Weber[1,2] and Sotiris E. Pratsinis[1]; [1]ETH Zurich, Switzerland; [2]University Hospital Zurich, Switzerland

The compounds present in human breath can be exploited to give physiological information to indicate the early-stage development of diseases and assist in guiding their therapy [1]. Specifically, breath acetone is a promising biomarker for non-invasive fat metabolism monitoring [2]. Portable, low-cost, low-power gas sensors for non-invasive medical diagnostics [3] should have a low operating temperature (i.e., power consumption). However, only a few low-temperature semiconducting metal oxide (SMOx) sensors (Pt/Sb_2O_3-Fe_2O_3 [4] and $BaSnO_3$ [5]) so far, as most sensors have insufficient robustness to humidity (i.e., poor sensor stability), and, to our knowledge, none of these sensors could quantify acetone concentrations in breath.

Heterostructure materials have been proposed to effectively eliminate the humidity cross-sensitivity of SMOx sensors, specifically CeO_2 and either In_2O_3 [6] or SnO_2 [7], for the humidity-robust detection of acetone and trimethylamine. Flame spray pyrolysis (FSP) technology enables the production of sensors with unprecedented performance [8], with control over the composition and morphology of the sensing materials.

Here, we introduce a low-power sensor operated at 150 °C that detects acetone with high sensitivity (i.e., down to 50 ppb) at 90% relative humidity (RH). It consists of a Ce–doped CuO nanoparticle sensing film deposited directly by single-step flame spray pyrolysis (FSP), as determined by XRD and XPS analysis. Most remarkably, this sensor features excellent selectivity towards key inorganic breath interferants in gas mixtures even at orders of magnitude higher concentrations (i.e., up to 20 and 25 ppm of H_2 and CO). In addition, it showed increased humidity robustness to changes in humidity between 10 and 90% RH, which is likely due to the presence of CeO_2 nanoclusters [6]. Finally, this sensor accurately detected acetone concentrations in the exhaled breath of 16 volunteers (r = 0.95, bias and precision of 90 and 457 ppb) in a standardized setting (i.e., low breath ethanol concentrations (< 400 ppb)), despite the presence of various other breath components that typically interfere with acetone detection (e.g., isoprene). In addition, this sensor can detect even other organic volatiles such as ethanol, which may be interesting for other applications such as the automotive fuel industry [9]. In the case of breath acetone detection, where ethanol interference in the background is undesired, this can be circumvented by adding a filter upstream of the sensor [10]. As a result, this sensor is most appealing for integration into low-power and mobile health devices for continuous metabolic health monitoring.

NM07.03.20

Rational Discovery of Complex Chalcogenides Using Mixed Fluxes Xiuquan Zhou[1], Wenqian Xu[1], Maria K. Chan[1], Duck Young Chung[1] and Mercouri G. Kanatzidis[1,2]; [1]Argonne National Laboratory, United States; [2]Northwestern University, United States

Advancements in many modern technologies rely on the continuous discovery of novel materials. However, the design of synthesis routes leading to new and targeted solid-state materials requires understanding of reactivity patterns. The the extent of control and predictability of synthetic outcomes for extended solids composed of more than three elements compared to that for many molecular compounds is low. Consequently, exploratory synthesis is an invaluable tool for materials discovery--as the pioneer in this field, John Corbett, described “It is always difficult to predict the unimaginable”. Due to the knowledge accumulating from exploratory synthesis and the progress made during the past decades, predictive synthesis, including identifying composition and structure that confer the desired properties and synthesizing the desired targets, may soon be within reach. However, this requires the ability to understand and predict viable reaction pathways. Therefore, novel synthetic strategies to reveal effective reaction pathways that can add a more “rational” component to exploratory synthesis are required to accelerate materials discovery and achieve the ultimate goal—synthesizable materials by design. Advances in synthesis science are necessary to increase efficiency and accelerate materials discovery. We present a highly effective methodology for the rational discovery of materials using high-temperature solutions or fluxes having tunable solubility. This methodology facilitates product selection by projecting the free energy landscape into real synthetic variables: temperature and flux ratio. We demonstrate the effectiveness of this technique by synthesizing the chalcogenide system of *A*(Ba)-Cu-*Q*(O) (*Q* = S or Se, *A* = Na, K, or Rb) using mixed *A*OH/*AX* (*A* = Li, Na, K or Rb; *X* = Cl or I) fluxes. We present 30 novel compounds, including more than 10 unique structural types, by systematically varying the temperature and flux ratios without requiring changing the proportions of starting materials. In addition, we found that the structural dimensionality of the compounds decreases with increasing reactant solubility and temperature. Our methodology serves as an effective generic strategy for the rational discovery of inorganic solids.

Development of Flexible Super Hybrid Electrode for Auto-Defogging System for Windshields of Electric Cars Woo-Seok Cheong[1], Young-Hoi Kim[1] and Young-Shin Kim[2]; [1]ETRI, Korea (the Republic of); [2]Daeki hitec, Korea (the Republic of)

Transparent heaters have been developed by using various types of transparent electrodes such as indium-tin oxide(ITO), carbon nano tube(CNT), graphene, metal nanowire, metal grid(mesh), including hybrid transparent electrode. However, windshield transparent heaters for defogging can’t be realized by those transparent electrodes, because of high sheet resistance. Recently, we designed ‘super hybrid electrode(SHE)’, which could be made by combining metal grids with oxide/metal/oxide electrode based on a newly developed electroplating method[1]. In this work, we successfully developed ‘flexible-super hybrid electrode’ (F-SHE), using flexible substrate, high transparent photo-resist (PR) for realizing flexible transparent heaters. The highly transparent PR surrounding the metal grids could be bent due to the decrease of the mechanical stress, sustaining the good properties of the sheet resistance

and the transmittance. F-SHE film showed the extremely low sheet resistance (0.2 ~ 0.6 Ω/), high transmittance (over 80% at 550nm), and small critical bending radius (~3mm), which can be applied for the auto-defogging system of automobile windshield heaters.

Ref[1] W.S.Cheong, et al, *"High-performance transparent electrodes for automobile windshield heaters prepared by combining metal grids and oxide/metal/oxide transparent electrodes"*, Adv. Mater. Technol. 2019, 4, 1800550.

This work was supported by the R&D project of MOTIE/KEIT. [20019194, Development of auto defogging system for electric cars].

Flame-Made Nanoparticle Sensing Film Coupled with Catalytic Filter Detects Carcinogenic Benzene in Indoor Air Ines Weber and Sotiris E. Pratsinis; ETH Zurich, Switzerland

Metal oxide gas sensors comprising heterostructured sensing layers are most promising for detecting gases down to parts per billion (ppb).[1] However, these sensors typically lack sufficient selectivity in complex gas mixtures. To tackle this challenge, flame-made catalytic filters may be used upstream of the sensors[2]. These filters convert interfering species (e.g., ethanol[3]) to inert CO_2, while letting target analytes pass for detection by the sensor. Carefully tailoring the surface properties of such catalytic filters and nanoporous sensing layers allows to optimize their selectivity, as was demonstrated previously for the detection of acetone[4] in breath during exercise[5] and in diabetes[6].
Nowadays, selective sensing systems are urgently needed to monitor indoor and environmental air and warn us from toxic pollutants. For example, benzene is a highly toxic and carcinogenic air pollutant that causes leukemia[7]. More than 1 million workers are exposed routinely to carcinogenic benzene contained in various consumer products (e.g., gasoline, rubbers, dyes) and released from combustion of organics (e.g., tobacco). Hence, it requires real-time monitoring to mitigate health risks.
Here, we introduce a compact WO_3 nano-catalyst filter made by flame aerosol technology and couple it to a similarly made Pd/SnO_2 sensing layer[8]. Both sensor and filter are integrated into a handheld device that is operated through a raspberry pi microcontroller, while a pump at the sensor outlet provides a continuous flow. Thereby, the catalytic filter effectively removes all interferants (including alcohols, ketones, inorganics, and aromatics) while the benzene passes and is detected by the downstream sensor. Most importantly, when tested on benzene-spiked indoor air this detector accurately ($R^2 = 0.98$) tracks its concentrations even below legal limits (i.e., 50 ppb) and in the presence of orders of magnitude higher toluene and *m*-xylene concentrations ($R^2 = 0.94$), in good agreement with mass spectrometry. Hence, this detector is promising for on-site and real-time monitoring to prevent harmful exposure.

Anisotropic van der Waals Epitaxy and Sliding of $CsPbBr_3$ Microplatelets on $ReSe_2$ Noya R. Itzhak, Ifat Kaplan-Ashiri, Hagai Cohen, Irit Rosenhek Goldian, Olga Brontvein, Katya Rechav and Ernesto Joselevich; Weizmann Institute of Science, Israel

The growth of highly crystalline semiconductor nanostructures with low defect concentration is essential for realizing their optoelectronic properties and for their efficient integration into functional nanodevices. Our group has shown that nanowires can grow on a single crystal or amorphous substrates using covalent epitaxy and graphoepitaxy to generate well-aligned and guided nanowires with controlled crystallographic orientation. However, covalent epitaxial relations often induce strain and stress in the nanocrystals, leading to dislocations and other defects, which affect the physical properties of semiconductor nanostructures. Substituting covalent substrates with 2D van der Waals (vdW) layered materials could relieve stress and strain issues, as weaker interactions are formed between the top layer of the vdW material and the formed nanostructure. Therefore, we suggest extending the guided growth approach by using vdW epitaxy on 2D materials. Here we present the vapor-solid growth of micro- and nano-platelets of well-ordered cubic $CsPbBr_3$ on 2D layered triclinic $ReSe_2$ substrate. X-ray photoelectron spectroscopy (XPS) and cathodoluminescence (CL) measurements revealed type I band alignment, with energy transfer from the $CsPbBr_3$ platelets to the $ReSe_2$ substrate. Such heterostructure could be integrated into an enhanced photodetector compared to $ReSe_2$ based photodetector. To further investigate the vdW epitaxial nature of the heterostructure, we characterized the heterostructure interface by applying lateral force and sliding the $CsPbBr_3$ platelets on the $ReSe_2$ using atomic force microscopy (AFM). Our results indicate that some sliding directions are preferable to others, which could be attributed to the in-plane anisotropy of the $ReSe_2$ surface. These results open a route for the ordered design of heterostructure devices with interesting energy transfer mechanisms and improved optical and electrical properties owing to the lower miss-match stresses induced by vdW vs. covalent epitaxy.

Unveiling Ultrafast Exciton Polariton Dynamics in Large-Area van der Waals Superlattices Tzu-Yu Peng[1,2], Jason Lynch[3], Jing-Wei Yang[1,2], Yen-Yu Wang[1,2], Xing-Hao Lee[1,2], Deep M. Jariwala[3] and Yu-Jung Lu[1,2]; [1]Department of Physics, National Taiwan University, Taiwan; [2]Research Center for Applied Sciences, Academia Sinica, Taiwan; [3]Electrical and Systems Engineering, University of Pennsylvania, United States

The discovery and large-area synthesis of two-dimensional (2D) materials with controlled thickness, composition, and crystal quality open up a much wider range of possibilities for the hetero-integration of novel and multi-functional photonic platforms. In this work, we develop 2D chalcogenide materials, assemble them into superlattices with oxide materials, and investigate the strong light-matter interaction in this novel materials platform. The large-area superlattices were grown via artificial layering of the Al_2O_3 and monolayer WS_2.[1] The monolayer WS_2 can keep the direct bandgap properties to serve as an efficient emitter at a center wavelength of 611 nm. We performed the angle-dependent transient absorption spectroscopy (TAS) measurement to determine the carrier dynamics in the WS_2/Al_2O_3 superlattices (N= 5) coupled with a waveguide cavity. By using the femtosecond time-resolved pump-

probe TAS, we obtain the strong light-matter interaction induced upper (568 nm) and lower (629 nm) exciton-polaritons splitting in the designed WS_2/Al_2O_3 superlattices at a large incident angle of 80 degrees under TE polarized light. In addition, we observed ultrafast lifetime of upper exciton-polaritons reduced from 1 picosecond to 0.6 picosecond with an increase probe angle. Moreover, we found the quasiparticle competition behavior between the upper and lower exciton-polaritons, and there has a significant nonlinear effect can be observed. In the end, we will discuss the working mechanism of the carrier dynamics in large-area superlattices coupled with a waveguide cavity and the outlook for van der Waals superlattices.

NM07.03.25
Optical and Magnetooptical Effects of Epitaxial Grown Ce:YIG/YAG Yuki Yoshihara[1,2], Pang Boey Lim[2], Mitsuteru Inoue[1], Kazushi Ishiyama[1] and Taichi Goto[1]; [1]Tohoku University, Japan; [2]Toyohashi University of Technology, Japan

Magnetooptical effects can be applied to many dynamic optical/photonic applications, e.g., spatial light modulator [1] and optical Q-switch [2]. In these devices, the magnetooptical and light-emitting parts are usually separated. For instance, the magnetic film is separately placed in front of/behind the light sources. In these optical systems, all optical elements need to be aligned carefully to minimize the optical loss, preventing from miniaturization of the device and increasing the fabrication cost. Hence, integrating all-optical components into one chip provides a large advantage for developing optical applications. To demonstrate such an integration, we fabricated the cerium-substituted yttrium iron garnet (Ce:YIG) film on the yttrium aluminum garnet (YAG) substrate. Ce:YIG is widely known as a magnetooptical film showing a large Faraday rotation at the near-infrared wavelengths [3,4]. YAG doped with Nd is widely used as solid-state laser material. The Ce:YIG film was hetero epitaxially grown on YAG substrate using radio frequency ion beam sputtering. The Ce:YIG films were deposited onto double-side polished and (111) oriented YAG substrate. The temperature of the substrate was held at 850°C using the heater. The substrate size is 10 mm by 10 mm. The thickness of the grown film was about 2 micrometers.
The x-ray diffraction peak s at (444) and (888) were observed, and other peaks were not, showing a single crystalline garnet phase. The reciprocal space map of the Ce:YIG/YAG sample showed a relaxed crystalline state. The magnetic properties measured by vibrating sample magnetometer (VSM) showed a magnetization of 91 emu/cc. The Faraday rotation loop was measured using a magnetooptical measurement system at a wavelength of 1064 nm. The Faraday rotation angle of -0.94°/μm was obtained. The remanent and coercivity of Faraday rotation angle were 0.09°/μm and 125 Oe. Therefore, these results showed the first integration of Ce:YIG on YAG substrate as an important milestone in developing magnetooptical elements combined with a light emitting system.

Wafer-Scale Growth of Amorphous Boron Nitride Thin Films Hyeongjoon Kim, Minsu Kim, Kyung Yeol Ma and Hyeon Suk Shin; UNIST, Korea (the Republic of)

Amorphous materials have been widely studied in many fields. Among them, amorphous boron nitride (aBN) has recently attracted attention because of its excellent electrical (dielectric constant of 1.89, high breakdown field of 7.3 MV/cm) and mechanical property (high hardness > 11 GPa)[1]. In particular, its ultralow dielectric constant showed the potential for use as an interlayer dielectric (ILD in integrated circuits). However, a limitation in aBN study is that it is difficult to grow pure aBN thin films. In this presentation, we demonstrate the growth of 6-inch wafer-scale aBN thin films by plasma enhanced chemical vapor deposition (PECVD) and their uniformity of thickness and dielectric constant. We found that the formation of hBN nano-crystallites in the aBN thin films results in the increase of dielectric constant as the thickness of the aBN thin films increases. Thus, we show the relationship of three parameters: the thickness of the aBN thin film, the amount of hBN nano-crystallites, and dielectric constant of the aBN thin film. In addition, we investigated the thermal stability and the diffusion barrier performance of the aBN thin films to see if they can be used as a capping layer or ILD in back end-of-line (BEOL). Lastly, we show the control of the density of the aBN thin films by changing the experimental parameters such as plasma power and flow rate of borazine as a precursor because their density is related to the mechanical property. These results pave the way for the practical application of aBN as an ultra-low dielectric material for electronic devices.

Control of Degree of Structural Disorder in Amorphous Boron Nitride Film Minsu Kim, Hyeongjoon Kim, Kyung Yeol Ma and Hyeon Suk Shin; Ulsan National Institute of Science and Technology, Korea (the Republic of)

As the size of the device decreases, the 'resistance and capacitance delay (RC delay)' determines the operating performance of the chip. In order to reduce the RC delay, it is necessary to reduce the dielectric constant of the material deposited between the metal electrodes in the downstream process of the integrated circuit. Existing low-κ Si-based materials have been studied to increase porosity so far. As a result, the dielectric constant is close to that of air, but its commercial use is limited due to the weakening of mechanical properties due to the high porosity.
Recently, amorphous boron nitride (aBN) has been considered as a next-generation ultra-low-κ material [1]. In this presentation, we demonstrate the change in dielectric constant of aBN according to its degree of structural disorder. The dielectric constant of aBN increases as boron and nitrogen atoms have an ordered structure which appears with the formation of hBN nano-crystallites in the aBN thin film. Thus, we show changes in the degree of structural disorder and the dielectric constant of the aBN thin film when carbon element is doped into it.

Defect Seeded Remote Epitaxy of GaAs Films on Graphene Muhammad Zulqurnain, Oliver J Burton, Lucy E Goff, Mohamed Al-Hada, Stephan Hofmann and Louise C Hirst; University of Cambridge, United Kingdom

Remote epitaxy is an emerging semiconductor film deposition technique, first reported in 2017 (Kim, Nature) which offers low defect growth of single crystal films which can be readily exfoliated from a growth template using a monolayer graphene interface. This approach enables film integration with dissimilar materials for novel device architectures, along with reuse of growth substrates for reduced cost, addressing longstanding challenges for the technologically important III-V materials family. CVD growth of graphene and wet transfer to a III-V substrate with a polymer handle is a potentially scalable and low cost approach to producing the required growth surface for remote epitaxy of these materials. Previous authors have compared remote epitaxy of GaAs using wet and dry transfer techniques, concluding that the formation of an interface native oxide during wet transfer prohibited single crystal formation via this technique (Kim, ACS Nano, 2021).
In this work, we have shown that single crystal GaAs films can be grown on a wet transferred CVD graphene monolayer, with an underlying GaAs substrate, through the controlled introduction of nanoscale defects with an argon (Ar) ion beam. Prior to pinhole introduction the presence of an oxide layer at the graphene/substrate interface is confirmed by XPS. Following Ar ion-beam exposure the pinhole defects are identified by Raman spectroscopy with the onset of the D peak at 1350 cm−1. A clear improvement in the crystalline quality of the epitaxial layer is observed in regions exposed to the Ar-ion beam. Single crystal GaAs films are formed in monolayer regions of the graphene exposed to Ar, confirmed by EBSD. The quality of the film is significantly improved in Ar-ion beam exposed regions with reduced roughness characterised by AFM, also reduced crystal misorientation and As antisite signatures are present in the Raman spectra of the GaAs film with increasing Ar-ion beam exposure time. A hybrid mechanism of seeded lateral overgrowth propagated by remote epitaxy on monolayer graphene is indicated, determined from the absence of wetting on multi-layer graphene, which screens the underlying crystal template. Furthermore, film exfoliation, as required for integration with off-wafer device architectures and substrate reuse, is still possible even with the presence of nanoscale defects in the graphene interface monolayer. The back side of the exfoliated epilayer revealed the occurrence of GaAs nucleation through defects in graphene in Ar-ion beam treated regions, confirmed by SEM showing equal spread of dark spots in monolayer graphene regions and further supported by mirrored features in SEM of the growth substrate after release of the GaAs film. Moreover, Raman spectra show that after film exfoliation the graphene is still attached to the substrate, and ready for subsequent growth without additional ion beam exposure.
The approach demonstrated here, circumvents the issue of additional screening from the interface native oxide formed under wet transferred CVD graphene, to allow remote epitaxial growth of GaAs using lower cost and scalable graphene process methods and therefore offers an alternative approach for the further development of remote epitaxy.

Remote Epitaxy for Freestanding GaN Membrane on Wafer-Scale 2D Materials Bo-In Park, Jekyung Kim, Yunpeng Liu, Hyunseok Kim and Jeehwan Kim; Massachusetts Institute of Technology, United States

Along with the rapid development of industries including communication, military, aviation, automobile, and high electric power, the demand for semiconductor technology is skyrocketing. In particular, GaN and SiC-based compound semiconductors for cutting edge optical and power devices are receiving highlights as the next-generation semiconductors that can change the world. The compound semiconductors are already being actively applied in the industries.
The principle of “Remote epitaxy” technology has been recently discovered. Researchers in the various fields relevant to epitaxy have begun to pay attention to the new scientific discoveries. Remote epitaxy, developed for the epitaxy of high-quality compound semiconductor materials, is realized by the unique surface and physical characteristics of several two-dimensional (2D) materials. Remote epitaxy is different from the existing epitaxy technology in way that it can produce freestanding membranes due to the easy separation and transfer from the substrate. We have demonstrated the feasibility of this technology over the past several years as well as developed scientific knowledge on the fabrication of various high-quality compound semiconductor materials.
In this study, remote epitaxy for the fabrication of freestanding, high-quality single crystalline GaN membrane is introduced. The manufacturing process of optimized 2D materials from various epitaxy processes is introduced and their characteristics are analyzed in detail. The development of defect-free 2D materials by remote epitaxy enabled the fabrication of high-quality single crystalline membrane at wafer scale.

Vapor-Liquid-Solid Growth of One-Dimensional van der Waals Nanowires and Their Heterostructures Thang Pham[1,2], Kate Reidy[1], Joachim D. Thomsen[1], Baoming Wang[1], Nishant Deshmukh[3], Michael A. Filler[3] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Northwestern University, United States; [3]Georgia Institute of Technology, United States

Transition metal trichalcogenides (TMTs) are one-dimensional (1D) layered materials containing trigonal prismatic chains of metals and chalcogens bonded via weak van der Waals (vdW) force. The materials host intriguing correlated physics in the bulk, such as charge density waves and superconductivity. However nanostructured forms of TMTs have been rarely explored due to the difficulty in nanomaterial synthesis and assembly. Niobium trisulfide (NbS_3) is one of the least studied members in the family of TMTs, in part because of obstacles in synthesizing the material with a pure phase and controlled composition.
Here we present a vapor-liquid-solid (VLS) growth of NbS_3 nanowires on several bulk and 2D vdW substrates, including graphene and hexagonal boron nitride. The growth employs an alloy of a metal (gold, Au) and an alkali metal halide (sodium chloride, NaCl) as a VLS catalyst. The materials show several distinct 1D morphologies, specifically wires, ribbons and walls; and two growth orientations, [010] and [100], in which the chain direction is parallel or perpendicular to the nanowire growth direction, respectively. We discuss the details of the growth mechanism based on the relationships we measure between dimensions and morphologies of NbS_3 and the catalyst volume, the growth time, and the growth substrate. We also compare the VLS

growth with uncatalyzed growth (e.g., vapor-solid) to explore the role of several synthesis parameters. Last but not least, we extend the VLS growth method to synthesize other TMTs, namely $NbSe_3$ and TiS_3. Our study introduces a new opportunity to expand the library of vdW materials towards emerging 1D materials and heterostructures.

9:30 AM NM07.04.05
MOCVD Process Development for Direct Synthesis of 2D-2D Heterostructures Songyao Tang[1], Annika Grundmann[1], Hleb Fiadziushkin[1], Amir Ghiami[1], Michael Heuken[1,2], Andrei Vescan[1] and Holger Kalisch[1]; [1]RWTH Aachen University, Germany; [2]AIXTRON SE, Germany

Favorable properties of 2D materials are recommending them as promising building blocks for future electronic devices. Recently, a variety of novel all-2D vertically-integrated devices have been demonstrated with superior performance. However, such delicate 2D vertical integration is commonly prepared through layer-by-layer stacking methods, the efficiency, reproducibility and scalability of which are severely hampered by the manual transfer and stacking procedures. On the other hand, metal-organic chemical vapor deposition (MOCVD) has been widely studied as a scalable and controllable technique to fabricate individual 2D layers, which also shows the potential of combining multiple processes to realize layer-by-layer deposition. Nevertheless, just a few publications regarding the successive growth of different 2D materials via MOCVD have been reported.
In this work, we report on the latest progress using MOCVD for the direct synthesis of 2D-2D heterostructures of transition metal dichalcogenide (TMDC) monolayers. A commercial AIXTRON CCS reactor with advanced ARGUS and LayTec in-situ monitoring systems is employed as the experimental platform. Tungsten/molybdenum hexacarbonyl (WCO/MCO), di-tert-butyl sulfide (DTBS) and di-iso-propyl selenide (DiPSe) were used as precursors with H_2 as carrier gas. 2" c-plane sapphire with a nominal 0.2° off-cut towards m-plane is chosen as substrate. A 30 min H_2 sapphire desorption (150 hPa, 1050 °C on wafer surface) was carried out before deposition. Scanning electron microscopy (SEM), atomic force microscopy (AFM), Raman as well as UV-vis and photoluminescence (PL) spectroscopy were used for characterization.
In order to obtain a clean and planar interface between two distinct layers, the lateral growth of the first underneath layer needs to be carefully controlled, which means that the monolayer should coalesce with minimal parasitic bilayer coverage formed. Previously, a two-stage migration-enhanced MOCVD process has been proposed by our group to serve this purpose in the case of WS_2 [1], with stage I being an optimized lower-temperature nucleation step. By ramping down the injection flux of WCO by -75% during the higher-temperature lateral-growth stage II in 144 min, the bilayer coverage of WS_2 is suppressed to <20% while the monolayer coverage exceeds 99%. Similar results could be achieved in the synthesis of WSe_2 monolayers. Although the nucleation density of WSe_2 (after stage I) is much lower than that of WS_2, fully-coalesced WSe_2 monolayers can still be achieved with <20% bilayer coverage via WCO ramp-down in 90 min. These two disparate processes are merged into one successive process to fabricate WS_2/WSe_2 heterostructures. The in-situ transient-reflectance data provide a real-time insight into the growth process. The detailed growth mechanism can be analyzed by comparing nanoscale morphology of (hetero)structures, revealing the difference between sapphire and the as-deposited WS_2 monolayer as the growth template for WSe_2. The distinct excitonic absorption peaks of WS_2 (near 600 nm) and WSe_2 (near 750 nm) can be read out from the absorbance spectra of heterostructures, which matches well with the PL emission spectra. The A peak of WS_2 is found to be red-shifted as WSe_2 gradually coalesces on top of WS_2. The formation of WS_2/WSe_2 heterostructures can also find support in Raman spectra. Further studies are ongoing to examine the quality of such layer-by-layer grown 2D-2D heterostructures.
In conclusion, based on two-stage migration-enhanced MOCVD processes, the direct synthesis of 2D-2D heterostructures can be realized in one MOCVD process without growth interruption. This work tends to draw more attention to the research field of direct synthesis of various 2D heterostructures as well as scalable fabrication towards all-2D devices.

Step-Edge Nucleation and Control of Domain Orientation in TMD Epitaxy on Sapphire Haoyue Zhu, Tanushree Choudhury, Nadire Nayir, Adri C.T. van Duin and Joan M. Redwing; The Pennsylvania State University, United States

Wafer-scale synthesis of semiconducting transition metal dichalcogenide (TMDs) monolayers is of significant interest for device applications to circumvent size limitations associated with the use of exfoliated flakes. Promising results have been demonstrated for epitaxial films deposited by vapor phase techniques such as CVD and MOCVD. However, the three-fold symmetry of TMDs such as MoS_2 and WSe_2, results in two energetically equivalent domain alignments, often referred to as 0° and 60° domains, when grown on flat high symmetry substrates such as c-plane sapphire and graphene. The oppositely oriented domains give rise to inversion domain boundaries (IDBs) upon coalescence which exhibit a metallic character and are generally undesirable. In this study, we demonstrate the epitaxial growth of unidirectional TMD monolayers on 2” diameter c-plane sapphire substrates with a significantly reduced density of inversion domains. Steps on the sapphire surface are shown to play a key role in TMD nucleation and impart a preferred orientation to the domains depending on the step edge structure and chemistry.
Metalorganic chemical vapor deposition (MOCVD) was used for the epitaxial growth of WSe_2 monolayers on c-plane sapphire in a cold-wall horizontal quartz-tube reactor. The as-received sapphire substrates, which are miscut ~0.2° toward the m-axis, consist of steps with sub-1 nm step height separated by 50-70 nm wide terraces. A three-step nucleation-ripening-lateral growth process, carried out at temperatures ranging from 850°C to 1000°C, was used to achieve epitaxial films using $W(CO)_6$ and H_2Se as precursors in a H_2 carrier gas. Density functional theory calculations demonstrate that the extent of Se passivation of the sapphire surface and the presene of oxygen remnants near the step edge are critical factors in determining the location of TMD nucleation on the step edge and the subsequent domain orientation relative to the underlying sapphire. Continued lateral growth for times ranging from 10-30 minutes results in fully coalesced TMD monolayers that are epitaxially oriented on the sapphire, as assessed by in-plane x-ray diffraction, with a reduced density of inversion domain boundaries (<15% areal coverage). The results demonstrate the important role of step structure and chemistry in nucleation and epitaxial growth of TMD monolayers.

Chemical Synthesis of Metal-Capped Semiconductor Nanowires Bo Shen, Liliang Huang and Chad Mirkin; Northwestern University, United States

Semiconductor nanowires (NWs) capped with metal nanoparticles (NPs) show multifunctional and synergistic properties, which are important for a diverse set of applications including catalysis, photonics, and electronics. Conventional colloidal synthesis for this class of hybrid structures requires complex and sequential seeded growth methods, and processes for preparing such wires are not universal. In this work, we present a new and general method for synthesizing metal-semiconductor nanohybrids based on particle catalysts prepared by scanning probe block copolymer lithography and chemical vapor deposition. By using metallic heterodimer NPs as catalysts for NW growth, semiconductor NWs capped with metallic particles (Au, Ag, Co, Ni) are formed. Importantly, these findings show that the growth processes for NWs on NPs are regioselective and controlled by the chemical composition of the metallic heterodimer. Studies show that the structures of multimetal-capped NWs are thermodynamically stable, and Density functional theory (DFT) simulations confirm that their spatial distributions are the most energetically favorable structures. Taken together, three different NW growth modes are postulated, including one without precedent: growth on a single metal domain, insertion between two metal domains, and growth at the interface of two metal domains. Consequently, this work provides a fundamental and general guide for the controllable synthesis of semiconductor NWs using

heterostructure catalysts, allowing one to make metal-semiconductor nanohybrids with high regioselectivity.

Substrate Role in the 0D Nanoparticle-Catalyzed Synthesis of 1D Epitaxial SnO_2 Nanostructures Jasmin-Clara Bürger[1], Sebastian Gutsch[1], Vanessa Wollersen[2,2], Di Wang[2,2], Christian Kübel[2,2] and Margit Zacharias[1]; [1]University of Freiburg, Germany; [2]Karlsruhe Institute of Technology (KIT), Germany

The epitaxial planar growth of laterally aligned tin oxide (SnO_2) nanowires along the substrate surface is superior for the integration of 1D nanostructures in sensors and electronic circuits - but is also highly challenging by its small parameter window demanding precisely controlled growth settings. In this study, we varied the substrate material and alignment in 1D planar SnO_2 nanostructure synthesis. Here, we provided experimentally-confirmed thermodynamic considerations and combined these with advanced microscopic FIB preparation of TEM lamellae of longitudinal and cross-sectional cuts of the laterally aligned SnO_2 nanostructures.[1] Prerequisites for an appropriate substrate are not only the chemical stability at growth conditions but also a monocrystalline or structured surface for guiding the growth direction. TEM investigations revealed the heteroepitaxial contact between the SnO_2 crystal lattice and the growth substrate surface and allowed for strain location within the NW cross-section. The theoretical and experimental results gave unique insights into the initial steps of the epitaxial growth of planar 1D SnO_2 nanostructures on crystalline surfaces for promising heterostructure architectures between the 2D substrate, the planar 1D SnO_2 nanostructure and the 0D gold catalyst particle.

Tailoring Semiconductor Polytype Selection During Molecular-Beam Epitaxy Rachel S. Goldman; University of Michigan, United States

Semiconductor polytype heterostructures, which consist of chemically homogeneous structures formed via an abrupt change in crystal structure, offer opportunities for performance exceeding those of composition-based semiconductor heterostructures. Of particular interest are heterostructures formed via an abrupt change in atomic plane stacking sequence, such as the transition from the wurtzite (WZ) polytype, with AB stacking, to the zincblende (ZB) polytype, with ABC stacking. At a fixed chemistry WZ/ZB heterojunction, the lattice mismatch and thermal expansion coefficient mismatch are typically < 0.1%, leading to a negligible interfacial defect concentration. Meanwhile, the WZ/ZB band offset and polarization discontinuity are expected to lead to the confinement of a two-dimensional electron gas (2DEG) at the interface, without the need for impurity doping and/or alloying. Depending on the type I (nested) vs. type II (staggered) band offset at the WZ/ZB polytype junction, such heterostructures would also be promising for high power electronics and single photon emitters. Recently, we discovered a metal-mediated growth process to nucleate the metastable ZB polytype during molecular-beam epitaxy of GaN [1]. Interestingly, for both nanowires and films, a transformation from the ZB to WZ polytype occurs after 1 hour of growth, at a thickness of 150 nm. Due to the consistency in the timing of the transformation, we hypothesize that the ZB-to-WZ transformation is not due to a random event but instead due to an extrinsic effect associated with the growth process. We will discuss the relative influences of effusion-cell-induced surface heating and electron beam-induced surface polarization on polytype selection and transformation, along with prospects for realization of GaN QDs-in-NWs single-photon emitters and lattice-matched polarization-doped WZ/ZB GaN high-electron mobility transistors.

Commensurate Aassembly of C_{60} on Black Phosphorus for Vertical Transistor Applications Tae Keun K. Yun, Yangjin Lee and Kwanpyo Kim; Yonsei University, Korea (the Republic of)

Two-dimensional (2D) layered materials have recently attracted enormous research interest as templates for fabrication of new van der Waals (vdW) heterostructures hosting other 2D materials, inorganic nanostructures, and organic molecules featuring unlimited combinations. Novel physical properties can emerge from the coherent interaction of components in various vdW heterostructures. Among various 2D materials, black phosphorus (BP) can function as a unique 2D template due to its anisotropic puckered atomic structure, which may lead to the strong epitaxial growth of organic molecules through well-controlled assembly. When the pristine surface of BP is preserved during the sample fabrication, the remarkable epitaxial assembly of C_{60} on BP is indeed achieved. BP template induces aligned C_{60} assembly with higher-order commensurism, which is confirmed by state-of-the-art transmission electron microscopy and theoretical analyses. We also fabricate the lateral and vertical devices with C_{60}/BP junction via lithography-free clean process and investigate the charge transfer in lateral devices and charge transport behaviors across C_{60} and BP interface in vertical devices showing tunable barrier from 0.2 to 0.5 eV. Optoelectrical properties of vertical devices are also investigated under infrared and visible light illumination yielding high photo-responsivities up to ~100 A/W under visible light and showing fast response time.

1:45 PM NM07.05.02
Freestanding Single-Crystalline Oxide Membrane and Its Pyroelectric Application Xinyuan Zhang[1], Celesta S. Chang[1], Shane Lindemann[2], Owen Erickwen[2], Marx Akl[3], Yunfeng Shi[3], Chang-Beom Eom[2] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Wisconsin-Madison, United States; [3]Rensselaer Polytechnic Institute, United States

Infrared (IR) imaging has significant demand in commercial, medical and military applications such as night vision, blood vessel surgery and gas sensing. Compared to photon detectors which requires complex cryogenic cooling and have limited spectral bandwidth, thermal detectors do not, and have the advantage of constant detectivity over the whole IR range, thus becoming the technology of choice. However, one crucial downside of thermal detectors is that the detectivity is several magnitudes of order lower than that of conventional HgCdTe photon detectors, preventing the production of high performance thermal IR detector. Recent development of various thin film lift-off methods offers new opportunity for realizing pyroelectric IR detector with high detectivity and fast response, but all of the previous methods have drawbacks, which are either time-consuming, not scalable, or produce film with nonuniform thickness. Consequently, it has been a big challenge to produce single-crystalline pyroelectric nanomembranes.

$Pb(Mg_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ (PMN-PT) and $LiTaO_3$ (LT) are perovskites with high pyroelectric coefficients and figure-of-merits, which are potential candidates for developing infrared detectors. In this study, we show a new buffer-free technique that enables freestanding, high quality PMN-PT and LT

nanomembranes. Single-crystalline film epitaxially grown on substrate without any buffer layer can be directly exfoliated by a nickel stressor with 100% yield. We confirm that pyroelectric property is not degraded after exfoliation and transfer processes. Our work is expected to improve the pyroelectric thermal detectors to show much better performance than the current state-of-the-art ones, as the detectivity and response time can be significantly improved by achieving ultra-thin (nanometer scale) film. Also, freestanding film will enable fabrication of suspended structure with good thermal isolation, thus increasing responsivity of the IR detector.

2:00 PM NM07.05.03
Optimization of 1D Core-Shell Heterostructures for Gas Sensing Nicola Pinna; Humboldt-Universitat Berlin, Germany

Hierarchical core-shell heterostructures composed of p-, n-type and insulating metal oxide shells deposited onto carbon nanotubes (CNTs) were synthesized using atomic layer deposition. Precisely controlled films of alternating metal oxides were uniformly deposited onto the inner and outer walls of the CNTs. The morphological, microstructural and electrical characteristics of the as prepared core-shell heterostructures were thoroughly investigated. The electrical resistance measurements highlighted the large influence of the metal oxides thickness and charge carriers types on increasing of many order of magnitude the baseline resistance of the core-shell heterostructures with various thicknesses of the metal oxide shell layers, suggesting that the conductivity of the sensors is dominated by Schottky barrier junctions across the n-p interfaces.
The behavior of our sensors was investigated for low concentrations of volatile organic compounds and pollutants. The gas sensing response of the heterostructures showed a strong dependence on the thickness of the metal oxide shell layers and the type of heterostructures formed. On the basis of the morphological, microstructural and electrical characterization and sensing results, the sensing mechanism which accounts for the marked variation in the resistance during the interaction of the target gas molecules will be discussed.

3D Mesoporous Networks of Linked Metal Chalcogenide Nanoparticles for Improved Photocatalytic Hydrogen Generation Activity Ioannis Vamvasakis and Gerasimos S. Armatas; University of Crete, Greece

Photocatalytic hydrogen production through water splitting has recently gained significant attention for efficient solar-to-chemical energy conversion.[1] However, despite immense research efforts on semiconductor materials, key challenges of obtaining catalysts with high activity and long-term stability still remain. Recently, the synthesis of highly crystalline mesoporous semiconductors has been the focus in the field of electro- and photocatalysis. These materials combine the high reactivity of semiconductor nanoparticles with mesoporosity, offering new perspectives in designing novel catalysts with improved efficiency and reliability. Unlike to bulk-like microstructures and individual nanoparticles, 3D mesoporous networks of connected nanoparticles can benefit from the large and accessible surface area within the assembled structure and enhanced light-harvesting efficiency arising from multiple scattering of light inside the pores.
Herein, we present the synthesis of chemically stable and robust mesoporous networks of β-$Ni(OH)_2$-modified and CdS and Ni_2P-decorated CdS/ZnS nanocrystal (ca. 4–5 nm) assemblies (NCAs) that show high photocatalytic activity for hydrogen evolution under visible light irradiation.[2] We utilize polymer-assisted self-assembly of colloidal nanoparticles to assemble mesoporous CdS and ZnS nanoparticle-linked frameworks with high interstitial porosity. This method utilizes the nanoparticles as building block units and based on the coassembly of these nanoscopic units with organic structure-directing agents to construct 3D structures with open-pore morphology.[3] The resulting materials feature a nanometer-sized framework perforated by uniform pores, which allows rapid mass transport and provides plenty of exposed surface-active sites available for reaction. Photocatalytic measurements coupled with UV–vis/NIR, TRPL and electrochemical spectroscopy studies suggest that the outstanding photocatalytic hydrogen production performance of these unique heterostructures manly arises from the accessible 3D open-pore structure and the favorable band-alignment with the respective co-catalyst, which suppresses carrier recombination and promotes efficient charge-transport at the junction interfaces. As thus, the β-$Ni(OH)_2$/CdS catalyst containing 10 wt% Ni reached a photocatalytic H_2-evolution rate of 1.4 mmol/h with an apparent QY of 72% at 420 nm, while demonstrating excellent stability in alkaline (5M NaOH) ethanol solution (10% v/v). The results of these studies can offer new insights into the design and development of efficient photocatalysts for energy conversion and environmental remediation applications.

Heterostructured Nanomaterial Sensors for the Selective Detection of Breath Markers Ines Weber and Sotiris E. Pratsinis; ETH Zurich, Switzerland

Chemo-resistive sensors bear huge potential in emerging applications such as breath analysis and air quality monitoring due to their low cost, high sensitivity and compact design. Despite decades of research and advancements in sensor material design (e.g., compositing with carbon nanotubes[1]), such sensors can rarely be found in real-life applications due to their limited selectivity.
Here, we present a novel approach to design selective sensing systems for the detection of the breath marker acetone, a bio-marker for lypolysis[2]. It is based on nanoparticle filters[3] comprising mixed heterostructures of metal oxide materials fabricated by flame spray pyrolysis that pre-screen chemo-resistive sensors.[4] These filters act as nano-catalysts and selectively convert undesired interferants to non-responsive species (e.g., ethanol[5]) while leaving the target analyte acetone intact. Moreover, such filters can be produced in a scalable and low-cost manner at room temperature[6] using flame-spray pyrolysis. In fact, catalytic filters made of Pt/Al_2O_3 nanoparticles markedly enhanced the acetone selectivity of heterostructured Si/WO_3 sensors (>250) towards various interferants (e.g., alcohols, isoprene, ammonia, H_2, and CO).[7] This enabled accurate acetone detection even in the presence of orders of magnitude higher interferant concentrations.
Therefore, this filter-sensor device was tested on real human breath to monitor acetone in various scenarios including dieting[8], exercising[9] and even to distinguish people in health from diabetes[10]. Due to the unique filter and sensor material design, this detector is capable of accurately detecting acetone concentrations in all three scenarios, in excellent agreement with bench-top proton transfer reaction time of flight mass spectrometry. Notably, this allowed to track acetone concentrations directly during exercise, giving information about cardio-respiratory fitness. Similarly, such sensors can be used to distinguish between healthy people and diabetes when following standardized protocols.[10] Finally, it may assist in guiding dieting and weight-loss, as we are currently investigating in a randomized clinical trial on intermittent fasting diets with 75 volunteers. Hence, this heterostructured filter and sensor is most promising as mobile health device for routing personalized metabolic health monitoring.

Pseudo-Graphene on SiC for High-Quality GaN Membrane Jekyung Kim, Bo-In Park, Dusik Bae, Doyoon Lee, Junseok Jeong, Yunpeng Liu, Hyunseok Kim and Jeehwan Kim; Massachusetts Institute of Technology, United States

Free-standing membranes are building blocks for various electronic and photonic devices since they can provide a large degree of freedom for the platform. Besides, along with their extraordinary material properties, single-crystalline free-standing membranes can reduce material costs. In this regards, fabrication of free-standing membranes requires successful separation of active materials from various types of substrates. However, conventional approaches have exhibited challenges in the sense of poor interface quality, complexity in choice of materials, and such. Recently, remote epitaxy has arisen as a new technology that can overcome current limitations enabling both high crystal quality and simplicity in the materials. In remote epitaxy, electrostatic potential is not completely screened by 2D material (e.g. graphene) inserted as a releasing layer between the substrate and the active material. In other words, remote interaction between two materials results in the successful epitaxial growth of the active material such as GaAs or GaN. The quality of 2D material, therefore, is highly crucial in achieving high-quality single-crystalline free-standing membranes.
In this study, we demonstrated a new 2D platform using graphene/SiC in remote epitaxy. We discovered that graphitized SiC has sp^2-bonded graphene layer on the very top surface and sp^3-bonded pseudo-graphene(pGr) between graphene and SiC. The graphene fully covers pGr providing sufficient van der Waals force above the epitaxial layer, enabling efficient transfer of free-standing membranes without any possible damage. This research includes systematic studies on pGr/SiC used as a releasing layer for free-standing GaAs/GaN membranes.

3:30 PM NM07.05.08
Enhanced Dielectric Strength and Capacitive Energy Density in Ultrathin 2D Glassy Polymer Films Maninderjeet Singh and Alamgir Karim; University of Houston, United States

Ultrathin polymer films present unique opportunities to understand the physics and properties of polymers at the nanoscale as the polymer films start to behave as 2D materials instead of their usual 3D behavior. Ultrathin polymer films have been shown to demonstrate differences in properties such as glass transition temperature, mechanical properties, polymer mobility, etc. as compared to their bulk counterparts. In this work, we demonstrate that ultrathin glassy polymer films (~100 nm) show an order of magnitude higher dielectric strength (E_{BD}) and two orders of magnitude higher capacitive energy density ($U_{max} \propto E_{BD}^2$) of ~100 J/cm^3 in standard localized point-contact measurements, as compared to the bulk polymer films when used as dielectric capacitors. The dielectric capacitors demonstrate 3-4 order of magnitude higher power densities as compared to electrochemical energy storage devices such as batteries, thus making them useful as high-power density energy storage devices. We believe that the enhancement of the dielectric strength and capacitive energy density is due to the tighter chain packing of polymers, cast from a good solvent into thin films, dried under conditions of slow evaporation of the good solvent. We test the density of thin polymer films by optical measurements and observe that the ultrathin films show higher densities and thus lower free volume as compared to their bulk counterparts, which might be a governing factor for the enhancement of the dielectric strength. Furthermore, we observe that the dielectric strength of annealed ultrathin polymer films decreases as compared to the as-cast films, which might be attributed to the surface segregation of chain ends upon annealing, which act as defect sites for the dielectric breakdown of the polymer films. Moreover, the ultrathin films of polymers having sub-room temperature glass transition don't show ultra-high dielectric strength and capacitive energy density, which might be due to the presence of excess free volume in these polymer films that act as defect sites for breakdown. This enhancement of dielectric strength in ultrathin polymer films might help in increasing the understanding of polymer behavior in ultrathin films.

3:45 PM NM07.05.09
Potential of Joule Heating Method for the Synthesis of a Variety of MoO_3 and WO_3 Nanomaterials Beatriz Rodríguez Fernández[1], Teresa Cuberes[2], Pedro Hidalgo[1] and Bianchi Mendez[1]; [1]University of Complutense, Spain; [2]Universidad Castilla la Mancha, Spain

Crystalline structure and quality, and dimensionality in nanomaterials are quite affected by the synthesis route. This is of paramount relevance when it comes to oxide nanomaterials, which can occur with a variety of phases. Among them, transitional metal oxides are considered very promising candidates for multiple applications like electronic devices among others. In this work, we expose a rapid synthesis of metal oxide nano- and microstructures via the resistive heating of metallic wires, Mo and W, due to the flow of an electric current. The method is proved as an effective route to obtain van der Waals (vdW) and non-vdW bonded materials as MoO_3 and WO_3, respectively. The growth mechanism is discussed in terms of local oxidation of the surface of the wire as well as diffusion and electromigration processes [1,2]. The processes will be discussed in the framework of Multiphysics modelling and compared with experimental results.
The detailed morphological, structural and chemical analysis of the MoO_3 and WO_3 nanomaterials, carried out by scanning electron microscopy (SEM), Raman spectroscopy, X-ray diffraction (XRD), transmission electron microscopy (TEM) and X-ray photoelectron spectroscopy (XPS), reveal that several phases are simultaneously stabilized, which is of great interest. In the case of MoO_3, nanomembranes of alpha-phase and nanospheres of beta-phase are produced, while monoclinic I, monoclinic II and triclinic phases of WO_3 are produced by the resistive heating of W metallic wire. In addition, the MoO_3 and WO_3 nanostructures have been embedded in a poly(vinyl alcohol) matrix to achieve nanocomposite films, and their optical and mechanical properties have been explored. In summary, our results show that resistive heating is a simple and low energy method to synthesized transition metal oxide nanomembranes and nanostructures in a fast and low-cost way with promising applications.

Portable Bulk-Water Disinfection by Electric Manipulating and Live Capturing Bacteria with Divergently Branched Porous Graphite Yifei Liu, Xianfu Luo, Weigu Li, Zexi Liang and Donglei (Emma) Fan; The University of Texas at Austin, United States

An easy access to clean water is pivotal for a sustainable modern society. Nevertheless, it remains arduous to develop efficient and low-cost portable water disinfection systems for point-of-use (POU) applications. The overcoming of this challenge is particularly imperative for the society's resilience. Here, we report an innovative POU disinfection scheme and device prototype for the capture and removal of pathogen in bulk water. The system is made of AC-electric-field-powered three-dimensional (3D) porous dendritic graphite foams (PDGF) integrated in a 3D-printed water-purification module. The device is simple, portable, and can reproducibly remove 99.997 % E-coli bacterial cells from bulk water using only a few voltages and among the lowest energy of 435.5 J L^{-1}. It successfully brings natural water in the Waller Creek at UT Austin to the safe level. The strategically fabricated PDGF materials are robust and low cost at only $1.42 per piece and demonstrates at least 20 repeated uses without functional degradation. Brownian dynamics simulations are carried out to shed light to the disinfection mechanism. The innovative scheme, material, and device prototype for water disinfection reported in this work could inspire new paradigms for POU water treatment.

SESSION NM07.06: Application of Various Dimensional Materials and Heterostructures III

8:00 AM *NM07.06.01
MoS_2 Thin-Film Transistor Backplanes for Display and Imaging Jong-Hyun Ahn; Yonsei University, Korea (the Republic of)

Thin-Film Transistors (TFT) are being widely used as a backplane to drive emissive devices such as LCD, OLED, micro-LED, and image sensors such as optical and X-ray. Amorphous-Si, Poly-Si, and oxide semiconductors are commonly used in backplane TFT. High carrier mobility, high on/off ratio, and stability are important characteristics for backplane TFT. Two-dimensional semiconductors, especially MoS_2, are proposed as an alternative material to improve the mechanical flexibility of the resulting devices. In this talk, we present the fabrication of MoS_2-based backplane TFT to drive flexible display and image sensors. For this purpose, we synthesized high-quality monolayer MoS_2 through a modified metal-organic chemical vapor deposition (MOCVD) process and fabricated a TFT array using conventional photolithography and etching processes. The good mechanical properties of MoS_2 enable the development of various flexible devices that cannot be easily reproduced with conventional materials. Examples of devices include wearable OLED display and X-ray image sensor.

8:30 AM NM07.06.02
Fabrication of 3D Hierarchical ZnO/ZIF-8 Nanostructure for Highly Sensitive and Selective Room Temperature Gas Sensor Jinho Lee[1], Young-Seok Shim[2] and Seokwoo Jeon[1]; [1]Korea advanced Institute of Science and Technology, Korea (the Republic of); [2]Silla University, Korea (the Republic of)

Semiconductor metal oxide (SMO)-based gas sensors have been utilized as powerful sensing material for high performance gas sensor, however, low gas selectivity still remains as a crucial problem for SMO-based gas sensor. Recently, a new method has been proposed to enhance gas selectivity, which employ nanoporous materials such as metal-organic frameworks (MOF) as a gas filter to physically modulate gas diffusion. However, the usage of MOF as a gas filter for metal oxide gas sensor still have issues on degradation of gas responses with diffusion process. Herein, we introduce a 3D hierarchical nanostructure with highly ordered 3D ZnO scaffold and zeolitic imidazolate framework (ZIF-8) were fabricated for room temperature gas sensing to enhance both the gas sensitivity and gas selectivity. The highly ordered and periodic porous nanostructure of ZnO enlarge the gas sensitivity with large surface area, good gas diffusion and enhanced light absorption. The ZIF-8 nanofilm were decorated on the surface of 3D ZnO nanostructure with the controlled film thickness. With the exquisite decoration process, the resulted hierarchical nanostructure shows highly ordered and periodic nanostructure, which can offer the advance in gas sensitivity. The 3D hierarchical ZnO/ZIF-8 nanostructure exhibit improved gas selectivity to NO_2 gas, which molecular size are compatible to pore size of ZIF-8. The gas response to relatively large gas molecules such as toluene and acetone are clearly suppressed compared to 3D pristine ZnO nanostructure, which is attributed to gas filter effects of nanoporous ZIF-8. Especially, 3D hierarchical ZnO/ZIF-8 nanostructure show enhanced NO_2 gas responses compared with 3D pristine ZnO nanostructure (22.8-fold improvement @ 0.1 ppm), which demonstrates the dual role of ZIF-8 film that gas filter effects and catalytic effects for enhance gas sensitivity. The rational design and realization of 3D hierarchical nanostructure for high performance gas sensor at room temperature suggests future perspective for target-purpose gas sensor based on nanostructured material.

8:45 AM NM07.06.03
Morphology-Dependent Zinc Oxide Structures and Their Applications to Negative Differential Resistance Behaviors in Mixed-Dimensional 0D/3D Zinc Oxide Quantum Dots/*p*-Si Heterointerface Devices Somi Kim[1], Taehyun Park[1], Hyung Joong Yun[2] and Hocheon Yoo[1]; [1]Gachon University, Korea (the Republic of); [2]Korea Basic Science Institute (KBSI), Korea (the Republic of)

Negative differential resistance (NDR) behavior has considerably been the focus of attention due to its novel switching properties, which exhibit an *n*-shaped current-voltage characteristic without a monolithic increase of current as the applied voltage bias increases. This study presents the findings of morphology-dependent NDR behavior in which three types of zinc oxide (ZnO) build a junction with *p*-Si in the form of quantum dots (QDs), nanoparticles (NPs), and sol-gel-derived films (hereinafter referred to as Film) with grain sizes of 10.14 nm, 39.91 nm, and 99.60 nm, respectively. The operation principle of NDR behavior and control of peak-to-valley ratio (PVCR) were elucidated through a comprehensive study, including an analysis of the energy band structure, morphological investigation, chemical structure, and electrical characterization, according to the ZnO morphology and dimension. The peak current of three types ZnO increased in the order of Film, NPs, and QDs, and it is emphasized that the maximum PVCR of 4.96 A/A was obtained in the mixed-dimensional 0D QDs/3D *p*-Si heterostructure devices. The differential resistance (R_{diff}) of the mixed-dimensional QDs/*p*-Si heterostructure devices was 0.3 mΩ, which was significantly larger than reported values in previous studies. As a result, the NDR properties including the peak and valley current of PVCR, can be accordingly controllable through the proposed morphological control scheme with the same ZnO material. It is worth noting that the mixed-dimensional QDs/*p*-Si heterostructure devices in this study exhibited the NDR behavior achieving 100% yield and high uniformity without external stimuli such as photo-induced or controlled atmosphere such as high vacuum and cryogenic environment. This is the result of experimentally demonstration that the NDR can be stably implemented in ambient environment, not under specific conditions, which enabling the development of further practical applications, such as the study of multi-value logic circuits with two threshold voltage (V_{TH}) characteristics using NDR behavior.

9:00 AM *NM07.06.04
Plasmon-Enhanced Photodetection in a Monolayer MoS_2 Phototransistor with Ultrahigh Photoresponsivity Yu-Jung Lu[1,2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan

Monolayer transition metal dichalcogenides (TMDs) with an atomically thin nature are promising materials for electronics and photonics, especially at highly scaled lateral dimensions. However, the characteristically low total absorption of photons in the monolayer TMD has become a challenge in the access to and realization of monolayer TMD-based high-performance optoelectronic functionalities and devices. Here, we report gate-tunable plasmonic phototransistors (photoFETs) that consist of monolayer molybdenum disulfide (MoS_2) photoFETs integrated with the two-dimensional plasmonic crystals (Ag, HfN, TiN). The plasmonic photoFET has giant enhancement in the photocurrent compared to pristine 2D material-based photoFETs. The achievement is based on the breakthrough of the realization and characterization of a gate-tunable atomistically-thin phototransistor device consisting of a monolayer MoS_2 photoFET integrated with a two-dimensional (2D) plasmonic crystal to enhance the light absorption rate, photo-carrier generation rate, photo-gating, and hot-carrier transfer rate. Moreover, this talk will describe different design of plasmonic phototransistors that is extensible to other types of 2D materials for ultrathin high-performance optoelectronic devices at highly scaled dimensions. Finally, we will discuss prospects for next-generation ultra-compact optoelectronic devices in the trans-Moore era.

9:30 AM BREAK

10:00 AM NM07.06.05
Fabrication of Microcavity and Quantum Wells Composed of Two-Dimensional and Three-Dimensional Materials Xuejing Wang[1], Yeonhoo Kim[1], Benjamin K. Derby[1], Xuedan Ma[2], Towfiq Ahmed[1], Suhyun Kim[3], Kibum Kang[3], Ting S. Luk[4], Young Joon Hong[5], Aiping Chen[1] and Jinkyoung Yoo[1]; [1]Los Alamos National Laboratory, United States; [2]Argonne National Laboratory, United States; [3]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [4]Sandia National Laboratories, United States; [5]Sejong University, Korea (the Republic of)

Emerging nanomaterials have attracted much attention due to their novel functionalities, but have also been hindered by lack of scalable synthesis and of ways of controlling characteristics. Atomically thin two-dimensional (2D) materials are good examples of novel materials set promising exotic properties and requiring established manufacturing approaches for practical applications. Heterostructuring is a powerful and general strategy to control physical properties of materials. Moreover, heterostructuring can offer novel characteristics differentiating the heterostructure from individual component in a structure. Recently, 2D/2D heterostructures prepared by stacking are being explored to observe quantum phenomena. Besides the 2D/2D heterostructures, heterostructuring with 2D and conventional materials in other dimensions (e.g. bulk-like structure for 3D and nanowires for 1D) has shown great potential for multi-dimensional heterostructures.
In this presentation I'll discuss how to prepare multi-dimensional heterostructures composed of 2D and conventional semiconducting materials. The experimental approach is remote epitaxial growth ZnO on 2D materials including graphene, hexagonal boron nitride, transition metal dichalcogenides. Hydrothermal synthesis, metalorganic chemical vapor deposition, and pulsed laser deposition were employed to fabricate microcavities and quantum wells embedding monolayer molybdenum disulfide layers. Cross-sectional transmission electron microscopy, microphotoluminescence, cathodoluminescence, and electron beam induced current microscopy measurements were utilized to investigate the interfacial structures and functional properties of the heterostructures with high spatial resolution.

Multiplication of Freestanding Compound Semiconductor Membranes from a Single Wafer by Alternating Growth with 2D Materials Ne Myo Han, Hyunseok Kim, Yunpeng Liu, Kuangye Lu, Celesta S. Chang and Jeehwan Kim; Massachusetts Institute of Technology, United States

Single-crystal compound semiconductors, such as III-N and III-V, are important building blocks for functional devices due to their high electron mobilities, wide range of bandgaps, and excellent optoelectronic properties. However, current methods to produce their freestanding membranes for heterointegration suffer from slow processes or poor material quality. Here, we demonstrate an approach to grow and harvest multiple wafer-scale single-crystal membranes with high throughput by introducing weak van der Waals interfaces between epitaxial layers. This is achieved by directly growing two-dimensional (2D) materials on compound semiconductors in their native deposition systems, which enables alternating growth of 2D material and compound semiconductor epitaxial layers in a single run. Each epilayer in the multi-stack structure is then sequentially harvested by mechanical exfoliation, producing multiple freestanding single-crystal membranes with extremely high throughput from a single wafer, primed for integration in mixed-dimensional heterostructures.

Reconfigurable Source-Gated Transistor Based on 2D Ferroelectric Heterostructure Joonseok Kim, Ting-Ching Chu, Hyeonseon Choi, Zhehao Zhu and Lincoln J. Lauhon; Northwestern University, United States

The integration of ferroelectric materials into conventional field-effect transistors (FETs) and optoelectronic devices creates new opportunities for low-power and non-volatile devices of relevance to neuromorphic computing. The remnant polarization can be used to modulate carrier concentration when ferroelectrics are employed as a dielectric or the Schottky barrier height if employed as the semiconducting channel, and the reduced screening in two-dimensional (2D) layered materials can enhance these effects. While 2D FETs with non-volatile output characteristics have been demonstrated, it can be challenging to achieve stable output current saturation in conventional thin-film transistors in which pinch-off occurs at the drain. In contrast, source-gated transistors (SGTs) produce pinch-off at the source electrode where the large Schottky barrier depletes the semiconductor. Pinch-off can be realized at low drain voltages and is independent of channel length. Furthermore, SGTs allow for reduced power consumption compared to conventional FETs with similar dimensions and geometries.
We have integrated the ferroelectric semiconductor In_2Se_3 into the source contact of monolayer (1L-) MoS_2 transistors to realize non-volatile mixed-dimensional SGTs with robust and tunable current saturation. Au is used as the drain electrode of the 1L-MoS_2 FET and the source contact is Ti. In this scheme, the remnant polarization of In_2Se_3 modulates the Schottky barrier at the Ti/In_2Se_3 metal-semiconductor interface and hence the resulting depletion of the MoS_2 channel beneath the contact and extending into the channel. When positive drain bias is applied, the output characteristics show strong current saturation. In contrast, a negative drain bias produces a linear response in the output, suggesting that the Ti/In_2Se_3 injection is responsible for the current saturation. The output impedance at positive drain bias above $V_{d,sat}$ reaches 8 GΩ, which is more than two orders of magnitude larger than the output impedance under negative drain bias. Transfer characteristics show a clear hysteresis loop at positive V_D, stemming from ferroelectric switching of the In_2Se_3. The ferroelectric hysteresis induces non-volatile reconfiguration of the saturation current by more than an order of magnitude dependent on gate bias history. Analysis of temperature-dependent I-V characteristics was used to estimate that the Schottky barrier is modulated by ~45 mV by the gate polarization. *In operando* Kelvin probe force microscopy (KPFM) under saturating drain bias confirms that the potential drops primarily at the source contact, consistent with expectations for an SGT. In summary, we have demonstrated the integration of a 2D ferroelectric interlayer into the vertical contact of a lateral MoS_2 transistor resulting in a novel non-volatile SGT with the potential to reduce the power consumption of reconfigurable devices and enable cascading neuromorphic circuits.

10:45 AM NM07.06.08
Scalable Preparation of Vanadium-Based Carbon Nanostructures for Hybrid Supercapacitor Applications Sunil P. Lonkar and Chiara Busa; Technology Innovation Institute, United Arab Emirates

The ever-growing demands and rapid development of energy storage devices and systems pressed the need for low-cost yet highly performing electrode materials. The transition metal oxide and sulfide-based hybrids holds great promise as the active electrode materials in supercapacitors, due to their large surface area and variable oxidation states. These properties enable significantly high energy storage *via* electrical double layer and pseudocapacitive charge storage mechanisms. Herein, we discuss a facile, scalable, and environment-friendly preparation process to produce transition metal sulfide and oxides based on resource rich metals such as Mn, Fe, V etc. and their hybrids with carbonaceous materials, such as carbon nanotubes and graphene. This strategy encompasses solvent-less mixing of a metal salt, surfeit yet non-toxic abundant elemental sulfur and carbon precursor under continuous ball milling and thermo-annealing. The resulting nanohybrids were thoroughly investigated by means of several techniques. XRD, HRTEM, SEM, Raman and BET could gather insights on the morphology and the fine material structure, as well as on the spectroscopic properties. Finally, the electrochemical properties as supercapacitor components were investigated in regards with varyingly increasing carbon content. The nanohybrids were tested in both aqueous and organic electrolytes for bettering energy and power performances. Charge storage performances and components stability in both symmetric and asymmetric devices were assessed via CV, GCD, EIS.

11:00 AM NM07.06.09
Structurally Intact Hydrophilic Carbon Fiber Paper – Nanoparticle Assemblies for CO_2 Reduction Connor Cox, Madeleine Wilsey, Kendra Watson, Omolade Fasusi, Brian Yegela, Ryland C. Forsythe and Astrid M. Müller; University of Rochester, United States

We report a green chemical approach to render carbon fiber paper hydrophilic for an unprecedently long time. Selective hydroxylation of carbon surfaces preserved the carbon fiber network, while imparting hydrophilicity that was sustained for more than 10 months, far longer than reported hydrophilization techniques, which are often much harsher and more destructive to the carbon fiber paper mesostructure. Our technology offers an environmentally friendly, scalable, and rapid process to obtain hydrophilic carbon fiber paper, opening the door for new applications, such as aqueous electrochemistry.
With its high surface area, electrical conductivity, robustness, chemical inertness, and low-cost, carbon fiber paper is an ideal support for nanomaterial catalysts. However, the native hydrophobicity of carbon fibers has limited adoption in aqueous electrocatalysis thus far. Existing processes for carbon fiber paper hydrophilization include plasma or chemical etching techniques, ozone treatments, or thermal treatments; these all suffer serious disadvantages. Plasma etches are difficult to scale, and both plasma and ozone treatments require major capital expense. These plasma and ozone treatments, alongside chemical etching or thermal processing, significantly damage and embrittle the material, compromising carefully engineered carbon fiber networks.
Our acid-free hydrophilization method allows for selective hydroxylation of carbon fiber surfaces without overoxidation, while preserving the mesostructure of the material. Systematic design and evaluation of thirteen unique chemical treatments allowed us to identify that hydroxyl, rather than carboxyl, surface functional groups imparted long-lasting hydrophilicity to carbon fibers. The rapid loss of hydrophilicity observed with harsher treatments, such as strong acids or high temperatures, was likely caused by overoxidation of carbon surfaces to aldehydes and carboxyls. Furthermore, the rapidity of less than 30 minutes and solution-processable nature of our process set it apart from previously published approaches for carbon fiber paper hydrophilization.
With this technology in hand, we were able to capitalize on the hydrophilicity of our treated carbon fiber paper to conduct aqueous electrochemical CO_2 reduction. After rendering carbon fiber paper hydrophilic, the properties which make carbon fiber paper an ideal nanoparticulate support can now be taken advantage of in an aqueous environment. Gold nanoparticles were uniformly distributed throughout the carbon fiber network to form carbon fiber paper – nanoparticles cathodes, which electrochemically reduced CO_2 to syngas with tunable $CO:H_2$ ratios. Generation of syngas through electrochemical CO_2 reduction can be paired with renewable energy sources to produce this important chemical feedstock without fossil fuels. The incorporation of our rapid green-chemical approach to hydrophilizing carbon fiber paper for the preparation of carbon fiber paper – nanoparticle assemblies with long durability is an important step toward the realization of electrocatalytic successor technologies.

SESSION NM07.07: Physics of Various Dimensional Materials and Heterostructures

1:30 PM *NM07.07.01
Strain Control of Phase Transitions in Freestanding Oxide Membranes Harold Y. Hwang[1,2]; [1]Stanford University, United States; [2]SLAC National Accelerator Laboratory, United States

The ability to create and manipulate materials in two-dimensional (2D) form has repeatedly had transformative impact on science and technology. In parallel with the exfoliation and stacking of intrinsically layered crystals, the atomic-scale thin film growth of complex materials has enabled the creation of artificial 2D heterostructures with novel functionality and emergent phenomena, as seen in perovskite oxides. We present a general method to create freestanding complex oxide membranes and heterostructures using epitaxial water-soluble buffer layers, with millimeter-scale lateral dimensions and nanometer-scale thickness. This facilitates many new opportunities we are beginning to explore; here we will focus on the strain control of ferrelectric, magnetic, and other phase transitions in oxide membranes.

2:00 PM NM07.07.02
Atomic Scale Design of the 2D/3D Interface Kate Reidy[1], Joachim D. Thomsen[1], Andrea Koneçná[2], Benedikt Haas[3], Baoming Wang[1], Eugene Park[1], Julian Klein[1], Prineha Narang[4], Christoph T. Koch[3], Juan Carlos Idrobo[5] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Brno University of Technology, Czechia; [3]Humboldt-Universität zu Berlin, Germany; [4]UCLA, United States; [5]University of Washington, United States

A fundamental understanding of the interface between three-dimensional (3D) metals and two-dimensional (2D) van der Waals materials is crucial for the integration of nanoscale devices into mainstream technologies.[1] The reasons for this are twofold: (1) since bulk metallic contacts, such as Ti or Au, are crucial for existing 2D device fabrication, for example in electronic gating, control, and readout; and (2) since 'mixed dimensional' 2D/3D heterointegration[2] allows novel functionalities that cannot be obtained by either material alone – for example exciton-plasmonic coupling, integrated spintronic circuits, and tunnel barriers in superconducting qubits. In all of these cases, the atomic structure at the interface between the metal and the 2D material (2D/3D interface) directly affects the device performance.[3]

Here, we explore the local electronic, optical and structural properties of well-controlled device-relevant 2D/3D interfaces using a combination of monochromated high-energy resolution electron energy-loss spectroscopy (EELS), atomic resolution STEM and *in situ* ultra-high vacuum (UHV) TEM. First, we demonstrate ultra-low defect-density 2D/3D interfaces using slow metal evaporation rates onto clean suspended 2D materials in UHV.[4] Focusing initially on the MoS_2/Au heterostructure, we investigate epitaxial Au nanoisland growth in its equilibrium Winterbottom shape, providing a quantitative estimate for 2D/3D interface energy through thermodynamic modelling. We use these well-defined interfaces to elucidate the effect of 2D/3D integration on electronic properties. Here, monochromated STEM-EELS allows us to map local changes of plasmonic and excitonic spectra of a MoS_2/Au heterostructure on the nanometer scale. We extend our analysis to the technologically relevant metals Ti and Nb and show that suspended 2D materials enable the formation of metal/2D/metal (3D/2D/3D) heterostructures. Such understanding of the structure-property relationship allows versatile design of 2D/3D heterostructures for next generation nanoscale devices, and we discuss mechanisms by which optimizing this 2D/3D interface is crucial for improving existing devices as well as generating novel 'mixed-dimensional' 2D/3D heterostructures.

2:15 PM NM07.07.03
Machine-Learning Assisted High-Throughput Computational Identification of Mixed-Dimensional Materials Joshua T. Paul[1,2], Nina Andrejevic[2], Lincoln J. Lauhon[1], Pierre Darancet[2,1] and Maria K. Chan[2,1]; [1]Northwestern University, United States; [2]Argonne National Laboratory, United States

The nano revolution started with the discovery of graphene and has led to a great deal of research into low-dimensional systems. These systems range from 0D nanoparticles to 1D nanowires and nanoribbons to 2D monolayers, all of which experience quantum confinement that can give rise to unique properties. More recently, mixed dimensional materials have received increasing attention due to the potential for synergistic and emergent properties in combinations of 2D, 1D, and 0D systems. These investigations have used intentionally synthesized mixed dimensional systems, but the question of what mixed dimensional materials occur in nature has yet to be tackled. In this work, we search the MaterialsProject database for crystals that contain sub-networks of atoms with differing dimensionalities (e.g., 1D nanowires between 2D layers). We perform this search with the Topological Scaling Algorithm, using atomic radii as a first pass and the CrystallNN algorithm as a second. We follow by using the Electron Localization Function to train an ensemble of neural network classifiers to distinguish bonds with a set of well-chosen materials examples. Subsequently, we apply the trained models to classify bond types and identify candidate mixed-dimensional heterostructures from a broad range of materials systems as a third pass. From these searches, we identify several mixed-dimensional crystal structures, which we then relax using Density Functional Theory while accounting for van der Waals forces. Finally, we calculate various properties in these crystals, including the electronic structure and thermodynamic stability.

Study of How Remote Epitaxy is Truly Remote Celesta S. Chang[1], Bo-In Park[1], Junseok Jeong[1], Kiseok Kim[1], Hyunseok Kim[1], Matthew Baron[2], Hyunjun Sim[2], Sangho Lee[1], Xinyuan Zhang[1], Young Joon Hong[3], Darrell Schlom[2] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Cornell University, United States; [3]Sejong University, Korea (the Republic of)

Growth of single-crystalline films by remote epitaxy has been studied for the past few years, however the underlying physics and mechanism of remote nucleation and growth have not yet been fully understood. As a result, remote epitaxy may be confused with van der waals epitaxy, or especially through-hole epitaxy that also involves the use of 2D layers.

Since 2D layers are atomically thin and therefore easy to damage, preparation of 2D-layer coated substrates for remote epitaxy can suffer from tearing, wrinkles, and pinholes of the 2D layer during transfer. This brings up the question whether remote epitaxy is actually happening remote, or whether through-hole epitaxy is dominating such that nucleation from direct epitaxy through pinholes eventually coalesce to form the epilayer.

One example of widely used through-hole epitaxy, is epitaxial lateral overgrowth, where growth takes place on a periodic mask covering the substrate. This method has been widely utilized for semiconductor materials to block dislocations threading from the substrate. However, it can only be applied to certain materials such as III-V, III-N materials like GaN or InGaAs that exhibit lateral growth mode. On the other hand, same methods for oxides would be impossible as they are known to be dominated by vertical growth mode. Also, as remote epitaxy is completed only when the epilayer is both single-crystalline and possible to be peeled off, for through-hole epitaxy to behave like remote epitaxy, stringent requirement for periods and widths of the mask should be imposed for clean exfoliation to take place.

In this talk, we first mimic through-hole epitaxy via graphene mask, where we intentionally nanopattern the graphene to have various widths and periods. Growth of BaTiO3 on SrTiO3 covered with graphene masks show that oxides exhibit a strong vertical growth mode such that a fully merged film is impossible to achieve with through-hole epitaxy. Second, by growing GaN on different thicknesses of graphene-coated GaN, we discuss the different nucleation behavior on graphene. Through our fundamental study, we hope to understand remote epitaxy better to provide building blocks for heterogeneous materials platforms for future cutting-edge applications.

3:45 PM NM07.07.05
Atomic-Scale Characterization of Engineered Strain Gradients in Free-Standing Oxide Membranes Harikrishnan Kunhikrishnan Premakumari[1], Varun Harbola[2], Jaehong Choi[1], Kevin J. Crust[2], Yonghun Lee[2], Yu-Tsun Shao[1], Gregory D. Fuchs[1], Harold Y. Hwang[2] and David A. Muller[1]; [1]Cornell University, United States; [2]Stanford University, United States

Due to the inherent difficulty of stabilizing large strain gradients in thin films or bulk materials, the study of flexoelectric effects has largely been limited to dislocations, cracks, or other defect sites. However, with the recent advances in lift-off techniques for producing freestanding membranes, it has become possible to engineer and study large strain gradients in nanostructures. Here, using a platform of lifted-off strontium titanate (STO) membranes transferred onto a nanofabricated array of silicon dioxide (SiO_2) nanopillars, we measure large strain gradients ($> 10^6$ m^{-1}) near the apex of the resulting folds in the STO membranes using scanning transmission electron microscopy. Through the flexoelectric effect, such high strain gradients induce a polarization of around 25 $\mu C/cm^2$, comparable to that in ferroelectric materials. Further, using electron energy loss spectroscopy (EELS), we track the energy shifts in the titanium $L_{2,3}$ edge and observe a monotonic increase of about 0.1 eV in the crystal field splitting energy as we move from a region of positive to negative strain.

4:00 PM *NM07.07.06

Two-Dimensional Crystals and Nanomembranes with In-Plane Dipoles for Energy Conversion and Spintronics Jian Shi; Rensselaer Polytechnic Institute, United States

In the design of high-performance spintronic or energy conversion devices, it has been recognized that in-plane electric dipoles in van der Waals crystals or two-dimensional quantum membranes could provide a plethora of opportunities. For example, it has been widely recently formulated that in-plane ferroelectric polarization in quantum well crystal could produce a unidirectional effective magnetic field through the Rashba-Dresselhaus effect leading to the creation of persistent spin helix. Further, the flexibility in the design of the phononic boundary conditions of low-dimensional crystals allows the possibility for the engineering of phonon dynamics-determined dipole-related physical properties. In this talk, I will present our recent progresses of understanding the relationships between physical properties and in-plane dipole dynamics in two-dimensional crystals and nanomembranes.

4:30 PM NM07.07.07
A Route to Fabricate Mixed Dimensional, Ultrathin Molybdenum Carbide/Selenide Heterostructures David Sanchez, Alexander J. Sredenschek, Da Zhou, Jiayang Wang, Daniel Cintron Figueroa, Andres Fest, Susan B. Sinnott, Joshua A. Robinson and Mauricio Terrones; The Pennsylvania State University, United States

The non-layered, superconducting group VI transition metal carbide (TMC) and layered, semiconducting group VI transition metal dichalcogenide (TMD) families have individually received much attention over the last century with recent advancements in the capability to fabricate ultrathin crystals for nanoelectronics. Tuning the electronic properties of these materials typically involves modifying the transition metal atom; however, we found that manipulating the nonmetal atom also yields significant differences in the physicochemical properties. A previous study by our group demonstrated that post-growth heat treatment of molybdenum carbide (α-Mo_2C) with hydrogen sulfide gas can be used to fabricate an ultrathin, molybdenum carbide/molybdenum disulfide (α-Mo_2C/MoS_2) heterostructure with enhanced superconducting properties [1]. In the present work, we extend the heat treatment process to selenium and successfully formed a non-layered/layered molybdenum carbide/molybdenum diselenide (α-$Mo_2C/MoSe_2$) heterostructure. We further describe the structure and property relationships of this heterostructure and highlight the differences between the selenization and sulfurization processes. We demonstrated the synthesis of ultrathin, single crystal α-Mo_2C nanoplatelets using a previously reported chemical vapor deposition approach [2]. We studied and identified that the type of selenium precursor and temperature used in the post-growth heat treatment have a significant impact on the resulting α-$Mo_2C/MoSe_2$ heterostructure. To corroborate the effects of these parameters on the formation of the heterostructure, we implemented structural techniques such as Raman spectroscopy, scanning electron microscopy (SEM), X-ray diffraction (XRD), and planar/cross-sectional scanning/transmission electron microscopy (S/TEM). Electronic transport measurements in a four-point probe arrangement were undertaken to study the changes to the superconductivity of α-Mo_2C and elucidate the transport behavior in the α-$Mo_2C/MoSe_2$ heterostructure. First-principles calculations were also performed to study the energetic and electronic characteristics of the interface. Finally, we propose a general conversion mechanism and highlight key synthesis aspects to fabricate ultrathin, atomically-sharp TMC/TMD heterostructures which are critical to applying these novel materials to nanoelectronics.

New Metallic Aerogels from 1D to 3D Structures—Electrical, Mechanical and Electrochemical Propoerties Caroline Celle, Jean-Pierre Simonato and Maribel Touron; CEA Grenoble, France

Intensive research is carried out on new emerging highly porous materials with high electrical conductivity and very low densities. Silver nanowires (AgNWs) are a dimension-wise building block material for conductive 3D-percolated networks. These materials, due to their spatial organization, are of interest for negative electrode of Lithium batteries.
S. S. Kistler discovered a new class of ultralight materials with remarkable properties in 1931 : the aerogels. since then, a wide range of composition has been studied to obtain unique properties such as lightweight or electrical conductivity. This research work focuses on new aerogels made from silver nanowires and polymers.
Cryogels are obtained by freeze-drying concentrated suspensions. As the solid components are freeze-templated, cryoprotectants, freezing rates and directions tune the final structure and thus the properties. Pure AgNWs networks lack stability. most binding agents for mechanical properties improvements cause drastic losses in electrical conductivity.
This research work focuses on new aerogels made from silver nanowires and polymers.
The synthesis principle used in this work is based on the assembly of one-dimensional nanowires to form a three-dimensional (3D) network. The organization in space of the solid elements of the aerogel is due to the freeze-drying process. Cryogels are obtained by freeze-drying concentrated suspensions. Variable freezing directions and rates are used to modify the ice-template and thus the final structure and properties. Pure AgNWs networks lack stability. Most of the binders used to improve the mechanical properties cause considerable losses in electrical conductivity.
In this work, we have synthesized new hybrid cryogels with controlled dimensions and good synergistic behaviour. The morphological, electrical and mechanical properties of these aerogels are characterized to provide a better understanding of the relationship between synthesis parameters and final properties. The electrical and mechanical properties as well as the electrochemical stability have been investigated and will be discussed. The unique structures obtained present a very high porosity (higher than 98 percent), a very low density (a few mg.cm−3) as well as a high electrical conductivity (hundreds of S.m−1) for a high mechanical strength (higher than ten of kPa) in spite of the high porosity. The applicative interest of these materials is explored. On the one hand, electromechanical characterizations of aerogels are studied in order to develop a piezoresistive sensor (electrical resistance variations of 20 percent for deformations of 50 percent are maintained over a hundred cycles). On the other hand, electrochemical characterizations are carried out in order to use the synthesized aerogels as anodes of lithium metal batteries. A first demonstration as an electrode has been performed in view of a future integration in solid state batteries.

NM07.08.02

Nucleation and Growth of Monolayer MoS_2 by Sulfurization of Faceted MoO_2 Crystals Yeonjoon Jung, Huijie Ryu, Hangyel Kim, Jaewoong Joo, Seong Chul Hong and Gwan-Hyong Lee; Seoul National University, Korea (the Republic of)

Fabrication of stable and clean van der Waals heterostructures has been required to develop 2D materials-based devices with high performance. Even though the vdW heterostructures have been demonstrated by stacking 2D materials, direct growth of 2D materials on other 2D or 3D materials is critical because the interfacial properties are determined by defects, crystallinity, and crystalline rotation angle at the heterointerface. Here, we synthesized highly crystalline monolayer MoS_2 by using a faceted MoO_2 crystals as a growth seed. A seamless heterostructure of metallic MoO_2 and semiconducting MoS_2 was fabricated. We explored how nucleation and growth of the MoS_2 occur on the surface and terraces of the faceted MoO_2 crystals. Although the multilayer are nucleated at different terraces of MoO_2, highly crystalline monolayer MoS_2 with superior optical and electrical properties can be grown on the SiO_2 substrate around edge of the MoO_2 due to different diffusivity on the SiO_2 and MoO_2. We also observed a strong charge transfer between the metallic MoO_2 and semiconducting MoS_2, leading to strong quenching of photoluminescence. Our study provides deeper understanding in growth of 2D materials on the bulky seeds and shows probability to grow high quality 2D materials by controlling nucleation sites and diffusivity of source materials on the target substrate.

NM07.08.04
Strain Modulated Charge Transfer of (0D–2D) $ZnS/ZnIn_2S_4$ Heterostructure Through a Facile *In Situ* Synthesis for Efficient Solar to Fuel Conversion Amr Sabbah[1], Indrajit Shown[2], Mohammad Qorbani[3], Li-Chyong Chen[3] and Kuei-Hsien Chen[1]; [1]Academia Sinica, Taiwan; [2]Hindustan Institute of Technology and Science, India; [3]National Taiwan University, Taiwan

Forming an intermediate electric field at the interface of two semiconductors to facilitate charge transfer and isolate redox reactions is still challenging for catalysis applications. However, great progress has been achieved regarding the rational design of different dimensional semiconductors, the in-situ growth of the heterostructure is considered the best choice to achieve a high-quality interface. In this study, we fabricate a $ZnS/ZnIn_2S_4$ (0D–2D) heterostructure catalyst, where cubic ZnS crystals are decorating a hexagonal $ZnIn_2S_4$ (ZIS) layer structured with a high difference in the solubility product constant K_{sp}, using a single pot hydrothermal approach. We used XRD, HRTEM, and band alignment studies to determine the origin of the interfacial charge transfer mechanism, which is based on lattice mismatch and related interfacial microstrain. The structural strain at the interface was caused by lattice mismatch in the composites caused by heterostructuring between two lattices due to the interatomic distances and different crystal symmetries. In addition, this interfacial mismatch strain can induce mid-gap states at the interface that facilitate electron and hole recombination forming a Z-scheme configuration. The low-temperature photoluminescence study was studied to reveal the nature of the defect state at the interface and to provide a clear explanation for the charge carriers' mechanism. The microstructure and spectroscopy analysis both disclose that the optimum ratio of ZnS and ZIS with this (0D–2D) catalyst exhibits improved charge carrier separation and shows significantly enhanced photochemical CO_2 reduction and hydrogen evolution.

NM07.08.05
Flexible and Transparent Nanocomposites with 3D Heterogenous Interfaces for Attachable Optics with Superior UV Protection Junyong Ahn, Seohan Yun, Taehyun Ryu and Junyong Park; Kumoh National Institute of Technology, Korea (the Republic of)

Ultraviolet (UV) rays caused by various electronic devices such as mobile phones and tablets can be harmful to the human body when continuously exposed, so interest in and demand for UV blocking materials and technologies are increasing. In the meantime, many cream-type products containing TiO_2 or ZnO nanopowders have been developed to block sunlight, but the library of film-type transparent materials that can be applied to optoelectronic devices is still not diverse. In this presentation, we present a flexible and transparent nanocomposite embedded with 3D networked ultrathin (< 60 nm) ZnO. Compared with typical 2D thin film materials, 3D networked ZnO has much more scattering and absorption interfaces in the vertical direction, resulting in higher UV blocking efficiency, assuming the same footprint. The morphology of the 3D network is determined by the sacrificial nanoporous template used, and the ZnO content of the nanocomposite is precisely controlled through the process parameters of atomic layer deposition. By optimizing the morphology of the 3D network and the ZnO content, we have successfully realized a flexible nanocomposite film that exhibits both visible transparency (> 60%) and excellent blocking efficiency (> 99%) in the UVB region. The usefulness of the developed nanocomposite film can be further enhanced through additional surface texturing to improve its adhesion function. We plan to present the UV blocking performance of the accessory-type nanocomposite film by attaching it to portable electronic devices and human skin.

NM07.08.06
Readily Transferrable Growth of Crystallographically Aligned GaN Thin Film on Multilayer Graphene Transferred onto Sapphire Substrates by Thru-Hole Epitaxy Hyunkyu Lee and Chinkyo Kim; Kyung Hee Univ, Korea (the Republic of)

We heteroepitaxially grew GaN films on multilayer graphene transferred onto r-sapphire substrates. XRD measurement and analysis revealed that GaN films, grown on multilayer graphene transferred onto r-sapphire substrates, were crystallographically aligned with an underlying substrate. Despite well-established crystallographic alignment with the underlying substrate, the GaN films were easily detached from the graphene/sapphire template by using a thermal release tape. Due to the usage of thick graphene multilayers, the GaN films were not grown by remote epitaxy. Extensive TEM analysis across the interfacial regions showed that small holes in the nanometer scale played a major role in establishing both crystallographic alignment and easy detachability. In contrast with remote epitaxy, no strict conditions on the number of a layer or defect-free high quality for graphene were required for our growth method, thru-hole epitaxy.

NM07.08.10
Evidence For a Giant Magneto-Electric Coupling in Composites of Coaxial Nanofibers of Nickel Zinc Ferrite and PZT Bingfeng Ge[1,2], Jiahui Liu[1,2], Jitao Zhang[2] and Gopalan Srinivasan[1]; [1]Oakland University, United States; [2]Zhengzhou University of Light Industry, China

Ferromagnetic-ferroelectric composites are of interests for studies on the nature of magneto-electric (ME) interactions between the two phases and for applications in useful technologies. The interactions are aided by mechanical forces, i.e., magnetostriction in the ferromagnet in a magnetic field and piezoelectric deformation in the ferroelectric in an electric field and the strength of ME coupling depends on efficient transfer of strain fromone phase to the other. A significant enhancement in the coupling strength can be accomplished in a nanocomposite in which the ratio of surface area-to-volume is orders of magnitude higher than in bulk or thick film composites [1,2].
This work is on the synthesis of nanofibers of nickel zinc ferrite, Ni(1-x) Znx Fe2O4 (x = 0.5-0.9) (NZFO) and lead zirconate titanate (PZT) by electrospinning and measurements of strengths of ME interactions in discs made of the nanofibers. Two types of fibers were made: (i) Core-shell nanofibers with either ferrite or PZT core and (ii) Composites fibers of ferrite and PZT. In electrospinning of core-shell fibers sol-gels of the ferrite and ferroelectrics were dispensed through a dual chamber needle. For composite fibers sols of equal volumes of ferrite and PZT were mixed and dispensed through a single needle. Electric fields, 1.5 – 2 kV/cm, was applied between the needle and a collector made of a rotating aluminum drum. Fibers are formed when the electrostatic forces overcome the surface tension. Core-shell fibers and composite fibers with an average diameter of 200-500 nm were prepared. Fibers were annealed at 700-900 C and characterized in terms of structure by electron microscopy, X-ray diffraction, and scanning probe

microscopy (SPM). Fibers were free of impurities, ferromagnetic parameters for the fibers compared favorably with parameters for bulk NZFO, but the saturation ferroelectric polarization was two orders of magnitude smaller than for bulk samples.
The fibers were pressed into discs for measurements of strength of ME coupling by static magnetic field H induced polarization and low-frequency ME voltage coefficients (MEVC). The fractional change in the remnant polarization dPr/Pr measured as a function of H= 0-7 kOe and a giant ME coupling was evident in discs made of core-shell fibers. The maximum change in dPr/Pr increased with increase in Zn concentration, from -3% for x=0.1 to 82% for x=0.3 and then decreased with increase in Zn concentration to -1% for x=0.5. A hysteresis in dPr/Pr vs H was measured for all of the discs. Discs of composite fibers, however, had much smaller dPr/Pr-values of -1 to -3%. Data on MEVC vs bias field *H* obtained by applying a static field H and an ac magnetic field h at 30 Hz, both fields parallel to each other and parallel to the plane of a disk of fibers. Discs of core-shell fibers showed a large ME response at H = 0 and was indicative of a built-in magnetic field likely due to anisotropy in the fibers. With increase in H, MEVC increased to values as high as 17 mV/cm Oe and then with increase in H decreased to near-zero value. The maximum MEVC for dics of NZFO-PZT composite fibers was small, on the order of 2-3 mV/cm Oe. Thus the results of this study showing a giant ME coupling in discs of core-shell fibers are indicative of their potential use for sensors and energy harvesting applications.
The research at Oakland University was supported by a grant from AFOSR and the National Science Foundation (DMR- 1808892).

2D Magnetic Nanosheets Made in Aqueous Suspension Paulo H. Michels Brito[1], Barbara Pacakova[1], Leander Michels[1], Sergio H. Toma[2], Koiti Araki[2], Josef Breu[3], Kenneth D. Knudsen[4,1] and Jon Otto Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]University of São Paulo, Brazil; [3]Universität Bayreuth, Germany; [4]Institute for Energy Technology, Norway

The development of 2D nanosheets in stable suspension that respond rapidly to and can be manipulated by applied magnetic fields may become highly desired, for instance extractions. Here we report the efficient and unique approach of decoration of 2D clay nanosheets in liquid suspension with magnetic nanoparticles only in one side. Superparamagnetic iron oxide nanoparticles were used to functionalize insulating transparent synthetic sodium fluorohectorite clay nanosheets with aspect ratio of about 20,000. The nanoparticle density on the nanosheets are tuned to different coverage fractions. Small Angle X-ray Scattering (SAXS), spectroscopy (FTIR, UV-VIS), microscopy techniques (SEM and AFM), and magnetic properties were used to characterize the magnetic nanosheets. This new material opens new possibilities of scalable applications.

Selected Area Chemical Vapor Deposition of Three Dimensional Nanoarchitectures John Lasseter[1], Steven Randolph[2] and Philip Rack[1]; [1]University of Tennessee, United States; [2]Oak Ridge National Laboratory, United States

We showcase selected area chemical vapor deposition (CVD) on 3D nanostructures by taking advantage of photothermal heat transport, which is intrinsic to the nanostructure and not limited to a specific substrate. Nanostructure templates are deposited through lithographic, direct write and other nanofabrication methods and results indicate the ability to initiate the process below the diffraction limit. Focused Electron Beam Induced Deposition (FEBID) is featured as a high-resolution nanofabrication method with short iteration times. The nanostructures are then irradiated under a focused, unpolarized laser with gas precursor flow and no electron beam to induce photothermal CVD. PtC_x FEBID deposits were systematically investigated to show the effects of laser pulse width, power, and repetition rate on growth rates. Finite element thermal simulations were performed and corroborate experiment - evidence points towards a deposition process dominated by the nanostructure thermal conductivity and geometry, but substrate thermal conductivity and the nanostructure optical absorbance still have some effect. Efforts to create functional nanostructures by utilizing magnetic ($Co_2(CO)_8$), plasmonic (dimethylgold(III) acetylacetonate) and O_2/H_2O gas coflows for material purification are presented, as well as the ability to modify FEBID deposits in parallel.

NM07.08.14
Emergence of Ferromagnetism in Aluminum/Silver Nanoparticle Composites Ken Hakamata[1], Taku Saiki[2], Akira Matsuo[3], Mahito Yamamoto[1] and Mitsuru Inada[1]; [1]Kansai University, Japan; [2]kansai University, Japan; [3]The University of Tokyo, Japan

The highlight of this study is that the magnetic properties of a composite of superparamagnetic aluminum nanoparticles (Al NPs) and diamagnetic silver nanoparticles (Ag NPs) exhibited ferromagnetism. In addition, temperature-independent paramagnetic components were observed in the composites that were not observed in both Al and Ag NPs alone. These results indicate the induction of unique magnetic moments in the nanoparticle composite and the presence of magnetic exchange interactions within the composites.

Al NPs were prepared by pulsed laser ablation of α-alumina powder in pure water. Scanning Electron microscopy and X-ray diffraction measurements showed that the Al NPs were polycrystalline with an average particle size of 19 nm. The magnetic properties of the Al NPs were measured by MPMS. The M-H curves showed superparamagnetism, but no temperature-independent Pauli paramagnetic component was found. Based on the electron spin resonance measurements, the origin of the magnetic moment seems to be the oxygen defects in the surface oxide layer of the Al NPs.

We prepared $(Al\ NP)_x/(Ag\ NP)_{1-x}$ composites by mixing the Al NPs and Ag NP paste, and investigated their magnetic properties by MPMS. It should be noted that the Ag NPs were weakly diamagnetic. With increasing x, the composites showed superparamagnetism, but the increase in saturation magnetization was not monotonic. The x=0.6~0.8 composites showed hysteresis in the M-H curves, indicating that the composites were ferromagnetic. In addition, for these composites, a temperature-independent paramagnetic component was observed in the M-T curves. Although the origin and mechanisms of the magnetic properties are under investigation, the experimental results show that the unique magnetic moment is induced in the composites, and the existence of the magnetic exchange interactions inside and/or interface of the composites.

Ni-Catalyzed GaP Nanowires and Nanosheets with Crystallographic Phase Control—Implications for Single-Material Heterostructures Bruno C. Silva[1,2], Lucas M. Nascimento[1], Helio T. Obata[1], Antonio A. von Zuben[1], Arandi G. Bezerra Jr.[3], Wido H. Schreiner[4], Fernando Iikawa[1], Martien Den-Hertog[2], Odilon D. Couto Jr.[1] and Monica A. Cotta[1]; [1]UNICAMP, Brazil; [2]Institut Néel, France; [3]Universidade Tecnológica Federal do Paraná, Brazil; [4]Universidade Federal do Paraná, Brazil

III-V semiconductor nanostructures have been considered for several applications, ranging from quantum computing to optoelectronics and energy conversion [1-3]. In particular, wurtzite Gallium Phosphide nanowires work as a substrate to direct band gap hexagonal Si and SiGe alloys [4]. However, the ability to change morphologies, from nanowires to nanosheets, provides a tool to better adapt the nanostructures to the intended applications. Two-dimensional GaP materials, which have not been explored so far, would make easier their integration into device fabrication processes, and controlling

crystallographic phase transition from zincblend to wurtzite provides the opportunity of creating heterostructures in a single material. Here, we explore these possibilities and report the growth of GaP nanostructures by Chemical Beam Epitaxy, catalyzed by Ni nanoparticles formed from thermal deposition of a thin Ni layer. Samples were obtained under different growth conditions, with temperatures in the range 530-590C and TEG and thermally-cracked PH3 as group III and V precursors, respectively. Electron microscopy analysis of the samples shows both nanowires and nanosheets, with the nanosheet population increasing with temperature. High resolution transmission electron microscopy reveals that nanosheets are primarily zincblend, while nanowires present a mixture of zincblend and wurtzite phases. The observed growth rates indicate that Ni serves as a better catalyst for Ga-based nanowires than Au. Atomic force microscopy of the nanosheets reveals width and length values up to 2 and 10 micra, respectively, with 50 to 100 nm thickness. Photoluminescence at low temperatures of the as-grown samples shows characteristic signal from wurtzite GaP crystal structure, with typical defect luminescence as well as optical emissions in the green spectral range at 2.16 eV and 2.20 eV with linewidths ~ 30 meV. These results indicate the feasibility of our approach to grow different types of GaP semiconductor nanostructures using Ni cataysts, and provide new possibilities of heterostructures for this single optoelectronic material. Low Thermal Budget Photonic Curing as a Rapid and Facile Method for the Preparation of Nickel Oxide/Carbon Composites Binod Subedi, Najma Khatoon and Douglas B. Chrisey; Tulane University, United States

Low thermal budget photonic curing technique can process metal organic precursors and convert them into nanocomposites in short period of time (few seconds). In this work, we demonstrate that nickel acetylacetonate (Ni(acac)) can be converted into nanocomposite thin films of nickel oxide and reduced graphitic oxide (NiO-rGO) using this technique. Systematic investigation of morphology, structure, and electrochemical properties of films prepared using different bank voltages of photonic curing (500V, 600V, and 700V) is performed. During photonic curing at these voltages, samples are processed using light energy with peak power per unit area 8.2 kW/cm^2, 14 kW/cm^2, and 22 kW/cm^2 respectively. The total energy irradiated per unit area is kept constant at $43J/cm^2$ for all films by varying the number of pulses. As the peak power used to process the sample increases, maximum temperature of the film also increases, which in turn affects the porosity, quality of crystallinity, and elemental composition in the composites. We studied these films using SEM, TEM, Raman Spectroscopy, and EDXS. We also used films prepared at 700V to construct a hybrid capacitor device with activated carbon as negative electrode and NiO-rGO as positive electrode. CV, GCD and EIS measurements were performed to study the energy storage properties of the films. Thermal profiles of films are also estimated using simulations based on physical properties of the precursor molecules and processing parameters used during photonic curing. Analysis of simulations and experimental results indicate that, to understand and optimize the resulting nanostructures, photochemical reactions also need to be taken into consideration. The study also sheds light into the importance of using higher power as opposed to processing over longer period.

Shape-Selective Filtration Using Lamellar Block Copolymer-Based 1D Slit Membranes Maninderjeet Singh and Alamgir Karim; University of Houston, United States

The growing need for highly efficient water purification and bioseparations necessitates innovations in ultra-filtration membranes. Block copolymer (BCP) membranes have emerged as a promising player for efficient ultra-filtration due to their uniform pore sizes and sharp cut-offs. Most of the work in BCP membranes has focused on using cylindrical pores. In this work, we demonstrate novel slit-based membranes using lamellar block copolymers. The lamellar BCPs are vertically oriented in one step film casting process by neutral solvent design. The vertically oriented BCPs are converted to slit membranes using a wet etching process. These slit-shaped membranes demonstrate sharp cut-offs for solute filtration. Furthermore, we demonstrate the first example of enhanced separation of 1-D nanomaterials (nanorods) as compared to the 0-D nanomaterials (nanoparticles) using these slit-based membranes, which is facilitated by the shape similarity of 1-D nanomaterials with the nano-slits. Additionally, we show that these slit-shaped membranes show permeability of similar-sized Lysozyme and BSA proteins while retaining the IgG antibodies, thus making them highly useful for bioseparations. We believe that these slit-shaped membranes will be useful for shape-selective filtrations across a spectrum of applications.

NM07.08.18
Charge Carrier Transfer Dynamics in 0D-2D Heterostructures Studied by Pump-Probe Transient Optical Method Mircea Cotlet; Brookhaven National Laboratory, United States

Mixed dimensional heterostructures present recent interest because they can add in optical, electronic and magnetic properties with respect to the elements used to make the mix. Emerging properties can be expected to occur or improved behavior of existing properties can be obtained rather than the added properties expected by the summation of individual properties. Improved or directed behavior can be achieved for example by understanding interfacial interactions between components which are part of the mix. For example carrier transport at the interface can be regulated if one understands the behavior of this process at the interface. Here we present femtosecond tranient optical studies of charge carriers in lead sulphide quantum dot-layered molybdenum sulphyde mixed heterostructures and describe the role of nanoparticle size and layer number of the 2D material on the kinetics of charge transport.

NM07.08.19
Direct Growth of Clean-Surfaced Monolayer Graphene on $SrTiO_3$ Substrates via Metal-Catalyst-Free Chemical Vapor Deposition Mingi Moon[1], Celesta S. Chang[2], Doyoon Lee[2], Yun Seog Lee[1] and Jeehwan Kim[2]; [1]Seoul National University, Korea (the Republic of); [2]Massachusetts Institute of Technology, United States

Graphene has been used as a major buffer layer in remote epitaxy, due to its thin, flexible, and sheer nature that allows the strong crystal potential of the substrate to easily penetrate and influence the nucleation of the epilayer. Thanks to the weak van der waals force of graphene, exfoliation of materials ranging from III-V, III-N to complex oxides has been demonstrated over the past few years. In the beginning, the quality of the obtained freestanding films - smoothness of the surface, percentage of the exfoliated area, or defect density - suffered largely from the quality of graphene as graphene had to be transferred to the host substrate by wet/dry transfer method. These methods are likely to create pinholes, wrinkles and polymer residues on the graphene surface that would highly affect the nucleation. In the efforts of developing direct growth of graphene and other 2D materials on III-V, III-N platforms, wafer-scale exfoliation with high crystallinity has become possible.

As complex oxides host a myriad of different physical properties such as ferroelectricity, piezoelectricity and ferromagnetism, the demand for obtaining wafer-scale with high crystallinity has been increasing. Similarly for complex oxides, several methods have been developed to grow monolayer graphene

on substrates such as MgO, SiO_2, and Al_2O_3 with the aid of metal catalysts. However, the use of metal catalyst itself can degrade the graphene quality during the synthesis of graphene. For example, once Cu catalyst is deposited or scattered on substrates, the following growth process involves evaporation of metal which leads to the creation of pinholes and voids at the graphene surface. Thus, the synthesis of clean-surfaced single layered graphene on oxide substrates has been challenging.

In this study, we demonstrate the method of growing clean-surfaced monolayer graphene on electrically insulating $SrTiO_3$ (STO) substrates using metal-catalyst-free chemical vapor deposition (CVD). Any potential of contamination was blocked in advance by the treatment of STO substrates with buffered oxide etchant (BOE) and annealing at 1000 °C. The CVD chamber was maintained at ultra-high vacuum (~10^{-6} Torr) before growth. Monolayer graphene was formed with the mixture of gas (Ar, H_2, and CH_4) at the atmospheric pressure followed by H_2 etching process to clean the surface of graphene. Quantitative evaluation of the number of graphene layers was carried out using Raman spectroscopy by transferring the graphene on SiO_2 wafer. The quality of as-grown graphene was determined by scanning electron microscopy (SEM) and transmission electron microscopy (TEM) confirming the clean surface and the thickness of as-grown graphene respectively. The change in lattice parameter of STO substrates before and after graphene formation due to carbon absorption was measured by X-ray diffraction (XRD) to estimate the lattice mismatch with the desired epilayer via remote epitaxy. Our growth of clean-surfaced monolayer graphene on STO substrates will provide a platform for remote epitaxy of perovskite-type complex oxides, which will drastically improve the quality of freestanding oxide films and eventually enable the demonstration of wafer-scale exfoliation that has been extremely limited.

NM07.08.22
Unconventional Behavior in Low-Resistance Metal Contacts to High-Purity, hBN-Encapsulated Monolayer Semiconductors Yang Liu, Song Liu and James Hone; Columbia University, United States

Two-dimensional (2D) monolayer semiconductors such as transition metal dichalcogenides (TMDs) have attracted intense attention in electronics and optoelectronics due to properties such as high mobility, direct optical bandgap, and mechanical flexibility. For most applications, optimum performance is attained using high-purity TMDs encapsulated with hexagonal boron nitride (hBN) to minimize extrinsic disorder. However, achieving high-quality contacts to hBN-encapsulated ultrapure monolayer TMDs remains challenging. Here we first report a well-developed flux growth strategy that could produce a series of centimeter-sized single-crystal TMDs with record low defect densities of ~10^9-10^{10} cm^{-2}, including 2H-WSe_2, 2H-$MoSe_2$, Td-WTe_2, 2H-$MoTe_2$ and 1T'-$MoTe_2$. Next, taking the ultraclean semiconductor WSe_2 as an example, we demonstrate a process for mechanical transfer of metal contacts embedded within hBN onto ultraclean monolayer TMDs that minimizes doping, strain, and interfacial roughness. Using this process, we further show efficient contacts to hBN-encapsulated ultrapure monolayer WSe_2. This method achieves excellent electric performance with room temperature contact resistance R_c near 5 , and enables hysteresis-free transistors with record-high mobility of 655 cm^2/Vs at room temperature. Furthermore, these contacts show an ultralong transfer length of 1 m, placing them in a regime distinct from previous reports for contacts to TMDs and bulk semiconductors. This work provides a general method of making strain- and doping-free hBN-encapsulated vdW contacts and highlights critical challenges for device applications.

NM07.08.23
Direct Synthesis of Vertically Oriented π-Conjugated Metal-Organic Frameworks on Conductive Substrates Sun Hae Ra Shin, Jinhui Tao, Maria Sushko, Nathan Canfield, Mark Bowden and Praveen Thallapally; Pacific Northwest National Laboratory, United States

The π-conjugated metal–organic frameworks (MOFs) are a new class of MOFs with strong in-plane π-conjugation and weak out-of-plane π-π stacking. The π-conjugated MOFs exhibit notable properties such as intrinsic porosity, crystallinity as well as excellent electrical conductivity mediated by delocalized π-electrons. These unique features have motivated increasing effort to explore the π-conjugated MOFs for promising device applications in optoelectronics, catalysis, and energy that require the π-conjugated MOFs in the form of thin film or coating. In this study, vertically aligned triphenylene catecholate-based MOFs were directly grown on conductive substrates by a simple hydrothermal method. Effects of substrate identity such as surface chemistry and roughness on crystal growth behavior such as nucleation density, orientation, and growth kinetics were investigated.

NM07.08.24
Three-Dimensional Nanofabrication with Sub-20 nm Resolution and Eight-Inch Wafer Scalability via Thermally Assisted Nanotransfer Printing Tae Wan Park, Young Lim Kang and Woon Ik Park; Pukyong National University, Korea (the Republic of)

Nanotransfer printing (nTP) is one of the promising nanofabrication methods due to its process simplicity, cost-effectiveness, and scalability for two-/three-dimensional nanostructures. However, various nTP techniques still have critical challenges for realizing sub-50 nm high-resolution pattern formation at wafer-scale. Here, we introduce a simple and practical thermally assisted nanotransfer printing (T-nTP) process that can effectively produce well-ordered sub-20 nm nanostructures over an 8-inch wafer by the use of a heat-rolling-press system that can provide uniform heat and pressure. The T-nTP process enables reliable pattern formation of metallic (Pt, Pd, Ag) and semiconducting (NiO, WO_3, $Ge_xSb_yTe_z$) materials with functionalities on diverse substrates including rigid Si, flexible polyethylene terephthalate (PET), and slippery glass. Furthermore, we show the formation of ultrafine (≤ 20 nm) 3D hierarchical nanostructures via the combined method of T-nTP and directed self-assembly (DSA) of block copolymers (BCPs). Moreover, we also demonstrate how to obtain a high-density NiO_x/Pt memristive crossbar nanoscale pattern with a width of 14 nm, showing excellent unipolar resistive switching behavior. We expect that the proposed novel T-nTP method will be applicable to high-throughput nanofabrication combined with other patterning techniques.

NM07.08.25
Reliable Pattern Transfer Printing from Nanoscale to Sub-Micron Feature Size Using Various Polymeric Replica Materials Young Lim Kang, Tae Wan Park and Woon Ik Park; Pukyong National University, Korea (the Republic of)

Nanotransfer printing (nTP) technology provides good reliability and compatibility with other lithography technologies in the fabrication of high-performance memory devices, wearable displays, and photovoltaics. To obtain various nanoscale to microscale patterns in nTP, the selection of replica materials is very important because of patternability from the contact effect between the target materials and desirable substrates. Here, we show a useful and practical thermally assisted nanotransfer printing (T-nTP) method to generate defect-free nano-/micro-structures on substrates using several polymeric replica materials as transfer-printing media. Specifically, we introduce several candidates for reliable pattern replication from Si master mold with various nano-to-micro patterns, such as poly(methyl methacrylate) (PMMA), polystyrene (PS), and poly(4-vinlypyridine) (P4VP). Furthermore, the realization of highly ordered patterns of metal (Pt) and oxide (NiO, Li_2CO_3) on arbitrary substrate can be achieved by using duplicated soft materials through angled deposition and transfer-printing process. Moreover, we show well-defined nanostructures on the diverse surfaces including Cu foil, slippery glass, flexible PET, and curved surface of goggle. We expect that this pattern formation method using soft materials will be applied to advanced emerging devices with complex patterns.

SESSION NM07.09: Growth and Synthesis of Various Dimensional Materials and Heterostructures III

Thursday Morning, December 1, 2022
Hynes, Level 2, Room 203

8:00 AM NM07.09.02
Optical Properties of Xene Heterostructures Grown by MBE Eleonora Bonaventura[1,2], Daya Sagar Dhungana[1], Christian Martella[1], Salvatore Macis[3], Stefano Lupi[3], Emiliano Bonera[2], Carlo Grazianetti[1] and Alessandro Molle[1]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Milano-Bicocca, Italy; [3]Sapienza - Università di Roma, Italy

The dimensional reduction brought by the advent of two-dimensional (2D) materials opened new routes for nanoelectronics and photonics applications. In this framework, the Xenes (artificial graphene-like monoelemental lattices) represented a new forefront because of their peculiarities [1]. Unfortunately, the high chemical reactivity and the strong hybridization effects with the native substrates limited their use to date: silicene on silver and tin on sapphire are two of the most striking examples in this respect. Despite the different nature of the above-mentioned substrates - metallic silver and insulating sapphire - their effect on the properties of Xenes is an intriguing framework where the epitaxial growth of the Xenes can be engineered by *ad hoc* processes. While the hybridization between the electronic states of silicene and the underlying silver are predominant in the former case [2], oxidation effects occur in the latter due to the reactivity of tin [3]. For these reasons, the Xene-based heterostructure concept takes on a certain relevance [4]. Vertical stacks of different layers of atomically thin crystals enable to create novel structures and in turn to control their electronic properties. Such stacks, in a close analogy to the van der Waals heterostructures, could offer an unprecedented degree of freedom in discovering new functionalities. Here, we report on the optical properties of new Xenes-based configurations, i.e. silicene-stanene on Ag(111) and stanene-graphene on Al2O3(0001), made accessible by spectroscopic measurements in the MIR-UV spectral range (from 0.12 to 6.5 eV) and Raman spectroscopy measurements. Our results highlight the role of the inter-layer in electronically and chemically decoupling the on top Xene from the native substrate, resulting in a different response when two layers are combined. The decoupling effect for silicene on stanene is studied in terms of the photo-thermal Raman response, revealing stark differences in the heat transport properties of single layer epitaxial Xenes and heterostructures [5]. In the case of stanene on graphene, X-ray photoelectron spectroscopy shows an effective role of graphene to avoid tin oxidation, whereas the optical analysis discloses an intriguing response from the tin layer different from that grown directly in contact with the Al2O3(0001) substrate. Finally, our findings support the possibility of tuning the well-known plasmonic response of either silver or graphene by combining different atomically thin layers on their surface.

Two-Step Annealing and Diffusion-Driven Exfoliation of Cerium-Doped Terbium Iron Garnet on Silicon Substrates Pang-Hsiao Liu[1] and Karthik Srinivasan[1,2]; [1]University of Minnesota Twin Cities, United States; [2]Cornell University, United States

Thin-film rare-earth iron garnets are very promising non-reciprocal materials for isolators or circulators in photonic devices due to large Faraday rotation and low optical absorption. However, integration of these garnets as thin films in photonic systems faces some challenges, including reduced magneto-optical properties due to poor crystallinity in as-deposited films and limited acceptable annealing of semiconductor devices. To solve these problems, cerium-doped terbium iron garnet (CeTbIG) thin films have been deposited on silicon wafers in this work by sputtering followed by various two-step annealing. During deposition, the Ce content was controlled using the bias voltage of the Ce-target for reproducible CeTbIG. A systematic study of annealing was conducted, involving a first low temperature anneal and a second crystallization treatment to determine when exfoliation will occur. Specifically, a 400ºC anneal for 3 minutes followed by a set of high-temperature treatments (950ºC for 30 seconds then 900ºC for 5 minutes) shows excellent crystallinity without the formation of any undesired phases. This is an improvement compared to traditional single-temperature anneals. Also, the high-temperature sequence caused vacancy diffusion, leading to the formation of a gap just inside the CeTbIG thin film at the substrate interface. This gap enables easy exfoliation. By analysis of diffusivities of iron and rare-earth cations from strain rate-stress data, it was determined that the diffusion mechanism may be related to Nabarro-Herring (lattice diffusion) model. The saturation magnetization and Faraday rotation of the exfoliated CeTbIG film were measured and found comparable to those of the CeTbIG film on the silicon substrate. By applying the two-step annealing an optimized CeTbIG exfoliated films were obtained. These films were transferred onto commercially integrated Si-waveguides for characterization of the magneto-optical properties.

Low-Temperature Growth of 3D Semiconductors with Improved-Quality Using Remote Epitaxy Guanyu Zhou, Rehan Younas, Tian Sun, Galen Harden, Yansong Li, Anthony Hoffman and Christopher Hinkle; University of Notre Dame, United States

Advanced semiconductor technologies such as three-dimensional (3D) monolithic integration and flexible electronics require low-temperature growth of materials that support high-performance devices. However, a big challenge of low-temperature growth is that insufficient atomic diffusion directly leads to poor film quality and consequently poor device performance. Conventional methods to improve growth quality, such as using surfactants, introduce unwanted impurities. Here, using remote epitaxy[1], we show that the quality of low-temperature grown 3D semiconductors are significantly improved on atomically-thin two-dimensional (2D) materials. This is because, from a growth kinetics point of view, atomic diffusion D, which significantly affects film growth quality[2], is exponentially dependent on substrate temperature T and potential-energy barrier for adatom diffusion V_s: $D \propto exp(-V_s/k_BT)$. Using remote epitaxy methods, the adatom-substrate interactions are actually attenuated due to the spatial separation by the 2D interlayer, decreasing V_s and improving the growth quality at low temperatures[3]. Moreover, the surfaces of 2D materials are relatively dangling bond free, providing greatly enhanced adatom diffusion and offering a new route toward improving overlayer growth quality at low-temperature. We demonstrate that, as model systems, GaN and ZnSe grown using WSe_2 and graphene exhibit superior quality with temperatures lower by >200 °C compared to direct growth as characterized by X-ray diffraction and Hall measurements. We also study the growth quality of GaN and ZnSe through tuning the adatom-substrate ionic interactions and the atomic diffusion by changing the thickness and the grain size of the WSe_2 layers, respectively, and find that the growth quality maximizes at an optimized thickness of WSe_2, whereas monotonously increases with larger WSe_2 grain size.
In addition to growth improvement, we further demonstrate an improved method to precisely obtain the band alignment of the ZnSe/WSe_2 heterostructure using X-ray photoelectron spectroscopy, taking advantage of the easy exfoliation of the grown 2D/3D heterostructure off of the substrates. This method

eliminates any concern from electronic structure changes due to quantum confinement caused by needing to use thin overlayers to remain photoelectron transparent in the conventional method.
Our results reveal the *benefits* of a reduced potential field through remote epitaxy, showing significant promise for reducing the growth temperature of 3D semiconductors and other materials as a solution to severe thermal budget constraints. The realization of low-temperature grown, high-performance materials through remote epitaxy can enable transformative new technologies that are greatly limited by severe thermal budget restrictions. Moreover, the 2D/3D heterostructures could also enable promising new heterostructures for novel device designs.

9:15 AM NM07.09.05
Atomically Clean van der Waals Interfaces for Reliable Remote Epitaxy of Complex-Oxide Membranes Sangho Lee[1], Kiseok Kim[1], Celesta S. Chang[1], Xinyuan Zhang[1], Min-Kyu Song[1], Mingi Moon[2,1] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Seoul National University, Korea (the Republic of)

Recent developments in graphene-based remote epitaxy and layer transfer techniques allow for generating a wide range of freestanding complex-oxide membranes with high-crystallinity including perovskite, spinel, and garnet. Such single-crystalline complex-oxide membranes can be easily stacked to form unique material systems, where structurally and chemically incompatible materials are interfaced with each other. Thus, material spectrum can be greatly expanded to explore new physical phenomena by creating the artificial heterostructures as well as to enhance material properties by avoiding the substrate clamping effect. However, graphene transfer – a typical graphene formation process on the growth substrates – inevitably introduces a significant number of unwanted defects such as wrinkles, holes, process residues, and interfacial contamination, which could disturb remote interaction between the substrate and epitaxial layer through graphene and thereby reduce crystal quality and exfoliation yield of membranes. Here, we propose a direct synthesis of two-dimensional (2D) material on the epitaxial substrates of complex-oxides including $MgAl_2O_4$ (MAO) and $Gd_3Ga_5O_{12}$ (GGG) to demonstrate reliable remote epitaxy of spinel $CoFe_2O_4$ (CFO) and garnet $Y_3Fe_5O_{12}$ (YIG) respectively via defect-free 2D interlayer. Atomically clean van der Waals (vdW) interfaces created by a direct growth of 2D material onto growth substrates offer an ideal platform for high-throughput production of single-crystalline complex-oxide membranes and efficient manipulation of physical properties at well-defined heterointerfaces.

Nucleation of Hexagonal Germanium Grains on Defect Engineered MoS_2 Monolayers Xuejing Wang[1], Ryan Kaufmann[2], Renjie Chen[3], Towfiq Ahmed[4], Michael T. Pettes[1], Paul G. Kotula[5], Ismail Bilgin[6], Swastik Kar[7] and Jinkyoung Yoo[1]; [1]Los Alamos National Laboratory, United States; [2]The University of British Columbia, Canada; [3]University of California San Diego, United States; [4]Pacific Northwest National Laboratory, United States; [5]Sandia National Laboratories, United States; [6]Ludwig-Maximilians-Universität München, Germany; [7]Northeastern University, United States

Hexagonal group IV semiconductors have shown great potential for optoelectronic devices as they possess direct electronic band gaps. However, challenges exist in reliable synthesis, which has been majorly limited to structural transfer in order to maintain the hexagonal in-plane lattices. In this work, we demonstrate the formation of hexagonal germanium (Ge) using molybdenum disulfide (MoS_2) monolayer substrates. Suggested by quantum molecular dynamics calculation, the hexagonal Ge is thermodynamically preferrable to cubic Ge on monolayer MoS_2 with sulfur vacancies in certain temperature ranges, which is verified experimentally by transmission electron microscopy analyses. Structural characterization and Raman measurements have revealed that strain at Ge grain boundaries can facilitate nucleation of hexagonal Ge phase. Our reported approach to nucleate hexagonal Ge paves the way to accomplishing continuous thin films of hexagonal group IV semiconductors. Moreover, this study provides understanding on the formation mechanisms of heterostructures composed of two-dimensional materials and conventional three-dimensional semiconductors.

Controlling the Location and Morphology of 3D Nanostructures During van der Waals Epitaxy Frances M. Ross; Massachusetts Institute of Technology, United States

van der Waals epitaxy enables the integration of 2D and 3D materials, optimally creating well-ordered 2D/3D interfaces with properties suitable for electronic devices. Critical aspects of the deposited 3D material, such as the density and location of nucleation sites and the morphology of epitaxial islands, depend globally on growth and materials parameters but locally on the condition of the initial van der Waals surface. Here we discuss how the 2D surface can be patterned before growing the 3D material so that a spatially inhomogeneous deposit results. We first discuss the importance of the substrate on which the 2D layer is supported. We demonstrate that freestanding regions of graphene show orders of magnitude lower nucleation density for Au, compared to the surrounding supported areas. This phenomenon, which we attribute to the effect of roughness on diffusion parameters, represents a method of patterning the deposited material that does not involve lithography of the top surface of the 2D layer. We next discuss the use of defects and step edges to modify nucleation sites, and consider the use of strain transfer across freestanding regions of the 2D material to control island shape and create stacked self-assembled structures. We finally describe nucleation and morphology control through heterogeneous sites, which may be catalytic nanomaterials or structures that modify surface energy locally. By combining these strategies, we suggest that modification of a 2D layer followed by van der Waals epitaxy presents versatile opportunities to form mixed dimensional structures that combine 3D materials on 2D surfaces.

Micro-and Nanowires of Ni and Mn Oxides and Their Heterostructures Synthesized by a One-Step Vapor Solid Method Javier Garcia-Alonso, David Maestre and Ana Cremades; Universidad Complutense de Madrid, Spain

The synthesis of transition metal oxide micro- and nanostructures with controlled dimensions, morphology and composition have gained increasing relevance in recent years due to their wide range of applications in many fields of research such as photocatalysis, spintronics, optoelectronics, and energy storage [1]. The achievement of controlled doping and the fabrication of heterostructures based on these oxides at the micro- and nanoscale are go-to topics that can broaden the field of applications of these materials. Different synthesis processes have been explored so far to obtain elongated structures of Mn and Ni oxides with controlled morphology, composition and structural properties, however in most cases the growth of heterostructures formed by these oxides require of more complex synthesis routes with different steps.
In this work, we present the synthesis and characterization of Mn and Ni oxides in form of elongated microstructures, nanowires, and hierarchical structures. Combination of NiO with metallic Mn and Ni powders were used as precursors. After thermal treatments at 1000 – 1500ºC under a controlled Ar flow the growth of high yield of elongated micro- and nanostructures through a one-step vapor – solid method is promoted. The elongated microstructures present a square base with dimensions usually in the range of tenths of microns and lengths up to hundreds of microns. Most of these elongated microstructures show the growth of nanowires with lower dimensions at their apex, leading to brush-like morphologies, as confirmed by electron

microscopy. These nanowires, in some cases following hierarchical growths, show diameters from tens to hundreds of nanometers and tend to grow from nucleation points related to variations in the Ni/Mn composition. The bigger microrods show Mn-rich areas mainly related to Mn_3O_4 while the bunch of nanowires at the apex is associated with Ni-rich areas mostly formed by NiO and diverse Mn-oxides, as demonstrated by XRD and micro-Raman spectroscopy. Considering that NiO is one of the few p-type oxides, this one-step growth can lead to the formation of p-n heterostructures at the micro- and nanoscale. Moreover, Ni doped Mn_2O_3 and Mn doped NiO are also promoted during the growth, as confirmed by energy dispersive x-ray spectroscopy (EDS).
X-ray photoelectron spectroscopy (XPS) spectra confirm variation mainly in the Mn(2p) and O(1s) core levels as a function of the probed regions along the elongated structures. Finally, photoluminescence acquired with a 325 nm laser indicates the presence of a broad visible emission centered around 500 nm at the region with nanowires, which can be related to the presence of Ni vacancies in the NiO areas.
The achievement of low dimensional elongated structures presenting a hierarchical growth based on transition metal oxides will improve the applicability of these materials in diverse fields of technological research.

10:30 AM NM07.09.09
***In Situ* X-Ray Studies of Remote Epitaxy of Perovskite Oxides on Graphene** Hua Zhou, Xi Yan, Hui Cao, Yan Li, Hawoong Hong, Nathan Guisinger and Dillon D. Fong; Argonne National Laboratory, United States

Remote epitaxy is a novel synthesis technique that allows for the fabrication of thin, freestanding single crystals and nanomembranes. It relies on a sacrificial graphene layer between a thin film and a single-crystalline substrate: during film deposition, the electronic interactions across the graphene are strong enough to enable epitaxial growth but weak enough to allow mechanical release of the film. Others have demonstrated methods for the fabrication of freestanding structures, but the procedures are often materials-specific in terms of the interlayer permitting epitaxial growth. Use of a more universal interlayer can facilitate the development of "stacktronics", where a variety of single crystalline materials can be laid atop each other at low to moderate temperatures, leading to the synthesis of complex van der Waals heterostructures. Details regarding nucleation and growth via remote epitaxy remain unknown, however, due to the many difficulties in studying synthesis in the growth environment with atomic-scale resolution. Thus, advances in stacktronics require improved understanding of remote epitaxy and insight into the impact of interlayer thickness and deposition conditions on the nucleation and growth of thin films. This necessitates *in situ* studies sensitive to the atomic-level structure conducted in the growth environment. *In situ* measurements are particularly important for the synthesis of complex oxides such as perovskite oxides, where small changes to the degree of oxygen incorporation can impact the properties of the film / interface as well as degrade the graphene interlayer.

In this talk, we will demonstrate a set of *in situ* studies of perovskite oxide thin film synthesis on polycrystalline graphene few layers, using synchrotron X-ray scattering to investigate the deposition of $SrTiO_3$ (STO) and $LaNiO_3$ (LNO) by molecular beam epitaxy (MBE) onto graphene-coated STO (001) substrates. X-ray phase retrieval methods are used to reconstruct the electron density profiles from X-ray crystal truncation rods measured under different growth conditions. Our *in situ* observations combined with post-growth spectroscopy provide a number of key insights regarding graphene in the synthesis environment and the resulting effects on the complex oxide / graphene heterostructure. We observe the effect of oxygen partial pressure on graphene-coated STO, finding that most of the graphene is removed at $pO_2 = 2 \times 10^{-4}$ Torr at 760°C. Lower oxygen partial pressures can be used for the growth of $SrTiO_3$ on graphene, which was confirmed by the deposition of 12UC STO on 1ML G. The crystallinity of the film, however, depends on both its thickness and the thickness of the interlayer: for example, 12UC STO is epitaxial when grown on 1ML G but polycrystalline when grown on 2ML G; 3UC STO is epitaxial on 4ML G but becomes more polycrystalline with increasing film thickness. The crystal quality appears to depend on the additional electron density lying above the topmost graphene layer (> 9 Å), as nuclei formed on these regions may have poor interaction with the underlying crystal substrate. We also find the etching of graphene in an ozone environment for LNO remote epitaxy even with the presence of an STO buffer layer on graphene interlayers. So, thicker oxide buffer layers and the use of single crystalline graphene may be necessary for the synthesis of nickelate heterostructures on graphene.

SESSION NM07.10: Growth and Application of Various Dimensional Materials and Heterostructures
Session Chair: Rachael Myers-Ward
Thursday Afternoon, December 1, 2022
Hynes, Level 2, Room 203

1:30 PM *NM07.10.01
Hydride Vapor Phase Epitaxy as a Platform for Materials Integration Aaron Ptak; National Renewable Energy Lab, United States

Hydride vapor phase epitaxy (HVPE) is an epitaxial growth technique developed many decades ago that has seen a resurgence in recent years. HVPE is well-known for producing very pure material at very high growth rates. This led to the development of, for example, high-quality GaN templates on sapphire substrates that enabled nitride devices grown by other techniques. In recent years, however, HVPE has moved into producing nitride and oxide devices on its own, and has now branched into arsenide and phosphide devices as well due to the advent of the Dynamic-HVPE technique. In Dynamic-HVPE, the substrate moves between adjacent growth chambers to create chemically- and structurally-abrupt heterinterfaces, which was not possible using more traditional HVPE methods.

Another beneficial property of HVPE is the ability to tune the kinetics of growth on different surfaces, leading to the ability to create useful surface features. These include peak-and-valley morphologies and other surfaces with stable facets that can be used to create, for example, quantum wires. HVPE growth parameters can also be tuned to planarize surface features when desired. This latter feature may enable simple substrate reuse by planarizing rough morphology resultant from reusing a substrate many times after device exfoliation. This talk will describe different aspects of the HVPE growth technique and how they can be used to develop materials with useful morphology.

2:00 PM NM07.10.02
Reconfigurable Heterointegration of Artificial Intelligence Chips Using GaAs/InGaP-Based Optoelectronic Devices Chanyeol Choi[1], Min-Kyu Song[1], Hyunseok Kim[1], Jihoon Kang[1], Hanwool Yeon[2], Celesta S. Chang[1], Jun Min Suh[1], Jiho Shin[1], Huaqiang Wu[3], Peng Lin[4] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]Gwangju Institute of Science and Technology, Korea (the Republic of); [3]Tsinghua University, China; [4]Zhejiang University, China

The deployment of conventional integration technologies still faces the issues including material degradation due to intimate contact between chips, fixed modality due to fixed connection to one single sensor, and limited data processing due to constraint for addition of processors in varying computing situation. In this work, we developed a novel reconfigurable 3D heterogeneous integration platform using optoelectronic devices for chip-to-chip communication. Freestanding GaAs/InGaP membrane was integrated into each chip by epitaxial lift-off (ELO) process. Chip-to-chip communication was enabled by optical transmission between GaAs LEDs and InGaP photodiodes. Optical communication without any electrical interconnect resulted not only in elimination of interference from physical contact, but also in great reconfigurability of the chips. Furthermore, the neuromorphic computing layers were embedded in each stackable chip as AI hardware accelerators for extremely efficient processing. This technique will solve the shortcomings of previous conventional 3D heterogeneous integration methods. With the Lego-like 3D heterointegration method based on the GaAs/InGaP stack, the sensor-computing systems can provide unlimited modality, highly efficient computing and adaptability to varying computing tasks.

2:15 PM NM07.10.03
High Indium Content InGaN Strain Relaxation Yunpeng Liu and Jeehwan Kim; Massachusetts Institute of Technology, United States

Light-emitting diode (LED) is the most popular light source in the modern world. Because LED owns higher efficiency and brightness compared with conventional light sources, it is widely used in the illumination and the display of numerous devices. Due to its tunable bandgap, indium gallium nitride (InGaN) has been used as the material to make blue and green LEDs. However, in order to decrease the band gap of InGaN, more indium has to be incorporated into the material, which leads to a high lattice mismatch between the InGaN layer and the GaN substrate. This mismatch causes the low quality of high indium content InGaN, which obstacles the approach to use InGaN as the base material for RGB (red, green and blue) pixels. Here, we propose a method to fabricate high quality LED based on InGaN with high indium content using remote epitaxy. Conventionally, when an epilayer is grown on the substrate using epitaxy methods such as molecular beam epitaxy (MBE) and metal organic chemical vapor deposition (MOCVD), the lattice structure of the epilayer always perfectly follows the lattice structure of the substrate. Therefore, the epitaxial InGaN layer is always strained on the substrate because they are connected by strong covalent bonds.
Remote epitaxy provides a way to avoid this constraint. When a layer of 2D material is deposited prior to the epilayer, the epilayer grown on the top of the 2D material still follows the crystalline structure of the substrate under the influence of the penetrated potential field from the substrate. However, unlike normal epitaxy methods, the epilayer of remote epitaxy spontaneously relaxes due to the slippery surface of the 2D material. The Van der Waal force on the 2D material doesn't limit the relaxation like the covalent bond. Therefore, high quality InGaN can be obtained with this method. we have demonstrated the remote epitaxy based on in-situ MBE grown amorphous boron nitride (aBN). By doing the in-situ remote epitaxy, contaminations are avoided, and epitaxial membrane quality is improved compared with the previous transferred graphene method. High quality single-crystalline GaN is obtained with this method. These results show that aBN can be a good candidate for the InGaN remote epitaxy and build the foundation for this work. By depositing InGaN on 2D/GaN substrate, the misfit strain can be relaxed from the beginning of the growth regardless of the indium composition. By avoiding the strain-relaxation process, most of the dislocations can be eliminated. Similarly, the relaxed film also helps alleviate the quantum-confined Stark effect.

High-Quality SiC Remote Epitaxy for Stackable Electronics Rachael Myers-Ward, D. Pennachio, Jenifer Hajzus, Andrew Lang and R Stroud; Naval Research Laboratory, United States

Remote epitaxy (RE) is a growth process performed on a graphene-covered substrate where the adatom registry is guided by the electrostatic fields penetrating through the graphene from the underlying substrate rather than interactions with the graphene lattice. The remote epitaxy is easily exfoliated from the substrate due to weak van der Waals bonding of the graphene to the substrate, enabling transfer to desired substrates and thus allowing heterostructures that typically cannot be created with current methods. This technique has the possibility of impacting several research areas including SiC and GaN SMART power, integration of opto- and electronic devices, improving HEMT performance by transferring to higher thermal conductivity substrate, flexible electronics and quantum sciences.

In this work, we focus on the RE of SiC grown on graphene on SiC (0001) using a hot-wall chemical vapor deposition reactor. Controlling the thickness of graphene is achieved using off-axis substrates, where 1 – 5 monolayers is possible. To maintain the graphene during SiC remote epitaxy, a study of the Ar/H_2 flow ratio during remote epitaxial growth was conducted. Single crystalline material was achieved for both the on- and off-axis substrates when a low C/Si ratio was used. This growth condition resulted in a stepped film morphology for the on-axis substrate while the off-axis substrate produced intermittent step bunching, consistent with typical off-axis growth at low C/Si ratios. Films were characterized using Nomarski microscopy, scanning electron microscopy, transmission electron microscopy and electron backscattering detection. In summary, the growth of high quality SiC RE is shown to result from both on- and off-axis SiC substrates and has the possibility to be used for power electronics and quantum sciences applications.

Research at NRL was supported by the Office of Naval Research.

3:30 PM NM07.10.05
DFT Atomic-Scale Modeling and Simulation of Ultrawide Bandgap (UWBG) Heterostructured Materials Ugonna C. Ohiri, Stephen Van Campen, Robert Howell and Josephine Chang; Northrop Grumman Corporation, United States

Ultra-wide bandgap (UWBG) materials (i.e., Eg > 3.4 eV) possess superior material properties for enabling the next-generation of high-power density and high-performance radio-frequency (RF) monolithic microwave integrated circuit (MMIC) devices. There has been recent major interest in developing high-performance diamond electronics, but there are still some challenges which exist for diamond as a material, such as incomplete ionization for highly n+ doped epilayer films and weak electron mobility at high operating temperatures.

Here, we report on a deep dive exploration into various UWBG materials (e.g., Diamond, Ga2O3, AlN, cubic boron nitride, hexagonal boron nitride, etc.), and understanding how these UWBG materials form intriguing heterogeneous interfaces with each other. High-throughput density functional theory (DFT) atomic-scale modeling and simulation studies will be presented on these various UWBG materials and a combination of UWBG heterointerfaces. Simulated electronic material parameters such as electronic band-structures, projected density of states (PDOS), electron/hole mobility, thermal conductivity, and Raman will be presented. For example, cubic boron nitride (c-BN) is strongly lattice matched to diamond, is isoelectronic with diamond, and is a strong candidate for enabling diamond/c-BN based two-dimensional electron- and hole gas (i.e., 2DEG and 2DHG) based field effect transistors and other interesting high-power device configurations. This presentation will highlight and also take a deeper exploration into various undoped and doped diamond/c-BN heterointerfaces.

Overall, the presented DFT modeling and simulation results will shed light into what combination of UWBG materials are within the physical design space

and will lay a general pathway for physically realizing high-power density and high-performance RF MMIC devices.

3:45 PM NM07.10.06
Amorphous 2D Materials – A Novel Platform for Remote Epitaxy and Nanopatterned Epitaxy of III-V Semiconductors with Low Decomposition Temperatures Kuangye Lu, Hyunseok Kim, Sangho Lee, Ne Myo Han, Yunpeng Liu and Jeehwan Kim; Massachusetts Institute of Technology, United States

III-V semiconductor materials such as indium phosphide (InP) offer outstanding photonic properties that outperforms silicon, but the cost of these wafers is extremely expensive. Although reusing original wafers can effectively minimize the cost, current techniques for wafer recycling of these substrates add significant costs in fabrication, nullifying the cost savings by reusing the wafers. Besides, unlike other III-V materials such as gallium arsenide (GaAs), commonly used epitaxial lift-off method for wafer recycling is not well studied for materials like InP due to lack of lattice-matched sacrificial layers, which makes reusing these wafers more difficult. Remote epitaxy and nanopatterned epitaxy are newly discovered methods that enable single-crystal growth of III-V semiconductor thin films and easy exfoliation of these grown films, thus promising for a new cost-effective pathway of reusing wafers. However, previous methods of transferring two-dimensional (2D) materials, which use polymethyl methacrylate (PMMA) or metal stressor layers to transfer 2D materials grown on foreign substrates like copper (Cu) or silicon carbide (SiC), introduce defects and damages on the 2D layer and/or substrates during the transfer process. Remote epitaxial and nanopatterned epitaxial films grown on the damaged 2D layer/substrate suffer from lower crystal quality and imperfect exfoliation, which undermines wafer reusability and device performance.

Here we report the MBE growth of amorphous boron nitride (a-BN) on InP wafers at low temperature that enabled improved quality of remote epitaxial and nanopatterned epitaxial films and their perfect exfoliation. We show fully covered a-BN on InP substrates despite their low decomposition temperatures. The surface of a-BN coated InP substrate remains smooth with a RMS roughness of around 3Å. We also demonstrate 100% coverage of single-crystal InP thin films grown on a-BN, with the film's quality significantly improved compared to the case of transferred 2D materials. In addition, the growth and exfoliation were successfully repeated multiple times, proving the feasibility for InP wafer recycling. Through this low temperature MBE growth approach with remote epitaxy and nanopatterned epitaxy, we successfully demonstrate large-scale flexible thin film exfoliation and recycling of InP substrates, which will lead to new opportunities in InP thin film-based photonics and novel heterostructures with significantly reduced cost.

From III-Vs to Si: Thin Film Electronics for Imaging and Energy Stephen R. Forrest, Rebecca Lentz, Byungjun Lee, jihun lim, Dejiu Fan, Bosun Roy-Layinde, Tobias Burger and Andrej Lenert; University of Michigan, United States

The combination of non-destructive epitaxial liftoff and cold weld bonding of III-V materials developed in our laboratory has opened the way to realizing a variety of thin film inorganic semiconductor devices that can serve applications that have heretofore not been accessible to conventional semiconductors.(Lee et al., 2014) For example, we have demonstrated devices as diverse as cylindrical and hemispherical imagers (the latter of which that undergo a topological transformation during fabrication),(Fan et al., 2019) and more recently, extremely high efficiency thermal photovoltaics that employ exceptionally long air-bridges where the very thin active semiconductor is suspended between gold pillars.(Fan et al., 2020) More recently, we have demonstrated air-bridge TPVs in Si to obtain more favorable economics for this important renewable energy storage application. In this talk we will discuss advances and state of the art in thin film electronics, considering current applications and prospects for the future.

van der Waals Epitaxy of Oxide Thin Films on Flexible Synthetic Mica for Modulation of Physical Properties by Bending Stress Yuta Arata, Hiroyuki Nishinaka, Minoru Takeda and Masahiro Yoshimoto; Kyoto Institute of Technology, Japan

Modulations of the physical properties of materials by doping, alloying, and straining play an important role in electronics and optoelectronics. Recently, it has been demonstrated that the various properties of single nanowires were modulated by strain [1, 2]. However, the difficulty of bending a single nanowire is a significant barrier to applying devices. On the other hand, thin films deposited on flexible substrates can be simply bent. However, conventional flexible substrates, amorphous organic compounds such as polyimide (PI) and polyethylene terephthalate (PET), do not allow epitaxial growth of single-crystal thin films. It has been demonstrated to transfer the thin films to the flexible substrates; however, complicated processes such as epitaxial lift-off and sacrificial layer etching were required [3, 4]. We utilized synthetic mica substrates to directly grow epitaxial oxide thin films via van der Waals epitaxy [5]. The synthetic mica substrates can be thinned and bent easily by cleaving. We used the cleaved synthetic mica to bend the thin film and the strain applied by bending to modulate the properties.
We grew ZnO thin films on the synthetic mica substrates and demonstrated the modulation of optical properties by bending strain. ZnO thin films were grown by mist chemical vapor deposition (CVD) using a solution of zinc acetylacetonate ($Zn(C_5H_7O_2)_2$) dissolved in a mixture of methanol and de-ionized water as a precursor. Epitaxial ZnO thin film was grown on synthetic mica at a growth temperature of 400 °C. To investigate the impact on the optical properties by strain, we measured photoluminescence (PL) of the ZnO thin film with and without bending. By bending with a radius of curvature of 5 mm, the peak energy was red-shifted to 0.02 eV compared with an unbent state. Thus, we have successfully modulated the PL peak of the ZnO thin film with the bending strain.
In addition, we grew epitaxial VO_2 thin film on the synthetic mica and demonstrated modulation of the metal-insulator transition temperature by the bending strain. We utilized SnO_2 buffer layers to grow epitaxially VO_2 thin films. VO_2 and SnO_2 layers were grown by mist CVD using vanadyl acetylacetonate ($VO(C_5H_7O_2)_2$) and tin chloride pentahydrate ($SnCl_4$ $5H_2O$) as precursors, respectively. Epitaxial VO_2 thin film were grown on the SnO_2 buffer layer on the synthetic mica at a growth temperature of 500 °C. Using the epitaxial VO_2 thin film with bendable, we measured the electrical resistance as a function of temperature with and without bending. VO_2 thin film exhibited metal-insulator transitions both with and without bending. By bending with a radius of curvature of 5 mm, the metal-insulator transition temperature increased by 2.5 °C compared to the unbent state.
In the symposium, we will discuss the magnitude of strain with bending and detailed measurements of PL and metal-insulator transition characteristics.

Heterogeneous Integration of Complex-Oxide Membranes Hyunseong Kum; Yonsei University, Korea (the Republic of)

We will discuss our recent results in producing thin complex-oxide membranes, as well as applications integrating complex-oxides onto conventional semiconductor devices. Detailed characterization of the transferred complex-oxide/semiconductor interface will be presented.

2:00 PM NM07.11.02
Controlling Exciton Dynamics at Organic/2D Interfaces with Nanoscale Molecular Patterns Kushal Rijal, Stephanie Amos, Pavel Valencia-Acuna, Fatimah Rudayni, Neno Fuller, Hui Zhao, Hartwin Peelaers and Wai-Lun Chan; University of Kansas, United States

Recently, the moiré pattern formed at 2D transition metal dichalcogenide (TMD) heterostructures has been used to control the dynamics of interlayer excitons (IX) at the TMD/TMD interface. At organic/TMD interfaces, similar periodic potentials can be created by controlling the nanoscale molecular pattern on top of the 2D layer. In this work, two molecules, PTCDI and PTCDA, which possess similar properties but form different molecular patterns on a MoS_2 surface, are investigated. Using photoemission spectroscopy, a large HOMO energy level splitting is observed in PTCDI on MoS_2, but not in PTCDA on MoS_2. Density functional theory calculation shows that the splitting originates from the different molecular patterns. The energy splitting causes very different IX's dynamics for the two heterostructures, which are studied by time-resolved photoemission spectroscopy. For PTCDI/MoS_2, the electron within the IX is spatially localized near the interface. On the other hand, for PTCDA/MoS_2, the electron within the IX is delocalized across the molecular film. Because of the spatial localization, the IX at PTCDI/MoS_2 shows an order of magnitude stronger photoluminescence intensity as compared to the IX at PTCDA/MoS_2. On the other hand, the IX at PTCDA/MoS_2 is more likely to dissociate into free carriers because of the electron delocalization within the IX. This work is supported by NSF grant DMR-2109979.

2:15 PM NM07.11.04
Growth of Thin-Film WS_2 for Solar Cell and Photodetector Applications Mohd Samim Reza, Tejveer S. Anand, Henam S. Devi and Madhusudan Singh; Indian Institute of Technology Delhi, India

Tungsten disulfide, a transition metal dichalcogenide (TMDs) semiconductor, has a bulk phase bandgap of 1.35 eV, very close to the Shockley-Queisser limit for two-level systems at AM1.5G solar spectrum, making it a compelling material for solar photovoltaic applications[1]. Its applications in photovoltaics are still in their inception due to the difficulty of obtaining a uniform, pin-hole-free WS2 thin film with good adhesion [2,3]. This work reports on a two-step process involving sulfurization to grow a WS_2 thin film on a SiO_2 substrate (University Wafers) using a custom-built 12-zone horizontal split furnace (Quazar Technologies) for possible solar cell and photodetector applications. A thin film (~10 nm) of tungsten was deposited on a SiO_2 substrate at a rate of ~0.6A using DC sputtering system (Angstrom Engineering). This thin film was subsequently heated to 800-1100°C under 0-300 sccm of Ar flow in the furnace in presence of elemental sulfur for sulfurization. X-ray diffraction (Rigaku Ultima IV, Copper Kα = 1.54Å) scans of the film revealed a sharp and intense peak at 14.12° (2H-WS_2 nanosheet: JCPDS 08-0237), corresponding to (002) growth with a = 3.154 Å and c = 12.362 Å. The other peaks at 28.12° and 43.20° are inferred to correspond to (004) and (006) crystal planes. Further, Raman spectra (Renishaw inVia confocal microscope-based Raman spectrometer) of the sample reveal in-plane (E^1_{2g}) and out-of-plane (A_{1g}) vibrational modes at wavenumbers 348.25/cm and 412.90/cm, confirming the WS_2 growth. The wavenumber difference and intensity ratio of E^1_{2g} and A_{1g} vibrational mode peaks are estimated to be 64.65 and 1.03, respectively, confirming the multilayer growth. Raman mapping over an area of 5.1 x5.1 µm with a step size of 300 nm suggests consistent growth free of directional bias in the sulfurization process. The peak differences range from 64.65/cm to 70.72/cm, with an average of 68.34/cm[4], while the intensity ratio ranges from 0.88 to 1.13, with an average of1.03, again confirming the uniform multilayer growth. Field-emission scanning electron microscope (FESEM, JEOL JSM-7800F Prime) scans indicate formation of nanoflakes. Surface photovoltage spectroscopy (KP Technology KP020+SPS040) was used to measure the work function (-4.613 eV). Atomic force microscopy scans (Asylum Research MFP3D-BIO) were used to estimate the surface roughness of the grown WS2 layer to be 62.33 nm, while the underlying tungsten layer had a surface roughness of 72.99 pm. This suggests that the process of bulk incorporation of sulfur leads to significant increase in surface roughness. As we expected to fabricate heterojunctions of WS_2 with a variety of solution-phase p-type materials in ongoing work, the resulting increase in surface contact area of the heterojunction is expected to provide a larger number of exciton dissociation sites expected to increase the short circuit current, and to reduce optical reflection of the device[5,6].

Chip-less Battery-less Wireless Electronic Skin by Single Crystalline Freestanding Membranes Yeongin Kim[1,2], Jun Min Suh[1], Jiho Shin[1], Yunpeng Liu[1], Hanwool Yeon[3], Kuan Qiao[1], Jiyeon Han[4] and Jeehwan Kim[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Cincinnati, United States; [3]Gwangju Institute of Science and Technology, Korea (the Republic of); [4]Amorepacific, Korea (the Republic of)

Electronic skin (e-skin) has been developed to obtain a non-invasive human health monitoring electronic system with its imperceptibility. So far, one of the major shortcomings in this field is the bulky wireless communication system that severely affects its wearability. We introduce a single-crystalline non-Si-based e-skin system where fully conformable, ultrathin, piezoelectric, compound semiconductor membranes are incorporated as power-efficient wireless communication modules and extremely high sensitivity sensors without needing bulky chips and batteries. The developed GaN surface acoustic wave-based device successfully measured three different inputs wirelessly. The consistency and accuracy of the measured heart rate and pulse waveforms over a 7-day period strongly demonstrate the reusability and long-term wearability of our device. This study will change the paradigm of e-skins by providing versatile wireless platforms for fully imperceptible e-skins with very high sensitivity and low power consumption.

Mixed-Dimensional Heterostructures via Confinement Heteroepitaxy Joshua A. Robinson; The Pennsylvania State University, United States

The last decade has seen an exponential growth in the science and technology of two-dimensional materials (2D), with emphasis on next-generation electronics due to their atomically thin nature and properties ranging from metallic to insulator. In this talk, I will discuss recent breakthroughs in two-dimensional atomic layer synthesis and properties, including novel confinement techniques to facilitate the formation of non-layered 2D metals, semiconductors, and insulators. In particular, I will discuss the utilization of confinement heteroepitaxy (CHet) as a platform to create novel heterostructures that are the foundation for a range of phenomena, from topological superconductivity to ultra-high frequency devices. By shrinking traditional metals and oxides to atomically thin structures, we find that their properties are completely different than their bulk counterparts, lending themselves to unique quantum, electronic, and optical applications not possible before.

Silver Functionalized Cellulose /CNT Composites for Phthalates Detection—A Sensitivity Enhancement Panchali Anuchani, Hansini Abeysinghe and Thusitha N. Etampawala; Faculty of Applied Sciences, University of Sri Jayewardenepura, Sri Lanka

Phthalates are widely known plasticizer types used in the production of flexible plastic products. However, these do not form chemical bonds with the matrix material, such that they can easily leach into the environment over time. Exposure to certain phthalates causes adverse health and environmental impacts. Therefore, some countries have already banned the use of some phthalates in consumer products. Despite these adverse effects, many countries are still using phthalates in plastic processing. Therefore, rapid and easy monitoring of the presence of phthalates in different environments is crucial. Recently our research team has introduced a novel phthalate adsorbing cellulose/carbon nanotube (CNT) composite material that can be coupled with Electrochemical Impedance Spectroscopy or Four-Probe conductivity measurement techniques to identify the phthalates in solutions, which shows potential for overcoming the limitations of already existing phthalate detecting methods. Adsorption of dielectric phthalate molecules with bulky side groups onto the highly electrically conductive CNTs present inside the cellulose matrix would increase the electron tunneling distances between the CNTs, resulting in a conductivity decrease. This conductivity decrease of the composite after phthalate adsorption was detected by performing three-electrode Electrochemical Impedance Spectroscopy (EIS) using a potentiostat. However, the developed composite was only sensitive down to 1000 (v/v) ppm concentrated phthalates in methanol solution at room temperature. Therefore, in this study, we introduced a method of enhancing the sensitivity of this developed composite material by following the approach of using heterogeneous integration of mixed dimensional fillers that has high affinity to phthalates. Specifically, the cellulose matrix was functionalized with Ag nanoparticles.. The impregnation of Ag nanoparticles was primarily confirmed by Raman Spectroscopy. Further experiments are in progress to confirm the presence and the distribution of Ag nanoparticles in the cellulose matrix. This impregnation would modify the hydroxyl groups of cellulose molecules by forming O^{-} $^{+}$Ag ionic bonds. These Ag^{+} O^{-} groups show the potential to create intermolecular interactions, including hydrogen bonds, ion-dipolar interactions, and van der Waals interactions with the phthalates. Since the incorporation of Ag onto cellulose promotes phthalate absorption along with the CNTs, which adsorb phthalates via the formation of π-π electron donor-acceptor interactions, seems to be the reason behind the enhanced sensitivity limit of the newly developed material compared to CNT/cellulose composite. The Ag nanoparticle functionalized cellulose/CNT composite paper successfully detected DNOP and DPHP with concentrations down to 1 ppm (v/v) in methanol solution at room temperature. Moreover, all these conductivity reductions after phthalate absorption were able to detect using a four-probe conductivity meter, which is much less sensitive than the potentiostat. Here, the current change variation of the composite paper before and after the absorption of phthalates was observed. High sensitivity, easy tunability of sensitivity based on the composition of integrated mixed dimensional materials, and the ability to directly test the phthalates without any other materials unlike with the potentiostat are some of the advantages observed with the use of mixed dimensional fillers (0D Ag nanoparticles and 1D CNTs) incorporated to the matrix (cellulose) of the phthalate sensing paper. This newly developed material shows more potential for developing into a portable, real-time, and in-situ phthalate-detecting sensor.

11:15 AM *NM07.12.05
2D van der Waals Heterostructures for Neuromorphic Applications Feng Miao; Nanjing University, China

Van der Waals (vdW) heterostructures are formed by stacking layers of different 2D materials and offer possibilities to design new structures with atomic-level precision. In this talk, I will show how these heterostructures provide unprecedented opportunities to realize emerging device applications, especially in the fields of neuromorphic electronics and optoelectronics.
I will first show that highly robust memristors with good thermal stability, which is lacking in traditional memristors, can be created from a vdW heterostructure composed of graphene/$MoS_{2-x}O_x$/graphene. With the help of *in situ* electron microscopy, we revealed the origin of good thermal stability and a possible switching mechanism.[1] We also demonstrated that artificial neuron devices and reconfigurable synaptic devices can be realized based on unique tuneable properties of various 2D materials.[2]
vdW vertical heterostructures can also be exploited to realize neuromorphic optoelectronic applications. We demonstrated a prototype reconfigurable neural network vision sensor that operates via the gate-tunable positive and negative photoresponses of a WSe_2/BN heterostructure, and in-sensor broadband convolutional processing using a band-alignment-tuneable $PdSe_2$/$MoTe_2$ heterostructure.[3-4] A neuromorphic vision system with brain-inspired visual perception can be further realized by networking such retinomorphic sensors with a memristive crossbar array.[5]
In the last part of my talk, our latest results on a scalable massively parallel computing scheme using continuous-time data representation in crossbar arrays[6] will be presented.

7:00 AM
New Insights into the Influence of Metal Sulfides Precursor on SO_2 Resistance Property for NH_3-SCR Catalyst Bora Ye[1], Bora Jeong[1], Myeung-Jin Lee[1,2], Kyung-yo Park[1,3], Donghyeok Kim[1,2], Jae il Jung[1,4] and Hong-Dae Kim[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Pusan National University, Korea (the Republic of); [4]Hanyang University, Kuwait

As emissions regulation of Nitrogen oxides (NOx) are tightened around the world, many industrial applications such as power plant, steel mill, and cement plants are demanding higher NOx removal efficiency. The selective catalytic reduction with NH_3 catalysts are mainly used for NOx removal technology based on its high efficiency in the temperature range of 350 to 400ºC [1]. But in many flue gases, the presence of SO_2 causes decreased the catalyst activity at temperature lower than 250 ºC.
In order to solve this problem, research on changing the surface acidity by exposing to SO_2 atmosphere or injecting sulfur to the catalyst has been conducted [2]. Therefore, in this study, metal sulphides (MS_2) precursor was used to make a catalyst that partially contains sulfur, has sulfur resistance, and can even act as a support. WS_2 and MoS_2, which are transition metal dichalcogenides (TMDs) materials containing W and Mo, which are mainly used as main catalysts of SCR catalysts, were applied to increase catalytic activity. In general, metal sulfides are converted to oxide form when exposed to high-temperature oxygen atmosphere, and because of their two-dimensional structure, they applied to inhibit aggregation by dispersing active materials.
Since the main reaction takes place in a small amount of vanadium, dispersing it on a support with a high specific surface area without aggregation is the main way to increase catalytic activity. By confirming the thermal decomposition behavior of MS_2, the optimal coexistence form of sulfides and oxides was found by optimizing the catalyst calcination temperature, and as a result, an optimal catalyst with resistance to SO_2 was prepared.

Peptide-Functionalized Layer-by-Layer Nanoparticles with Improved Blood Brain Barrier Permeability for Glioblastoma Treatment Priya Ganesh, Nicholas Lamson and Paula T. Hammond; Massachusetts Institute of Technology, United States

Glioblastoma is an aggressive brain tumor that accounts for almost 50% of all brain and central nervous system tumors, but the current standard of care gives a median survival of only 15 months. The greatest obstacle in the treatment of glioblastomas is the blood-brain barrier (BBB), the endothelial cells that line the vessels of the brain and are stitched together into a barrier by tight junction complexes. The BBB is designed to prevent pathogens from entering the brain, but its inability to distinguish between harmful substances and therapeutics leads to a fundamental problem in brain drug delivery. One approach to overcoming this barrier is encapsulating drugs in nanoparticles whose surfaces are engineered (usually, with the addition of ligands) to promote binding to various receptors of the BBB, thus triggering transcytosis and allowing the nanoparticle and its drug contents to cross the BBB.

Previous research has shown that electrostatic absorption (as opposed to covalent functionalization) is a quick and effective method for attaching cationic, tumor-penetrating peptides to anionic nanoparticles synthesized through an iterative layer-by-layer (LbL) approach [1]. Here, we demonstrate that LbL nanoparticles functionalized with BBB-targeting peptides, including Angiopep-2 and RAP12, can penetrate the BBB to deliver their contents to the brain. We probe how different characteristics of the nanoparticles (e.g. polyanion used to present surface chemistry in the outermost layer) and peptides (e.g. charge, size) affect stability of the LbL nanoparticles in a variety of salt and temperature conditions. Particles that exhibited the highest stability were screened through cell culture and mouse models of the BBB, and certain peptides lead to increased uptake both *in vitro* and *in vivo* in the mouse brain. Ongoing work includes molecular dynamics simulations to understand interactions between the BBB-targeting peptides and the outermost polymeric layer of the nanoparticles, with a focus on matching *in silico*conformation results with outcomes from biological experiments to enable future prediction of the effectiveness of various peptide-outer layer combinations.

11:15 AM SB01.01.03
Leveraging Inverse-Opal Nanomaterials for Ultra-Sensitive and High-Throughput EV Subpopulation Isolation in Clinical Samples Andrew A. Lin, Zhimin Jiang, James Pikul and David Issadore; University of Pennsylvania, United States

Extracellular vesicles contain multiple protein and nucleic acid cargoes from their cells of origin which circulate peripherally in bodily fluids such as blood, saliva, and urine; as a result, clinicians and scientists have sought to leverage EV-derived biomarkers to diagnose, stage, and manage cancer. However, the nanoscale size (30-300 nm diameter) and high background in clinical samples (10^{12} EVs/mL in serum) of EVs makes the isolation of EV subpopulations especially challenging.

In response to this challenge, we have developed a new approach to EV isolation which leverages inverse-opal nanomaterials to perform precise and high-throughput EV sorting directly from clinical samples via billions of nanomagnetic sorters operating in parallel. IOs have previously shown multiple favorable material properties including high mechanical strength and large surface areas. The chips leverage these advantages via our fabrication process, which involves the electrodeposition of ferromagnetic nickel followed by a gold passivation layer onto a self-assembled microlattice whose thickness can be tuned from 20 to 50 μm and with internal trap sizes tunable from 400 to 650 nm. This yields $>10^9$ nanoscale magnetophoretic sorting devices in a postage-stamp-sized three-dimensional lattice without the requirement for capital-intensive nanolithography. With this large-scale parallelization of traps in three dimensions, we demonstrate via finite-element simulations as well as experiments with magnetic nanoparticles that our device can isolate 50 nm magnetic nanoparticles from suspension at flow rates in excess of 50 mL/hr.

To demonstrate the viability of this platform for the isolation of EVs, we proceeded to isolate immunomagnetically-labeled EVs in a model system of pancreatic cancer. We isolated EVs whose sizes, surface proteins, and internal cargoes all matched those isolated via conventional methods while achieving a ~100% increase in yield. We demonstrate the ability to isolate EVs directly from human plasma via multiple antibody panels including a preliminary tumor-specific panel. By expanding on the proof-of-concept device characterization and initial testing shown here, this new approach can enable low-cost, rapid, and precise sorting of EV subpopulations for clinical questions.

11:30 AM SB01.01.04
Biomimetic Virus-Based De Novo Niche for Soft Tissue Engineering So Young Yoo; Pusan National University, Korea (the Republic of)

Extracellular niches play a crucial role in overcoming the surrounding harsh pathological environments as well as for stem cell differentiation and other important functions. Nanofibrous arginine-glycine-aspartic acid-engineered M13 phage has recently been considered as an extracellular matrix-mimicking bioinspired nanofiber that serves as an instructive tissue engineering material, providing a vascular niche and cytoprotective function at injured sites, which is an essential option for stem cell therapy. Herein, the novel and essential therapeutic cues provided by an engineered phage are exploited, contributing to de novo
soft tissue niche engineering, where the interplay of biomimetic phage cues with sur-rounding organ tissues is identified and cells are implanted between tissues to achieve an appropriate soft tissue niche that enables the proper functioning of the implanted stem cells at the injured site. These biomimetic phage nanofiber cues are considerably supportive for cell therapy, as they establish promising therapeutic extracellular de novo soft tissue niches for curing ischemic diseases.

11:45 AM SB01.01.05
Magnetic Control of the Endothelium Permeability via Magneto-Mechanical Actuation Using Iron Oxide Nanoparticles Mohammad Kanber, Homeira Faridnejad, Obum Umerah and Juan Beltran-Huarac; East Carolina University, United States

Cancer treatment is one of the major health problems that burdens our society. According to the latest publication of the American Cancer Society, the cancer mortality rate has reached 32% in 2021. Tumor hypoxia is one of the main cancer complications, wherein solid tumors grow as they develop larger resistance to current therapies due to the extracellular matrix remodeling of cancer cells. Extracellular remodeling involves the development of abnormal vasculature that can be twisted leading to a dead end and subsequent back blood pressure flow. This imposes certain limitations on drug therapy due to the heterogeneous tumor hypoxic microenvironment. One way to overcome this problem is to disrupt the vascular endothelial-cadherin (VE-cadherin) junctions, using superparamagnetic iron oxide nanoparticles (SPIONs). Direct treatment of SPIONs can cause uncontrolled leakiness and subsequent tumor migration, thus prompting the appearance of new metastatic sites. In this project, we use an indirect approach to internalize ND-PEG SPIONs into human

umbilical vein endothelial cells (HUVECs). Then these particles are magnetically activated to induce leakiness on HUVEC monolayers. We control the magnetic activity of ND-PEG SPIONs using non-heating AC magnetic fields. Intracellular ND-PEG SPIONs can assemble near the cytoskeleton and induce hypostress, which can affect cellular integration and VE-Cadherin proteins and in turn the adherens junctions. Our findings indicate that the controlled mechanical motion induced over ND-PEG SPIONs by magnetic torques can disrupt these junctions and enable the passage of therapeutic drugs. This approach can also have the potential to avert cancer migration. This innovative magnetic control provides an effective remotely-controlled drug delivery method harnessing the physics and biology of endothelial adherens junctions. This approach can open a new avenue for targeted drug delivery to specific anatomic regions within the body for a broad range of disease interventions.

SESSION SB01.02: Immuno-Materials/ Drug Delivery
Session Chairs: Jennifer Carpena-Núñez and Georgios Sotiriou
Monday Afternoon, November 28, 2022
Hynes, Level 1, Room 104

2:00 PM SB01.02.02
Ultrahigh Drug-Loaded Micelles for the Treatment of Triple-Negative Breast Cancer and Their Bone Metastases Richard d'Arcy[1], Patrick Gerber[1], Rebecca Cook[1], Julie Rhoades (Sterling)[2] and Craig Duvall[1]; [1]Vanderbilt University, United States; [2]Vanderbilt University Medical Center, United States

Triple-negative breast cancer (TNBC) is responsible for 15-20% of breast cancers and are unresponsive to therapies targeting estrogen, progesterone and HER2. Conventional chemotherapeutics are front-line for TNBC but resistance to these drugs make it a particularly challenging cancer to treat. Nanomedicine offers an exciting modality to better target, treat and potentially prevent resistance, e.g. by significantly increasing the maximum tolerated doses (MTD) of drug and consequently increasing the overall tumoral drug concentration. This effect is dependent on having a high drug loading capacity (LC), with 'ultra'high drug loading (LC = 35%) observed to give the highest potential MTDs.

Herein, we have rationally designed through carefully tailoring pi-interacting and hydrogen-bond donating co-monomer ratios a polymeric nanocarrier library capable of loading paclitaxel with an LC in the 'ultra'high range, and which also possess a tunable, Reactive Oxygen Specie (ROS)-triggered release mechanism. These particles were found to have field-leading MTDs for paclitaxel (150 mg/kg, dosed 2-times per week for 2 weeks). We further investigated the difference between fast or slow drug release formulations in a xenograft mammary fat pad model of TNBC (MDA-MB-231s). Using only a single dose of ultrahigh paclitaxel-loaded micelles at their MTD (150 mg/kg), the Slow-release group displayed a significantly longer median survival than the Fast-release (59.5* v 47.5 days); both were significantly better than conventional paclitaxel treatment, Taxol and the saline control (only 34 and 26.5 days respectively).

With this slow release formulation we further evaluated their ability to treat an aggressive bone metastasis model in mice intratibially inoculated with 4T1-bone-cloned cells. When treated 2x/week over 3 weeks we found significant reduction in bone lesions and tumor burden, and with complete tumor eradication in 2/7 mice when treated at 75 mg/kg paclitaxel or 5/8 when treated at 150 mg/kg.

This study therefore highlights the importance of controlling the release rate from nanomedicines as well as the importance of ultrahigh loading of nanoparticles. Together, these factors maximize the overall drug dose as well as its retention time in the tumor, ultimately improving therapeutic outcomes.

2:15 PM SB01.02.03
Cross Linked Cyclodextrin Nanoparticles Enable Effective Delivery of Immunostimulatory Agents to Glioblastoma Associated Myeloid Cells Elias A. Halabi Rosillo, Sophie Lugani, Juhyun Oh, Rainer Kohler, Hannah Peterson, Christopher Garris and Ralph Weissleder; Harvard Medical School, United States

Myeloid cells create a highly immunosuppressive environment in glioblastoma multiforme (GBM) and contribute to poor immunotherapy responses. Based on the hypothesis that small molecules can be used to stimulate myeloid cells for more efficient effector functions, we developed a cyclodextrin nanoparticle (CDNP) approach to deliver dual NFKb pathway-inducing agents into these cells. Using fluorescently labeled CDNP analogs we were able to visualize the accumulation of the particles in live mice implanted with GBM to show that CDNPs have a high affinity to myeloid cells (primarily tumor associated dendritic cells and macrophages). When CDNPs were loaded with a TLR8 agonist (R848) and a cIAP inhibitor (LCL-161) we were able to show that interleukin (IL)-12 production could be jumpstarted in these cells. Herein show that CDNP-mediated myeloid re-education through TLR and non-canonical NFkB signaling can drive anti-tumor immunity in GBM.

2:30 PM SB01.02.04
Rational Design of Next-Generation mRNA Nanovaccines for Immunization Against Respiratory Syncytial Virus Afsaneh Radmand and James Dahlman; Georgia Institute of Technology, United States

mRNA-based lipid nanoparticle (LNP) vaccines (nanovaccines) have shown their safety and efficacy against COVID-19 in clinics. Along with this major clinical advancement, the high throughput *in vivo* screening platforms has advanced to bring about the full potential of nanovaccines. Such systems allow a more comprehensive understanding of the factors affecting biological responses and their clinical relevance with minimal sacrifice of animals. Here in this work, we used high throughput *in vivo* LNP screening system, to quantify the functional mRNA delivery (mRNA turn into protein) of hundreds of lipid nanoparticles in the same animal. By leveraging this system, we discovered next-generation nanovaccines against the respiratory syncytial virus (RSV). RSV is an RNA virus that encodes for 11 proteins and two of which (F & G) are capable of inducing neutralized antibodies. In particular, we focused on RSV-F for the following two reasons. First, it is well-conserved across viral serotypes and antigenic subgroups (A & B). Second, most of the neutralizing antibodies produced by natural RSV infection predominantly target RSV-F.
For the screening, we designed 100 LNPs with distinct chemical compositions. Then we barcoded each LNP in the microfluidic formulation. Followed by characterization as material quality control, barcoded LNPs that meet criteria (monodisperse; < 200 nm) were pooled as libraries and administered intramuscularly. Then, by next-generation sequencing on barcoded LNPs in the harvested tissue, we identified the nanovaccines (RSV1 and RSV2) that deliver the target mRNA to antigen-presenting cells in lymph nodes and muscle at levels comparable to Moderna and Pfizer-BioNTech lipid nanoparticles. We, therefore, further explored RSV1 and RSV2 with RSV-F mRNA. Next, we immunized mice with these LNPs varying doses of RSV-F mRNA and quantified the antibody response in serum following prime and a boost. We found that RSV1 and RSV2 led to similar antibody responses at high doses compared to Moderna LNP used as a positive control. But at a low dose, RSV1 and 2 led to a lower antibody response, suggesting that protein expression is necessary but not sufficient criteria during vaccine development at a preclinical stage in mice.

To enhance the immunogenicity of these LNPs at low doses, we hypothesized we could provide the LNPs with self-adjuvanting properties by modulating the mass of ionizable lipid mass (one of the essential components of lipid nanoparticle) per mass of mRNA in lipid nanoparticle formulation. As a result, we found an enhancement in RSV1 and RSV2 vaccine efficacy both in terms of protein expression and antibody response with the increased lipid:RNA ratio. We hypothesized that this effect could be due to two reasons. First, increasing the protein expression leads to an enhanced antibody response. Second, the increased mass of ionizable lipids serves as an adjuvant to stimulate the innate immune response. If the second hypothesis is true, stimulating the innate immune response would further enhance the adaptive immune response. Therefore, we included a TLR7 adjuvant into our LNP formulation, an endosomal single-stranded RNA agonist, and investigated the humoral and cellular response. We found that TLR7 adjuvant further enhanced the quality of produced anti-RSV F antibodies but did not enhance the cellular response.
In summary, we discovered two LNP vaccine candidates by *in vivo* high throughput LNP screening system. We also investigated factors affecting their response, and rationally enhanced their immunogenicity for immunizing against RSV at a preclinical stage in mice. We envision this study will guide scientists to design more effective nanovaccines for immunization against viruses and help accelerate mRNA-based vaccines.

2:45 PM BREAK

3:15 PM *SB01.02.05
Peptide Assemblies as Active Immunotherapies to Treat Chronic Inflammatory Diseases Elizabeth J. Curvino, Shamitha Shetty, Emily F. Roe, Yaoying Wu and Joel Collier; Duke University, United States

Chronic inflammatory diseases such as rheumatoid arthritis, psoriasis, and inflammatory bowel disease are currently treated using monoclonal antibodies and other biologics that neutralize key inflammatory mediators such as cytokines. Although beneficial for many, a large proportion of patients do not respond to them or stop responding as they develop anti-drug antibodies against the repeated injections. Anti-cytokine biologics also are expensive and have stringent storage requirements, limiting access to only the most well-resourced areas of the globe. Active immunotherapies, where therapeutic B-cell or T-cell responses are generated in the patient against selected targets, may provide alternatives with fewer dosing requirements, better shelf stability, and lower non-response rates. However, platforms for safely and predictably generating therapeutic anti-inflammatory adaptive immune responses have yet to be developed clinically. In this talk, active immunotherapies against several targets, including TNF, IL-1β, IL-17, phosphorylcholine, and complement proteins will be described, based on supramolecular peptide and protein assemblies. Design rules for eliciting predictable B-cell and T-cell responses against chosen targets using supramolecular peptide assemblies will be discussed, along with strategies for raising therapeutic responses in tissues of interest, including the gut. In preclinical mouse models of psoriasis, acute septic shock, inflammatory bowel disease, and rheumatoid arthritis, supramolecular active immunotherapies have exhibited considerable therapeutic efficacy, and these results will be highlighted.

3:45 PM SB01.02.06
Observation of Immune Activation Through Simultaneous Cell Receptor Monitoring Using Lanthanide Doped Upconverting Nanoparticles Ariel Stiber, Jason Casar, Chris Siefe, Vincent van Unen, Mark Davis and Jennifer A. Dionne; Stanford University, United States

Immune synapse (IS) formation, maintenance, and communication are conducted through the bonding of cell receptors. Long-duration cell receptor tracking throughout the synaptic activation process is difficult with current organic and inorganic fluorophores and quantum dots due to issues of biocompatibility, quenching, and photobleaching. Lanthanide doped upconverting nanoparticles (UCNP) are photostable over hours, and have the ability to convert incident photons to a higher frequency allowing for biologically transparent Near-IR (NIR) excitation and visible emission. Here, we show how UCNPs can be used as in-situ optical emitters to simultaneously observe multiple cell receptors throughout the stages of immune activation during a 6-8 hour IS interaction.

We colloidally synthesize 15 nm diameter hexagonal phase $NaYF_4$ nanoparticles, each doped with a different Lanthanide emitter — 2% Er, 0.5% Tm, or 2% Ho as well as the sensitizer Yb at 20%. The nanoparticles are shelled with inert, 4 nm thick $NaYF_4$ to minimize quenching. To disperse these UCNP in aqueous solutions, we wrap them in poly(maleic anhydride-alt-1-octadecene) (PMAO) hydrolyzed with 4-Dimethylaminopyridine (DMAP). Upon illumination at 980 nm these particles upconvert to visible light in the red, blue, and green. To target immune cells, we use a carbodiimide crosslinker to functionalize each nanoparticle with one of three antibodies targeting the cell receptors — CD69 (early activation marker), ICOS (co-stimulatory), and PD1 (co-inhibitory) — through neutravidin-biotin linkages. We confirm the functionalization of these nanoparticles using TEM, FTIR, UV-Vis, and fluorescence characterization methods. Live-dead assays with cloned cytotoxic T lymphocyte (CTL) cells that recognize cytomegalovirus (CMV) confirm the nanoparticles lack of cytotoxicity. We then image these nanoparticles on immune cells using scanning confocal microscopy. We demonstrate the ability to simultaneously track cell receptor expression through the stages of immune cell activation over the course of 8 hours without signal instability. As a control we parallely track these activation factors using Fluorescent Activated Cell Sorting (FACS). Additionally, we demonstrate the ability of UCNP to dynamically observe receptor binding kinetics in response to temperatures ranging between 20 and 40°C, as well as binding kinetics of the cytokine immunotherapy, Aldesleukin or IL2. Our work lays the foundation for future in-situ studies of simultaneous cell receptor tracking using a larger assortment of UCNPs with a functionalization platform that can be generalized to a variety of proteins and cell types.

Spatiotemporally Resolved Stimuli-Responsive Sequential Drug Delivery System to Curb Antibiotic Resistance Development Meera Patel, Alexander Corbett, Nesha Andoy and Ruby Sullan; University of Toronto, Canada

The emergence of antibiotic resistance has become a major public health threat. To slow down the development of antibiotic resistance, our group is developing a smart hydrogel drug delivery system to efficiently inhibit growth of Gram-negative bacteria. Although the target for many available antibiotics for Gram-positives can also be found in Gram-negative bacteria, the outer membrane permeability barrier limits drug efficacy to small hydrophilic antibiotics only. To overcome this limitation, we develop a laser-responsive drug delivery platform that can sequentially deliver a membrane potentiator, Ethylenediaminetetraacetic acid (EDTA), followed by a large hydrophobic antibiotic, rifampicin. For this, we leverage on the photoactivity of polydopamine nanospheres (PDNS), the temperature-dependent properties of liposomal carriers, and the flexibility afforded by hybrid hydrogel systems. The different phase transition temperatures (T_m) of phospholipids facilitated creation of liposomal drug nanocarriers that would release the loaded cargo at different temperatures. Membrane-disrupting molecules will be released first to prime the outer membrane of Gram-negatives, hence rendering the bacteria more susceptible to the hydrophobic antibiotic that will only be released after the pathogens have been exposed to the membrane permeabilizer. Having the ability to prime Gram-negative bacteria to the otherwise active “Gram-positive antibiotics” will broaden the repertoire of drugs that can be used for any type of bacterial infections. Furthermore, due to the photothermal activity of PDNS, an externally controlled laser can be used to trigger this sequential release of antimicrobials. Having drug delivery systems that can respond to an external stimulus and have that spatial and temporal control over drug bioavailability is a significant step towards preventing the unnecessary exposure of other microorganisms to antibiotics, helping mitigate antibiotic resistance development.

Novel Therapeutic Modalities Using Nanofiber-Based "Intelligent" Drug Delivery Daewoo Han[1], Serdar Tort[2] and Andrew J. Steckl[1]; [1]University of Cincinnati, United States; [2]Gazi University, Turkey

Development of novel materials platforms for controlled ("intelligent") release of functional molecules has emerged in materials research for medical applications. Controlled release of functional molecules in response to external stimuli is the key for intelligent release. Coaxial electrospinning technique[1] is a versatile method to integrate multiple functional materials into novel delivery systems, producing core-sheath fibers with advanced features: (a) combination of multiple functional materials; (b) encapsulation of functional molecules (drug, proteins, etc.) with controlled release kinetics; (c) protection of encapsulated molecules from outer environment. Intrinsic properties of nanofiber membranes (high surface-to-volume ratio and porosity) enable much quicker response to external stimuli compared to equivalent solid films. Complex nanofibers produced by coaxial electrospinning have been used in various advanced platforms for chem/bio/medical applications.

To obtain release triggered by external stimuli, self-immolative polymer (SIP) has been incorporated into the outer sheath layer encapsulating the releasing core materials.[2] As SIP is depolymerized ("unzip") upon cleavage of the head-molecule by specific target, stimuli drug molecules are released. A multi-phased controlled release was developed by integrating two different pH-responsive polymers into core-sheath fibers.[3] Fibers with Eudragit L100 core and S100 sheath provide 3-phase response within physiological pH range: pH < 5, no release is observed from either core or sheath layer; pH=5-6, sustained release from the core is obtained with different release kinetics; pH > 6, both core and sheath materials are quickly dissolved. This approach is very promising for targeted oral drug delivery because human organs have different pH values.

Other methodologies utilizing electrospun fibers include transdermal patches of parylene coated PCL fibers containing the drug pramipexole. These patches have demonstrated long-term drug delivery, ease-of-use, and no first-pass effect. Without parylene, 100% pramipexole load is released within 12 h, while parylene coating provided only 52% release over 10 days.[4] Microneedles loaded with electrosprayed nanoparticles for painless drug delivery via skin penetration were also demonstrated. Extremely small needles caused least pain to the host while directly delivering the loaded drug into the blood or interstitial fluid streams.[5] While patches and microneedles were developed to minimize physical disruption, implantation into the body is needed for certain cases. We developed a nanofibrous implant for localized chemotherapy against brain cancers. To circumvent the blood-brain-barrier, implanting the drug delivery device after tumor resection provides highly effective drug delivery to the targeted area. Our implantable device provides continuous drug release up to 160 days, significant increase of median survival and long-term survival rates of 50%.[6]

Modeling Coronavirus Spike Protein Dynamics—Implications for Immunogenicity and Immune Escape Genevieve Kunkel, Mohammad Madani, Simon White, Paulo Verardi and Anna Tarakanova; University of Connecticut, United States

The ongoing COVID-19 pandemic is a global public health emergency requiring urgent development of efficacious vaccines. With continual waves of COVID-19 outbreaks since 2019, in addition to the outbreaks associated with SARS-CoV and MERS-CoV over the last two decades, the threat presented by coronaviruses is everchanging and long-term. This provides reason to develop more targeted, 2nd generation vaccines for continual treatment as new variants emerge. The SARS-CoV-2 surface Spike (S) glycoprotein represents a prime target for vaccine development because antibodies that block viral attachment and entry, i.e. neutralizing antibodies, bind almost exclusively to the receptor binding domain (RBD). Here, we develop computational models for a large subset of S proteins associated with SARS-CoV-2—including Delta, and Omicron variants—implemented through coarse-grained elastic network models and normal mode analysis. We then analyze local protein domain dynamics of the S protein systems and their predicted thermal stability to characterize structural and dynamical variability among them. Our results are compared against existing experimental data and used to elucidate the impact and mechanisms of SARS-CoV-2 S protein mutations and their associated antibody binding behavior. We construct a SARS-CoV-2 antigenic map to highlight the location and accessibility of antibody binding domains in SARS-CoV-2 S proteins. We then offer predictions about the neutralization capabilities of antibody and S mutant combinations based on protein dynamic signatures. SARS-CoV-2 S protein dynamics are compared to SARS-CoV and MERS-CoV S proteins to investigate differing antibody binding and cellular fusion mechanisms that may explain the high transmissibility of SARS-CoV-2. Our results provide insights into the dynamics-driven mechanisms of immunogenicity associated with coronavirus S proteins and present a new approach to characterize and screen potential mutant candidates for immunogen design, as well as to characterize emerging natural variants that may escape vaccine-induced antibody responses.

Protein-Adjuvant Co-Delivery via Encapsulation in Lipid Nanovesicles for Enhanced Vaccine Immune Responses Dong Jae Lee, Bon Il Koo and Yoon Sung Nam; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

After more than two years, the coronavirus pandemic is finally coming to an end. Many countries around the world have lifted mask mandates, people are returning to their daily lives, and international travel levels are slowly reaching pre-pandemic numbers. While each country took different approaches to combat the coronavirus pandemic, one thing was common among all countries: encouraging the public to get vaccinated. Traditional vaccines consist of antigenic proteins mixed with adjuvants which increase the immune responses. Although a simple mixture may be enough in several cases, separated delivery of the antigen and adjuvants leads to lower immune responses. Co-delivery of the antigen and adjuvant results in more efficient cross-presentation

and higher immune responses.

Here, we report on enhanced vaccine immune response from the co-delivery of protein antigen-nucleic acid adjuvant mixture encapsulated in lipid nanoparticles. The antigen and adjuvant were encapsulated in multilamellar lipid nanovesicles coated with hyaluronic acid for enhanced antigen cross-presentation. Compared to the unencapsulated mixture, encapsulation of the antigenic protein and the nucleic acid adjuvant increased the delivery efficiency to the immune cells and the resulting immune responses. Delivery efficiency was confirmed using confocal microscopy, and the immune responses were analyzed using flow cytometry. Analyses of the immune responses from the bone marrow-derived dendritic cells (*in vitro*) and splenocytes (*in vivo*) of C57BL/6 mice showed increased levels of anti-antigen antibody (immunoglobulin G), cytokines (interferon gamma) and expression of surface markers (CD40, CD80, CD86) with encapsulated vaccine samples compared to unencapsulated control groups. Our results show that encapsulation of the protein antigen-nucleic acid adjuvant co-delivery mixture in lipid nanovesicles is a promising and effective method for vaccine immunization.

SB01.03.02

Luminal Coating of the Intestine for Oral Peptide Delivery Gillian Audia[1,2], Yuhan Lee[2] and Jeffrey M. Karp[2]; [1]Northeastern University, United States; [2]Brigham and Women's Hospital, United States

Though oral drug delivery is the patient-preferred route of administration, oral protein delivery remains evasive due to the challenges of navigating the low pH environment and digestive enzymes present in the gastrointestinal tract. Ultimately, these challenges result in low bioavailability of orally delivered protein drugs that preclude the translation of oral formulations to the clinic. Here we develop an orally administered gut-coating formulation that provides a transient coating of the bowel that can be used to protect protein drug cargo and direct it to the tissue wall. We identified a sucrose octasulfate aluminium complex and further engineered the pH-dependent material into a complex coacervate formulation linked via pH-independent electrostatic interaction, which allowed an effective transient physical coating on the gastrointestinal mucosa, independent of gastric acid exposure. The formulation protected biological agents from gastric acid exposure and degradation, which enabled oral delivery to the small bowel mucosa. Horseradish peroxidase (HRP) loaded into the gut coating material maintained activity before and after exposure to simulated gastric fluid (pH=1), while naked HRP showed complete loss of activity. HRP is released from LuCI gradually, with 62% of cargo released in the first four hours, and another 10% of cargo released over 24 hours. This technology will have the potential to enable oral delivery of protein therapeutics while protecting them from degradation from the gastric environment.

SB01.03.03

Chiral Plasmonic Hybrid Nanostructure Based Cascade Enzymatic Reaction for Enhanced Photodynamic Cancer Therapy Haeun Kang[1], Subin Yu[1], Ryeong Myeong Kim[2], Ki Tae Nam[2], Sehoon Kim[3] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of); [3]Korea Institute of Science and Technology, Korea (the Republic of)

Nanozymes, which are defined for nanomaterials with enzyme-like properties, have attracted significant attraction as promising alternatives for natural enzymes due to its attractive features. Compared with natural enzymes, nanozymes possess the advantages of facile synthesis, high stability, low cost, and easy for mass-production. Despite these advantages, nanozyme's low catalytic efficiency as a result of limited selectivity for substrate and its intrinsic low performance have still remained challenges.[1] To overcome these drawbacks, in this study, chiral plasmonic hybrid nanozymes were introduced to maximize interaction with circularly polarized light (CPL) and cascade enzymatic reactions were designed for photodynamic cancer therapy. Glucose oxidase (GOD)-like activity of chiral gold nanoparticle (D-Au NP) showed significant enhanced enzymatic performance with right-handed circularly polarized light (RCP), while peroxidase (POD)-like activity of palladium deposited chiral gold nanoparticles (L-Au NP@Pd) increased with left-handed circularly polarized light (LCP). In addition, D-glucose, the substrate for GOD-like activity showed significantly enhanced catalytic effect with D-Au NP rather than L-Au NP. These results show that chirality of nanozymes play a key role in the enzymatic performance with CPL. Also, introduction of chiral hybrid nanozymes in this cascade enzymatic reaction platform increased the overall therapeutic effects for photodynamic cancer therapy. When D-Au NP and L-Au NP@Pd were localized in the tumor site via EPR effect[2], RCP was irradiated to generate H_2O_2 from D-glucose through GOD-like activity of D-Au NP. Then, LCP was irradiated to generate hydroxyl radical through POD-like activity of Pd.[3] Under 808nm-CPL light irradiation, *in vitro* phototherapy effect was investigated on Hela cells. Interestingly, cancer cell viability was significantly decreased when LCP and RCP were irradiated sequentially, suggesting that enhanced amount of hydroxyl radicals were generated. Therefore, endowing the chirality to nanozymes, the chiral hybrid nanozymes herein introduced can open up new horizons for diagnosis, treatment, and theragnostics as advanced nanozymes candidates.

Hybrid Nanotubes (HyNTs)—Iontophoretic Molecular Delivery System Bowen Zhang, Kazuhiro Oyama, Yuiko Mizuguchi and Takeo Miyake; Waseda University, Japan

Delivering biomolecules into living cells and tissues has become an important challenge in medical and biological fields. Conventional techniques such as virus vector and electroporation are utilized commonly for small molecule delivery, but still remain several problems of low efficiency and low viability for large molecules such as biological proteins and organelles. To overcome this problem, we demonstrate the macromolecular delivery into adhesive cells with hybrid nanotubes (Au nanotube/conductive polymer) that promotes the flow of ions at an applied voltage (about 50 mV) below the cell membrane potential [1-2]. As a result, we have succeeded in developing an electric nanoinjector that delivers macromolecules such as green fluorescent protein (GFP) and DNA plasmid into cells.

SB01.03.05

Unveiling the Behaviour of MOF Drug Nanocarriers with Nanoscale Multimodal Spectromicroscopy Maeva Chaupard[1,2], Ruxandra Gref[2] and Marta de Frutos[1]; [1]Laboratoire de Physique des Solides, France; [2]Institut des Sciences Moléculaires d'Orsay, France

The current sanitary crisis has demonstrated the constant need for new technologies in health care. For decades, nanotechnologies have been gaining interest as efficient tools for health improvement. Among them, drug delivery systems are designed as smart vessels to provide slow and controlled release of drugs targeting the diseased organs or tissues. For more than 15 years, metal-organic framework nanoparticles (nanoMOFs) have been studied as promising drug nanocarriers.[1] They are currently viewed as potential candidates for cancer or infection therapies.[2]
NanoMOFs are porous nanoparticles created by the self-assembly of metal clusters and organic linkers. They exhibit a high drug payload that reaches about 30 wt%.[3] In addition, their versatile composition allows their properties to be tuned to the therapy. A careful selection of building blocks can lead to biocompatibility, biodegradability, an amphiphilic inner environment to load hydrophilic drugs, or synergetic bioactivity of both linkers and metals. Among the many assembly possibilities, iron trimesate nanoMOFs have gained interest for their additional theranostic capacities.[4] Furthermore, a polymer corona can be coated onto the nanoMOF's surface to convey additional properties to the nanosystem. Recent studies have highlighted the use of cyclodextrin and mannose grafting to provide stealth and tissue targeting.[5] Others have also shown the possibility of pH-responsivity using cyclodextrins.[6] Nonetheless, many questions remain about these complex nanosystems regarding their drug distribution and interaction with biological matter. Although phosphate molecules were shown to be involved in the biodegradation of iron trimesate,[3,7] the degradation mechanism is still not fully unravelled. Besides, an in-depth understanding of their cellular fate is needed to develop biomedical applications.
Here, we present a label-free approach for studying individual nanoMOFs at the nanoscale, which could also be applied in the analysis of their interaction with cells. We demonstrate that spectromicroscopy could be the key to unravelling the drug distribution and biodegradation mechanisms. Indeed, using STEM-EELS (Scanning Transmission Electron Microscopy coupled with Electron Energy Loss Spectroscopy), we simultaneously image and analyse iron trimesate nanoMOFs with a spatial resolution below 10 nm. First, with a multimodal approach, we studied the infrared, UV-vis and soft X-ray spectral ranges to perform a fine structure analysis of both the organic and inorganic parts. Secondly, we acquired chemical maps to determine the distribution of each component throughout the specimen. Finally, we highlight the possibilities of characterizing each step of the nanosystem's development: from the framework synthesis and its interaction with drugs to the degradation mechanism and the biological evaluations.

Si-SiO_2 Core-Shell Nanoelectrode Arrays for Intracellular Sensing and Stimulation Yiming Wang, Daniel Loh and Daniel Nocera; Harvard University, United States

Intracellular electrochemical analysis is a powerful tool for detecting cellular metabolites and understanding cellular processes. However, it is challenging to make submicrometer sized electrodes and modify them with desired sensing modules. It is essential to develop methodologies to fabricate and modify nanoelectrodes with reproducibility and scalability. Taking advantage of well-established nanofabrication technologies in semiconductor industry, our group developed techniques to produce high aspect ratio silicon nanowires in a wafer scale. In the current work, we manufactured high aspect ratio Si-SiO_2 core-shell nanoelectrode arrays with electrode area compatible with conventional nanoelectrodes, but with great scalability and reproducibility. We further developed a general modification method for the nanoelectrode arrays for parallel intracellular sensing and stimulation.

SB01.03.07
Characterizing Nano-Bio Interactions on Hematopoietic Stem Cell Targeting Layer-by-Layer Nanoparticles for Gene Therapy Bhuvna Murthy, Tamara Dacoba, Simone A. Douglas-Green and Paula T. Hammond; Massachusetts Institute of Technology, United States

Sickle cell disease (SCD) is the most commonly inherited blood disorder in the United States that affects ~100,000 people. This autosomal genetic disorder is caused by a single mutation on hemoglobin found on red blood cells (RBCs). In deoxygenated conditions, the mutated hemoglobin causes RBCs to sickle. Gene therapy is a potential cure, where hematopoietic stem cells (HSCs), precursors to RBCs, could be targeted to correct the mutation. We will use the layer-by-layer (LbL) technique, to develop a library of nanoparticles functionalized with HSC targeting antibodies to deliver therapeutics. Nanoparticles are layered with negatively charged polymers including hyaluronate, which has increased circulation times in vivo, as well as polyacrylate and poly-L-glutamate, which have decreased clearance by immune surveillance cells. When nanoparticles enter biological fluids, nano-bio interactions occur, where proteins adsorb to their surface, forming a "fluid biological barrier" known as the protein corona (PC). PC affects nanoparticle circulation times, immunologic toxicity, and colloidal stability; it can be used to tune targeting of nanoparticles as its properties vary based on surrounding biological fluid and tissues. Here, we characterize properties of the PC on HSC-targeting LbL nanoparticles for gene therapeutic delivery in SCD and assess how these interactions affect uptake into cells.

To characterize the PC, our library of nanoparticles were incubated with varying concentrations of fetal bovine serum (FBS) at physiological temperature (37C) for 30 minutes. Incubations were performed at high and low volume ratios of nanoparticles to FBS to assess the effect of varying amounts of protein. To remove unbound protein, nanoparticles were centrifuged, and the pellet was washed and resuspended in water. Protein-coated nanoparticles were assessed for size and surface charge using dynamic light scattering and laser Doppler velocimetry. Protein concentration was quantified using a Bicinchoninic acid assay and protein composition was observed using SDS-PAGE. Effects of PC on nanoparticle uptake in cells were also measured; protein-coated nanoparticles were prepared, as previously described, before incubating with EL4 cells, which have the CD45 marker characteristic of HSC-derived cells. Uptake of Cy5-labeled nanoparticles was analyzed using fluorescence activated cell sorting.

We determined nanoparticles maintain colloidal stability through protein interaction based on consistent size and surface charge measurement. SDS-PAGE showed distinct band patterns, indicating proteins of varying molecular weight, for each outer layer polymer of the nanoparticles, which suggests surface chemistry and charge affects PC composition. Analysis of nanoparticle uptake demonstrated that outer layer chemistry affects nano-bio interactions as hyaluronate and polyacrylate outer layers did not have significant changes in uptake in EL4 cells, while poly-L-glutamate nanoparticles showed an increase in uptake. Most notably, nanoparticle uptake was highest at incubation in biologically relevant conditions, with 10% FBS at a nanoparticle to FBS ratio of 1:10. Incubation with 100% FBS at the same ratio resulted in lower uptake in all nanoparticles, suggesting higher protein content interferes with uptake.

Overall, it was determined that outer surface chemistry of nanoparticles affects properties of protein corona as well as uptake in cells. It was also determined that varying protein concentration and volume ratio of nanoparticles to protein are effective methods of assessing PC for nanoparticles. PC

characterization in these HSC-targeting nanoparticles is essential to tuning specificity of targeting and can significantly affect immunological clearance and circulation times, causing non-specific uptake. Understanding its role in nano-bio interactions is integral in nanoparticle targeting and in creating an effective nanoparticle for gene therapeutic delivery.

SB01.03.08
H_2O_2-Activatable Antioxidant Polymeric Prodrug Nanoparticles as Therapeutics for Renal Ischemia/Reperfusion Injury Hyunbin Shin, Sooyeon Kim, Nanhee Song, Hayoung Jun, Hanui Jo and Dongwon Lee; Jeonbuk National University, Korea (the Republic of)

During organ transplantation, blood vessels are temporarily tied to prevent bleeding and organs which do not receive sufficient oxygen and nutrients undergo ischemic damages. To prevent damages to these organs, blood must be rapidly re-supplied. Paradoxically, however, blood resupply induces greater organ damages which is called ischemia-reperfusion (IR) injury. Renal IR injury is an inevitable complication in various clinical settings including kidney transplantation and major vascular surgeries. Renal IR injury contributes to the development of acute kidney injury which still remains a major clinical challenge. One of major culprits of renal IR injury is the massive production of reactive oxygen species (ROS) including hydrogen peroxide (H_2O_2) that initiate inflammatory signaling pathways, leading to renal cell death. It can be also hypothesized that effective elimination of overproduced H_2O_2 provides a promising strategy to prevent renal IR injury.
Vanillyl alcohol (VA) is an herbal agent in oriental medicine and has been used for the treatment of ischemic brain injury and coronary arterial diseases due to its potent antioxidant and anti-inflammatory activities. Ursodeoxycholic acid (UDCA) is one of bile acids and has been well known to inhibit the generation of intracellular ROS and suppresses the production of pro-inflammatory cytokines. However, UDCA and VA alone cannot be used for the prevention of renal IR injury due to their insufficient therapeutic activity and the lack of H_2O_2 scavenging ability. It can be therefore postulated that therapeutics that are able to not only scavenge H_2O_2 rapidly but also deliver both VA and UDCA concurrently to the target site have great potential for the prevention of renal IR injury. To realize the concurrent delivery of sufficient amount of both VA and UDCA and H_2O_2 scavenging with single nanoparticles, we developed H_2O_2-activatable antioxidant and anti-inflammatory polymer, PVU73 by exploiting the concept of polymeric prodrug that incorporates bioactive compounds (VA and UDCA) in the backbone and releases them during degradation. As a polymeric prodrug of VA and UDCA, PVU73 was designed to covalently incorporate VA and UDCA in its backbone through a peroxalate linkage that can be readily cleaved by H_2O_2 and also scavenge H_2O_2. PVU73 could be formulated into nanoparticles of a mean diameter of ~220 nm by a conventional single emulsion method. For preferential targeting to kidney with IR injury, PVU73 nanoparticles were coated with fucoidan that has high affinity to p-selectin which is an adhesion molecule overexpressed on the endothelium in the inflammatory site. The translational therapeutic potential of fucoidan-coated PVU73 (Fu-PVU73) nanoparticles was evaluated using a mouse model of renal IR injury. The results revealed that Fu-PVU73 nanoparticles hold great potential as therapeutic agents for renal IR injury due to their H_2O_2 scavenging ability and potent anti-inflammatory activities. We anticipate that Fu-PVU73 nanoparticles have tremendous therapeutic potentials for not only renal IR injury but also various ROS-associated inflammatory diseases.

SB01.03.09
Tumor-Targeting Oxidative Stress Nanoamplifiers as Immunogenic Cell Death-Inducing Anticancer Nanomedicine Nanhee Song, Nuri Kim, Manseok Yang, Gayoung kwon, Soonyoung Kwon and Dongwon Lee; Jeonbuk National University, Korea (the Republic of)

Compared to normal cells, cancer cells are under oxidative stress associated with a high level of reactive oxygen species (ROS) and are also more susceptible to insults of pro-oxidants that generate ROS or scavenge antioxidants such as glutathione (GSH). Cancer cells employ a variety of adaptation mechanisms in response to excessive oxidative stress. In order to maintain redox balance, increased oxidative stress leads to up-regulation of antioxidant system activity. Among endogenous antioxidants, GSH is a major ROS-scavenger and plays fundamental roles in sustaining cellular redox homeostasis. It has been reported that quinone methide (QM) intermediate generated from the hydrolysis of phenyl ester instantaneously depletes intracellular antioxidant GSH, leading to mitochondria-dependent apoptosis. The combination of ROS generation with GSH depletion has been suggested to cooperatively accumulate ROS to amplify oxidative stress, leading to enhanced cell death. Additionally, it has been also reported that a ROS level above a cytotoxic threshold level elicits the immunogenicity of dying cancer cells. Elevated oxidative stress elicits immunogenic cell death (ICD) that is a type of apoptotic cell demise and boosts anticancer immunity.
In this study, we developed disulfide-bridged phenylene benzoate (ssPB) to exert therapeutic effects of GSH-depleting prooxidants. ssPB was rationally designed to fulfill the requirements for not only QM generation but also self-assembling behaviors. ssPB was expected to form self-assembled nanoconstructs and undergo esterase-catalyzed hydrolysis of phenolic ester to produce two QM intermediates that deplete intracellular antioxidant GSH, leading to enhanced intracellular ROS accumulation that can result in cancer cell death. 2'-Benzoyloxycinnamaldehyde (BCA) is a derivative of cinnamaldehyde that is a major component of cinnamon and exerts potent anticancer and antiproliferative activities by including ROS generation. On the basis of assumption that the convergence of GSH depletion with ROS elevation cooperatively amplifies oxidative stress and induces immunogenic apoptosis, we designed F-ssPBCA nanoparticles as a tumor-targeted oxidative stress amplifier as well as ICD inducing anticancer nanomedicine, composed of ssPB, BCA and tumor-targeting fucoidan. Under the tumor condition, F-ssPBCA nanoparticles significantly elevate oxidative stress to kill cancer cells and also evoke ICD featured by the release of CRT (Calreticulin), HMGB-1 (high mobility group box-1), and adenosine triphosphate (ATP). While ssPB and BCA alone are insufficient to boost ICD individually, their cooperative therapeutic activities significantly amplify oxidative stress in cancer cells, leading to ICD. To test this concept, the biophysical properties of F-ssPBCA nanoparticles were extensively examined and their anticancer therapeutic activities were also examined using cell culture models and xenograft mouse models. The results in this study demonstrate that prooxidants-mediated massive ROS accumulation is a highly effect strategy to kill cancer cells selectively and even evoke ICD. We therefore anticipate that oxidative stress amplifying F-ssPBCA nanoparticles hold tremendous translational potential as tumor-targeting anticancer nanomedicine with immunostimulating activities.

SB01.03.11
Iridium Oxide-Protein Hybrid Film for Neural Interfaces Application with Enhanced Electroactivity and Bioactivity Enable Electrically-Manipulatable Physical and Chemical Neuronal Activation Guan Xun Lee and Pochun Chen; National Taipei University of Technology, Taiwan

Iridium oxide (IrO_x) is a promising electrode material of implantable neural therapeutic devices owing to the remarkable performance on neural stimulation. However, the current IrO_x electrode lacks biocompatibility and bioactive interactions with nerve tissues. Even the commonly-used polymeric surface coating results in the weak physical adhesion between organic/inorganic interfaces, limiting the chronic application. Accordingly, we proposed a smart iridium oxide- plasma protein (IrO_x-PP) electrode with enhanced electroactivity, electrochemical stability, biocompatibility, and bioactivity that can permit controllable topographical, electrical, and chemical stimuli to enhance neuronal activity. Electrochemical deposition facilitated the formation of inorganic/organic nanoparticle (NP)-protein corona structures in which the soft NP-corona allowed a repeatable burst-to-zero-to-burst PP release and the hard NP-corona with an order atomic structure that enabled enhanced electrochemical sability and bioactivity. The incorporated PP contributed to nanorough surface structures that led to higher current storage capacity, lower impedance, better cell growth and more significant neurite outgrowth than that of pristine IrO_x. Electrical stimulation (ES) on IrO_x-PP permitted synchronous neuromodulation, on-demand PP release and cell uptake, leading to 2.5-fold higher cell density and more significant neurite outgrowth than that on IrO_x. Such bioactive inorganic-organic hybrid electrode with synergistic effect of physical and chemical neuromodulation is expected to be a revolutionary platform to provide more effieicent and biocompatible implanted neural

therapies.

SB01.03.12
A ROS-Scavenging 'Stealth' Polymer, Poly(thioglycidyl glycerol)(PTGG), Outperforms PEG in Protein Conjugates and Enhances Protein Stability to Environmental and Biological Stressors Richard d'Arcy[1], Farah El Mohtadi[2], Nora Francini[1] and Nicola Tirelli[3]; [1]Vanderbilt University, United States; [2]University of Portsmouth, United Kingdom; [3]Istituto Italiano di Tecnologia, Italy

Poly(ethylene glycol)(PEG) is a low-fouling polymer commonly used for extending plasma half-lives of biologics but does suffer significant drawbacks; for example, PEGylation offers no protection from denaturation (e.g. via lyophilization, storage or oxidation). Furthermore, a growing incidences of PEG immunogenicity has put into question its biological inertness, and already led to the market withdrawal of peginesatide (Omontys), pegloticase (Krystexxa) and the cessation of pegnivacogin (Revolixys) trials, while dozens of other PEGylated formulations present antiPEG antibodies, accelerated blood clearance, infusion reactions and reduced efficacy overtime, thus highlighting a clear need for next-generation 'stealth' technologies.
Accordingly, we identified the lack of (pharmacological) activity as a missed opportunity as PEG offers no inherent protection from environmental stressors, but proteins are readily susceptible to chemical changes that can arise along the manufacturing line (production, sterilization, lyophilization), as well as in vivo after administration. The addition of excipients (antioxidants, cryo/lyoprotectants) only partially address the issue as they are not chemically bound to the protein, so their protective function ceases after administration.
We have thus rationally designed a new 'active-stealth' polymer, poly(thioglycidyl glycerol)(PTGG), composed of a cryo/lyoprotective glycerol-derived side-chain and an antioxidant polysulfide backbone. In human plasma, PTGG was significantly less immunogenic than PEG (up to 35% less complement activation), but also features a potent ROS-scavenging and anti-inflammatory action (~50% reduction of TNF-α in LPS-stimulated macrophages at only 0.1 mg/mL). PTGG was efficiently conjugated to proteins via a one-pot processes; molar mass- and grafting density-matched PTGG-lysozyme conjugates demonstrated superiority to their PEG analogs in terms of both enzyme activity, and stability against freeze-drying or oxidation. In rats, PTGG-ovalbumin conjugates (used as a model immunogenic protein) displayed a considerably longer circulation than PEG-ovalbumin ($t_{\beta 1/2}$ = 28.2 vs 14.1 hours, 1.4-fold higher AUC on first dose) without an associated ABC effect ($t_{\beta 1/2}$ = 26.3 vs 10.7, second dose). These findings, and in particular its double 'active-stealth' character, position PTGG as a promising alternative to PEG for conjugation to biologics.

SB01.03.13
Magnetic Properties of Iron Oxide Nanoparticles with Different Geometries Alexis G. Lavin, Nataniel Medina, Wenndy Pantoja and Gerardo Morell; Universidad de Puerto Rico, United States

The functional hybrids based on iron oxide nanoparticles are interesting for multimode imaging and synergistic cancer therapies. In this research, we optimized morphologies as hexagonal, cubic, spherical, and star-shaped. We synthesized them using a thermal decomposition process, optimizing parameters as organic solvents batch time residence and different temperatures. The HR-TEM images show homogeneous and dispersed nanoparticles with sizes between 10 and 120 nm. The XRD patterns contain peaks associated with the spinel structure type (Fd3m) characteristic of Fe_3O_4 (magnetite, JCPDS File No. 19-0629). Magnetic studies were performed at different temperatures, finding the highest saturation magnetization (Ms) 68.24 emu/g at 300K by the star-shaped geometry. The relaxivity studies indicate that they induce T_2 responses according to their size and morphology. We propose specific geometries and surface coordination with various moieties to increase the response for biomedical applications

Supramolecular-Assembly-Enabled Synthetic mRNA Switch for Efficient and Accurate Cell Fate Control Yaxin Hu, Qiuyu Lu, Cheuk Yin Li and Yi Kuang; Hong Kong University of Science and Technology, China

Synthetic mRNA switches are promising tools capable of regulating target protein levels (output) in response to specific molecular signals (input). Conventional synthetic mRNA switch commonly consists of two domains: an input sensing module and a output coding module. The sensing domain interacts with input via noncovalent interactions to repress output production. Leaky expression of output signal is an innate limitation of conventional synthetic mRNA switch. Here, we engineered a novel readout control module to alleviate the signal noise generated by leaky output expression. This readout control module is based on aptamer-protein interaction. An array of aptamers is used as scaffolding to assemble inactive output protein. Only in the absence of input, ample amount of output protein can saturate the aptamer array to form functional protein assemblies. While in the presence of input, the leaky output protein production is insufficient to trigger assembly formation. Synthetic mRNA switches carrying this readout control module can sense different input with higher signal-to-noise ratio, offering efficient and accurate output signal production. This novel design combines chemistry and synthetic biology principles to offer a generally applicable synthetic mRNA switch model, featuring the near-complete sequestering of output signal noise, stronger input sensitivity, and a wider output operation range. With these prominent properties, we believe this novel switch model can efficient and accurate orthogonal control of cell fate, bringing enormous potentials in building complex synthetic mRNA circuits for next-generation diagnostic and therapeutic purposes.

8:30 AM SB01.04.02
Tuneable Glycosylated Polypeptide Nanoparticles by *N*-Carboxyanhydride Emulsion Polymerisation Nicola Judge[1], Ruairi Brannigan[1,2] and Andreas Heise[1]; [1]Royal College of Surgeons in Ireland, Ireland; [2]Dublin City University, Ireland

Biodegradeable nanoparticles produced by emulsion polymerisation find applications in many fields such as nutraceutical, agriculture, and medicine. Crucial aspects of tuneability have recently focused on the shape, size and core composition as a way to control the drug loading, biodistribution and targeting capabilities within medicinal drug delivery applications. Consequently, glycosylated nanoparticles have received increased interest in the field as the tuneable nature of the emulsion process combined with the well documented targeting ability of glycans has the potential to create libraries of well-designed delivery vehicles.
Our interests lie in a new class of nanoparticles fully based on synthetic polypeptides which allow for a premeditated surface through the utilisation of a high molecular weight surfactant remaining adsorbed onto the surface. Therefore we have recently developed a novel route for the synthesis of

glycosylated degradable nanoparticles composed of a polypeptide core and a glycopeptide shell. Herein, the synthesis and analysis of a series of degradable glycosylated polypeptide nanoparticles (GlycoPep NPs) is described. GlycoPep NPs were synthesised by miniemulsion ring-opening polymerisation (ROP) of *N*-carboxyanhydrides (NCA) in aqueous conditions; during which varying glycopolypeptides were utilised as surfactants. The size of the GlycoPep NP's could be tailored based on the core and surfactant polypeptide composition and the concentration ratio. Dynamic light scattering (DLS), Nanoparticle Tracking Analysis (NTA), Transmission Electron Microscopy (TEM) and Asymmetric Field Flow Fractionation (AF4) confirmed the highly stable and reproducible nature of the particles produced. The nanoparticles could be lyophilised and resuspended in water and buffer solutions, enhancing their bio-applicability. We will look to elucidate their binding interactions by utilising the pendant sugar within the surfactant as the system is only composed of bio-relevant materials. This methodology therefore opens up a library of bio-inspired glycosylated polypeptide nanoparticles which can be highly tuned giving them significant potential for the delivery of therapeutic agents.

8:45 AM SB01.04.03
Cyclodextrin-Based Metal-Organic Frameworks as Nano Platforms for Biomedical Applications Min Peng, Anna M. Kaczmarek and Kristof Van Hecke; Ghent University, Belgium

Cyclodextrins (CDs) form a family of naturally abundant, inexpensive, cyclic oligosaccharides, consisting of truncated cone-shaped molecules, with a hydrophobic cavity and a hydrophilic surface. Through the coordination of CDs with alkali metal ions (Cs^+, K^+,…), biocompatible, carbohydrate CD-based, porous metal-organic frameworks (CD-MOFs) can be obtained. These CD-MOFs are attractive materials for practical applications as they can be considered as biocompatible, biodegradable and sustainable nanoporous MOF alternatives. Hence, CD-MOFs have already found a wide range of applications, such as molecular adsorption, separation and recognition, drug delivery, as host template for nanoparticle synthesis, and light emission and sensing.

In this work, we first designed macro- and nanosized core, as well as core-shell, γ-cyclodextrin metal-organic frameworks (γ-CD-MOFs) and used them as platforms for the encapsulation of dye molecules to develop the first CD-MOF-based ratiometric optical thermometer materials. A novel dye combination was employed for this purpose, i.e., the duo rhodamine B (RhB) and fluorescein (FL). RhB is highly temperature-sensitive, whereas FL is lesstemperature-sensitive, and its luminescence emission peak is used as a reference. Promising results in terms of thermometric properties were obtained for a whole series of dye-encapsulated γ-CD-MOF materials based on this dye combination, with high relative sensitivities, even up to $5\%K^{-1}$, for the dye-encapsulated 75%RhB-25%FL nanosized γ-CD-MOF, among the highest performance values reported so far for luminescent dual thermometers. In our study, we have additionally developed a simple yet effective preparation method for core−shell γ-CD MOFs, allowing effective manipulation of the γ-CD-MOF shell growth. The proposed method allows incorporation of the FL and RhB dyes in the γ-CD-MOFs in a more controlled manner, enhancing the efficiency of the developed ratiometric (macro) γ-CD-MOF thermometers.

In recent years, the incorporation of metal or metal oxide nanoparticles (NPs) into porous MOFs to form NP-MOF structures has attracted great interest. Although procedures for the deposition of Ag and/or Au NPs (AgNPs, AuNPs) in MOFs have already been reported, their application with CD-MOFs has not been investigated thoroughly yet. Both AgNPs and AuNPs are plasmonic, which means they could be exploited to concentrate light at a certain wavelength, providing local heating and, thus, be employed for photothermal therapy and can play a beneficial role when it comes to CD-MOFs used as drug delivery systems, as local heating can speed up the drug release.

In this work, we therefore investigated different routes of depositing AuNPs and AgNPs in a convenient manner into nanosized CD-MOFs. The loading of the NPs can be easily steered by increasing or decreasing the amount of used metal precursors. The NPs can be synthesized at low temperatures which do not affect the structure nor crystallinity of the nano CD-MOFs. We could also show that small and very uniform AuNPs and AgNPs can be obtained upon dissolving the CD-MOF template. Therefore, this is an ideal route to yield well water-dispersible metal nanoparticles without the use of any ligands or surfactants. Analogously to the first employed dye combination of RhB and FL, the thermometry properties of the nano CD-MOFs, with deposited AuNPs and AgNPs, were obtained upon embedding a mixture of a different dye combination, i.e. the RhB and rhodamine 110 (Rh110) pair in the pores of the CD-MOFs.

This is the first work where CD-MOFs are proposed for the development of luminescent thermometric materials, and in combination with plasmonic AuNPs and AgNPs. By employing this approach, various fluorescent dyes can be combined, which opens new possibilities toward the future development of a wide range of ratiometric biological (plasmonic) nanothermometers.

9:00 AM SB01.04.04
Investigation of Nanoscale Distance-Dependent Antibody-Antigen Binding for Mast Cell Activation Leonie Schneider, Carmen Martínez-Domínguez, Kersten S. Rabe and Christof M. Niemeyer; Karlsruhe Institute of Technology, Germany

Cellular immune responses in mast cells are regulated in the early stages of cell signalling and play a pivotal role in the initiation and development of type I hypersensitivity reaction. The spatial organization of IgE's high-affinity transmembrane receptor, FcεRI, into molecular clusters stimulates inflammatory mediator degranulation, cytokine production and phospholipid production.[1] Receptor-clustering is mediated by multivalent antigen binding of the IgE antigen binding fragments (Fab) of receptor-bound antibodies on the cell surface. Here, the spatial tolerance of Fabs towards repetitive nanopatterns of antigens is crucial for initiation or inhibition of an immune response.[2] To investigate structural constraints of antibodies binding to multivalent antigens to initiate effector functions and cell activation, we utilize supramolecular DNA architectures decorated with small hapten molecules and present them to the cell membrane. This Multiscale-Origami Structures as Interfaces for Cells (MOSAIC) technology allows precise control over the number, stoichiometry and arrangement of the signalling molecules on the nanometer scale, imitating the ultrastructural features of biomolecular assemblies.[3]

In this contribution we report on hapten-decorated DNA origami nanostructures (DON) to investigate the spatial tolerance of free and membrane-associated antibodies on the nanoscale regarding antigen-mediated effects on mast cell activation. We designed distinctive nanoscale arrangements of haptens to induce receptor clustering and for the first time investigated the relation between antigen-binding affinity and mast cell signalling, an important feature for tailoring next generation monoclonal antibodies (mAb) for immunotherapy.
We synthesized rectangular DON with a size of 70 x 100 nm^2 as molecular pegboards and incorporated protruding oligonucleotides for DNA-directed immobilization on solid surfaces and dinitrophenol (DNP)-ligands with precisely defined distances. We investigated the interaction kinetics of anti-DNP IgE and anti-DNP IgG to these DNP-decorated DON with distinct DNP-distances of 6 – 30 nm aiming for a better understanding of the native structure and Fab flexibility of antibodies. We also investigated the binding kinetics of DNP-decorated DON and FcεRI-receptor-bound anti-DNP IgE antibodies on the surface of rat basophilic leukemia (RBL)-2H3 cells, a model for mast cells, using LigandTracer technology.[4] To put our results in a biological context, we performed cell signalling assays to study the effect of antigen-antibody binding affinity and receptor-clustering on cellular activation.[5] To the best of our knowledge, these studies are the first to investigate the distance dependence of free and receptor-bound IgE antibodies using surface-immobilized hapten-decorated DNA origami to elucidate fundamental biological principles of mast cell activation.

AI-Enhanced ND Biosensor Automates Sensitivity Prediction to OXPHOS Inhibitors Jingru Xu[1], Mengjia Zheng[2], Chenjie Xu[2] and Edward Chow[1]; [1]National University of Singapore, Singapore; [2]City University of Hong Kong, China

Hepatocellular carcinoma (HCC) is the one of leading causes of cancer-related mortality worldwide. Spalt-like transcription factor 4 (SALL4) is an oncofetal protein in HCC, and high SALL4 expression level is correlated to poor prognosis. However, SALL4 lacks well-structured small molecule binding pockets, making it difficult to design targeted inhibitors. There was a therapeutic strategy based on the increased oxidative phosphorylation (OXPHOS) in SALL4^{hi} HCC cells. SALL4-induced high expression level of OXPHOS serves as a therapeutically targetable vulnerability in HCC that specific OXPHOS inhibitors can be applied.
Here, we developed a workflow that utilized molecular beacon, a nucleic-acid-based, activatable sensor with high specificity to the target mRNA, delivered by nanodiamond, to establish an artificial intelligence (AI)-based platform for rapid evaluation of patient-specific drug sensitivity. Specifically, when the HCC cells were treated with the nanodiamond-medicated OXPHOS biosensor, high sensitivity and specificity of the senor allowed the identification of OXPHOS expression in cells. Assisted by a trained convolutional neural network, drug sensitivity of cells towards an OXPHOS inhibitor, IACS-010759, can be accurately predicted. The whole assessment could be accomplished within two days, enabling rapid and efficient clinical decision support for HCC treatment.

Nanomaterials as Building Blocks in Functional Biomaterials Design Mark W. Tibbitt; ETH Zürich, Switzerland

Engineering responsive biomaterials from reversible interactions enables the design of injectable drug delivery platforms and materials for 3D bioprinting. Among the emerging motifs to assemble these materials, polymer–nanoparticle interactions have been introduced as a useful strategy to assemble polymer–nanoparticle materials. In this approach, engineered nanoparticles are used as constituent building blocks in the material design, allowing for a broad range of functionality in biomaterials design. In this presentation, we will describe our efforts in the design of polymer–nanoparticle hydrogels as bioinks for 3D printing. We designed a universal carrier ink composed of PEGylated polymer nanoparticles, cellulose derivatives, and a range of secondary polymers. The rheology enables extrusion-based printing, and the inclusion of secondary polymers provides a strategy for stabilization of the printed constructs. This strategy has been applied in the design of printed constructs for tissue engineering and multimodal drug delivery. In addition, we have advanced this platform by including a supramolecular binding motif based on polypseudorotoxane formation of alpha-cyclodextrin (aCD) on the surface of the PEGylated nanoparticles. This approach enabled tunable mechanical properties as well as modular design of polymer–nanoparticle hydrogels via exchange of the nanoparticles and polymers. Supramolecular reinforcement of polymer–nanoparticles further expanded the scope of applications, including the design of injectable materials for sustained biomolecule release.

Enzymatic Responsive Supramolecular Assemblies for Targeting Subcellular Organelles Weiyi Tan, Meihui Yi, Jiaqi Guo, Qiuxin Zhang, Adrianna Shy, Yuchen Qiao and Bing Xu; Brandeis University, United States

Subcellular compartmentalization is a key feature of eukaryotic cells. Selectively targeting subcellular compartments, though holding many exciting opportunities for biomedicine, remains rather underdeveloped. Enzyme-instructed self-assembly (EISA), an approach that integrate enzymatic reactions and self-assembly, provides a new way for subcellular targeting. In this talk, we briefly introduce the development of supramolecular self-assemblies for targeting mitochondria, endoplasmic reticulum, Golgi apparatus, nucleus, and cell membrane. We mainly focus on the use EISA of peptide assemblies, which spatiotemporally controls the formation of supramolecular nanofibers, for subcellular targeting and its applications, such as developing novel cancer therapeutics.

11:00 AM SB01.04.08
Synthesis of NIR-II Absorbing Gelatin Stabilized Gold Nanorods and Its Photothermal Therapy Application Against Fibroblast Histiocytoma Cells Samuel O. Oluwafemi; University of Johannesburg, South Africa

The excellent photothermal properties of gold nanorods (Au-NRs) make them one of the most researched plasmonic photothermal nanomaterials. However, their biological applications have been hampered greatly due to surfactant-induced cytotoxicity. We herein report a simple synthesis of highly biocompatible gelatin stabilized Au-NRs (gelatin@Au-NRs) to address this issue. The optical and structural properties of the as-synthesized gelatin@Au-NRs were investigated by Zetasizer, Ultraviolet-Visible-Near Infrared (UV-Vis-NIR) spectroscopy, high-resolution transmission electron microscopy (HR-TEM), and Fourier transform infrared spectroscopy (FTIR). The as-synthesized gelatin@Au-NRs were highly crystalline and rod-like in shape with an average length and diameter of 66.2 ± 2.3 nm and 10 ± 1.6 nm, respectively. The as-synthesized gelatin@Au-NRs showed high stability in common biological media (phosphate buffer saline and Dulbecco's Modified Eagle's Medium) compared to CTAB capped Au-NRs. Similarly, the gelatin@Au-NRs showed an improved heat production and outstanding cell viability against two different cancer cell lines; KM-Luc/GFP (mouse fibroblast histiocytoma cell line) and FM3A-Luc (breast carcinoma cell line) compared to CTAB capped Au-NRs and PEG@Au-NRs. An in vitro photothermal therapy study against KMLuc/ GFP showed that gelatin@Au-NRs effectively destroy the cancer cells.

11:15 AM SB01.04.09
Manufacturing of Halloysite Nanotubes/Barium Titanate Nanoparticles Reinforced Functional Hydrogels for Bone Tissue Repair Anuj Kumar, Ankur Sood, Ritu Singhmar and Sung Soo Han; Yeungnam University, Korea (the Republic of)

Bone defects caused by fractures, diseases, hereditary deformations, and surgical reconstructions are serious clinical challenges, wherein the self-healing of large bone defects is not able to bridge the gap and requires a biomaterial-based scaffold to facilitate bone repair under a native-like three-dimensional (3D) microenvironment. However, the design and fabrication of an appropriate scaffold is a great challenge for efficient cellular responses to develop new bone tissue. Therefore, the search for developing a suitable scaffold for bone repair is still unaccomplished. Herein, hydrogel as a 3D polymeric network provides the most suitable dynamic microenvironment to repair damaged bone tissues. The efficiency of hydrogels in repairing bone tissue is limited due to

their low mechanical properties and bioactivity, which presents challenges in designing effective hydrogels with robust mechanical attributes and acceptable bioactivity. In our study, we synthesized functional hybrid hydrogels by incorporating halloysite nanotubes and barium titanate nanoparticles, and as-obtained hydrogels showed promising porous and surface characteristics (i.e. microstructure and roughness), improved mechanical properties, enhanced *in-vitro* bioactivity, and satisfactory cytocompatibility (*in-vitro*).

11:30 AM SB01.04.10
Monitoring Nanoparticle Dissolution via a Fluorescence-Color Shift Christian Ritschel[1], Joanna Napp[2,3], Frauke Alves[2,3] and Claus Feldmann[1]; [1]Karlsruhe Institute of Technology (KIT), Germany; [2]University Medical Center Goettingen (UMG), Germany; [3]Max Planck Institute for Multidisciplinary Sciences, Germany

Optical imaging (OI) has emerged as a cost-effective, versatile method for biomedical monitoring and is used to visualize and distinguish cellular compartments and tissues as well as to study active cellular processes.[1] Specific markers with suitable fluorescence characteristics, sufficient physiolgical and photochemical stability, as well as high biocompatibility are essential for the success of OI.
For this purpose, a variety of molecular fluorescent dyes has been suggested and was attached in different ways to carrier molecules or carrier structures.[2] Alternatively, fluorescent nanoparticles, such as quantum dots, plasmonic metal nanoparticles, or up-converting nanoparticles have been widely used and are typically characterized by higher chemical and photochemical stability as compared to molecular fluorescent dyes.[3]
Aiming at theranostic nanoparticles, we have developed the concept of inorganic-organic hybrid nanoparticles (IOH-NPs).[4] These IOH-NPs are characterized by a saline composition with an inorganic cation and a functional organic anion. The functional organic anion can be a fluorescent dye and/or a pharmaceutical drug, which contains a phosphate, sulfonate, or carboxylate group. Together with a suitable inorganic cation, the functional organic anion forms insoluble saline nanoparticles in water.
The optical detection of nanoparticles is usually related to a change in intensity, not a change of the wavelength. In some cases, the change of the fluorescence intensity was used to the point of an on-off or off-on behavior. Such fluorescent nanoparticles were exploited, for example, to study cellular uptake, drug delivery, drug release, and all kinds of sensing effects, which can be partly performed in real-time. However, a change of the emission intensity has the disadvantage of being concentration-dependent, which either requires a distinct on-off/off-on emission characteristics or a normalization of the emission intensity on a suitable reference. In this regard, a wavelength change of the emission as a response of a certain effect would be more effective. However, a wavelength shift is more complex in regard of the selection of the fluorescence markers and has only been reported in a few cases until now.[5]
Aiming at a fluorescence-based monitoring of the dissolution of nanoparticles and specifically the differentiation of the intact solid nanoparticles and the homogeneous solution after the nanoparticle dissolution, we have examined different strategies involving two different fluorescent dyes. We were successful with a mixture of $[La(OH)]^{2+}[ICG]^{-}_{2}$ and $[La(OH)]^{2+}_{2}[PTC]^{4-}$ inorganic-organic hybrid nanoparticles (IOH-NPs) (ICG: indocyanine green, PTC: perylene-3,4,9,10-tetracarboxylate), which show an emission shift from red (intact nanoparticles in aqueous suspension) to green (aqueous solution after dissolution). Special advantages of the IOH-NPs comprise an aqueous synthesis, a simple material composition, an unprecedented high dye load (70-85 wt-% of total nanoparticle weight).[6]
This novel system of fluorescence markers – including synthesis, nanoparticle characterization, and first *in vitro* studies – will be presented with this contribution.

Design and Fabrication of a Highly Sensitive and Selective Non-Enzymatic Glucose Sensor by a Nafion-Modified Nanoporous Platinum Electrode Yu-Lin Lee, Yun-Yang Sun and Pochun Chen; National Taipei University of Technology, Taiwan

lzheimer's disease has been reported to be related to the level of glucose concentration in the brain. This study develops a non-enzymatic glucose sensor using a nanoporous platinum electrode. First, we decorate nanoporous platinum on a commercial gold electrode by cyclic voltammetry electrodeposition. Then, we further modified Nafion on the surface of nanoporous platinum to improve the selectivity of the glucose sensor. We characterize the Nafion-modified nanoporous platinum electrode's morphology, crystallinity, and composition by SEM, XRD, and FTIR, respectively. We evaluate the glucose sensor by electrochemical methods, including cyclic voltammetry, chronoamperometry, and electrochemical impedance spectrum in an artificial cerebrospinal fluid (ACSF). The nanoporous platinum and Nafion-modified nanoporous platinum show their sensitivities of $38.31\mu Acm^{-2}mM^{-1}$ and $27.42\mu Acm^{-2}mM^{-1}$ in ACSF, respectively. Additionally, the Nafion-modified nanoporous platinum remains desirable sensitivity and presents excellent selectivity to interferences, including dopamine (DA), ascorbic acid (AA), fructose, and lactose.

Designing Biomaterials to Heal the Body Molly Stevens; Imperial College London, United Kingdom

Bio-responsive hybrid materials are of growing importance with potential applications in therapeutic delivery and tissue engineering. In this talk, I will provide an overview of our recent developments in the design of biointerfaces with interesting features such as the incorporation of biological and topographical cues to enhance tissue regeneration, wound healing and cell differentiation [1]. I will show how we are using remote fields for in vivo remote-triggered hydrogelation of lipid based nanocarriers for controlled drug delivery [2] and advanced manufacturing strategies to engineer complex 3D architectures that mimic anisotropic multiscale tissue structures and to generate spatially arranged bioinstructive cues [3]. I will discuss the multi-scale

approach that we use to inform the design of smart biomaterials - from molecular dynamics simulation that help us understand self-assembly and organisation at the nanoscale [4], to Raman-based techniques used to visualise the molecular composition of living tissues [5] and to characterise single nanoparticles in a high-throughput label-free manner using our patented SPARTA™ technology [6]. SPARTA™ has become an integral tool for the design of nanotherapeutics, with recent examples including DOPC-containing lipid nanoparticles for nucleic acid delivery and dendrimersome-based systems for controlled delivery of antibacterial drugs, and for profiling extracellular vesicles (EVs) for detection of breast cancer through a minimally invasive liquid biopsy. Finally, I will discuss how we are establishing effective translational pipelines to drive our innovations to clinical application.

Stimuli-Responsive Surface Coating Properties of T_2 MRI Contrast Agents Dylan M. Ines, Jake Villanova and Vicki L. Colvin; Brown University, United States

Iron oxide nanocrystals (IONCs) are FDA approved Magnetic Resonance Imaging (MRI) contrast agents with high biocompatibility, hepatobiliary clearance, and contrast performance. It has been demonstrated that polymeric nanocrystal surface coatings have a significant impact on T_2 contrast performance (relaxivity). These non-magnetic polymers at IONC interfaces can influence the diffusion of bulk water within the local magnetic field of the nanocrystal core – thus impacting relaxation dynamics. Specific environmental or molecular stimuli can induce changes in contrast performance, increasing signal-to-noise and highlighting pathological areas of interest. The result is a "smart" molecular imaging contrast agent that exhibits stimuli-responsive contrast changes. "Smart" T_2 contrast agents currently rely on *interparticle* clustering effects to increase relaxivity. Compared to an individual IONC, clusters increase their effective diameter and generate greater magnetic field inhomogeneities and promote T_2 relaxation. However, clustering is clinically problematic due to aggregation and toxicity concerns. Thus, "smart" T_2 contrast agents that exhibit *intraparticle* changes in surface coating to modulate relaxivity are promising candidates for clinical applications. For example, IONCs that can decrease their hydrodynamic diameter or polymeric grafting density in the presence of environmental or molecular stimuli can improve their relaxometric properties and display higher signal-to-noise. Particularly when cleavable peptide sequences are incorporated into IONC surfaces, the coatings can undergo substantial changes when in the presence of certain proteases which are established biomarkers of cancer, traumatic brain injury, or other pathologies. Proteases cleave a target portion of the IONC surface coating, directly modulating its thickness, stability, and/or grafting density.

Here, we highlight a shift in optimizing contrast performance by modulating surface coating properties instead of magnetic core properties. Additionally, a novel framework for conceptualizing the impact of surface coatings on water diffusion and resulting contrast performance was developed. This framework provides a more detailed explanation for contrast performance trends found in the literature and informs the rational design of high-performance contrast agents. The effects of grafting density and thickness on relaxivity were measured for various surface coatings. The impacts of physiologically relevant pH ranges and metal cation concentrations on contrast performance were evaluated for a range of surface coatings. Contrast performance was also evaluated upon IONC conjugation to a target peptide sequence. Stimulus-responsiveness was probed by introducing clinically relevant proteases to the conjugated IONC system and measuring changes in relaxivity.

X-Ray Nano-Contrast Agents with Targeting Specificity for Breast Cancer Detection Manos Gkikas[1], Kalyan Ramesh[1], Alice Truong[2] and Mary Rusckowski[2]; [1]University of Massachusetts--Lowell, United States; [2]University of Massachusetts Medical School, United States

X-ray-computed tomography (CT) is considered one of the powerful diagnostic techniques for preclinical and clinical studies due to deep tissue penetration, high resolution, cost effectiveness, rapid scan times and patient comfort. Non-invasive disease detection with pronounced signal enhancement at the site of injury is a great challenge in medicine and allows for detection in early stages. Designing polymer-stabilized metallic nanoparticle (NP) X-ray contrast probes for spectral CT imaging that can be statistically discriminated from biological fluids, tissue, and bone (a property that is impossible to achieve with conventional CT), and are empowered by molecular recognition, aligns towards that direction. Although X-ray contrast with high-Z metals has been successfully shown in cells and small animals, the probes usually focus on intravenous imaging and NP fate, while there are only few cases reporting disease-targeting NPs with prolonged imaging capabilities. We have established a Team (UML/UMMS) to develop ligand-specific X-ray contrast probes for breast cancer cells, aiming to achieve early disease diagnosis at low NP dosages and enhanced detection. Our approach combines targeting specificity with dual-energy CT (DE-CT) or photon-counting spectral CT (PCD-CT), a state-of-the-art form of CT that allows for visualization of tissue composition based on intensity of signal, which is dictated by atomic number and density of contrast materials, and thus is enhanced by metallic NPs. Au offers significant advantages towards materials differentiation since its K-edge is 81 vs. 4 keV of Ca, while its density is 19.6 vs. 1.6 g/mL of Ca. Since X-ray absorption is highly dependent on K-edge and density of materials, we synthesize Au-based nano-contrast agents with high affinity for breast cancer cells and enhanced retention, and CT contrast comparable to FDA-approved iodinated molecules. Our materials are tested in vitro as well as in vivo using a breast cancer animal model. Among our recent findings is the ability to detect breast tumors for up to 21 days using only 0.5 mg Au. Future directions include theranostic materials, combining our enhanced prolonged diagnosis with radiation therapy or chemo/immuno drugs.

Point of Care Diagnostic Ammonia Sensing by Responsive Silver Nanoparticles Padryk Merkl and Georgios Sotiriou; Karolinska Institutet, Sweden

Ammonia is produced and consumed in the human body as a normal part of homeostasis, with the urease activity of intestinal bacteria thought to contribute significantly to blood ammonia levels. The ammonia found in blood is largely dominated by the ionised (NH_4^+) form although to a lesser extent the unionised NH_3 form can be found. Here ammonia levels are used to refer to the total ammonia content of both ionised and unionised ammonia.
The liver plays a critical role in maintaining blood ammonia levels below the threshold considered to be hyperammonaemia (>50 μM) in adult humans. Elevated blood ammonia levels can give rise to diffuse symptoms ranging from minor cognitive or behavioural changes to coma. In well-equipped hospital diagnostic labs ammonia levels are routinely analysed by enzymatic assays, however, due to the specialised equipment and cold-chain requirements their application in resource limited settings can be challenging. An alternative analytical method for determination of ammonia levels is the Berthelot reaction and its subsequent derivatives. This relies on the reaction of ammonia with the hypochlorite ion to cause conversion of phenol to the strongly blue coloured

indophenol. A similar reaction scheme is exploited in this study, whereby the reaction of the hypochlorite ion with silver nanoparticles is exploited to derive ammonia sensitivity. Silver nanoparticles are produced by flame spray pyrolysis as either a powder or deposited on porous glass-fibre filter paper. The addition of hypochlorite to the silver nanoparticles causes their oxidative dissolution and therefore a strong decrease in the plasmonic absorbance. However, in the presence of ammonia the hypochlorite can be neutralised preserving the plasmonic properties of the silver nanoparticles and therefore also their colour. A thin silica coating was applied to the silver nanoparticles and optimised to provide stable ammonia determination in isotonic solutions down to physiologically relevant ammonia concentrations. Measurements were also demonstrated from simulated serum by applying a perfluorosulfonic acid polymer (Nafion™), which displays selective transport of small positively charged species. Furthermore, the silver nanoparticles directly deposited onto filter paper were used for ammonia concentration determination in a paper-based point of care naked eye format. This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (ERC Grant agreement # 758705). Funding from the Karolinska Institutet, the Swedish Research Council (2021-05494), and the Swedish Foundation for Strategic Research (FFL18-0043) is kindly acknowledged.

Biodegradable Piezoelectric Nanofibers for Tissue Regenerative Engineering Yang Liu, Thinh Le and Thanh D. Nguyen; University of Connecticut, United States

Every year, millions of Americans suffer from bone and cartilage diseases like osteoarthritis. Artificial “engineered” bone and cartilage grafts constructed *in vitro* by using synthetic biomaterial scaffolds – have received considerable attentions. Yet, the constructed tissues often rely on potentially toxic growth factors and/or seeded stem cells which pose risks of immune rejection, limited supplies and undesired cell differentiation into cancers. Alternative to the biochemical factors, electrical cues can be used as a safe and effective stimulation for tissue regeneration. Herein, for the first time, we present a cell-free and growth factor-free biodegradable piezoelectric (poly (L-lactic acid)) (PLLA) nanofiber scaffold which under applied force can act as a battery-less electrical stimulator to promote chondrogenesis and cartilage regeneration. We have reported the piezoelectric tissue scaffold and the piezoelectric PLLA in several journals of Science Translational Medicine, PNAS and Nano Energy (Science Transl. Med. 14, (627), eabi7282, 2022; PNAS 117.1 (2020): 214-220, PNAS 115.5 (2018): 909-914, and Nano Energy 76 (2020): 105028.). The PLLA scaffold with applied force can generate piezoelectric charge to significantly improve chondrogenic effect of adipose stem cells *in vitro*. Rabbits conditioned with critical-sized osteochondral defects and receiving piezoelectric scaffold + exercise treatment showed a significant hyaline-cartilage regeneration with completely healed cartilages that exhibit abundant chondrocytes and collagen type II. The hybrid biodegradable piezoelectric scaffold/stimulator system, presented herein, could be used to not only heal cartilage but also bone, nerve, muscle etc. without the need of invasive removal process, offering a significant impact on the field of tissue regenerative engineering.

***In Situ* Upconverting Nanoparticle-Based Force Sensors for Gastrointestinal Imaging** Cindy Shi, Jason Casar, Chris Siefe, Beatriz Robinson, Mia Cano, Julia Kaltschmidt and Jennifer A. Dionne; Stanford University, United States

Mechanical forces play a fundamental role in a myriad of biological processes such as stem cell differentiation, cardiovascular health, cancer progression, and digestion. The enteric nervous system is of particular interest for its neuromuscular complexity and bi-directional communication with the central nervous system, playing a significant role in neurodegenerative pathology. Quantifying colonic mechanical forces is important for understanding disease development, but current biological force measurement techniques are limited: ex vivo techniques such as atomic force microscopy and traction force microscopy do not measure forces in accurate physiological conditions, while in vivo measurement techniques like stents and catheters cause uncomfortable colon distension and risk damage or rupture. Nanoscale markers such as resonant energy transfer-based molecular tethers, oil droplets, and quantum dots also lack the robust signal to overcome a rapidly changing biological environment.
Here, we demonstrate upconverting nanoparticles (UCNPs) as minimally invasive optical force sensors, delivered in polydimethylsiloxane (PDMS) pellets for in vivo gastro-intestinal tract imaging. UCNPs change their color via a ratiometric change in their two emission peaks in a linear fashion with externally applied pressure. Furthermore, they are photostable, absorb in the near-infrared tissue transparency region, can be functionalized to target specific biological structures, and do not require toxic heavy metals like cadmium for synthesis. We synthesize monodisperse 13-nm diameter cubic phase SrLuF:Yb, Er, Mn@SrLuF UCNPs, then use dual confocal-AFM microscopy to exert forces on these particles and determine their dynamic range of mechanosensitivity in the nanoNewton to microNewton force regime. We vary the Mn dopants concentration from 0% to 10% and optimize the Mn concentration to maximize color change and mechano-sensitivity. Next, we embed the UCNPs in PDMS mimics of mouse fecal pellets to create a colonic probe. We calibrate the spectral response of the UCNPs embedded in PDMS using dual confocal-AFM, demonstrating that red-to-green emission ratio changes repeatably over multiple compression and decompression cycles from 0 to 100 nanoNewtons. Finally, we deploy these pellet probes in excised mouse colons from both wild type and Etv-/- knockout mice to image and quantify forces in healthy colon pumping and irregular colon pumping, respectively. We compare the time-averaged force and location-dependent force exerted by the colons, as well as total time for pellet transition to demonstrate that our UCNP mechanosensor is able to distinguish between biological phenotypes with bright, robust optical signal that can penetrate colon wall tissue without damaging it. This platform provides a straightforward method for imaging intraluminal force dynamics in the colon and can be extended a range of other hollow neuromuscular organ systems, such as the stomach or heart cavities.

4:15 PM SB01.05.06
***In Vivo* Tracking of Long Circulating Bimodal PEGylated Au@SiO_2 Nanoparticles (NPs) Combining Near Infrared (NIR) Optical Imaging (OI) and µ-Computed Tomography (µCT)** Megi Bejko[1,2], Clement Vecco-Garda[2], Coralie Genevois[3], Nestor Pallares-Lupon[4], Richard Walton[4], Franck Couillaud[3], Olivier Sandre[1] and Stéphane Mornet[2]; [1]Laboratoire de Chimie des Polymères Organiques, France; [2]Institut de Chimie de la Matière Condensée de Bordeaux, France; [3]Bordeaux Research Institute On Cancer, France; [4]L'institut de Rythmologie et Modélisation Cardiaque, France

Thanks to their physicochemical features, Au NPs present a broad scope for innovative treatments in oncology with applications ranging from imaging to drug delivery, and photo-induced therapy.[1] One of the particularities of this element is the high atomic number and thus high X-ray absorption coefficient, endowing them with substantial contrast enhancement in X-Ray CT scans. These properties combined with the biocompatibility and tunable surface chemistry, has encouraged the use of Au NPs for µCT imaging in vascular, cardiac and cancer fields.[2] The high spatial resolution (1 µm) afforded by µCT imaging, allows non-invasive quantification of local accumulated Au in zones of interest. This enables robust full body evaluation of the *in vivo* fate of Au NPs in rodents, which is beneficial in a preclinical setting. However, studies regarding the *in vivo* fate of Au NPs for µCT imaging rely on injecting large amounts (up to 1.1 g Au/kg) to promote sufficient local concentration, necessary to enhance contrast of tumors at high-resolution.[3] This is done to counteract the poor pharmacokinetics (PK) of the NP as well as the low sensitivity of µCT. Herein, we propose to combine two complementary imaging techniques: µCT with classic NIR OI. Thereby, bimodal core-shell NPs with an Au core and fluorescent SiO_2 shell is designed to associate high spatial resolution and non-invasive quantitative analysis of µCT with the high sensitivity of NIR OI. Combining these two imaging modalities enables full tracking of the *in vivo* fate of the NPs. In addition, physicochemical features of the NPs are adjusted to promote long blood circulation times and prevent injection of

clinically irrelevant doses.
For this, fluorescent SiO_2 is grown on 15 nm Au NPs following known sol-gel protocols.[4] The SiO_2 shell reduces the high attraction potential of the Au surface, which has a Hamaker constant 50x higher than amorphous SiO_2.[5,6] This surface modification is a first step towards long circulating NPs by minimizing plasma protein adsorption. The second step consists on the covalent grafting of polyethylene glycol (PEG) (M_w=4 kDa) on to the SiO_2 shell in a dense brush conformational regime giving an R_F/D (R_F: Flory radius, D: distance between two anchoring sites) value of 5. This value is higher than the threshold R_F/D = 4.0, above which NPs possess prolonged blood circulation times as reported for SiO_2 NPs by our team.[7] A final neutral NP surface charge (+3 mV, pH=7.4) is purposely generated as reports show better PK when compared to their positive counterparts.[8] A low quantity of Au (0.06 g Au/kg) is then *i.v.* injected in mice (N=9) possessing subcutaneous prostate cancer (RM1), genetically modified to overexpress the luciferase firefly enzyme. The PK of the NPs is evaluated by OI where the maximal tumor accumulation is observed 24h post injection and NP circulation persisted up to 72h post-injection. µCT imaging is then acquired on anesthetized mice (N=6) 24h post-injection. The images reveal micro-distributions of Au in organs of interest (*i.e.* liver, spleen) and tumor periphery at a higher spatial resolution than OI. Thanks to prior calibration of µCT signal, the 3D distribution and quantity of accumulated Au with respect to the quantity of NPs injected is determined in peripheral tumors and key organs.
In conclusion, two complementary imaging techniques are combined, allowing a full non-invasive tracking of bimodal NPs using realistic administered doses (reduced by a factor 20): OI provided PK and biodistribution of circulating NPs and µCT quantitatively evaluated 3D distribution within organs and tumors.

The outstanding functions of living organisms are the result of a diverse range of biomolecules and their hierarchical architectures, which in some cases have still not been discovered. To fully investigate and exploit such inspiring structures and design principles, a comprehensive visualization of the entire, intact organism at sub-cellular resolution is required. For example, in the study of structure-function relationships in skeletal muscles, high spatial resolution is required to elucidate morphological details of single myofibrils, whereas full spatial coverage is required to understand how different parts of muscles are distributed and associated together throughout the entire body. Several imaging techniques, such as tissue clearing, computed tomography, and electron microscopy, have been used for studying biological systems. However, none of these approaches solely provides nanometer resolution beyond centimeter-scales with sufficiently high contrast and throughput. Expansion microscopy (ExM) combined with the labeling of functional groups of proteins with fluorophores would be an appealing candidate for achieving such a goal. By physically expanding the specimens, ExM can image the microstructure inside the biological systems with a lateral resolution of 60 nm. Once a swellable hydrogel is synthesized inside the biological specimens, the hydrogel-organism hybrids can expand fourfolds in water, and the nanostructures smaller than the diffraction limit of light can be resolved under a diffraction-limited optical microscope. However, the application of ExM has been limited to relatively simple specimens, such as cultured cells, tissue slices, and small organisms, such as bacteria. The ExM imaging of more vertebrate bodies, which contain a great number of highly sophisticated nanostructures, has not yet been demonstrated due to the difficulty of expanding mechanically tough body parts. Recently, we reported whole-body ExM, which enables the expansion of whole mouse embryos. Whole-body ExM requires the digestion of the whole mouse embryos with a mixture of collagenase and post-gel ethylenediaminetetraacetic acid (EDTA) treatment. However, whole-body ExM relies on prolonged and harsh enzyme treatment, and the minimum digestion time required for the uniform expansion of the whole mouse embryo has not been quantified. In this study, the effect of digestion duration and digestion conditions on the expansion uniformity of the whole mouse embryo is investigated. This study presents an enhanced digestion strategy that guarantees the uniform expansion of the whole mouse embryo despite the shortest possible digestion period. Using the optimized methodology, we visualize the nanoscale features of several organs throughout the whole mouse embryo with a 60-nm resolution.

4:45 PM SB01.05.08
Novel Single-Molecule Electrical Detection Method with Applications in Cancer and Covid19 Detection Keshani G. Pattiya Arachchillage, Subrata Chandra and Juan M. Artes Vivancos; University of Massachusetts, Lowell, United States

Cancer is one of the most frequent causes of death globally.[1] Blood samples, or other body fluids, can contain cancer biomarkers such as circulating free tumor nucleic acids (ctNA), which are promising for early cancer detection in liquid biopsies.[2],[3] Detecting ctNA in the blood is challenging because of the low ctNA concentration and the low frequency of mutations compared to wild-type sequences.[2] Nanotechnology bioelectronics methods can help to address this challenge. In particular, the Scanning Tunneling Microscopic (STM)-assisted break junctions method (STM-BJ)[4] has recently allowed the first demonstration of detection and identification of RNA from E.Coli via single-molecule conductance.[5] This is an ideal emerging technique for liquid biopsy bioelectronics since it is extremely sensitive, specific, and non-invasive.
This work focuses on characterizing ctNAs using the STM-BJ to investigate an effective method for their ultra-sensitive detection in complex samples. The study's central hypothesis is that the sequences of ctNAs can be used to detect cancers by finding their unique electronic fingerprints. We focus the study on KRAS, BRAF, and NRAS as effective cancer biomarkers in agreement with data from the Pan-Cancer Analysis of Whole Genomes (PCAWG) Consortium of the International Cancer Genome Consortium (ICGC) and The Cancer Genome Atlas (TCGA).[6],[7] We have already obtained preliminary data for wild-type and mutated RNA sequences for a few candidate cancer biomarkers (Ex: KRAS Exon 2 Wild type, G12V, and G12C mutations). We expect to understand the bioelectronics interface between genetic material and nanostructured electrodes. Our initial analysis and the results pave the way for the early detection of bioelectronics fingerprints from biomarkers through liquid biopsy using nanotechnology. The same idea can be applied to other applications such as covid detection. We conducted a comprehensive literature survey and bioinformatics analysis to identify the most appropriate candidate nucleic acid sequences for all human coronaviruses, SARS-Cov2, and other SARS-Cov2 variants such as Delta, Omicron, etc and obtained some preliminary single-molecule conductance data. This emerging method may allow beginning treatments early, potentially saving many lives from cancer and covid patients in the future.

Enzyme Responsive Peptides for Endocytosis and Targeting Golgi Apparatus Weiyi Tan and Bing Xu; Brandeis University, United States

Golgi apparatus (GA) is the hub of intracellular trafficking, but selectively targeting GA by synthetic molecules remains a challenge. Here we show that an unconventional type of peptide, as substrates of enzymes (e.g., alkaline phosphatase, thioesterase), for instantly targeting GA of cells. Preliminary mechanistic studies indicate that the peptides, above or below their critical micelle concentrations, enter cells mainly via caveolin-mediated endocytosis or macropinocytosis, respectively. The peptides, at about 5-10 times of the imaging concentrations, buildup in ER and GA, disrupt protein trafficking, thus lead to cell death via multiple pathways. This work illustrates the first example of an enzyme responsive and redox active molecular platform for targeting GA and controlling cell fates.

SB01.06.02
Low Impedance Stretchable Epicardial Electrodes for Treating Cardiac Diseases Sung-Hyuk Sunwoo[1,2]; [1]Seoul National University Hospital, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Conventional cardiac implants, including cardiac resynchronization therapy (CRT) systems and implantable cardioverter defibrillators (ICDs), have modulated cardiac conduction and following contraction process in heart failure patients. However, the transvenous lead implantation is incompatible with large-area electrophysiological mapping and selective multi-channel stimulations. Moreover, there are several lead-related drawbacks in conventional CRTs and ICDs. Several reports point to the rigid metal leads as the cause of post-implant issues, such as intravascular thrombosis, lead infection, myocardial damage, and even myocardial perforation. Here, this poster presentation introduces fabrication of soft and conductive epicardial mesh electrodes using a stretchable low-impedance nanocomposite comprising silver-gold core-shell nanowires (Ag-Au NWs) with platinum black (Pt black) in an elastomeric matrix. The soft and conductive epicardial mesh electrodes with low impedance presented a potential solution to the abovementioned issues. The high stretchability, conductivity, biocompatibility, and electrochemical properties of the elastomeric nanocomposite enable excellent quality of electrogram recording and electric stimulations on the animal heart. The various cardiac arrhythmias, such as ventricular bradycardia and ventricular fibrillation, can be monitored and successfully treated with pacing. Electrical pacing using epicardial mesh electrodes supported not only treating arrhythmias but also the effective contraction of the heart.

SB01.06.04
Light-Responsive Unique Plasmonic Nanomaterials Conjugated with Bioorthogonal Catalysts for Theragnostics Subin Yu[1], Dohyub Jang[2], Haeun Kang[1], Wen-Tse Huang[3], Minju Kim[1], Ru Shi Liu[3], Sehoon Kim[2] and Dong Ha Kim[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of); [3]National Taiwan University, Taiwan

Any chemical reaction which occurs inside the living system without interference from the biochemical reaction, so-called a bioorthogonal reaction, can be a new powerful strategy to manipulate the biological system.[1] To achieve the bioorthogonal reaction, the selection of bioorthogonal catalyst is important, which provide a platform for the changing of substrates to activated species, such as drug, photosensitizers, and fluorescent. [1] Especially, palladium (Pd) is the highly efficient catalyst for the bioorthogonal reaction of prodrugs and pro-fluorophores, however, the intrinsically insufficient catalytic activities have restricted their biological *in vivo* application. [2] Herein, we introduced the unique light-responsive plasmonic nanomaterials conjugated with the palladium as bioorthogonal nanocatalysts for combinatorial photothermal and photodynamic cancer treatment along with tumor imaging. The light can modulate the catalytic performance of these bioorthogonal nanocatalysts in terms of LSPR induced hot carrier generation, local field enhancement, and heat, which in return, would enhance the bioorthogonal nanocatalysts activities for cleavage reaction, and generate more activated photosensitizer from pro-photosensitizer at the given condition. The pro-photosensitizer conversion experiments with our hybrid bioorthogonal nanocatalysts under light illumination showcased the significant enhancement of conversion efficiency, confirming the enhancement of bioorthogonal reaction efficiency by using plasmonic features. In addition, the photothermal effect was incorporated to achieve synergistic photothermal and photodynamic therapy. Taken together, our bioorthogonal nanocatalysts open up a new paradigm to achieve an efficient bioorthogonal reaction to treat cancer.

SB01.06.05
Hyaluronate Based Upconverting Nanoparticles for Transdermal Delivery Hye Eun Choi, Mina Kwon and Ki Su Kim; Pusan National University, Korea (the Republic of)

Photomedicine has garnered widespread scientific interest since it utilizes photons for direct or indirect stimulation of therapeutic effects. In the visible light spectrum, short-wavelength blue light is highly advantageous in photomedicine since it carries more energy than red or green light. However, the limitations of blue light illumination sources are poor tissue penetration and the potential threat of damaging healthy cells. For overcoming these technical limitations, the anti-stokes upconversion (UC) process has been actively investigated which allows producing visible illumination deep inside the tissue by converting two or more red photons of low frequency into a single photon with a higher frequency. In particular, the UC could be realized through the triplet-triplet annihilation (TTA) process in which the photon energy is absorbed by a sensitizer chromophore and subsequently transferred to an acceptor chromophore through triplet-triplet energy transfer. As a result, two excited acceptor molecules undergo the TTA process producing singlet fluorescence of higher frequency. Thus, transdermal delivery of the light source can be implemented by loading the UC chromophore on biocompatible polymeric nanoparticles, such as hyaluronic acid (HA) and poly(ε-caprolactone) (PCL).
In this study, we encapsulated palladium(Ⅱ) tetraphenyl tetrabenzoporphyrin (PdTPBP, λex=635 nm) as a photosensitizer and perylene (λem=470 nm) as an acceptor based red-to-blue UC chromophores into polycaprolactone grafted hyaluronic acid nanoparticles (HA-PCL/UC NPs), which can serve as the transdermal delivery carrier of the blue light source that can be activated using red light illumination. We have successfully synthesized HA-PCL NPs through the oil-in-water (O/W) emulsion method by conjugating HA and PCL using 1,4-diaminobutane as a linker, which was confirmed by 1H NMR and FTIR. The TEM and DLS characterization revealed HA-PCL NPs are of spherical shape and nanoscale size range suitable for efficient deep penetration into the skin tissue. The permeation of HA-PCL/UC NPs was measured through porcine skin tissue over 24 hours and showed the applicability of our NPs in real skin tissue. The low cytotoxicity and enhanced cellular uptake in HA-PCL/UC NPs were confirmed through in vitro experiments. For optical properties, HA-PCL/UC NPs that steady emitted blue light showed outstanding UC quantum yield in a water environment under 635 nm laser irradiation. In conclusion, our results suggest that the developed HA-based red-to-blue upconverting NPs can be utilized as transdermal light delivery in a variety of biomedical applications, such as drug delivery, antibacterial therapy, bioimaging, and diagnostic imaging.

SB01.06.06
Superhydrophobic Hybrid Nanoparticle Coatings Against Biofilm Growth Stefanie . Dietl, Padryk Merkl and Georgios Sotiriou; Karolinska Institutet, Sweden

Device-related infections are a major burden both to the patients and the healthcare system. These infections often occur due to biofilm formation. Biofilms are dense microcolonies of bacteria adherent to a surface that secrete a glue-like matrix of extracellular polymeric substances. Since biofilms are often resistant to conventional antimicrobial interventions, their formation can lead to severe and persistent infections. They often require the removal of the device and can lead to severe complications. These biofilm-based infections urgently call for the development of new therapeutic or preventative strategies.[1]
An attractive approach to prevent biofilm formation is the physicochemical modification of the surface. Such a modification can prevent the initial attachment of bacteria and therefore prevents the formation of the microcolonies, which could become a biofilm. Surface charge, surface hydrophobicity, and surface composition significantly impact the bacteria's attachment. This has been successfully applied to design hydrophobic and superhydrophobic surfaces that can reduce the colonization and adhesion of bacteria and prevent biofilm formation. Rare earth oxides have been successfully applied for the development of hydrophobic and superhydrophobic surfaces due to the adsorption of gaseous organic compounds. However, a thorough characterization of the antibiofilm properties and comparison with other metal oxides is lacking.[1,2]
Flame spray pyrolysis was used here to produce hydrophobic and hydrophilic nanoparticle coatings of rare earth oxides and other metal oxides to investigate the dependence of biofilm formation on surface hydrophobicity and composition. Nanoparticles were deposited directly on substrates by flame spray pyrolysis in a single step. In this technique, a combustible liquid precursor solution containing the metal of choice is atomized and subsequently ignited.[3] The coatings were fabricated by depositing highly porous metal oxide nanoparticle coatings onto a water-cooled substrate.
The initial hydrophilic coating was converted to a hydrophobic coating by the adsorption or infusion of silicone oil. By tuning the metal oxide coating and silicone oil a range of stable hydrophobic and hydrophilic coatings were prepared and their effect on biofilm formation investigated.
The affinity of metal oxide and rare earth oxide nanoparticle coatings to adsorb volatile organic compounds and the subsequent wettability of the coatings was investigated. The coatings were applied and assessed for the inhibition of biofilm formation by clinically relevant pathogens on medical device mimicking surfaces.

Piezoelectric Accelerated Tissue Engineering Using HA Nanoparticle Embedded Nature Protein-Based Coaxial Nanomembrane Ji Yeon Lee[1], Chan Hee Park[2] and Cheol Sang Kim[2]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Jeonbuk National University, Korea (the Republic of)

Amidst problems associated with the aging population, addressing fracture patients with poor bone quality associated with the loss and deformation of cellular matrix proteins has been a major challenge. Recently, nanofibers have attracted significant attention as substrates that mimic the structural microenvironment of the native extracellular matrix. Despite their morphological advantages, nanofiber-based tissue engineering therapies limit electric signaling pathways that control cell-to-cell physiological interactions. Here, we exploit piezoelectric protein-based coaxial nanofibers enhanced by the alpha-helix to beta-sheet transition to produce appropriate bioelectrical signals, which provide electroactivity for matrix production *via* cell growth and proliferation. The coaxial nanofiber is composed of a hydroxyapatite (HA) nanoparticles-embedded piezo-protein shell and a polycaprolactone (PCL) core with simvastatin (SIM). Gradual biodegradation of the protein reveals HA nanoparticles, which support adhesion of proteins and involvement in cell differentiation with mineralization, while continuous release of SIM assists the rapid growth of HA. The designed beta-sheet protein shell/PCL core nanofibers are promising candidates for tissue engineering and mechanoelectrical transduction platform due to their phased functionality in electrophysiological activity, biodegradability, HA nucleation, and mineralization. Overall, the proposed strategy has the potential to meet the challenging requirements in inducing rapid tissue function reconstruction. This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korea government (MSIT) (No. 2021R1C1C2011542) and NRF-2017-Fostering Core Leaders of the Future Basic Science Program/Global Ph.D. Fellowship Program.

Biofilm Eradication by Photothermal Near-Infrared Activated Spherical Silver Nanoaggregates Padryk Merkl[1], Shuzhi Zhou[1], Apostolos

Zaganiaris[1], Mariam Shahata[1], Athina Eleftheraki[1], Thomas Thersleff[2] and Georgios Sotiriou[1]; [1]Karolinska Institutet, Sweden; [2]Stockholm University, Sweden

Near-infrared (NIR) light finds many important applications in biomedicine due to the ability of NIR light to penetrate tissue which provides allows for minimally invasive therapeutic and diagnostic devices in-vivo. Typical NIR extinction optimisation strategies rely on plasmonic nanostructures with complex, non-spherical geometries with typically difficult synthetic routes. This provides an immediate limitation for the translation of derived technologies to commercial therapeutic products. The photothermal effect, whereby the absorbed light is converted into heat due to non-radiative decay processes, is often applied to derive biomedical treatments. The temperature increases which can be produced can be harnessed to kill cancerous or infected tissue. Biofilms are a highly resistant form of bacterial infections often found in-vivo on infected implanted medical devices such as catheters. Biofilms form a dense and inhomogeneous structure and their treatment by typical strategies such as antibiotics is challenging. This study presents the single-step aerosol self-assembly of plasmonic fractal-like nanoaggregates by flame spray pyrolysis that are formed of spherical silver nanoparticles with tuneable extinction from the visible to NIR wavelengths. The extinction spectrum of the nanoaggregates was tuned by introducing a SiO_2 spacer during flame aerosol synthesis allowing optimisation of NIR extinction at the readily available laser line at 808 nm. Simulations of the optical properties of such fractal nanoaggregates were performed using the coupled dipole approximation to further elucidate the origin of the optical performance. Aerosol self-assembly of particle films was performed on polydimethylsiloxane coated substrates directly from the flame synthesis and further encased with a top polymer layer, forming plasmonic photothermal nanocomposite films. These photothermal nanocomposites were applied to eradicate established biofilms of clinically-relevant *E. coli* and *S. aureus* strains using 808 nm NIR irradiation. This project has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (ERC Grant agreement # 758705). Funding from the Karolinska Institutet Faculty Board, the Swedish Research Council (2016-03471), the Torsten Söderberg Foundation (M87/18), and the Swedish Foundation for Strategic Research (FFL18-0043) is kindly acknowledged.

Nanoparticles 'Clicked' onto Nanofibrous Scaffolds for Meniscal Repair Emily Sharp[1,1], Ryan C. Locke[1,2], Bian Jang[1], Tao Gui[1], Su Jin Heo[1], Nathaniel Dyment[1], Zhiliang Cheng[1], Ling Qin[1] and Robert L. Mauck[1,1,2]; [1]University of Pennsylvania, United States; [2]Philadelphia VA Medical Center, United States

Click chemistry is a class of reactions wherein molecular pieces are easily joined together, like buckling two pieces of a seat belt [1]. In the context of tissue engineering, click chemistry can serve to fabricate innovative delivery mechanisms capable of regenerating damaged or diseased tissues via spatiotemporal-controlled release. Dense connective tissues, such as knee menisci, sustain demanding load-bearing functions via a complex arrangement of extracellular matrix proteins that surrounds and protects tissue specific cell types. Following injury, endogenous cells within these tissues are unable to promote tissue regeneration and instead form less functional scar tissue. Thus, therapies that activate and recruit endogenous cells to promote tissue regeneration may significantly improve treatment and quality of life for millions of patients annually. Click chemistry-based delivery systems present a novel way of achieving these therapeutics. We previously showed that activation of Hedgehog signaling via a small molecule agonist, Purmorphamine (Pur), accelerated wound closure and attenuated cartilage erosion that results from meniscus injury [2]. **Here, we overcome challenges to Pur delivery, such as rapid clearance and off-target toxicity, via delivery from polymeric nanoparticles (NPs) localized to the injury site by immobilizing NPs on a nanofibrous repair scaffold via click chemistry.**
Rather than employing copper-catalyzed azide-alkyne cycloaddition as done by Lancuski et. al. [3], we utilized strain-promoted azide-alkyne cycloaddition (SPAAC) to functionalize electrospun polycaprolactone (PCL) nanofibrous scaffolds with azide groups that click with PEG-PCL NPs (prepared via oil-in-water emulsion) containing the alkyne counterpart (DBCO). These azide-modified scaffolds, when compared to electropsun PCL controls lacking azide groups, selectively reacted with DBCO-conjugated fluorophores, validating the successful fabrication of a 'clickable' scaffold. Scratch assays using murine and porcine meniscus fibrochondrocytes revealed that Pur-loaded, DBCO-conjugated NPs increased the migration of meniscus fibrochondrocytes compared to free Pur delivery. We then implanted NP-conjugated scaffolds *in vivo* using a nude rat xenotransplant model. For this, adult porcine meniscal explants were incised to create a horizontal defect that was either left unfilled or filled with NP-conjugated scaffolds (Pur-loaded and empty). All groups were evaluated at 3 and 14 days and analyzed for cell invasion via staining of nuclei and matrix deposition with H&E. We observed increased cell infiltration from day 3 to 14. More notably, there was a marked increase in cell number with implantation of Pur-loaded NPs compared to empty controls. This study validates a new approach to produce nanofibrous azide-functionalized PCL scaffolds via SPAAC click chemistry. The reaction between azide-modified PCL nanofibers and fluorophore-DBCO was highly specific, fast, repeatable, and stable over the long-term after repeated washes. This indicates that azide-modified PCL scaffolds may be used to immobilize DBCO-modified NPs. When tested *in vivo*, Pur delivery via NP-conjugated scaffolds accelerated meniscal repair via increased cell infiltration. These data support the novel use of click chemistry-based approaches for sustained and localized delivery of small molecule drugs for dense connective tissue repair. Clinically, this delivery method has the potential to overcome many challenges in musculoskeletal tissue repair by providing sustained and local release. More generally, this study demonstrates the applicability of click chemistry-based mechanisms in biomedical therapeutics.

Implantable Drug Delivery Vehicle Using Bipolar Membrane Sung-Geun Choi, Ji-Eun Han, Myung-Gyun Choi and Seung-Kyun Kang; Seoul National University, Korea (the Republic of)

Implantable drug delivery can localize drug effect only on diseases region, resulting in the minimization of the amount of mis-delivered drug and its side effect as well as the maximization of drug efficacy. The previous implantable drug delivery systems use convection of drug solution or, diffusion of drug solute for drug effect localization onto legion. However, each method has clear limitation; convection method causes mis-delivery to normal tissue due to drug solution flow and diffusion method is impossible to control drug release rate. In addition, these methods focus on exposing drug only to the surface of disease region, and therefore it is hard to target drug to lesion located in deep tissue. The bipolar membrane under electric field according to bias direction and amplitude can control drug release rate. Under forward bias, bipolar membrane has ionic conduction and release ionized drug while under reverse bias, it inhibitions drug from leakage due to ionic depletion zone. The strength of applied voltage can decide drug release rate. This drug release type by electrophoresis can focus drug on legion. Furthermore, electric field passing through the legion, called iontophoresis, can guide drug to reach for the deep legion, resulting in increase in the biodistribution of drug.

SB01.06.15

Investigating The Effect of A Dynamic Magnetic Field on The Rate of DPSC Neuronal Differentiation Alexander C. Wang[1], Sahil Sood[2], Rebecca Sullivan[3], Hillel Schein[4], Nikhita Srivinas[5], Oran Goodman[6], Adam Hansen[7] and Miriam Rafailovich[7]; [1]Sewickley Academy Senior School, United States; [2]Lambert High School, United States; [3]Yeshiva University High School for Girls, United States; [4]Davis Renov Stahler Yeshiva High School for Boys, United States; [5]Lausanne Collegiate School, United States; [6]The Frisch School, United States; [7]Stony Brook University, The State University of New York,

United States

Neurodegenerative diseases pose a major health risk, as neurons are unable to repair themselves. Previous research at our lab has shown an increase in the differentiation rate of dental pulp stem cells (DPSCs) into neurons via plating on Poly-lactic Acid (PLA) and 20% resorcinol diphenyl phosphate (RDP) clay polymer blends. Furthermore, there is evidence that the usage of a spinning, dynamic magnetic field (MF) successfully stimulates superparamagnetic iron-oxide nanoparticles (NP) to attach to neuron cell surfaces and induced axon regeneration in mature neurons. Therefore, we were interested in whether a PLA+20% RDP clay surface in combination with NP and MF treatment will further promote neuronal differentiation. Preliminary results have shown a significantly higher neuronal differentiation rate in cells with all four elements present.
We spin casted silicon wafers with either pure PLA or PLA+20% RDP chloroform-based solutions to create thin polymer films and two initial experimental groups based on surface chemistry. Following, DPSCs were plated onto wafers, which were placed in cell plates, and cultured in DPSC media for three days. On day 3, DPSC media was exchanged for neuronal media. On the following day, the 24 wafers designated as NP+ were treated with iron-oxide nanoparticles. For the next six days, every other day, 12 cell plates, all of which contained NPs, were placed in the MF for 30 minutes each. The MF stimulated NPs by rotating multiple magnets above the cell plate. The rotation speed was programmed to be one Hz in C++. The DC motor that rotated the magnetic ring was connected to an Arduino board and received program input from a laptop. At this point, four total experimental groups were established, PLA NP+ MF-, PLA+20% RDP clay NP+ MF-, PLA NP+ MF+, and PLA+20% RDP NP+ MF+.
Before DPSC media was changed to neuronal media on day 3, we tested cell modulus rigidity on an atomic force microscope, with lower values indicating softer, neuron-like cells. PLA NP- MF- and PLA+20% RDP clay NP- MF- cells displayed an average relative modulus value of 0.54 and 0.55, respectively. Day 9 modulus testing showed that PLA NP+ MF- cells displayed an average relative modulus of 0.54, PLA NP+ MF+ 0.48, PLA+20% RDP clay NP+ MF- 0.62, and PLA+20% RDP clay NP+ MF+ 0.51. Cells with MF treatment all had lower modulus values than their non-MF treatment counterparts, indicating higher neurogenic rates. We attribute the rigidity added by the NPs to higher modulus values in day 9 cells compared to day 3 cells. Furthermore, the rigidity of RDP clay increases the modulus values of PLA+20% RDP clay cells.
We performed EVOS imaging on each sample to provide comparative data on morphology. Three cells on each image had their aspect ratios (cell length/width) calculated via ImageJ, allowing us to quantifiably compare morphology, as neurons display higher aspect ratios than DPSCs.
EVOS testing on day 3 (pre-neuronal media) provided baseline morphology of DPSCs. The cells had unbranched cell bodies, with a relatively low 3.56 aspect ratio. In day 11 images, axon and dendritic development were largely visible in PLA NP+ MF+ and PLA+20% RDP clay NP+ MF+ cells, showing an average aspect ratio of 15.00 and 18.78, respectively. However, aspect ratios of PLA NP+ MF- were only 6.85, meaning that the average aspect ratio of PLA NP+ MF+ cells and PLA+20% NP+ MF+ cells were 119% and 174% higher than the NP+ MF- control, respectively.
As a final confirmational test, RT-PCR gene analysis will be performed on day 28 to compare the expression of the NES, TUBB 3, and NEFM genetic markers. NES and TUBB 3 are early-stage neuronal developmental markers, and NEFM is a late-stage neuronal development marker. We hypothesize that during RT-PCR testing, the NEFM gene will be upregulated in MF+ cells and that the NES and TUBB 3 genes will be downregulated in MF+ cells, correlating with neuronal development.

SB01.06.16
Impact of Titanium Dioxide (TiO_2) Nanoparticles on the Formation of a Living Skin Equivalent Sarah Yim[1], Annie Hu[2], Jeffrey Zhang[3], Matthew Sharin[4], Navya Gautam[5], Harsha Rajkumar[6], Darshini Podder[7], Sherlyn Wu[8], Diya Rai-Gersappe[9], Noah Kim[10], Shi Fu[10], Miriam Rafailovich[10], Marcia Simon[10], Ian Lau[11], Nicole Niculescu[10] and Christopher Gazis[10]; [1]Seoul International School, Korea (the Republic of); [2]Great Oak High School, United States; [3]Shenzhen Middle School, China; [4]Lawrence High School, United States; [5]Hauppauge High School, United States; [6]Fremont Christian High School, United States; [7]Jericho High School, United States; [8]Stuyvesant High School, United States; [9]Vassar College, United States; [10]Stony Brook University, The State University of New York, United States; [11]Tufts University, United States

Titanium dioxide (TiO_2) is used in many commercial products due to its ability to absorb UV rays and achieve a highly white color [1]. While nanoparticles of TiO_2 do not penetrate the stratum corneum easily, if they are ingested or used in wound healing products, they come in contact with viable tissue and can easily be absorbed. Cells containing low concentrations of nanoparticles are still viable, but the particles can interfere with executing their normal functions. Skin is one of the few functional organs that can be manufactured in vitro. Organotypics can then be used to probe the impact of different substances on cell assembly and functionality. Here we investigate the impact of exposure to rutile TiO_2 nanoparticles for keratinocytes and fibroblasts, which are then used to self assemble into a viable skin construct. Dermal fibroblasts and keratinocytes were exposed separately in culture to 0.4 and 0.8 mg/ml of TiO_2 nanoparticles for 24 hours. Visual analysis of Alexa Fluor 488 – phalloidin stained fibroblasts showed that actin filaments remained straight after TiO_2 treatment, indicating a healthy cytoskeleton. From the flow cytometry of treated keratinocytes and fibroblasts, showing that initial TiO_2 association in fibroblasts was significantly greater (almost 100% compared to 50% in keratinocytes), and this number remained near 100% for several days. Next, we evaluated fibroblasts cell proliferation rates for 5 days with the treatment concentration of 0, 0.2, 0.4, 0.8, and 1.2 mg/mL respectively; keratinocyte proliferation rate comparisons were conducted by evaluating colony formation efficiency (CFE). Results demonstrated that presence of TiO_2 nanoparticles did not significantly impact cell proliferation which occured at the same rate as the control for either cell type. We then examined the impact of TiO_2 on cell modulus, which increased with increasing concentration, indicating increased stiffness. Lastly, we examined fibroblasts' ability to contract collagen gels and in this case as well no difference in the ability to contract was observed.

On the other hand, when these cells were used to create four types of constructs, large disruption of the skin structure was observed. Four types of constructs were assembled, a control with no TiO_2, two constructs where TiO_2 was only in either the keratinocyte (epidermal) layer or the fibroblast layer and one where the particles were in both layers [2]. While histological analysis showed that TiO_2 treated fibroblasts did not adversely impact the formation of the dermal layer in any of the constructs, the presence of the particles in the keratinocytes layer showed much more dramatic effects. At a concentration of 0.4 mg/ml a functional skin construct was created, but large TiO_2 aggregates were observed at the surface of the stratum corneum, which appeared almost as if the TiO_2 in the cells had been secreted, aggregated, and removed from the construct. Higher concentrations, 0.8 mg/ml showed far more large aggregates. In this case, though, large regions without stratum corneum formation were observed, strongly disrupting the tissue. Reduced expression of filaggrin was observed in these layers indicating incomplete differentiation of the keratinocytes disrupting stratum corneum formation.

SB01.06.17
Impact of TiO_2 on HUVEC Angiogenesis and Bacterial Infection Sarah Yim[1], Annie Hu[2], Jeffrey Zhang[3], Matthew Sharin[4], Navya Gautam[5], Harsha Rajkumar[6], Darshini Podder[7], Sherlyn Wu[8], Diya Rai-Gersappe[9], Noah Kim[10], Shi Fu[10], Miriam Rafailovich[10], Marcia Simon[10], Ian Lau[11], Nicole Niculescu[10] and Christopher Gazis[10]; [1]Seoul International School, Korea (the Republic of); [2]Great Oak High School, United States; [3]Shenzhen Middle School, China; [4]Lawrence High School, United States; [5]Hauppauge High School, United States; [6]Fremont Christian High School, United States; [7]Jericho High School, United States; [8]Stuyvesant High School, United States; [9]Vassar College, United States; [10]Stony Brook University, The State University of

New York, United States; [11]Tufts University, United States

Exposure to TiO_2 has been shown to have detrimental effects on different types of tissue. We had previously shown that exposure of HeLa cells to TiO_2 rutile nanoparticles increased their susceptibility to bacterial infection, which was attributed to upregulation of enzymes which disrupt the inner and outer balance of membrane cholesterol [1]. Here we explore its impact on endothelial cells which comprise the tissue used to form vasculature. Bacterial infection of veins or arteries can be very serious as the bacteria is then spread systemically through the blood. We first exposed HUVEC cells to 0.1 and 0.2 mg/ml of rutile TiO_2 nanoparticles for 24 hours and then exposed the cells to staph aureus for 90 minutes. The cells were then lysed and the bacterial colonies were counted. Surprisingly, in this case, exposure to TiO_2 reduced the infection by 27% and 40% for the two concentrations, respectively. Since the cells were incubated without external illumination, this antibacterial action was not caused by electron emission from the particles. This was further confirmed when no effect on bacterial survival was measured when the bacteria were cultured with just TiO_2 in the media. RT-PCR indicated upregulation of ABCA1 but downregulation of ABCG1. Further work is in progress to quantify the impact on cholesterol generation.

HUVEC cells are also involved in angiogenesis when plated on a matrigel (10 mg/mL) matrix. HUVEC cells were incubated with TiO_2 at concentrations of 0, 0.1, 0.15, 0.2 mg/mL and the formation of the angiogenesis network was continuously imaged over a period of 16 hours. To track the gel mechanics during the network formation process, red fluorescent microbeads with the size of 1 um were mixed with Matrigel. Over the16-hour period, time lapse imaging was performed every 20 minutes to record both the network development and microbeads displacement. The HUVEC networks were then quantified by the following attributes as the function of time: the amount of the nodes, total length of the tubes, clustered area size, amount of the tubes and branches of the network. Meanwhile, each single microbead's displacement was computed via OpenCV's digital image speckle correlation (DISC) algorithm in comparing the consecutive time frames. The results showed that in each case network formation was initiated roughly 4 hours earlier in the cells exposed to TiO_2, but the average length of the tubes was significantly shorter and the number of nodes formed by cells not participating in angiogenesis was greater. The network splines are composed of single cells stretched between nodes, where increased flexibility translates into longer tube length. DISC analysis indicated that the traction forces on the matrigel exerted by cells exposed toTiO_2 were smaller than those exerted by the unexposed cells, consistent with decreased ability to stretch between nodes. The modulus of the cells were also measured using atomic force microscopy, and the data showed that the cells exposed to the nanoparticles were stiffer which is also consistent with decreased ability to stretch. Taken together, these results indicate that exposure to TiO_2 increases the rate of angiogenesis, while decreasing the network lattice parameter and the forces exerted on the matrigel support.

SB01.06.18
Evaluating the Effect of Resorcinol Diphenyl Phosphate (RDP) Concentrations in Clay on the Neurogenic Differentiation of Human Dental Pulp Stem Cells (hDPSCs) Rebecca Sullivan, Hillel Schein, Nikhita Srinivas, Oran Goodman, Alex C. Wang, Sahil Sood, Adam Hansen, Miriam Rafailovich, Anna Cho and Kuan-Che Feng; Stony Brook University, The State University of New York, United States

Neurons are used to communicate information between the human body and the brain. Currently, there is no cure for neurological diseases, however, clinical trials have shown stem cell differentiation to be a promising treatment for these conditions.
In this experiment, hDPSCs were plated onto coated silicon wafers. Several properties of the substrate's surface may affect cell differentiation including surface mechanics, surface chemistry, and surface topography. This project examined the effect of surface chemistry on cell differentiation by adding varying concentrations of RDP-Clay to the silicon wafer coating and comparing the results. RDP consists of one phosphate and two phenyl groups that are toxic to cells, but the RDP was mixed with clay so the phosphate groups would be adsorbed into the clay, thereby releasing the phenyl groups, thereby eliminating RDP's toxicity and enabling the phosphates to allow for cell growth. Solutions of RDP-Clay and PLA were made in chloroform and spun cast onto HF etched Si wafers. In order to probe the role of the phosphate as opposed to simply a nucleation site for the PLA, 20% 30B Clay was also used in combination with PLA. Differentiation of DPSC on tissue culture plastic (TCP) has already been reported [1] and here we compare the effect of the PLA and PLA/Clay substrates. Pure PLA, PLA with 20% RDP-Clay, PLA with 30% RDP-Clay, and PLA with 20% 30B clay were spun cast out of the chloroform solution onto HF etched and polished silicon wafers, annealed overnight in vacuum of 10-3 Torr, T=180 C, to remove solvent and sterilize. The surfaces of the coated silicon wafers were analyzed using an atomic force microscope. Pure PLA had the flattest surface of 7.282 nm, 20% RDP-Clay had a surface roughness of 67.6 nm, 30% RDP-Clay had a surface roughness of 87.1 nm, and 20% 30B Clay had the roughest surface of 91.442 nm. In all cases, the substrates nucleated with greater crystallinity and hence, roughness. Substrates were then coated with laminin and the cells were plated directly. The moduli of the cells on the different substrates were measured on day 5, before changing to neurogenic media and 9 days after differentiation. Late stage differentiation will be confirmed and compared between the different substrates via RT-PCR. Preliminary Results indicate that in all cases the modulus of the cells decreased on day 14 relative to day 5, consistent with eventual differentiation. Additionally, as cells differentiate into neurons, their shapes become longer and thinner, creating a larger aspect ratio. The days 5, before changing to neural media, and day 14, after having been in neural media for 9 days, EVOS images show that as time progressed, the aspect ratio increased. Between days 5 and 14, PLA control had an aspect ratio increase of 40%, and TCP had an aspect ratio increase of 110%. Compared to PLA, TCP was 58.57% greater, 20% 30B was 26.73% greater, 30% RDP-Clay was 26.83% greater. 20% RDP-Clay had the highest aspect ratio which was 42.81% greater than PLA. RT-PCR will be performed at day 28 of culture, which will determine the preferred substrate for differentiation.

Combining Optical Thermometry and Drug Delivery in Novel Hybrid Nanomaterials for Theranostics Anna M. Kaczmarek; Ghent University, Belgium

The design and development of non-contact luminescence nanothermometers is important for many applications, including the biomedical field. This discipline has advanced tremendously in the last decade, however still showing a lot of room for improvements, especially when it comes to combining multiple functionalities in just one nano-sized material.
One of our goals has been combining thermometry with drug delivery through the design of various advanced (hybrid) architectures. We aim at materials which can be used for diagnostic purposes based on very precise temperature readings and deliver the desired therapeutic on demand (pH change, near infrared laser irradiation, etc). We push our efforts further to design materials which would be decomposable after a certain period of time in the human body, eliminating the risk of nanoparticle accumulation, which is one of the current concerns of using nanoparticles in biomedical applications.
In this presentation we will overview our current successes in this field as well as highlight the challenges and potential ahead.

8:45 AM SB01.07.03
Inorganic-Organic Hybrid Nanoparticles—High-Load Drug Carriers with Theranostic Features Claus Feldmann[1], Frauke Alves[2] and Joanna Napp[2]; [1]Karlsruhe Institute of Technology, Germany; [2]Max Planck Institute for Multidisciplinary Sciences, Germany

Inorganic-organic hybrid nanoparticles (IOH-NPs) basically have a composition $[M]^{2+}[R_{Drug}OPO_3]^{2-}$ and contain a drug anion $[R_{Drug}OPO_3]^{2-}$ and an inorganic cation (e.g., $[ZrO]^{2+}$, $[La(OH)]^{2+}$, $[GdO]^{+}$, $[Bi(OH)]^{2+}$).[1] The inorganic cation guarantees the insolubility of the IOH-NPs in water and allows the nucleation of nanoparticles with high colloidal stability in aqueous suspensions. Due to the saline composition with equimolar amounts of drug anion and inorganic cation, IOH-NPs exhibit unprecedented high drug loads of 70-90% of the total nanoparticle mass.[1,2]
Specific examples are $[ZrO]^{2+}[BMP]^{2-}$, $[ZrO]^{2+}[CLP]^{2-}$ or $[ZrO]^{2+}[FdUMP]^{2-}$ with the anti-inflammatory agent betamethason phosphate (BMP) (81 wt-% per nanoparticle), the last-line antibiotic clindamycin phosphate (CLP) (82 wt-% per nanoparticle), or the cytostatic agent 5'-fluoro-2'-deoxyuridine 5'-monophosphate (FdUMP) (75 wt-% per nanoparticle). *In vitro* and *in vivo* studies show high uptake as well as excellent biocompatibility and activity. The IOH-NP concept has been transferred to >50 different nanoparticles and drugs, and offers widespread advantages:[1,2]
- New patented class of materials
- Easy synthesis in water
- Extremely high drug load (70-90 % of total nanoparticle mass)
- Platform concept with flexible composition
- Realization of drug cocktails, optionally with chemotherapeutic, antibiotic, antiviral or anti-inflammative agents in one nanoparticle
- Higher efficacy and/or significantly lower side effects due to targeted transport of the chemotherapeutic cocktail into the tumor
- Transport of active agent (instead of prodrugs)
- Simultaneous release (in time and in place) of drug cocktail for effective reduction of resistances (in general) and metastases (cancer)
Localization and tracking of drug release by imaging methods (OI, PAI, MRI, PET)
With this contribution, we present the current status and perspectives of the IOH-NPs with drug cocktails.

Protein Cages with Functional Surface Loops for Theranostics Jeroen Cornelissen and Sandra Michel-Souzy; University of Twente, Netherlands

Different types of protein cages are nowadays studied in the fields of nano- and materials science, because of their well-defined size and structure in the nanometer regime. Compared to more traditional polymer-based nanoparticles, these – often – virus-based materials are extremely uniform, and the position of functional groups is precisely defined. Encapsulins are protein cages found in bacteria that have interesting properties with respect to (thermal) stability and cargo loading. In the past we and others have studied the application of encapsulins, but so far, their preparation, durability and functionalization are restricted to fundamental studies.[1]
Here, we report the design of encapsulins from two different origins (e.g., *T. maritima* and *B. linens*) with functional loops on its surface.[2] This allows for site specific genetic or chemical modification to combine targeting and detections moieties on both the surface and the protein cage interior. We, furthermore, optimized the cages' production and showed that, under the selected conditions, these are stable over time periods of a least a year. The research presented in the contribution, therefore, paves the way for further straight forward engineering and production of the encapsulins, for therapeutics, diagnostics or vaccine development.

9:15 AM SB01.07.05
Ultrasmall SiO2@Au Nanoshells for Photothermal Nano-Theranostic and -Therapeutic Applications Luis Manuel[1], Vinoin D. Vincely[2], Caroyln L. Bayer[2] and Kevin M. McPeak[1]; [1]Louisiana State University, United States; [2]Tulane University, United States

Nanoshells made of thin Au layers on SiO2 cores exhibit strong resonances in the biological transmission window. Several examples in the literature show the use of these particles in biomedical applications, such as the photothermal ablation of cancer cells. However, many photothermal-based approaches rely on nanoshells with resonances primarily due to scattering effects but nanoparticles with absorption-dominant resonances better suit such approaches. Ultrasmall nanoshells that exhibit absorption-dominant resonances are ideal biological agents due to their low surface-to-volume ratio, ease of clearance, and cellular uptake rates but have not been developed due to synthetic challenges.
Herein, we decrease the size of nanoshells beyond previous limitations (i.e., sub 100 nm), making them better suited for absorption-based applications. As a case study, we compare absorption-dominant to scattering-dominant nanoshells as contrast agents in photoacoustic imaging, highlighting the role of the nanoshells' optical properties and the implications for absorption-based biomedical applications. Additionally, we tailor nanoshells further for photoacoustic imaging by considering heat transfer effects on the surrounding medium. Optimum nanoshells have 50 nm SiO_2 and 6.8 nm Au shells. The dominant extinction phenomenon is confirmed using an integrating sphere to separate light absorption from scattering, which is not typical of studies on colloidal samples.

Carbon Nanotube Technology—An Efficient Platform for Virus Enrichment and Detection Mauricio Terrones[1,2] and Nestor P. Lopez[1]; [1]The Pennsylvania State University, United States; [2]Shinshu University, Japan

The global COVID-19 pandemic is exerting devastating impacts on individual livelihoods, local communities, and the global economy. Accurate, real-time, and widespread testing is needed in order to track the disease, prevent further infections, and gain basic fundamental understanding of the disease, such as the number of infections, infection rate, etc. This talk will discuss the design and fabrication of disposable cartridges using a label-free virus enrichment platform consisting of microarrays of aligned carbon nanotubes (CNTs) in conjunction with gold metal nanoparticles. These trapped viruses are detected and identified using Raman spectroscopy in conjunction with Machine Learning models. More importantly, after viral capture, these viruses remain viable permitting subsequent in-depth characterizations by various conventional methods. This technology successfully enriched rhinovirus, influenza virus, coronavirus and parainfluenza viruses, and maintained the stoichiometric viral proportions when the samples contained more than one type of virus, thus emulating coinfection. Viral capture and detection took only a few minutes with a 70-fold enrichment enhancement; detection could be achieved with as little as 102 EID50/mL, with a virus specificity > 95%. This enrichment method coupled to Raman virus identification constitutes an innovative system that could be used to quickly track and monitor viral outbreaks in real-time.

Dynamic Structures and Machines That Feed Living Systems Leila Deravi; Northeastern University, United States

We are developing bio-inspired systems, structures, and machines that can perform complex tasks in response to controlled stimuli. A molecular-level approach to building these materials that can produce programmable transformations in response to specific chemical inputs will be discussed for applications ranging from sensors to supplements.

11:00 AM SB01.08.02
Externally-Triggerable Liposomes for Personalized, Non-Invasive Control of Local Anesthesia Alina Rwei; TU Delft, Netherlands

Pain has a major impact on quality of life and affects billions of people worldwide. Yet, current treatments are either associated with significant side effects (i.e., opioids), suffer from insufficient durations of action (i.e., local anesthetics), or inability to provide adequate treatment with the patient's changing physical conditions and pain states. Here we present externally-triggerable liposomes as a vehicle to provide spatio-temporal control of pain relief, enabling non-invasive control of the duration, intensity and timing of pain relief via external triggers, such as light and ultrasound. Inspired by the natural lipid degradation process via peroxidation, we have engineered near-infrared-light- and ultrasound-triggerable liposomes that encapsulate the local anesthetic tetrodotoxin. Our results show significant triggering of lipid peroxidation upon exposure to external energy, leading to the effective activation of drug release events. The drug release can be activated repeatedly upon exposure to the external trigger. *In vivo* results show successful generation of nerve block upon exposure to a low- and biocompatible dosage of near infrared light and/or ultrasound. These results demonstrate the promising potential of utilizing such systems for personalized pain therapy, in which patients can control the intensity, duration, and timing of therapy via light and/or ultrasound.

11:15 AM SB01.08.03
Magnetothermal Control of Nerve Growth Dekel Rosenfeld; Tel Aviv University, Israel

Nerve injuries are common with lifelong consequences. Despite their ability to regenerate, the full recovery of peripheral nerves is limited, and determined by several factors including the severity of the injury, patient age, medical history, onset of intervention post-injury and the slow rate of axonal growth. While chemical factors can accelerate the axonal growth process, recent studies have demonstrated that it can also be achieved via electrical and optogenetic stimulation. However, the governing mechanisms of those approaches require further investigation. In this project, we trigger calcium influx via activation of heat sensitive ion channels to achieve calcium-dependent accelerated nerve growth. To this end, we use the magnetothermal approach that relies on heat dissipation from functionalized magnetic nanoparticles with diameter of 20-22 nm, exposed to weak alternating magnetic fields. We triggered the opening of the transient receptor potential vanilliod 1 heat sensitive ion channel (TRPV1), a calcium permeable non-selective cation channel. We demonstrate accelerated axonal growth followed TRPV1 activation in a dorsal root ganglion explant model, quantified via neurofilamet elongation and Schwann cell migration.
Our method presents a novel approach to use magnetic materials and magnetic nanocomposites for nerve regeneration in a calcium-dependent process. Considering the limited regeneration capabilities of the nervous system, we present a strategy to overcome this limitation via remote stimulation and uncover new mechanism focusing on the role of TRPV1 in mediating axonal growth.

11:30 AM SB01.08.04
Seeing the Sound—Ultrasound and Infrared Responsive Nanomaterials for Non-Invasive Neuromodulation Xiang Wu and Guosong Hong; Stanford University, United States

Understanding complex neural circuitry and its correlation with specific behaviors requires spatially and temporally precise modulation of neuron subtypes in certain brain regions. For decades, neural stimulation has been predominantly achieved with traditional electrical stimulation. More recently, optogenetics has gained great popularity due to its rapid control of neural activities with visible light and its dissection of neural circuitry by selectively

modulating specific neuron subtypes. However, deep-brain neural modulation usually involves invasive implantation of stimulation electrodes and optical fibers due to the limited penetration of electric fields and visible light in the brain tissue. These brain implants lead to acute damage and chronic gliosis in the brain tissue, while tethering the animal to an electrical wire or an optical fiber interferes with naturalistic behaviors of freely moving subjects.
To address these challenges, we developed ultrasound and second near-infrared (NIR-II, 1000-1700 nm) responsive nanomaterials for non-invasive neuromodulation. First, we developed ultrasound-mediated nanoscopic light sources—mechanoluminescent nanomaterials for non-invasive optogenetics. These nanomaterials can be delivered via the endogenous circulatory system and provide millisecond timescale switching of local light emission upon deep-penetrating focused ultrasound stimulation. We demonstrated that the ultrasound-mediated light emission from the nanomaterials circulating in the blood was sufficient to activate channelrhodopsin-2 (ChR2)-expressing neurons in the brain and trigger behavioral response in live mice in a non-invasive manner, a technique which we termed "sono-optogenetics". We envisage that sono-optogenetics provides a unique tool of rapid screening of different target regions in the brain for optogenetic neuromodulation, owing to the ease of changing the location of ultrasound focus in the brain by eliminating fiber optic implantation. **This work was published in PNAS (Wu, X. et al. Sono-optogenetics facilitated by a circulation-delivered rechargeable light source for minimally invasive optogenetics. *Proc. Natl. Acad. Sci. USA* 116, 26332–26342 (2019)) and was awarded the Science and PINS Prize for Neuromodulation in 2020.**
Second, to afford non-invasive, remote neuromodulation in freely behaving animals, we developed polymeric nanomaterials termed MINDS (macromolecular infrared nanotransducers for deep-brain stimulation). MINDS can efficiently absorb light in one of the biological transparency windows, the NIR-II window, modulating neural activity via temperature-sensitive transient receptor potential (TRP) channels. MINDS have a photothermal conversion efficiency of 71% at 1064 nm, the wavelength at which light attenuation by brain tissue is minimized. As a result, through-scalp wild-field NIR-II illumination can activate TRP channels sensitized by MINDS up to a depth of 5 mm in the mouse brain, leveraging a bioinspired mechanism underlying infrared sensitivity in rattlesnakes (as demonstrated by the Nobel Laureate David Julius). Specifically, MINDS act as an NIR-II sensitizer to activate TRP-expressing neurons in the hippocampus, motor cortex and ventral tegmental area of mice with minimal tissue damage under wide-field NIR-II illumination, resulting in substantial behavioral and electrophysiological changes. Due to its non-invasive and tether-free interface, our NIR-II neuromodulation technique enables the study of animal behavior in its most natural state and is particularly suitable for modulating neural activities in socially interacting experiments involving multiple subjects, such as in the IntelliCage, in the future. T**his work was recently published in *Nat. Biomed. Eng.* (Wu, X. *et al.* Tether-free photothermal deep-brain stimulation in freely behaving mice via wide-field illumination in the near-infrared-II window. *Nat. Biomed. Eng.* https://doi.org/10.1038/s41551-022-00862-w (2022)).**

SESSION SB01.09: Antimicrobial and Anti-Pathogenic Nanomaterials I
Session Chairs: Herdeline Ardoña and Xiaoyuan Chen
Wednesday Afternoon, November 30, 2022
Hynes, Level 1, Room 104

1:30 PM *SB01.09.01
Nanostructured Nanomaterials in Biomedical Applications—From Graphene to Virus Assemblies Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

Nanostructuring interfaces and colloidal assemblies enable the convergence of processing methods and functions with high correspondence at the nanoscale. There is high interest in the electrical and thermal conductivity properties of graphene. However, they play a key role in mediating redox function and the generation of radical oxygen species in biological applications. Their application as anti-pathogenic agents is only now being appreciated and deemed scalable. This talk will focus on graphene (G) and graphene oxide(GO) nanomaterials as ultrathin films to result in anti-microbial properties. We also describe the preparation of very stable colloidal templates of graphene with anti-microbial properties. Interestingly, these colloidal particle templates can be used to prepare virus nanoparticles that can have theranostic applications. Lastly, we demonstrate their use as 3D printed devices with low toxicity for biomedical applications.

2:00 PM *SB01.09.02
Antibacterial and Antiviral Materials for the Prevention of Transmission of Hospital Acquired Infections Raechelle D'Sa and Jenny Aveyard; University of Liverpool, United Kingdom

Many infectious diseases can be spread through the viral or bacterial aerosols or contaminated surfaces. Bacterial diseases that are caused by multi-drug resistant bacteria such as methicillin-resistant *Staphylococcus aureus* (MRSA) and *Pseudomonas aeruginosa* are especially challenging to treat. Both of these organisms can reside on surfaces for weeks and are in the top 12 list of the World Health organisation of priory pathogens. Developing materials that can eradicate the bacteria on contact is essential to prevent the transmission of these infections. In the current COVID19 pandemic, although direct inhalation of infectious aerosols is the main mechanism of transmission, surfaces have also been shown to play a role in transmission. Nitric oxide is a well document antibacterial and antiviral molecule that has broad spectrum activity. In this study, nitric oxide donor molecules were embedded into polymeric surfaces/matrices for a sustained and controlled release of the molecule for over 72 hours. The kinetics and concentration of release was studied by chemiluminescence. The antibacterial efficacy was tested against planktonic and biofilm adhered bacteria and optimal material demonstrated a 4 log reduction for MRSA and 2 log for P. aeruginosa. Antiviral efficacy was measured against the Delta and Omicron variants of the SARS-CoV-2 virus. Time course studies demonstrated a faster kill rate with the Delta variant. Cytocompatibility studies demonstrated at antibacterial and antiviral concentrations, the materials were not cytotoxic. Therefore these materials should good promise for the prevention of bacterial and viral infections from surfaces.

2:30 PM BREAK

3:30 PM SB01.09.03
Lipid Core Nanocapsules for Antimicrobials Drug Delivery Janaina Artem Ataide[1], Angela F. Jozala[2] and Priscila G. Mazzola[1]; [1]UNICAMP, Brazil; [2]UNISO, Brazil

Over the past years, the development of biodegradable nanoparticulate systems for drug delivery has aroused great interest. Substantial advances happened in the development of functional nanomaterials towards biomedical materials, mainly for targeted therapies and drug delivery. Lipid core nanocapsules (LCN), a class of nanocapsules in which a polymeric shell is arranged around an inner core and is formed by a dispersion of a liquid lipid and a solid lipid, have gained attention since they can vehicle actives soluble in their lipidic core or polymeric shell. PCL (poly-E-caprolactone), a biocompatible and biodegradable polymer, has been used to encapsulate a wide range of drugs, achieving targeted and controlled drug delivery. Fluconazole, a bis-triazole antifungal, and rifamycin SV, an ansamycin antibiotic, could benefit from encapsulation. Our objective was to encapsulate fluconazole and rifamycin SV in

LCN, aiming to improve existing treatments by controlling their release. Empty-LCN (unloaded), Flu-LCN (LCN loaded with fluconazole) and Rif-LCN (LCN loaded with rifamycin SV) were prepared as previously described. Empty-LCN presented mean diameter of 220 nm, with PDI around 0.13 and zeta potential of -27 mV, while Flu-LCN and Rif-LCN presented around 230 nm diameter, PDI 0.15 and -28 mV zeta potential, determined by DLS in ZetaSizer Nano ZS equipment. Total drug concentration was determined by HPLC/UV, as well as encapsulation efficiency after separating non-encapsulated drug by ultrafiltration-centrifugation. Fluconazole presented a type II distribution in LCN, with encapsulation efficiency calculated as 8.0%, drug content of 798 µg/mL and drug loading of 0.17%. On the other hand, rifamycin SV presented a type III distribution, with encapsulation efficiency of 66.2%, drug content of 743 µg/mL and drug loading of 1.28%. Profile of drug release from LCN was determined by in vitro Franz-cell diffusion. Around 53% of fluconazole was released in the first 7h, reaching 77% in 48h; while less than 5% of rifamycin SV was released in the first 8h, reaching 21% in 48h. *In vitro* antimicrobial activity of free drugs and LCN formulations was determinate using minimal inhibitory concentration (MIC) method against *S. aureus*, *P. aeruginosa* and *C. albicans* microorganisms. Empty-LCN did not show any antimicrobial activity. Free-Flu and Flu-LCN did not showed activity in the tested concentrations for *S. aureus* and *P. aeruginosa*, and a MIC of 0.39 µg/mL for *C. albicans*. Free-Rif and Rif-LCN showed MIC of $3.1x10^{-3}$ µg/mL for *S. aureus*, 100 ug/mL for *P. aeruginosa*, and no activity against *C. albicans*. LCN formulations with fluconazole and rifamycin SV were successfully produced. Depending on drug characteristics, higher encapsulation efficiency and drug loading was achieved, with a more prolonged release. Antimicrobial activity of fluconazole and rifamycin SV was maintained after encapsulation in LCN formulations, and no activity was reported for empty-LCN.

3:45 PM SB01.09.04
Antimicrobial Potential of High-Drug Loaded Calcium Phosphate Nanoparticles Engineered by Flame Spray Pyrolysis Vasiliki Tsikourkitoudi and Georgios Sotiriou; Karolinska Institutet, Sweden

Infectious diseases resulting from pathogenic microorganisms are one of the most significant global health threats, while overuse of antimicrobial drugs has caused an emergence of antimicrobial resistance. Thus, novel approaches are needed to address the unmet medical need for eradication and prevention of infections caused by antimicrobial resistant bacteria.
Recent advances in nanomedicine have shown the potential of nanoparticles as carriers for antimicrobial drugs, such as antimicrobial peptides, in improving the treatment of infectious diseases. Their large surface-to-volume ratio renders them unique antimicrobial agents with high drug loading capacity.
In this regard, here, we propose a novel antimicrobial drug delivery platform based on calcium phosphate (CaP) nanoparticles. We fabricated CaP nanoparticles by flame spray pyrolysis (FSP), an intrinsically scalable and reproducible nanomanufacturing process. We exploited the versatility of this method for the synthesis of CaP nanocarriers with tailored properties. We further established an experimental protocol for loading biologics by physisorption on flame-made CaP nanoparticles. More precisely, we loaded bovine serum albumin (BSA) and bradykinin as model protein and peptide, respectively, and investigated the effect of their concentration and incubation time on loading efficiency. We implemented the established protocol by loading antimicrobial peptides (LL37 and a mannose receptor-derived one, MRC-1) on CaP and assessed their stability against proteolytic degradation and their therapeutic potential against bacterial infections both *in vitro* and *in vivo*.
High loading values, reaching 350 mg/g and 600 mg/g of CaP for BSA and bradykinin, respectively, were obtained, whereas maximum LL37 loading (~800 mg/g) outperformed all loading values found in the literature. High loading values were attributed to typical fractal-like structure of flame-made agglomerates/aggregates. The protective potential of CaP nanocarriers against enzymatic degradation of LL37 was evaluated by gel electrophoresis in a degradation assay using Proteinase K. LL37 loading on CaP nanoparticles kept LL37 intact, as the peptide resisted degradation up to 240 min.
To verify if LL37 also retained its antimicrobial function after being physisorbed onto CaP nanoparticles, we studied its antimicrobial activity against both Gram-positive (*Streptococcus pneumoniae*) and Gram-negative (*Escherichia coli*) pathogens by monitoring the bacterial growth under incubation with different concentrations of LL37, either free or loaded on CaP nanoparticles. Similar antimicrobial activity for free LL37 and LL37-loaded CaP was observed for *S. pneumoniae*, whereas for *E. coli*, LL37-loaded CaP exhibited better antimicrobial performance than free peptide.
Finally, we explored the *in vivo* antimicrobial efficacy of the flame-made CaP nanoparticles after loading MRC-1 peptide. We first visualized the biodistribution of MRC-1-loaded nanoparticles in mice by administering fluorescently labelled peptide-loaded particles and imaging using an IVIS Spectrum-CT imaging system and verified that the peptide loaded particles reached the lungs. Then, MRC-1 peptide loaded CaP nanoparticles were administered intranasally to mice previously infected by *S. pneumoniae*. The administration of MRC-1 peptide loaded CaP nanoparticles was shown to reduce development of pneumococcal disease *in vivo* enhancing mice survival.
In a nutshell, we present synthesis of a biocompatible/biodegradable nanocarrier by an intrinsically scalable and reproducible synthesis method. Typical fractal-like structure of flame-made nanoparticles promoted high drug loading efficiency and enabled protection of antimicrobial peptides from enzymatic degradation, enabling their safe delivery. High loading values achieved along with the *in vitro* and *in vivo* protective effect of the nanoparticles facilitate clinical translation of flame-made CaP nanoparticles as drug carriers.

SESSION SB01.10: Biomimetic Nanotherapeutics
Session Chairs: Juan Beltran-Huarac and Georgios Sotiriou

Hynes, Level 1, Room 104

9:00 AM SB01.10.01
Novel Nanozymes to Replace Natural Enzyme in Biosensing and Beyond Moon Il Kim; Gachon University, Korea (the Republic of)

Recently, nanozymes have been intensively studied due to their superior qualities such as extremely high stability with robustness even under stringent conditions, tunable catalytic activity and specificity, and ability to be synthesized on a large-scale at low costs. In this presentation, I will discuss our current progresses how to develop novel nanozymes and their representative applications in biosensing technology. First, I will describe a new and simple colorimetric strategy for the detection of nucleic acids, which relies on target DNA-induced shielding action against the peroxidase mimicking activity of magnetic nanoparticles (MNPs) or oxidase mimicking activity of cerium oxide nanoparticles (CeO_2 NPs). Second, I will discuss a nanostructured multi-catalyst system consisting of MNPs and an oxidative enzyme entrapped in large pore sized mesoporous silica for convenient detection of biologically important target molecules. The oxidative enzyme in the multi-catalyst system generates H_2O_2 through its catalytic action for a target molecule, which subsequently activates MNPs to convert a selected substrate into a colored product. Besides, I will introduce highly efficient electrochemical biosensing system by employing conductive nanocomposite and ultrafast colorimetric immunoassay system by employing a nanocomposite entrapping magnetic and platinum nanoparticles. Finally, I will also describe biosensors based on new nanozymes including Fe-aminoclay, Cu-nanoflower, N & B-doped graphene, and Fe-N_4-graphene, as well as nanozyme-mediated paper-based analytical devices. These achievements should accelerate and widen the utility of nanozymes as next-generation alternatives to natural enzymes in biosensing and beyond.

9:15 AM SB01.10.02
Multimodal Lipid Nanoparticle Imaging for Assessing Tumor Biodistribution Across Multiple Scales Jeremy M. Quintana, Thomas S. Ng, Huiyu Hu, Ralph Weissleder and Miles Miller; Massachusetts General Hospital, United States

Covid-19 vaccines based on mRNA delivery via lipid nanoparticles (LNP) have provided evidence of the therapeutic potential of this platform, and expanded efforts are underway to develop LNP for delivering immunomodulatory nucleic acid payloads to treat various solid cancers. While a variety of studies have explored new combinations of lipid and therapeutic components, there is relatively little data on how LNP behave spatially within solid tumors, particularly at dynamic and single-cell levels. To better examine how LNP transport within the tumor microenvironment, we have developed a strategy to track their quantitative biodistribution by positron emission tomography (PET). Combination of LNP-PET with magnetic resonance imaging (MRI) supports soft-tissue anatomical and functional context of LNP distribution, while LNP labeling with lipid-conjugated fluorophore supports microscopy evaluation at subcellular resolution. As a proof of principle, we based our model LNP on clinical formulations and used derivatives of 1, 2-distearoyl-sn-glycero-3-phosphoethanolamine-poly(ethylene glycol), which were synthesized to incorporate fluorophore and PET radionuclide chelator into the lipid interface. Modified LNP were formed with average diameters in the range of 80-150 nm, and were evaluated in the 4T1 murine model of metastatic breast cancer, a disease where LNP are being clinically tested. We hypothesize these functionalized lipid nanoparticles will allow us to more closely study rate-limiting factors related to efficacy and off-target toxicity, especially in the context of metastatic disease in breast cancers.

9:30 AM BREAK

10:00 AM SB01.10.04
Graphene Oxide and Healthcare Applications—Nets, Crowded Body Fluids, Cell Highways Valentina Palmieri[1,2], Giordano Perini[2], Alberto Augello[2], Marco De Spirito[2] and Massimiliano Papi[2]; [1]National Research Council, Italy; [2]Catholic University of Sacred Heart, Italy

Around ten years ago, graphene oxide has attracted a wide scientific community interest for applications in healthcare as new antibiotics safe for eukaryotic cells. However controversy emerged and subsequent biophysical studies elucidated the instability of this nanomaterial in body fluids rich in electrolytes, proteins, and more. With the formation of nets and the adsorption of soluble factors on its surface, cells and microorganisms do not interact with single bidimensional flakes but with large aggregates. Here we discuss how the adsorption of ions and molecules on nanomaterials surface can be exploited to modulate graphene oxide antimicrobial activity. Furthermore, the formation of the so-called protein corona on graphene oxide will be discussed in light of drug delivery, and diagnostic applications. The protein corona layer on tridimensional graphene scaffolds will be also debated for the future improvement of graphene oxide bioactivity in 2D and 3D.

10:15 AM SB01.10.06
Enhancing Osteogenic Possibilities Through Bone Tissue Engineering Kalpana Katti, Krishna C. Kundu, Sharad V. Jaswandkar and Dinesh R. Katti; North Dakota State University, United States

Current clinical therapeutic approaches for critical size bone defects regeneration suffer from severe limitations such as limited availability, increased risk of infection, donor site morbidity, and insufficient transplant integration. These limitations necessitate scaffolds with accelerated bone defect repair. We report the use of a unique interlocking polymer clay nanocomposite scaffold system incorporated with bone morphogenic proteins 2 and 7 (BMP-2 and BMP-7). In addition coculturing the porous polymer clay scaffolds with osteoblast cells (hFOB) and mesenchymal stem cells (MSCs) is used to to evaluate the long-term effect of BMPs on bone regeneration for a period of 9 weeks. The total release of BMP-2 and BMP-7 was observed from the scaffolds by day 16. We observed improved cell proliferation, viability, and osteogenic differentiation of the cells with the BMPs incorporated scaffolds. Gene expression studies indicate a significant increase in the bone-related proteins, osteogenesis-related proteins, and Wnt-factors-related proteins with BMPs coated samples compared with uncoated samples, indicating that BMPs played a crucial role in initial osteogenesis and ECM formation. In addition, Alizarin Red S staining and scanning electron microscopy images show a significant increase in the mineralized bone nodule formation with BMPs coated samples compared with uncoated samples suggesting BMPs played a decisive role in bone regeneration. Furthermore, at 9 weeks, nanoindentation experiments on BMP-2/BMP-7 coated scaffolds showed a 120% increase in the elastic modulus, indicating enhanced ECM formation. Thus, BMPs play a crucial role in osteogenesis at the initial stages well beyond the time period of total release of BMPs. This study provides valuable insight into the mechanisms of the BMPs association in bone regeneration and demonstrates the feasibility of the interlocking scaffold system as a bone graft for critical size bone defects repair application. Induction of osteogenesis using the nanoclay materials as well as enhanced osteogenesis is enabled in the unique scaffold block interlocked system.

SESSION SB01.11: Virtual Session: Responsive Nanomaterials Development II

10:30 AM *SB01.11.01
Understanding Structural, Chemical and Physical Variations in Lipid Nanoparticles Georgios Pyrgiotakis, Charles Dahlheim, Donald Johnson, Linda Obenauer-Kutner, Raquel Feliz, Denette Murphy and Erinc Sahin; Bristol-Myers Squibb, United States

Lipid Nanoparticles have been around since the early nineties and have been successfully commercialized in the drug delivery space over the last two decades. Recently, the successful development of the SARS-Cov-2 vaccines established them as a promising technology for the targeted delivery of genes, DNA/RNA, and pharmaceutical products. Further they can be decorated with moieties that hold potential to tissue-specific delivery. Their manufacturing has unique challenges, as complex nanoscale physicochemical phenomena can impact their quality attributes such as size, drug loading, targeting agent availability, and particle morphology. Here, we present approaches that can help shed light to some of these nanoscale phenomena and enable study of 1) particle size and structure variations via Asymmetric Flow Field Flow Fractionation (A4F), 2) drug and targeting agent loading distribution via fractionation with size exclusion chromatography, and 3) real-time particle size measurement during manufacturing via Spatially Resolved Dynamic Light Scattering (SR-DLS). Our data show detection and quantitation of structural and compositional variability within LNPs. We also demonstrate the potential of the SR-DLS as a process analytical technology for real-time, in-line measurement of particle size integrated within manufacturing.

11:00 AM SB01.11.02

2D Nanohybrid Artificial Antibody for Diagnosis and Therapy of Pathogen Infection Sin Lee[1], Yoonhee So[1], Hyunji Lee[1], Yesol Myeong[1], Chul-Su Yang[1], Hwankyu Lee[2] and Jong-Ho Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Dankook University, Korea (the Republic of)

For the selective recognition of diverse targets ranging from pathogens to small analytes, antibodies have been widely used due to their high binding affinity and specificity. However, antibodies have several limitations of low stability, long production time, short shelf-life, and high cost. Therefore, it is of great significance to develop artificial antibodies that can circumvent the shortcomings of antibodies for sensing and therapy. Herein, we report a facile strategy for the synthesis of artificial antibodies consisting of luminescent transition metal dichalcogenide (TMD) nanosheets and nonbiological polymeric recognition phases for the selective detection of the target pathogens, *Escherichia coli* O157:H7 (*E. coli* O157:H7) and *Staphylococcus aureus* (*S. aureus*). The TMD nanosheets with a neutral dextran phase at their interface selectively recognized *S. aureus*, whereas the nanosheets bearing a carboxymethylated dextran phase selectively recognized *E. coli* O157:H7 with high binding affinity. The mechanism responsible for the selective recognition of the artificial antibodies against the specific bacteria was thoroughly identified by experiments and molecular dynamics simulations. The WS_2 artificial antibody could selectively detect the target bacteria at the concentration as low as a single copy of bacterium from human serum based on the strong Raman signal of WS_2. In addition, the $MoSe_2$ artificial antibodies selectively killed the pathogenic bacteria under near-infrared (NIR) irradiation. Finally, the $MoSe_2$ artificial antibodies were successfully applied for the selective detection and killing of the pathogenic bacteria in the wounds of infected mice under NIR irradiation. This new artificial antibody approach can be extended for recognition of a variety of biomolecules for selective sensing and therapy.

11:15 AM SB01.11.03
The Effect of Microsphere Growth and Static Magnetic Field on Osteogenic Differentiation of Dental Pulp Stem Cells Angeline Sun[1], Kuan-Che Feng[2], Emir Mulic[2], Sooraj Shah[2], Yiwei Fang[2], Yu-Chung Lin[2], Marcia Simon[2] and Miriam Rafailovich[2]; [1]Taipei American School, Taiwan; [2]Stony Brook University, The State University of New York, United States

Dental pulp stem cells (DPSCs) have great potential in regenerative medicine due to their noninvasive extraction, low immunogenicity, and multipotency [1]. Previous research revealed that under the influence of chemical stimuli, DPSCs can differentiate into functional osteoblasts that secrete extracellular matrix (ECM) [1, 2]. The osteogenic potential of DPSCs is of great importance due to its therapeutic applications in bone mineralization and reconstruction [3]. Through careful modifications of the cell microenvironment such as three-dimensional culture methods [4] and magneto-mechanical stimulations [5], the osteogenic differentiation of DPSCs can be enhanced significantly. This study aims to investigate the effect of microsphere formation and static magnetic fields on osteogenic differentiation.

After trypsinization after passage four of DPSCs, cells were placed in U-bottom non-adhesive suspension wells or flat-bottom wells covered with 50, 100, and 150 uL 2% agarose to induce microsphere formation. Different volumes of agarose produce different degrees of curvature, thereby influencing the compactness of the microspheres. Through EVOS imaging, we observed that agarose wells were better at forming dense aggregates compared to suspension wells. At different timepoints after microsphere growth (5 and 7 days in wells), the cells were plated onto 6-well tissue culture plates. After 7 days of plating, ascorbic acid and β-glycerophosphate were added into the medium to induce osteogenic differentiation. After 28 days of plating, PCR was performed to quantify mRNA of osteocalcin (OCN) and dentin sialophosphoprotein (DSPP). All results were normalized with the housekeeping gene GAPDH related to Day 0. The results confirmed the observations from EVOS that agarose wells induced greater osteogenic potential. DPSCs in 100 uL agarose wells plated 5 days after growth expressed the greatest level of OCN. Unexpectedly, suspension wells seem to induce greater odontoblastic potential than agarose wells. The expression of DSPP was highest in suspension wells plated 5 days and 7 days after growth.

The synergistic effect of magnetic fields and magnetic scaffolds has been proposed to enhance osteogenesis through activating signaling pathways [5]. For the magneto-mechanical stimuli, cells were plated onto different scaffolds and incubated in the presence or absence of magnetic fields. The three types of compression-molded scaffolds were pure polylactic acid (PLA), a biodegradable polyester frequently used in tissue engineering [6], 95% PLA and 5% RDP clay, and 90% PLA and 10% magnetic iron oxide microparticles. Using atomic force microscopy (AFM) to characterize surface topology, we found that all three scaffolds were of nanoscale roughness, with the scaffolds containing iron oxide being the roughest. After 28 days of incubation, EVOS was used to image cell morphology and biomineralization. Cells were stained with Alexa Fluor 488, DAPI, and Xylenol Orange to visualize actin, DNA, and calcium deposition respectively. We observed calcium deposition between the DPSCs. PCR results of the osteogenic-related genes confirmed the synergistic effect as the expression level of DSPP and OCN in cells grown in presence of magnets on iron oxide scaffolds were significantly higher than cells grown on pure PLA with magnets present and cells grown on iron oxide scaffolds without magnets. SEM will be used to determine the conformation of extracellular matrix proteins deposited on the different scaffolds and their ability to template the mineralized deposits. Raman spectroscopy will be used to determine the nature of the mineralized tissue.

11:30 AM SB01.11.04
Design and Production of Multifunctional Implantable Patches Combined with Drug-Loaded Nanoparticles for Treatment of Breast Cancer Beril Ustunkaya[1], Eda Güney[1], Eric M. Tan[2,1], Ozlem Kutlu[2] and Gozde O. Ince[1,2]; [1]Sabanci University, Turkey; [2]Sabanci University Nanotechnology Research and Application Center (SUNUM), Turkey

Breast cancer is the second most common cancer type worldwide [1]. Human Epidermal Growth Factor Receptor 2 positive (HER2+), Hormone Receptor positive (HR+) and triple-negative being three different subtypes of breast cancer, research has been dedicated to exploit their molecular mechanism, treatments, and recurrence [2]. Herein, we propose a novel implantable multifunctional patch design that will provide the tumor treatment for different subtypes of breast cancer, and will trigger immune response to prevent the recurrence in the long run. The multifunctional patch carries a nanoparticle system that enables combined photothermal and photodynamic therapy for cancer treatment, and also biomolecules that will activate the immune system against the possible recurrence. The nanoparticle system is comprised of three functional subunits one of which enables site-specific delivery as it includes specific proteins to the different breast cancer subtypes, and the others provide treatment by photothermal, and photodynamic therapies. These functional nanoparticles will be excited by two different Near Infrared (NIR) lasers which are of 808 nm and 1060 nm to trigger the treatment at the intended site. The activation of the immune system will be achieved by the biomolecules as they are released from the blow-spun patches. The chemical compositions and the morphologies of both the nanoparticles and the blow-spun patches will be investigated by Fourier transform infrared spectroscopy (FTIR), and Scanning Electron Microscopy (SEM), respectively. The sizes and the zeta potential of the fabricated nanoparticles will be characterized by the Dynamic Light Scattering (DLS) method. The degradation performances of the blow-spun patches will be examined in phosphate buffered saline (PBS) and lysosome-mimicking solution (LMS), and enzyme-linked immunosorbent assay (ELISA) will be used to study the release of biomolecules from the patches. While the cellular uptake of the nanoparticles and their success in the phototherapy will be investigated by microscopic technique, the success of the patches in the stimulation of the immune system will be studied in vitro on T helper cells and B cells with dendritic cell morphology (BDCM). This novel multifunctional patch design will offer both the specific treatment for breast cancer subtypes and the long-term preventative effect against the possible recurrence.

Photo-Initiated Chemical Vapor Deposition of Polymer Thin Films onto Electrospun Nanofibers for Controlled Drug Release Eda Güney[1], Abdurrahim Can Egil[1], Faruk Can[2] and Gozde O. Ince[1,2]; [1]Sabanci University, Turkey; [2]Sabanci University Nanotechnology Research and Application Center (SUNUM), Turkey

Drug release kinetics highly depend on the surface chemistry of the scaffolds. Surface modifications can be performed by different techniques to alter the surface properties of the scaffolds and thus to provide controlled drug release. However, the conventional modification techniques have several disadvantages such as non-uniformity on the surface, lack of precise process control, weak stability, and possibility of the fiber destruction [1]. In this study, we propose a novel technique to coat the surface of the drug-loaded electrospun nanofiber scaffolds for controlled drug release applications without causing any damage to the fibers and the drug which is being encapsulated. The surface modification will be carried out by photo-initiated chemical vapor deposition (piCVD) technique, which will allow the material to maintain its own properties and also to provide controlled drug release. First, the drug-loaded scaffolds will be produced using biocompatible and biodegradable polymers by electrospinning process. Then, the surface of the fabricated scaffolds will be coated with polymer thin films by the piCVD technique. The piCVD technique will involve photopolymerization of one or more vapor-phase monomers using an initiator and their deposition on the scaffold surface to produce the desired thin films. The photopolymerization will be carried out by short-wavelength emission of UV-light at 254 nm under mild deposition conditions. A kinetic study will be conducted to determine the optimal deposition conditions. The drug release performances of the uncoated and polymer-coated nanofiber scaffolds will be examined comparatively. While the changes in fiber structure after the coating will be examined by scanning electron microscopy (SEM), the chemical characterization of the scaffolds will be performed by Fourier transform infrared spectroscopy (FTIR). The proposed surface modification approach seems to be a promising avenue of research for controlled drug release applications.

Nanotoxicological Assesment and Cell Internalization for Cancer Cells of Luminescent Nanoparticles Dalia H. Chavez[1,2], Karla O. Chavez Garcia[3] and Gustavo Hirata[3]; [1]Instituto Educativo del Noroeste AC, Mexico; [2]Centro de Enseñanza Técnica y Superior, Mexico; [3]Centro de Nanociencias y Nanotecnología, Mexico

The detection of cancer cells by bioimaging with luminescent nanoparticles instead of usual dyes is being eagerly investigated. In this study we prepared upconversion (UCNPs) and downconversion (DCNPs) nanoparticles (NPs) by sol-gel method. The UCNPS uses a near infrared beam (NIR λ=980 nm) as the excitation source to upconvert the energy into light in the visible region. The present study used UCNPs: Y_2O_3/Gd_2O_3:Yb^{3+}/Er^{3+} capable of emitting red or green photons of 660 nm and 550 nm wavelength. The DCNPs were: Y2O3:Eu^{3+} and Eu^{3+}/Bi^{3+} excited at λ=250 nm and 330 nm with red emission at 660 nm. The functionalization was done by aminosilanes and folic acid (FA-UCNPs and FA-DCNPs). Folic acid binds to the folate receptor on the surface of certain types of cancer cells, and this binding promotes internalization of the NPs via endocytosis. The NPs were characterized by TEM, EDS, and FTIR. Cytotoxicity was also analyzed using the MTT (methy-134 thiazolyltetrazolium) colorimetric assay. Finally, cellular uptake of FA-UCNPs was determined using flow cytometry and epifluorescence microscopy; we also did a comparison between cellular uptake of spheroidal NPs and two-dimensional (2D) cell culture models, also known as monolayers, finding that the architectural arrangement of 3D cell cultures allowed up to 20% more internalization of FA-UCNPs than in 2D cell arrangements.

Fibronectin (FN), one of the proteins organizing the extracellular matrix (ECM), plays an important role in the cell adhesion process. Especially, differently distributed FN of the ECM can determine inflammatory M1 polarization or pro-healing M2 polarization of macrophages, which modulate inflammation or wound healing, respectively [1]. This action occurs when the integrin of a cell recognizes and ligates to the tripeptide amino acid sequence of Arg-Gly-Asp (RGD) presented by FN. In addition, it has been studied that the polarization of macrophages can be controlled by modulating the array of liganded nanostructures [2].
Here, we report the submolecular-level-controlled size and spacing of liganded nanoparticle arrays for dynamic macrophage modulation. The size and spacing of liganded gold nanoparticles (GNP) assembled on a nano-sized magnetite template are precisely tuned from 3 to 20 nm via various seed-mediated growth. The liganded GNP-magnetite nanoassemblies are bound to the substrate via the flexible polymer linkers, which can shrink by in situ magnetic fields. When the space of liganded GNP is about 3 nm compared to the case of 13 nm or 20 nm, integrin binding to RGD ligand is promoted, and pro-healing polarization is stimulated. As the size of the liganded GNP increases from 13 nm to 20 nm, integrin binding improves, and anchoring the liganded GNP-magnetite nanoassemblies to the substrate using a permanent magnet promotes macrophage adhesion as much as 3 nm-spaced liganded GNPs. Increasing the spacing of liganded GNPs from 3 nm to 17 nm prevents integrin binding; therefore, inflammatory polarization appears. The results of this research are confirmed both in vitro and in vivo.

12:30 PM SB01.11.08
Detection of Circulating Tumor Cells from Clinical Blood by Electrically Charged Fe3O4 Nanoparticles Yuxin Wang, Zicheng Deng, Jiajie Diao and Donglu Shi; University of Cincinnati, United States

Tumor metastasis has been found to be associated with circulating tumor cells (CTCs) that shed from the primary tumor and enter the circulation. The

characteristics of CTCs offer highly valuable information in assessing tumor aggressiveness and predicting the subsequent growth at distant organs. Therefore, detection and isolation of CTCs can serve as an effective tool in cancer diagnosis and prognosis through liquid biopsy. As a result of extreme rarity of CTCs, however, it has been extremely challenging to sensitively detect, effectively capture, and accurately identify CTCs from clinical blood. Current CTCs detection technologies mainly rely up on either the biomarker-conjugated magnetic beads or size-sensitive microfiltration membrane with certain limitations in sensitivity. In this presentation, we report an alternative but more sensitive CTC detection approach based on the cancer cell surface charge which is metabolically regulated by glycolysis without any conventional biomarkers. Based on the well-known Warburg effect, the cross-membrane movement of lactate inevitably removes labile inorganic cations, resulting in a net of negative charge on the cancer cell surfaces. A positively charged nanoprobe is designed and engineered to bind electrostatically onto the negatively charged cancer cells for capture and isolation. Since high glycolysis capacity is a hallmark characteristic of all cancer cells, the charge-based CTC detection can apply to different cancers regardless of their phenotypes. Our preliminary results show strong binding of the positively-charged nanoprobe on the cell surfaces of multitude of cancer types while insignificant binding is observed for the negatively charged nanoprobe counterpart. Also discussed is the relationship between the cancer cell surface charge and the glycolysis capacity which is the key that dictates the CTC detection sensitivity.

Protein Engineered Biomaterials for MRI-Traceable Drug Encapsulation Dustin Britton, Lindsay Hill, Michael Meleties and Jin Montclare; New York Univ, United States

Inspired by nature's biopolymers, we engineer artificial protein materials on the genetic and chemical level leading to new properties, specifically traceability. We employ synthetic and chemical biology to construct our materials and endow them with theranostic ability. In particular, we have fabricated protein-derived nanomaterials: coiled-coil fibers and helix-elastin block polymers. We investigate the fundamental self-assembly and molecular recognition capabilities of these systems. More importantly, we are able to harness these structure as well as others to interface with small molecule therapeutics and cells. Our studies lead to insights in how we can program self-assembling protein biomaterials to be visualized and deliver therapeutics.

1:30 PM SB01.12.04
Reconstructing Bone Defects Using *In Vivo* Nanocomposite Scaffold Printing Adnan Memic; King AbdulAziz University, Saudi Arabia

Critically sized boine defects commonly caused by traumatic injuries and tumor removal can overwhelm the regenerative capacity of the native tissue. Reparative strategies such as auto, xeno, and allografts are clinically insufficient to treart such defects. For the first time, we introduce the use of handheld melt spun three dimensional printers that can deposit materials directly within the defect site to properly fill the cavity and form free-standing scaffolds. Our 3D nanocomposite filaments can be deposited using low-temperature printing to avoid overheating of the surrounding tissues. The *in situ or in vivo* printed scaffolds have moderate adhesion to wet bone tissue, which can prevent scaffold dislocation. The printed scaffolds showed a high level of biocompatibility and were osteoconductive supporting the osteodifferentiation of mesenchymal stem cells.

Fast Growth of AgMOF—Micro and Nano Crystals as Antibacterial Coating for Ti-Based Implants Vincenzo Paratore[1], Domenico Franco[2,3], Giovanna Calabrese[2], Salvatore Guglielmino[2], Sabrina Conoci[2,3] and Guglielmo G. Condorelli[1]; [1]Università degli Studi di Catania, Italy; [2]Università degli studi di Messina, Italy; [3]IBMTech s.r.l., Italy

Bacterial infections are quite common in post-operative recovery for prosthetic bone replacements due to the bacteria capability of adapting to commonly used drugs. This leads to rejection of the prostheses and a subsequent return to the operating room for the replacement of the prosthesis. The study of new antibacterial materials and of their anchoring on implants surfaces has, therefore, a key role in scientific research. Various inorganic and organic materials have been used for this purpose, and, among them, MOF (Metal Organic Framework) possess great potentiality. They are composed by organic ligands and metallic subunits, bond together to obtain a framework. They present a series of active sites, micro and nano porous structures and highly modulable surface areas. Silver-based inorganic materials gained interests in biomedical applications thanks to Ag^+ ions antibacterial properties.
We synthesized a silver-based MOF using a new synthetic method through which less toxic solvents, lower temperatures, and much shorter times are involved compared to commonly used approaches. We chose 1,4-benzene dicarboxylic acid as ligand because of its low toxicity and the weak bond with Ag^+ that allow slow release of Ag^+ ions in solution. The developed approach makes it possible to control the growth of specific crystalline phases in solution and on the implant surface as well.
We developed a fast low temperature synthetic method using dimethyl sulfoxide as solvent. Starting from $AgNO_3$, and using ammonia to stabilize Ag^+ ions, we obtained a mixed crystalline phase in 3h and the pure product in 5h at 70°C. To reduce synthesis times, we used two modulators (KCl and benzoic acid). In these conditions, the pure product was obtained in 3h with both modulators at 70°C. The silver ions release has been studied in water solution in neutral conditions and at different pH levels to verify a possible increased release during infections, in which pH values drop. Antibacterial properties were then evaluated to obtain the Minimum Inhibiting Concentration (MIC) and the Minimum Bactericidal Concentration(MBC) . For gram-negative MIC and MBC were observed at 7.8 µg/ml and for gram-positive MIC and MBC were observed at 31.3 µg/ml and 62.5 µg/ml respectively.
We also grow this material on a classic titanium scaffold for bone transplantation. To achieve surface growth, we treated titanium scaffolds and functionalized its surface with organic ligands like p-phosphono benzoic acid. By immersing the scaffold in an Ag^+ ion solution it was possible to obtain preferential crystallization sites for the MOF. Using similar synthesis methods, we obtained a continuous coverage of the Ti substrate.

2:00 PM SB01.12.06
Surface-Enhanced Raman Scattering Sensing of Various Analytes Based on the Polymer-Metal Composite Sensor Particles Nikunjkumar Visaveliya; The City College of New York, United States

Surface-enhanced Raman scattering (SERS) spectroscopy is one of the most powerful analytical techniques to detect trace amounts of various analytes, in which significant field enhancement can be realized upon adsorption of molecules (analytes) on the surface of metal nanostructure. A key component for better results and analysis through this method is the SERS substrate that needs to be equipped with plenty of hotspots as well as metallic-rich and relatively roughened surfaces. Despite a large number of SERS substrates being routinely utilized, there is still room and hence search is continuing for the

dynamic substrates that reveal the extraordinary sensing outcomes. Particle-based SERS substrates based on polymer-metal composite particles in which polymer as support can provide the platform to meet such requirements by systematically depositing metal nanostructures at the surface of polymer particles. The characteristics of the polymers such as biocompatibility, swellability, porosity, transparency, metal loading ability, and high surface area are particularly useful in the formation of the efficient particle-based substrate. Microfluidics is a promising technique for the fabrication of polymer-supported sensor particles of nanoscale and microscale with uniformity because of their advantages over the batch platform. For nanoscale sensor particles, the metal nanoparticles can be incorporated and anchored at the surface of polymer nanoparticles electrostatically in the swellable shell layer, and a ligand-free metal layer can be deposited by a metal-catalyzed metal enforcement process. Here, the development of the polymer-metal composite particles at nanometer and micrometer length scales, and their applications as sensor particles for SERS sensing are presented. Microfluidic techniques were utilized for the generation of uniform sensor particles of micrometer length scale with the precise distribution of metal nanoparticles in the interior and at the surface. Furthermore, metal-catalyzed metal enforcement approaches initiated for achieving a ligand-free metal surface for direct analyte interactions because of the availability of a large number of hotspots in roughened metallic surface, and experimental demonstration of sequential SERS analysis of multiple analytes through microfluidics has been established that is demonstrated in this work.

2:15 PM SB01.12.07
3D Nano-Biohybrid Carbon Nanotube Forest for Cardiac Tissue Engineering Roya Bagheri, Masoud Kasraie, Xinqian Chen, Zhiying Shan and Parisa Abadi; Michigan Technological University, United States

Biohybrid cell-material structures have applications in tissue engineering, disease modeling, biorobotics, etc. Conductive materials, in particular, are useful in applications such as bioelectronics and pacing. The scaffolds that are used for making biohybrid structures have so far been limited to those with low electrical conductivities. Carbon nanotube forests have high electrical conductivity as well as mechanical compliance and stability, which are not offered by other commonly used cell scaffolds. Here, we developed a new 3D biohybrid structure using CNT forests and cardiomyocytes. The CNT Forest was fabricated on a silicon wafer by a chemical vapor deposition technique under atmospheric pressure. The sterilization procedure of CNT forests started with soaking the samples in 70% ethanol, followed by UV light exposure overnight. After sterilization, samples were coated with 1 wt.% gelatin. Physical characterization of the scaffolds was performed by scanning electron microscopy (SEM), four-point probe conductivity measurement, and electrochemical impedance measurement. The cardiomyocytes were isolated from 1-3 day old neonatal rat hearts and cultured on the CNT forest - gelatin scaffold for 19 days. All animal protocols were approved by the Michigan Technological University Institutional Animal Care and Use Committee. The cytocompatibility of the CNT forest - gelatin scaffold was assessed through the live/dead assay on day 2, and PrestoBlue assay on days 2, 8, and 11 from the start of culturing. The performance of cardiomyocytes on the scaffold was investigated using immunofluorescence cardiomyocyte labeling (Alpha actinin and Troponin T) and SEM imaging. The morphology and microstructure of the CNT forest - gelatin scaffolds were studied with SEM imaging. The CNT Forest had wavy and entangled CNTs with an average height of ~ 200 microns. The SEM images of CNTs before and after coating demonstrated that the CNTs were bent and formed micron-scale islands due to electrocapillary forces produced by gelatin. The electrical characterization of the scaffold showed that the coated CNT scaffold is conductive in liquid, and the impedance decreases due to the presence of gelatin. The live-dead assay indicated 89% viability on day 3 for the CNT forest-gelatin scaffold, which was in the range with the control. The PrestoBlue assay, which quantifies absorbance by dead cells, showed no toxicity for the scaffolds. The SEM images of cardiomyocytes on the scaffold showed the cells were spread and well-adhered to the structure on top and along with the height of CNT forests forming a 3D network. The cells expressed mature cardiomyocyte markers for alpha-actinin (actin-binding proteins cardiac marker) and troponin T (cytoskeletal organization cardiac marker) in fluorescence imaging. The cardiomyocyte cells were well-adhered to the CNT forest-gelatin scaffolds with no sign of toxicity for 11 days of culturing. They formed a 3D network and showed markers of mature cardiomyocytes. Our results indicate that the unique multi-scale structure of the CNT forest scaffolds makes them ideal for a highly conductive scaffold for biohybrid material-cardiomyocyte structures.

2:30 PM SB01.12.08
Engineered Implants with Smart and Sustained Release of Antimicrobial Agents Hessah Alotaibi[1,2], Etelka Chung[3], Vikaramjeet Singh[1], Guogang Ren[3] and Jie Huang[1]; [1]University College London, United Kingdom; [2]King Faisal University, Saudi Arabia; [3]University of Hertfordshire, United Kingdom

Infections caused by microorganisms during implant-mediated tissues regeneration therapy can lead to further complications and ultimate failure of the healing process. Therefore, an implant empowered with controlled and sustained release of antimicrobial agents is highly desired for tissue engineering applications. Here, we present a novel antibacterial film for wound healing applications constructed from metal organic frameworks (MOFs) and polymers for a sustained release of antimicrobial agents. Cyclodextrin metal organic frameworks (CD-MOFs) are embedded into biodegradable and biocompatible polymers, polycaprolactone (PCL) and polyethylene oxide (PEO). The concentration of polymers and MOFs was carefully optimized to obtain a highly flexible and strong film with a thickness of about 500 µm . The γ-CD-MOFs have been extensively exploited for their applications in biomedicine due to the biocompatible nature of its building blocks, i.e. γ-cyclodextrin and potassium ions. CD-MOFs possess two types of highly organised channels, hydrophilic (1.7 nm) pores resulted from CD coordination with potassium and inherent hydrophobic cavities (0.9 nm) of CD itself. However, their real potential in pharmaceutical sector is compromised due to their susceptible nature to water and poor processability of CD-MOF powder. In this work, cavities of CD-MOFs were utilised by *in situ* synthesis of ultra-small silver nanoparticles (AgNPs) with an average size of 2-5 nm. CD-MOFs. The optimised maximum concentration of CD-MOFs in the resulted film is 10% (w/w) with homogenous distribution of CD-MOFs nanoparticles. The CD-MOFs film shows a moisture triggered sustained release of AgNPs for more than 72 hr. The antimicrobial efficacy of the film was tested against E.Coli, S.aureus, and, and fungi Candida using zone of inhibition diameters (ZOI) and the results were 0.87 ± 0.06, 1 ± 0.1 and 0.97 ± 0.15 cm. The novel CD-MOFs film shows a great potential to be used as an antimicrobial film for the sustained release of antimicrobial agents in biomedical applications.

Advanced and Functional Lightweight Composite Components from Nanocellulose Daniel Soderberg; KTH Royal Institute of Technology, Sweden

For almost a decade, significant efforts have been made to fabricate material concepts from nanocellulose, e.g. barriers, films, foams, and fibres (filaments). As a result of combined knowledge of fibre suspension hydrodynamics, fibre technology and nanoscale interactions it has been shown to be possible to spin continuous filaments from a 100% nanocellulose dispersion with good mechanical performance and a possibility for functionalization e.g. conductivity or piezo resistivity. As a continued effort the technology has been further developed to allow scalable manufacturing in larger volumes, which allows research on applications that uses these filaments. Given the nature of the filaments, it is shown that it is possible to achieve components with transparency, mechanical performance and a possibility to serve as a basis for further functionalisation.

11:15 AM SB02.01.02
Solid Biofoams like Wood MIkko Alava, Juha Koivisto, Luisa Jannuzzi, Leevi Viitanen and Tero Mäkinen; Aalto University, Finland

Mimicking natural biological structures allows us to exploit tried design concepts for advanced material solutions. Wood is an example of an interesting natural material to replicate, as it exhibits excellent anisotropic mechanical properties and also performs well as a thermal insulator. We demonstrate a process of creating a cellular structure similar to natural wood -- a solid foam -- from forest-derived bio-constituents (M. Reichler et al., Sci. Reports 11,1 (2021)). As such, the resulting material has anisotropic mechanical properties such as elastic modulus and yield stress and exhibits complex mechanical response similar to natural wood. The heat conductivity is low due to the low density and closed pore structure. This novel paper recyclable material can be used as a substitute for oil-based packaging and insulation foams such as expanded polystyrene or polyurethane.

11:30 AM SB02.01.03
Association of Bacterial Nanocellulose with Fibroin to Develop a Wound Healing Bioproduct Priscila G. Mazzola[1], Carolina Talarico[2], Janaina Artem Ataide[1], Norberto Aranha[2] and Angela F. Jozala[2]; [1]UNICAMP, Brazil; [2]UNISO, Brazil

Bacterial nanocellulose (BC) is an extracellular polysaccharide secreted mainly by bacteria of genera Gluconacetobacter. Different from vegetable cellulose, BC is produced in pure form, free from other polymers. Previous studies have already reported the potential of BC in medical applications. A promising and innovative alternative to optimize the benefits attributed to BC would be its association with polymeric composites, such as fibroin; with the aim of overcoming its limitations and increasing the field of its applications. Thus, we aimed the development of bioproduct for healing by associating BC and fibroin (BC-FB). The incorporation of nanocellulose into fibroin was carried out by immersion at 25 °C, followed by its characterization by Fourier transform infrared spectroscopy (FTIR-ATR), scanning electron microscopy (SEM) coupled with energy dispersive spectroscopy (EDS), and mucoadhesion were performed. FTIR-ATR showed the presence of characteristic groups from BNC and fibroin in the final bioproduct, as well in EDS analysis. Based on SEM images, it was possible to note a similarity in formed network between BC and BC-FB, and a reduction in pores in the second sample. During mucoadhesion assay, the force necessary to remove BC-FB was lower than the force for only BC (0.456 N and 0.493 N, respectively). There was also a decrease in the mucoadhesive strength after incorporation of fibroin (from 1.656 N to 1.276 N). Once the structure is essential for materials, the BC-FB membrane could be explored in other research, such as filter membrane or bone regeneration. Additionally, the membrane production by immersion did not use hazardous substances, promoting environmental-friendly practices and reducing costs.

11:45 AM SB02.01.04
Cellulose Functional Materials for Fiber-Based Energy Harvesting and Storage Devices Jose Tiago Carvalho[1], Raquel Barras[1], Rodrigo F. Martins[1], Diana Gaspar[2] and Luis Pereira[2,1]; [1]FCT NOVA, Portugal; [2]Almascience Colab, Portugal

Developing sustainable options for energy conversion and storage in textiles is needed to power future wearable “Internet of Things” (IoT) electronics. This process must consider new possible alternatives that address questions of sustainability, reuse, repair, or even a second life application. Herein, we pair stretch-broken carbon fiber yarns (SBCFYs), as current collectors, and an in-situ regenerated cellulose-based ionic hydrogel (RCIHs) as an electrolyte, to fabricate 1D fiber-shaped supercapacitors (FSCs). The areal specific capacitance reaches 433.02 μF cm $^{-2}$ at 5 μA cm $^{-2}$, while the specific energy density is 1.73×10 $^{-2}$ μWh cm $^{-2}$. The maximum achieved specific power density is 5.33×10 $^{-1}$ mW cm $^{-2}$, at 1 mA cm $^{-2}$. The 1D FSCs possess a long-life cycle, 92 % capacitance retention after 10000 consecutive cyclic voltammetry cycles, higher than similar ones using reference PVA/H_3PO_4 gel electrolyte. We also propose Triboelectric Generator Yarns (TEG yarns) using a new method for depositing PDMS directly onto conductive carbon yarns. The in-situ PDMS curing method described in this study allows the fast formation of a uniform thick coating over conductive surfaces regardless of their roughness. Single-electrode configuration TEG yarns are developed, and their electrical output is optimized by precisely adjusting the PDMS layer thickness and by changing the chemical and physical nature of the SBCFYs surface, reaching a power density of 74.1 μW cm^{-2}. We demonstrate that asymmetric electrophoretic deposition of nanocrystalline cellulose films results in increase of 100% of the TEGs electrical output to around 142.7 μW cm^{-2}.

SESSION SB02.02: Lignocellulose Processing and Understanding II

Nanopolysaccharide Interaction with Bacteria—Effect of Surface Functionality Aji Mathew, Andrea A. Sanchez, Jing Li and Edouard Pesquet; Stockholm University, Sweden

The interaction between different nanopolysaccharides and *E. coli* was evaluated by exposing E. coli to cellulose nanocrystals (CNC), TEMPO-oxidized cellulose nanofibrils (T-CNF) and ligno-cellulose nanocrystals (L-CNC). The observations of the bacteria cultures showed that none of the films had a cytotoxic effect over the *E. coli* when in indirect contact. Nevertheless, T-CNF and L-CNC, showed cytostatic effect on the growth of the cells, with T-CNF being the most prominent. The nanomechanical properties and interacting forces between the nanopolysaccharide film surfaces and the *E. coli* were studied using in situ PeakForce quantitative nanomechanical mapping (PFQNM). The PFQNM results demonstrated that the different types of nanopolysaccharides affect in site selectivity of the films against cell adhesion, and that all the studied samples altered the nanomechanical properties of cell envelops in different ways. The surface morphology of *E. Coli* cells was affected when in direct contact with the nanopolysaccharide films during incubation, except for *E. coli* cells attached to the CNC films. For all the cases, a stiffing effect was observed on the cell walls (based on the DMT modulus) after exposure to the nanopolysaccharide surfaces; being lowest for CNC compared to T-CNF and L-CNC. It was not possible to determine any obvious effect on the bacterial cells exposed to CNC films, but in the case of T-CNF and L-CNC substantially decreased cell growth and reduced the adhesion force, corroborating the great potential as antibiofouling material and capacity to interact with cytoplasm leading to cell leakage and possibly cell death. Overall, these studies pave the path for understanding how different types of nanocellulose and nanochitin can be used to tailor bacterial inhibition/proliferation properties on different materials.

2:00 PM SB02.02.02
The Interaction Between CO_2 and NaOH-Dissolved Cellulose as a Potential in Cellulose Technology Aleksandra M. Kozlowski and Merima Hasani; Chalmers University of Technology, Sweden

The growing awareness of consumers, governments, and industries on their influence on the environment generated the world trend to search for solutions to mitigating climate change. Perhaps the most popular subject refers to carbon dioxide capture and applications of green resources for this reason. From the perspective of renewable and sustainable materials, it is hard to think about better candidates than biopolymers. Over the past few years, a lot of attention has been given to understanding the mechanism of action between various saccharides and CO_2; yet the most abundant of them all, cellulose, remained in the shadow of investigations. The reason behind this low interest could be the perception of cellulose as a difficult to process, with applications more related to the paper, textile, or packaging industry. However, in our study, we present that cellulose exhibit a strong affinity for alkali-dissolved CO_2 that leads to coagulation of polymer and formation of novel material with a perspective for industrial applications.
Here, we take the control over the gas delivery and conclusively study the effect of CO_2 on cellulose dissolved in NaOH at two different temperatures (25 and 5 °C). The *in-situ* analysis gives an inside to carbonation (cellulose *vs* inorganic species), changes in temperature and pH. It allows hypothesising on the initial mechanism of interaction between cellulose and CO_2 that results in polymer coagulant. Furthermore, the created coagulants, analyse from the perspective of structural and crystallinity changes, prove competitive to alcohol precipitates. This opens for the employment of CO_2 in the process of cellulose regeneration. Our findings are presented with the implication for cellulose processability, in the context of cellulose derivatives and regenerated fibres production, as well as effective exploitation of CO_2 gas.

2:15 PM SB02.02.03
Targeted Functional Methylcellulose-Nanocomposite Materials via Self-Limiting Electrospray Deposition Michael Grzenda[1], Maria Atzampou[1], Jonathan M. Blisko[2], Rachel Vladimirsky[1], Kelly Hughes[1], Christopher E. Shuck[3], Xin Yong[2], Jeffrey Zahn[1] and Jonathan P. Singer[1]; [1]Rutgers, the State University of New Jersey, United States; [2]Binghamton University, The State University of New York, United States; [3]Drexel University, United States

Electrospray deposition (ESD) uses strong electric fields to produce generations of monodisperse droplets from solutions/dispersions that are driven towards grounded targets. Self-limiting electrospray deposition (SLED) is a phenomenon recently discovered by our group in which targeted, 3D coatings can be achieved by spraying insulating polymers below their glass transition temperatures, which trap charge and repel incoming spray droplets. Recent work from our group has shown that methylcellulose (MC) exhibits self-limiting behavior when sprayed from water/ethanol solutions and is also capable of forming nanowire morphologies. This unique spray regime is an intermediate between the electrospinning of wire mats and particle sprays. As part of this prior work, it was demonstrated that because MC forms fibril gels, the shear of spray leads to shear thickening and homogenous gelation of the MC that allows for nanowire particles to form, eventually forming a forest as deposition continues. However, when conductive particles are added to SLED sprays, the buildup of charge required to repel incoming material becomes disrupted as particle loading increases. As would be expected, this relationship is not dependent solely on concentration. Here, we are able to show that an interaction exists between particle morphology and the formation of the MC nanowire in composite sprays. While larger spherical particles, 200 nm and above, will disrupt nanowire formation, smaller particles, 50 nm and below, become incorporated in the nanowire. Furthermore, the concentration of smaller particles changes the length of the nanowire. We take advantage of these phenomena to use MC nanowires to prevent and reduce the percolation of conductive particles during spray which allows for highly controlled deposition. For conductive particles, we use 2D Ti_3C_2 MXene of two different sizes as well as spherical ITO which all have similar sheet resistances. To quantify the growth of these materials and examine the dynamic interaction of composition, particle properties, and feature geometry, photolithography patterned chips with gratings of varying widths and spacings were designed. These chips were sprayed with composite materials of varying concentration, and the widths of the features after spray were measured. Scanning electron microscopy shows these deposited materials are able to maintain unique low-density morphologies. Using these findings, it was possible to design highly controlled, optimally loaded, functional targeted sprays of MC containing either MXene or ITO. As a demonstration, MXene containing spray was used to functionalize interdigitated electrodes with features and spacings as low as 50 microns and a substantial increase in capacitance was measured. Upgraded patterns on polyimide substrates demonstrate the compatibility of this process with flexible electronics.

2:30 PM SB02.02.04
Elucidating Emergent Properties of Lignocellulosic Biopolymer Assemblies Through Macromolecular Modeling Peter Ciesielski, Lintao Bu, Meagan Crowley, Vivek Bharadwaj, Bennett Addison, Braden Pierce, Yannick Bomble and Michael Crowley; National Renewable Energy Laboratory,

United States

Lignocellulosic materials are a class an incredibly complex, highly diverse, and multifunctional polymer nanocomposites. Even within a cell wall, the biopolymer structure and composition vary locally to provide different properties and functionalities to each tissue type. For example, the secondary cell walls found in xylem tissue contain large bundles elementary cellulose fibrils, decorated with hemicellulose and lignin, to impart mechanical integrity. In contrast, the compound middle lamella found between adjoining cells contains little or no cellulose but is rich in lignin and pectin to provide adhesive properties. Aside from differing biopolymer compositions, modifications to monomer composition (such as the ratio of syringyl to guaiacyl units in lignin) and backbone decoration (such as acetylation of xylan) are also used by plants to impart specialized functionality to lignocellulosic assemblies. Furthermore, process-induced modification, such as lignin extraction and enzymatic hydrolysis, impart additional changes that alter the properties of the material. In this presentation, I will overview molecular modeling methods used by our group to identify structure/property/function relationships in lignocellulosic biopolymer assemblies. First, I will describe the construction of macromolecular models of secondary cell walls containing cellulose, hemicellulose, and lignin using best available experimental data to assign their spatial proximity and nanoscale arrangement. Variations of these models are employed in simulations of mechanical deformation to investigate the impacts of polymer composition and macromolecular architecture. We find that alterations is in lignin monomer ratio impacts mechanical moduli and propensity to form defects in cellulose fibrils during mechanical deformation. Next, I will present our recent molecular models for the compound middle lamella tissue, which has been identified as the primary location of failure during chemo-mechanical deconstruction. Variations in biopolymer composition and moisture content produce large changes in the mechanical properties of this tissue type, which have practical implications for biorefining and bio-based material design strategies.

2:45 PM SB02.02.05
Tunable Hydrogels of Cellulose Nanocrystals Cross-Linked with Water Soluble Polysaccharides Teemu Suutari[1], Ville Rissanen[2], Suvi Arola[2], Tekla Tammelin[2] and Eero Kontturi[1]; [1]Aalto University, Finland; [2]VTT Technical Research Centre of Finland Ltd, Finland

Hydrogels based on nanosized cellulose have potential in a wide range of different applications. Often, cellulose nanofibers (CNFs) are used for hydrogel preparation, as the highly flexible CNF fibrils have an inherent tendency to entangle, forming gels already at very low concentrations. Cellulose nanocrystals (CNCs), on the other hand, are highly crystalline structures and as such do not exhibit similar gelling properties and are therefore utilized in hydrogels to lesser extent. However, the gelling property can be a limiting factor for easy CNF manipulation, while the more fluid-like CNC can be utilized at broader concentration ranges, allowing hydrogel tunability at much wider parameter space.

In this work we have investigated different water-soluble polysaccharides in their ability to function as cross-linkers and facilitate CNC hydrogel formation. For this, we have tested 15 different water-soluble polysaccharides, such as xanthan, hydroxypropyl cellulose, carboxymethyl cellulose (CMC), hydroxyethyl cellulose (HEC) xylan, guar, and three types of mixed linkage glucans (MLGs), among others. CNCs from different sources were used, including bacterial cellulose and cellulose from bleached softwood pulp both treated with HCl gas hydrolysis and 2,2,6,6-tetramethylpiperidine-1-oxyl (TEMPO) radical-mediated oxidation. The CNCs and polysaccharides were mixed at different ratios and the performance of the formed hydrogels were tested in their rheological properties and their porosity was investigated using thermoporosimetry.

One possible application for hydrogels includes immobilization of photosynthetic cells. Photosynthetic cells can be utilized as a renewable, sustainable, and economical method for biofuel, food, and medicinal compounds production. Thus far, these cell factories have been mostly maintained in suspension cultures. For improved efficacy of light utilization, energy loss and water consumption, cells can be immobilized in different structures, such as alginate. However, capturing cells in these structures can inhibit the transfer of substrates and the produced chemicals, while still facilitating undesired cell division. Hydrogels made from nanocellulose offer a great alternative for cell immobilization, as cellulose is abundantly available, biocompatible, and biodegradable. Also, nanocellulose hydrogels provide controllable transparency, good gas barrier properties and can be tuned in their permeability and wet strength. Furthermore, they offer good mechanical stability and high porosity, both which are beneficial for a long-term cell survival and efficient production of desired chemicals. Therefore, the prepared nanocellulose hydrogels were evaluated in their suitability for cellular immobilization, biocompatibility, and long-term cell viability by entrapping a wild-type cyanobacterial strain Synechocystis sp. PCC6803 within the gels and monitoring the long-term photosynthetic activity. The most promising cross-linkers in terms of good hydrogel formation, mechanical properties, biocompatibility, and long-term cyanobacteria performance were found out to be HEC, CMC, and all three MLGs.

To further finetune the properties and to optimize the hydrogel performance, the fundamental interactions of the hydrogel components were studied using a CNC model films in surface plasmon resonance and quartz crystal microbalance. These interaction studies revealed that e.g., the binding of MLGs on CNCs was concentration dependent, but the extent of binding was not affected by the molecular weight of MLG, implying that any MLG type is suitable for robust construction of hydrogels from CNCs. The polysaccharide-CNC thin films were further characterized using atomic force microscopy and ellipsometry.

Studying Wood-Water Relationships with Molecular Dynamics—How Far We Are Now? Dominique Derome[1], Wenqiang Liu[1], Ali Shomali[2], Chi Zhang[2], Benoit Coasne[3] and Jan Carmeliet[2]; [1]Université de Sherbrooke, Canada; [2]ETH Zurich, Switzerland; [3]Univ Grenoble Alpes, France

Wood is an orthotropic cellular biomaterial. As a plant and as a building material, water impacts the behavior of wood. Wood is also a hierarchical material. At the base of this hierarchy lies the cell wall material. As water molecules are adsorbed by the hydrophilic matrix that make up the cell walls, the induced fluid-solid interaction forces result in swelling of these cell walls. Thus, this process, at the origin of wood-moisture relationships, lies at the nanoporous material scale.

The layer S2 of the wood cell wall is actually a composite polymeric material. Stiff crystalline cellulose bundles to form fibrils that are embedded by a profoundly organized matrix of different hemicelluloses, galactoglucomannan and glucuronoarabinoxylan, and of two states of guaiacyl lignin, non-condensed and condensed, considering here coniferous species. We have reproduced these assemblies and subjected them to different in-silico experiments. Using grand canonical Monte-Carlo and molecular dynamics, we have obtained adsorption and desorption isotherms of different polymeric systems. Water is known to rearrange the internal structure of the material of the S2 cell wall. The in-silico systems obtained at different moisture content can be probed to provide insights on the extent of this rearrangement in terms of configuration and in terms on its influence on the physical properties of the material.

Atomistic simulations used to mimic water adsorption and desorption in amorphous polymers, allow observations on mechanical behavior like swelling and shrinking, mechanical softening in compression and shear, and on the stick-slip behavior of the stiff fibrils pulled out of the matrix. We observed

hysteresis not only in water sorption but also in mechanical properties. This hygromechanical behavior can also be observed in particular from the breaking and reforming of hydrogen bonds.

Atomistic modeling is an insightful tool for the in-depth study of the coupled effects of water sorption on hygric and mechanical properties of different polymeric components. Molecular modeling can contribute to support and complement experimental methods which yield, most frequently, indirect structural information. With molecular modeling, there is a freedom of investigating unlimited possibilities of configurations, ranging from individual wood polymer materials to composite structure resembling subunits of wood S2 cell wall. This presentation will cover recent methodological developments towards good practices for such simulations and the recent insights on wood cell wall S2 layer hygromechanical behavior.

4:15 PM SB02.02.08
Examining the Development of Secondary Cell Walls in Arabidopsis Inflorescence Stem Using Hard and Soft X-Ray Scattering Joshua T. Del Mundo[1], Sarah Pfaff[1], Liza Wilson[1], Masoud Ghasemi[1], Guillaume Freychet[2], Mikhail Zhernenkov[2], Eliot Gann[3], Daniel Cosgrove[1], Esther Gomez[1,1] and Enrique Gomez[1,1,1]; [1]The Pennsylvania State University, United States; [2]Brookhaven National Laboratory, United States; [3]National Institute of Standards and Technology, United States

The durable secondary cell wall gives vascular plants the structural foundation needed to grow upwards. Fundamental research of the synthesis and material properties of secondary cell wall is the first step to developing new bio-derived materials and the utilization of lignocellulosic biomass as a renewable energy source. It is a composite material composed of cellulose microfibrils, hemicellulose, and lignin. The process of how these components come together to form the secondary cell wall in the plant is currently poorly understood. To track the development of secondary cell wall formation at different stages, we use the base of *Arabidopsis thaliana* inflorescence stems harvested at different heights. The total inflorescence stem height is proportional to the progress of secondary cell wall development in the interfascicular fiber (IFF) cells in the stem base. At lower stem heights (5 cm), we see little secondary cell wall in the IFFs and at higher stem heights (34 cm), we see full lignification of IFFs. Small-angle X-ray scattering (SAXS) tracks the changes in cellulose microfibril spacing and microfibril angle distribution. Wide-angle X-ray scattering (WAXS) tracks the relative crystalline cellulose content, chain packing, and coherence length. To investigate the effects of the content and structure of xylan, a principal hemicellulose, on secondary cell wall formation, we examined the stems of irx14 mutants. We found that compared to the wild type, the irx14 mutants had altered cellulose microfibril angle distribution and coherence length, but not individual cellulose chain packing distribution. To determine the spacing of lignin domains in secondary cell wall, we applied resonant soft X-ray scattering (RSoXS). Lignin is unique from other cell wall components in that it is highly aromatic, to which the secondary cell wall owes its hydrophobicity and resistance to degradation. RSoXS probes the sample with an X-ray beam tuned around the carbon absorption edge, increasing the contrast between lignin and other cell wall components without the need for labelling. At energies where the contrast between cellulose and lignin is enhanced, we see a broad nanometer-scale feature at high stem height, but not low stem height.

4:30 PM SB02.02.10
Cellulose-Based Biosensing Platforms—Fabrication and Detection Strategies Rodrigo F. Martins[1,2] and Elvira Fortunato[1,2]; [1]FCT UNL, Portugal; [2]UNINOVA, Portugal

The development of accurate, reliable, and inexpensive analytical platforms is of utmost relevance to several fields from clinical diagnosis to environmental screening. Moreover, the use of inexpensive materials and cost-effective manufacturing processes for production of such devices is very attractive and must be aligned with the European Green Deal and the United Nation's Sustainable Development Goals. In that sense, cellulosic materials are appealing candidates to be used as low-cost disposable materials for biosensing platforms, with great emphasis in point-of-care (POC) settings, particularly in resource-poor countries. Here, we show the use of cellulose-based substrates with both passive and active roles in biosensing platforms allied with cost-effective, energy-efficient and scalable fabrication routes. These biosensors were developed with both optical and electrochemical mechanisms, due to their meritorious ability to offer high selectivity and sensitivity, ease of fabrication and usage, easy miniaturization, low cost and versatility. Specifically, we present examples of (i) cellulose-based colourimetric biosensors using wax printing technology combined with colourimetric detection using both natural and biomimetic receptors for a multitude of applications, ranging from bacteria detection to diabetes control[1]; (ii) cellulose-based Surface-Enhanced Raman Scattering platforms, produced using both physical and chemical routes, for the detection of antibiotics, cancer biomarkers and spike protein from SARS-CoV-2 virus, where the influence of different types of cellulosic materials is demonstrated[2,3,4]; (iii) cellulose-based electrochemical biosensors, using laser-induced graphene electrodes with tailored conductive and electrochemical properties, applied for amperometric, enzymatic biosensing schemes for glucose detection and with potential for sensing of other metabolites [5]. In conclusion, the biosensing concepts explored herein pave the way toward developing robust analytical devices with the potential to be integrated with stand-alone multifunctional platforms to be used in POC settings.

Physical Properties of Polypropylene Plastic Resins Composite with Natural Derived Cellulose Fibers Mikyung Kim and Songhyun Yoon; DYETEC

Institute, Korea (the Republic of)

Recently, an eco-friendly industry that is carbon-neutral has become important, and active application of eco-friendly materials with increased biomass content is required for plastic products applied to automobiles. As eco-friendly materials for automobiles, plastic composites using natural fibers such as wood powder, kenyaf, and hemp as reinforcing materials are being applied as interior materials for automobiles such as door trims. However, wood powder or plant fiber combined in plastic resin as a reinforcing material for improving biomass content and improving plastic properties contains impurities such as sugar, pectin, and hemicellulose in addition to cellulose components, which may cause unique odor problems and durability degradation.
This research attempted to apply regenerated cellulose fibers such as tencel and rayon, which are generally used in the textile industry, as a plastic resin reinforcement for automobiles. Since the regenerated cellulose fiber is a purified cellulose fiber in which impurities have been removed in a manufacturing process, it was determined that the application to a plastic composite is better than plant fibers such as wood powder, kenaf, and hemp. Therefore, in order to improve the biomass content of automotive plastic materials and the durable properties of plastic composites, mixing and composite properties with polypropylene resin were investigated using naturally derived regenerated cellulose fibers such as tencel and rayon. Tencel and rayon fibers are cellulose-based fibers and are hydrophilic, so their compatibility with industrial resins such as polypropylene is low. In this work, by silanizing and surface modification of the regenerated cellulose fiber to impart hydrophobic properties, compatibility with the polypropylene resin is improved and the physical properties of the composite are expected.

SB02.03.02
Hydrogel Supercapacitor Fabricated by Lignin-Mediated Laser-Induced Graphitization Rikuto Miyakoshi, Shuichiro Hayashi and Mitsuhiro Terakawa; Keio University, Japan

Supercapacitors have drawn remarkable attention among energy storage devices due to their fast storage capability and enhanced cyclic stability. Hydrogels are one of the promising materials to be used for supercapacitors since they can easily absorb and retain liquid electrolytes. If conductive structures can be directly patterned on hydrogels, the hydrogel can fulfill both roles as an electrolyte retainer and supporting material. Laser-induced graphitization is a compelling technique to directly pattern electrically conductive graphitic carbon on a polymer by simply irradiating a laser beam. To the best of our knowledge, the one-step fabrication of electrically conductive structures on hydrogels by laser-induced graphitization has yet to be demonstrated. In this study, we demonstrated the direct fabrication of electrically conductive graphitic structures on hydrogels by laser-induced graphitization using lignin. Agarose hydrogel containing lignin, both biomass materials, were chosen as a precursor material for realizing the fabrication of a fully-biomass supercapacitor. The irradiation of 522-nm femtosecond laser pulses modified the surface of the hydrogel to a visibly-black colored structure that exhibit electrical conductivity. The Raman spectrum obtained from the structure showed peaks that correspond to D, G, and 2D bands, suggesting the formation of graphitic carbon. The fabricated structures exhibited a higher conductivity for higher lignin concentrations. No visible modification was observed after laser irradiation when no lignin was added to the agarose hydrogel. It should be noted that lignin is an organic material that exhibits high optical absorbance of 522-nm light. Therefore, the addition of lignin into the agarose hydrogel increases the absorbed energy, as well as the carbon content, which may lead to the facilitation of graphitization. To investigate the capability of the fabricated structures for supercapacitors, a pair of structures to be used as electrodes were fabricated on agarose/lignin hydrogels containing NaCl. Capacitance behavior was confirmed from the structures, demonstrating the one-stepped fabrication of hydrogel-based supercapacitors. The prepared hydrogel acts as the electrolyte retainer and supporting material of the fabricated supercapacitor. The proposed method offers a facile fabrication of a hydrogel-based supercapacitor.

SB02.03.03
Vertical Integration of Multi-Electrodes into a Single Sheet Of Paper and the Control of the Equivalent Circuit for a High-Density Flexible Supercapacitor Yeon Woo Kim, In Hyeok Oh, Jung Hyeon Jin, Seung Deok Seo and Suk Tai Chang; Chung-Ang University, Korea (the Republic of)

Paper is an excellent substrate for flexible devices due to its various advantages such as flexibility, porosity, lightness, thinness, and low cost. Its inherent characteristics can be also exploited to overcome the limitations of conventional substrates, such as weak adhesion and large mass densities. Here, we propose a facile method for fabricating vertically integrated multi-electrodes into only a single sheet of paper. Despite the randomly distributed fibrous networks in a paper, the multi-layered electrodes were uniformly formed and completely separated by applying a removable hydrophobic wax barrier confinement inside a single sheet of paper. The integrated multi-layer electrodes can be used as ultra-thin supercapacitor paper with flexible circuit diversion. Using multi-layered electrodes, we demonstrated the control of the equivalent circuits in the supercapacitor paper by simply changing the contact pad grounding. By changing the circuit structures, the multi-layer electrodes exhibited excellent electrochemical properties without device volume changes and additional components. The single incorporated electrode inside the paper with electrodeposited MnO_2 exhibited a high areal capacitance of 711 mF cm^{-2}. Moreover, the single sheet of supercapacitor paper with integrated multi-electrodes exhibited greater energy and power densities than a single electrode with the same area by factors of 3.8 and 1.75, respectively, based on the control of the equivalent circuit.

This research was funded and conducted under the Competency Development Program for Industry Specialists of the Korean Ministry of Trade, Industry and Energy(MOTIE), operated by korea Insstitute for Advancement of Technology (KIAT). (No. P0012453, Next-generation Display Expert Training project for Innovation Process and Equipment, Materials Engineers), and supported by a National Research Foundation of Korea (NRF) grant funded by the Korean government (MSIT) (2022R1A2C1005739)

SB02.03.04
Reinforced Ferromagnetic Properties in CNC@$CoFe_2O_4$/P(VDF-TrFE) Nanofiber Composites for Magnetic Energy Harvester Su-Chul Yang and Manseong Song; Dong-A University, Korea (the Republic of)

After the fourth industrial revolution, the worldwide commercialization of electronic devices has been proceeding. According to the rising demand for electronic devices, demands for energy sources have also been increasing. To satisfy it, energy harvesters which can scavenge energy from ambient circumstances have been developed. Despite the diverse ways to convert energy obtained from the environment to a practical energy source, there are several limits to its application into daily life. The energy harvesters working under contact mode, in particular, would be exposed by performance degradation due to the continued contact or restricted in specific areas where the physical contact is not permitted. In this respect, the issues mentioned above could be solved by introducing the magneto-mechano-electric (MME) materials. The MME effect is defined as the electrical polarization in the ferroelectric piezoelectric (FP) phase induced by strain originated from physically adjacent ferromagnetic magnetostrictive (FM) phase under external magnetic field, and it is basically based on the non-contact mode. When it comes to polymer-based MME composites, representatively, it has been drawn attention from many research groups because of its advantages including generated voltage which is sufficient enough to operate the low voltage device, high cost-efficiency, and versatility of applicable structure due to the high flexibility. The reported method in general to achieve high output voltage from this type of MME composites so far was the surface or composition modification for FM phase material which is responsible for stress causing the polarization of the FP phase. Many researchers have tried to treat the FM phase materials by adding a coating agent to control the morphological character or regulating the chemical composition via post-treatment. In consequence, the overall process was getting longer due to the additional treatment, moreover, the ferromagnetism related to MME properties in direct, fundamentally, was diminished ascribed to the lower actual weight fraction of FM

phase compared to the pure state.
In this research, the new way to reinforce the ferromagnetism, which is in proportional to MME properties, in magnetic filler was suggested. To be specific, the cellulose nanocrystal(CNC) was incorporated into the reaction for the synthesis of the CNC@$CoFe_2O_4$(CFO) nano hybrid filler. The prepared fillers exhibit higher overall ferromagnetic properties including maximal saturation magnetization (M_s) of 71.8 emu/g and remnant magnetization (M_r) of 32.9 emu/g increased by 22.5% and 24.2%, respectively, in comparison with conventionally synthesized pure CFO nanoparticles even without any further treatment. To interpret the origin of the results, the morphological, surface chemical structural, crystallographic, and ferromagnetic analysis were performed. Through the investigation, it was found that the reinforced magnetic properties were largely due to the expanded crystallite size attributed to the nucleation site provided by introduction of CNC. Thereafter, to investigate the influence from reinforced ferromagnetism of hybrid fillers to the MME properties in composites, the CNC@CFO/P(VDF-TrFE) nanofiber composites was designed. It was observed that the ferromagnetism in composites with hybrid filler was enhanced, manifesting M_s of 4.17 emu/g and M_r of 2.03 emu/g increased by 36.8% and 51.5%, respectively, compared to composites prepared with equal contents of CFO without CNC. Finally, the MME composites were subjected under cyclic magnetic driven voltage measurement based on the bending motion. As a result, it was confirmed that the output voltage generated from the MME composites with CNC was 219.7 mV which is as higher as 72% than the composites prepared without CNC. On the basis of these results, it was concluded that the prepared MME composites with CNC are of the potential for non-contact energy harvesting application.

SB02.03.05
Photocatalytic Degradation of Lignin Model Compounds Using 2D-MoO_3/Noble Metal Nanoparticles Hybrid Nanostructures Jihoon Park and Youngsoo Kim; Yeungnam University, Korea (the Republic of)

Hybrid nanostructures that consist of two-dimensional nanomaterials and plasmonic nanoparticles have been receiving great interest in the academic and industrial fields. The hybrid nanostructures exhibit unique optical characteristics in combination with the physicochemical properties of 2D nanomaterial and the plasmonic optical effects. Thus, hybrid nanostructures have been widely investigated for optical sensors, solar cells, and electronic devices. In addition, the 2D/plasmonic nanoparticles hybrid nanostructures enable improved photocatalytic performance owing to enhanced charge carrier generation and efficient charge transfer. Lignin, which is a natural bio-polymer, is composed of a number of aromatic rings with diverse functional groups such as carbonyl, hydroxy, and methoxy groups. Therefore, it can be expected that the efficient decomposition of lignin is able to alternate various polymeric materials that came from fossil fuels. In this research, we employed MoO_3/metal nanoparticle hybrid nanostructure to drive photocatalytic degradation of the lignin model compound. We prepared a hybrid nanostructure through the exfoliation of bulk MoO_3 and photoelectrochemical deposition of noble metal nanoparticles such as Au, Ag, Pd, and Pt on the exfoliated MoO_3 nanosheet. Furthermore, we compared the photocatalytic degradation efficiency of the lignin compound with respect to the type of metal nanoparticles and performed a mechanism study of the degradation. The hybrid nanostructures were characterized by UV-Vis spectrophotometer, TEM, and XRD. As well as, qualitative and quantitative analyses for the lignin compound and the products after degradation were carried out using UV-Vis spectrophotometer, HPLC, and NMR.

SB02.03.06
Bouligand Multilayers—Artificially Constructed Cellulose Nanocrystals Chiral Films Daria Bukharina, Lindsay Southard, Saewon Kang, Peng Min and Vladimir Tsukruk; Georgia Institute of Technology, United States

Natural photonic crystals, such as cellulose nanocrystals, have the ability to self-assemble into complex hierarchical structures, however, because of the homochirality in nature they can only assemble into left-handed chiral structures. Here, we will demonstrate bottom-up approach to assemble cellulose nanocrystals thin films of both handednesses. First, we assembled linearly oriented CNC monolayer via shear-induced alignment. Then, artificial chiral Bouligand nanostructures were constructed via Layer-by-Layer (LbL) deposition technique by depositing each next layer in clockwise and counter-clockwise fashion rotating the substrate at a fixed angle. The chiroptical properties measurements of the obtained thin films resulted in mirror-imaged circular dichroism (CD) spectra, indicating successful construction of both left- and right-handed CNC films. Those chiroptical properties and films' anisotropy will be controlled by changing the rotation angle and the number of deposited layers, i.e., film's thickness. Our fabrication strategy has several advantages. First, doctor blade deposition technique allows to produce large-area films. Second, LbL deposition guarantees precise control of the rotation angle and direction. Atomic force microscopy will confirm the alignment of the monolayers deposited, as well as their thickness in conjunction with ellipsometry. CD and UV-vis studies will reveal chiral optical activity of the deposited films. Lastly, effectiveness of artificially obtained chiral photonic CNC films will be confirmed by the g-factor, dimensionless factor characterizing the efficiency of the light-passing-through-the-film polarization and will be presented. Such control of the CD response with respect to the peak sign, position and intensity is unique for CNC films.

SB02.03.07
Wood-Derived Lignocellulosic Nanofibrils Based Triboelectric Nanogenerator for Electronic Integration Asif Abdullah Khan[1], Md. Masud Rana[1], Nicolas R Tanguy[2], Xiao Zhang[2], Nicole Tratnik[2], Heyu Chen[2], Dayan Ban[1] and Ning Yan[2]; [1]University of Waterloo, Canada; [2]University of Toronto, Canada

Triboelectric nanogenerators (TENGs) are a transformative energy harvesting technology owing to their high-power output, simple architecture, small size, and low cost. They are highly promising to provide embedded powering capabilities to next-generation of disposable wearable electronics (i.e. as part of glasses, shoes, or fabrics) that are completely autonomous. TENGs generate electrical energy by harvesting chaotic and low frequency mechanical energy from environmental or human motions (i.e. waves, wind, walking, running) through the coupling of triboelectric effect and electrostatic induction.
To date, PTFE and other fluorinated polymers accounted for negative tribolayers in more than 50% of reported TENGs in the literature. However, there are growing global interests in replacing petroleum-based non-biodegradable plastics by green natural materials to attain a higher sustainability and a lower environmental impact. As a result, (ligno)cellulose, ubiquitous as a low-cost, renewable, biocompatible, and biodegradable material, has attracted significant attentions. Previous studies demonstrated the potential of using renewable lignocellulosic materials as the tribopositive layer replacing other common tribopositive substrates (such as metals, metal oxides, and petroleum-based polymers).
Here, we report the discovery of a natural tribonegative material, LCNFs, wherein the lignin bound on the surface of the cellulose nanofibrils possess strong tribonegative properties by acting as an electron-withdrawing component. Specifically, we demonstrated that LCNF nanopaper performed as a highly tribonegative layer in TENGs, outperforming PTFE and conventional petroleum-based plastic tribonegative materials. When LCNF nanopaper was combined as a tribonegative layer with aluminum as a tribopositive one in a zigzag structure to form a cascade type of TENG, it could be used as a power source to run a wireless communication node, which had never been achieved before by any reported TENGs containing a natural material as the tribonegative layer. Our results illustrated the excellent promise of using lignocellulosic materials as green alternatives to fluorine-containing polymers in high power output TENGs for developing green self-powering wireless disposable electronics. We report for the first time a natural wood-derived lignocellulosic nanofibrils (LCNF) tribolayer that could replace fluorine-containing petroleum-based polymers as a tribonegative material for TENGs. The high tribonegativity was due to the presence of natural lignin on the surface of LCNF. The LCNF nanopaper-based TENGs produced significantly higher voltage (~160%) and current (~120%) than TENGs with PTFE as the tribonegative material when paired with various polymeric/metallic tribolayers. Furthermore, assembling LCNF nanopaper tribolayer into a cascade TENG generated an output sufficient for powering a wireless communication node, capable of sending a radio-frequency signal to a smartphone every 3 minutes. This study demonstrates the excellent promises of using LCNF to make high-

performance and more environmentally friendly wireless self-powered electronics; and thus pinpoints a new approach for fabricating sustainable triboelectric nanogenerators using natural lignocellulosic materials instead of conventional fluorine-containing petroleum-based polymers as

SB02.03.08
Edible, Strong and Water-Repellent of Bacterial Cellulose by Biosynthesis/Physical Modification and Its Potential Application on Food Packaging
Ka Man Cheung and To Ngai; The Chinese University of Hong Kong, China

The ubiquitous petrochemical-based plastics have caused serious waste pollution in the environment. In the last few decades, scientists have tried to exploit a variety of degradable bio-based polymers to replace plastics and take effort for improving their properties. Bacterial cellulose (BC) has been a spotlight on food packaging, including green route of biosynthesis, low energy purification process and high quality of product with strong mechanical properties[1]. However, the high hygroscopicity of such material becomes its major obstacle to be used as food packaging.

Herein, a new strategy for fabricating the edible, strong, translucent, water-repellent, and biodegradable BC-based composite packaging was proposed via biosynthesis, with the help of organic-biobased additive in the culture medium and the alginate-polyol composite as the physical coating. After the modification, a completely edible, non-toxic film with steady, strong mechanical properties in both dry and humid environments can be achieved, further displaying the advancement including large-scale production and simple reaction with low energy-efficient process. All in all, this composite material demonstrates a high potential in contributing to a more environmentally friendly kind of food packaging material and reduces the reliance on the use of plastics.

Low Poisson's Ratio Stretchable Films Prepared by Hydrogel Temperature Responsiveness Jisu Shin and Jonghwi Lee; Chung-Ang University, Korea (the Republic of)

In the research on stretchable films such as wearable display elements or sensors that can be attached to the skin, shrinkage of the film width due to the positive Poisson's ratio has been a problem. Recently, research on auxetic structures with negative Poisson's ratio is being conducted as a solution, but there are limitations in the application because it is 3D-printing structure form which is not a film. Herein, we conducted a study on a film with a low Poisson's ratio by using cellulose nanocrystal (CNC), poly(N-isopropylacrylamide) (PNIPAm), and hydroxypropyl cellulose (HPC) as fillers and using the alignment of fillers and the shrinkage characteristics of the hydrogels. The composite film was aligned with fillers using directional melt crystallization (DMC) method. DMC is a method for obtaining a porous structure by controlling the three-dimensional temperature gradient. Through the DMC, porous structure with CNC, PNIPAm, and HPC can be obtained, and this is confirmed through SEM. In the case of PNIPAm and HPC, it can be observed through SEM that the existing pores are formed into a re-entrant structure due to hydrogel shrinkage. This re-entrant structure makes low Poisson's ratio. After shrinking process, stretchable films are manufactured by infiltration of polydimethylsiloxane (PDMS), and polyurethane (PU) to the aligned foam. For CNC film, the Poisson's ratio is 0.103, and for CNC with PNIPAm film's Poisson's ratio is 0.043. This is significantly lower than the PDMS Poisson's ratio of 0.5, and as the concentration of fillers increases, the Poisson's ratio tends to decrease. In the case of the CNC and PU film, which is more stretchable than PDMS, the Poisson's ratio is 0.102 and the strain and young's modulus values are 500% and 1.28 MPa respectively, which is higher than the CNC with PDMS films. The areal strain ratio of CNC with PNIPAm is 6% and in order to further enhance the effect of the re-entrant structure, it was manufactured by replacing with HPC, and this film of areal strain ratio is 19%. The maximum transmittance of the films in this study reached up to 80% by UV-vis. Through transparency and complementation of physical properties, this film research can be applied to more diverse future material applications.

SB02.03.11
Preparation of Ionically Modified Self-Assembled Films Based on Cellulose Nanocrystals Diana Gaspar[1,2], Paul Grey[2], Bruno Mendes[2], Madalena Roque[2], Rodrigo F. Martins[2] and Luis Pereira[1,2]; [1]AlmaScience, Portugal; [2]FCT-NOVA, Portugal

Many approaches exist in the quest for efficient, abundant, cheap and eco-friendly photonics that can be easily integrated with other platforms for practical applications.
Approaches using 3D metamaterials, mesoporous semiconductors or plasmonic are promising. However, they tend to be complex in fabrication involving methods that require high energy input (such as vacuum and physical vapour deposition) for the deposition of materials, and in many cases not so green materials, nor sustainable, are expensive and colour limited.
Currently, we are facing a never-increasing interest to move to more sustainable materials that can achieve equivalent results for less energy input, and Nature is a privileged source of inspiration for the greatest technological advances. The steady and long optimization over millennia of periodic structures as the ones present in chameleons or iridescence mechanisms in beetles or butterflies, attract a lot of attention to natural micro and nanostructures. One attempt to mimic those assemblies is being pursued using cellulose nanocrystals (CNCs) that are able to self-organize into a chiral nematic liquid crystalline phase in aqueous suspensions. When the solvent is dried the chiral arrangement is retained and solid films are obtained that behave like 1D photonic crystals with iridescent colours. The intrinsic left-handedness of such structures is capable of interacting selectively with left and right-circular polarized light (LCPL and RCPL).
The manipulation of the pitch and therefore the reflected colour is particularly interesting and one of the topics that catch the attention in this field. Approaches to manipulating the self-assembly of the CNC by either using external stimuli such as magnetic and electric fields, drying process with different interfaces or playing with the chemistry behind the acid hydrolysis are examples of solutions to shift the photonic bandgap throughout the visible and infra-red spectrum.
With this work, we demonstrate that CNC suspensions low concentrations (~4-5wt.%) with proper evaporation-induced self-assembly conditions lead to the formation of films with interesting photonic properties with a left-handed twisted arrangement. The novelty of this is the use of strong acid cation resins to mediate the counterion exchange on commercial CNCs. It was observed that the addition of different concentrations of alkali salts to the CNCs suspension leads to a blue shift of the photonic bandgap with higher salt concentrations. Also, it was observed that the ageing of the suspensions can enhance the distinction between LCPL and RCPL (initial $\Delta CPL \approx 42\%$ to an $\Delta CPL \approx 60\%$), while the photonic bandgap remains nearly unchanged. Combining the photonic character of the tailored CNC films, whose photonic bandgap can be match with the bandgap of light sensitivity of semiconductor materials based on ZnO, it will be possible to create devices capable of discrimination between LCPL and RCPL signals in the blue region.

SB02.03.12
Paper Transistors for Logic and Analogic Applications Rodrigo F. Martins[1,2]; [1]UNINOVA, Portugal; [2]FCT UNL, Portugal

The aim of this presentation is to report the physics and electronics behaviour of a dual gate paper transistor where paper is simultaneously the substrate and the dielectric, while a metal-oxide-semiconductor (IGZO) is used as the active channel, and a back floating electrode is used, able to present logic

functionalities simply by varying the amplitude and frequency of the input gate signals. These transistors operate at drain voltages of 1 V with low power, exhibiting $I_{ON}/I_{OFF} > 10^4$ and mobility ≈ 2 $cm^2V^{-1}s^{-1}$, serving the specifications for a broad range of smart disposable low-power electronics. To sustain all this, an analytical compact model was developed able to precisely reproduce the response of paper-based dual-gate FETs and provide a full understanding of their unique and innovative operational characteristics.

SB02.03.15

Environmentally-Friendly Chemical and Physical Methods for Deweaving and Functionalization of Waste Cotton Fabric Ivan J. Yuan[1], Hannah Tao[2], Andrew Yuen[3], Elizabeth Zhang[4], Aleena Sheikh[5], Michael Cuiffo[6] and Miriam Rafailovich[6]; [1]Shanghai High School International Division, China; [2]Academy for Information Technology, United States; [3]Jericho High School, United States; [4]Massachusetts Institute of Technology, United States; [5]MDQ Academy, United States; [6]Stony Brook University, The State University of New York, United States

As the demand for cellulosic fibers increases, the amount of cotton fabric waste produced also increases. Many methods currently available for recycling cellulose involve costly and potentially hazardous reagents such as ionic liquids and N-methylmorpholine-N-oxide [1]. We will show that mild physical and chemical treatments can deweave cotton fabric into fibers that can then be re-weaved or repurposed for many applications.
Diagonally-cut cotton muslin fabric pieces of around 0.25 g were deweaved using a 40 mL solution of 0.5 M citric acid, 0.5 M sodium nitrate, or a 3:1 mixture of the two aforementioned solutions, being stirred at 600 rpm and 50°C. Samples were subsequently washed, with multiple rinses of vacuum filtration with deionized water (>18mΩ/cm), and then vacuum dried. The solution was shown to successfully deweave material, however significant decreases in solution volume, pH, and fiber bleaching imply that the solution requires replenishment by adding fresh stock solution with each reuse. Around 93% of the mass of the untreated fabric was retained after deweaving, and suspended microfibers could be observed in the final solution.
The untreated fabric and deweaved fibers were examined using Fourier-transform infrared (FTIR) spectroscopy, which indicates preservation of the β-glycosidic linkage (898 cm^{-1}) in cellulose as well as other peaks characteristic of cellulose. Comparison of the peak associated with the C=O stretching vibration (1727 cm^{-1}) shows that this peak is insignificant for the untreated cotton fabric and the fibers deweaved with sodium nitrate, but is clearly seen in the fibers deweaved with the 3:1 mixture and is even higher in the fibers deweaved with citric acid, suggesting that esterification between citric acid and cellulose occurred. This is supported by the results of a back titration experiment, using sodium hydroxide and then hydrochloric acid, performed on the citric acid-deweaved sample. After titration, the fiber surface exhibited a color change to that of the indicator's acidic form, which could result from citrate groups added during esterification.
Tensile strength tests were conducted on individual fibers to characterize mechanical changes after deweaving. Compared to fibers from the untreated fabric, fibers deweaved with citric acid have a lower ultimate tensile strength (175 MPa compared to 404 MPa) but a greater elongation at rupture (5.8% compared to 4.6%). However, the untreated fibers snapped upon reaching the ultimate tensile strength, while the fiber strands within the deweaved fibers were gradually pulled apart, pointing to the decrease in friction between fiber strands. This is supported by previous results from X-ray computed tomography and scanning electron microscopy, which show that the fiber bundle is less tightly packed after deweaving. Negative zeta potential values (-3 to -6 mV) on the solution with suspended microfibers may be due to dissociation of carboxylic acid groups from esterification, further indicating the presence of interfiber repulsion that can increase the spacing between fibers. The arrangement of cellulose polymers within the strands of fibers, and thus the strength of individual strands, is likely preserved as the total crystallinity index and the lateral order index computed with FTIR peak heights [2] show no substantial changes. Therefore, the decrease in fiber strength is likely due to physical, rather than chemical, changes.
Preliminary tests demonstrate the possibility of scaling up the deweaving procedure by using larger parallelogram-shaped pieces of fabric. Experiments are being conducted to quantify the degree of esterification, clarify the chemical basis for deweaving, retain and analyze the produced microfibers, and scale up the process.

Binary Cooperative Thermal Treatment of Cellulose and MoS_2 for Preparation of Sustainable Paper-Based Electrochemical Devices for Hydrogen Evolution Leonardo H. Hasimoto[1,2], Jefferson Bettini[1], Edson R. Leite[1], Renato S. Lima[1,2], Lifeng Liu[3] and Murilo Santhiago[1,2]; [1]Brazilian Nanotechnology National Laboratory, Brazil; [2]Universidade Federal do ABC, Brazil; [3]International Iberian Nanotechnology Laboratory (INL), Portugal

The simple, fast, scalable, and integrative preparation of sustainable electrodes using earth-abundant materials toward energy applications is a long-standing challenge. In this work, we attempted to achieve such features by developing a binary cooperative thermal process using cellulose sheets and molybdenum disulfide (MoS_2) toward hydrogen evolution reaction (HER). The thermal process converts cellulose into a highly conductive hydrophobic carbon-based material while generating chemical defects on MoS_2. The latter is of fundamental importance to improve the catalytic activity for HER through activating the well-known inert MoS_2 basal planes. Thermal desulfurization was confirmed by X-ray photoelectron spectroscopy, Kelvin probe force microscopy, Raman spectroscopy and energy-dispersive X-ray spectroscopy. Interestingly, a desulfurization gradient was observed at the MoS_2 particles, where the edges are more defective than the basal planes. The resulting defect-like MoS_2 particles are highly active toward HER. In addition, the porosity of paper enables simple filtration of catalysts and the possibility to tune electrochemically active surface area by simply adding isopropanol before the electrolysis. Finally, we showed an ultrafast coating method using a commercial MoS_2 spray on sheets of paper that enables H_2 bubble generation at specific regions of the electrode. The overpotential (η) positively shifted more than 300 mV when compared with non- treated MoS_2, reaching η = 240 mV to obtain 10 mA cm^{-2} of HER current density.

Modification of Lignocellulose at Diverse Dimensions for Tuning Functionalities of Materials Kai Zhang; University of Göttingen, Germany

In order to modify lignocellulose and convert it into functional materials for various scenarios in an environmentally friendly way, the development of corresponding chemical and also accompanying engineering methods is often required. Chemical modifications of lignocellulose demonstrate a promising strategy for endow it with various functionalities, while distinct challenges exist for the lignocellulose at various dimensions ranging from molecular to nanoscale. Herein, own advances regarding modifications of lignocellulose at diverse dimensions, either as polymers or as nanostructures, for functional materials will be presented. The introduction of diverse pending functional groups either along the cellulose chains or on nanocellulose surface will affect the structure formation and the exposure of the functionalities in the functional materials. By addressing the chemical modifications for tuning the functionalities in the final material design, further potential solutions will be opened for sustainable development to boost the use of this renewable, biobased material.

Development of Low-Cost Bio-Filled Additive Manufacturing Composite Feedstocks Xianhui Zhao[1], Halil Tekinalp[1], Erin Webb[1], Hongli Zhu[2] and Soydan Ozcan[1]; [1]Oak Ridge National Laboratory, United States; [2]Northeastern University, United States

Biomass fibers have been commonly used for reinforcing polymers (e.g., polylactic acid [PLA]) because of their low density, low cost, renewable nature, biodegradability, and abundance. In this study, pine/PLA composites were produced with a high loading (40 wt%) of pine fibers to reduce the composite feedstock cost for the additive manufacturing application. To improve composite performance, low-cost aspartic acid was incorporated. The aspartic acid loading was optimized, and the composites prepared were characterized to understand the effect of aspartic acid content on different composite properties using tensile testing, dynamic mechanical analysis (DMA), thermogravimetric analysis (TGA), gel permeation chromatography (GPC), differential scanning calorimetry (DSC), scanning electron microscopy (SEM), and rheological testing. Results show that the Young's modulus of the composites was improved by 30% with the addition of a small amount of aspartic acid (0.7 wt%). The coupling agent was found to be effective in tuning the properties of the composites for specific applications.

9:45 AM SB02.06.03
Laser-Induced Carbonization of Sodium Chloride-Impregnated Cellulose Nanofiber Films for Efficient Moisture-Electric Energy Transformation Jakyung Eun, Seonghye Ha, Jaehyun Na and Sangmin Jeon; Pohang University of Science and Technology, Korea (the Republic of)

We developed high-performance moisture-driven power generators (MPGs) using sodium chloride (NaCl) impregnated cellulose nanofiber films (CNFs). CNFs impregnated with different amounts of NaCl were obtained by immersing CNFs in NaCl solutions of various concentrations. An infrared laser was employed to photothermally convert the CNFs to porous graphitic carbon films (GCFs) under ambient conditions. By focusing the laser beam on the top surface of the CNF, the laser intensity was the highest on the top surface and gradually decreased toward the bottom surface. Since the focal temperature of the laser beam (~2000 °C) was higher than the boiling point of NaCl, the NaCl particles near the top surface evaporated more rapidly, creating a NaCl concentration gradient along the thickness direction. In addition, the top surface became more graphitized than the bottom surface, producing a more porous structure on the top surface. When the GCF was exposed to moisture, the dissociated sodium ions migrated along the preformed concentration gradient, producing electricity. The maximum voltage and current outputs were 0.65 V and 550 μA/cm^2, respectively, at 90% relative humidity (RH). In particular, the current density output was produced continuously rather than pulsed, and was the highest current reported so far. Such a high current density was obtained by impregnating excess ions and implementing a high NaCl concentration gradient using LIG along the thickness direction of the extremely thin GCF. Furthermore, the porous structure of the GCF was found to produce higher performance than the graphene oxide-cellulose nanofiber composites (GO-CNF) with NaCl due to the presence of more water pathways for ion transport between electrodes. The developed device demonstrated its applicability by turning on four green light-emitting diodes (LEDs) operating at an onset potential of 2 V for 48h using six GCFs (each 3 mm × 3 mm × 240 μm in size) connected in series without a separate rectifier circuit and capacitor. Since moisture is ubiquitous, it has great potential for a wide range of applications such as sweat-powered wearable devices and remote environmental sensors.

10:00 AM SB02.06.04
Hybrid Materials from Cellulose Nanofibrils and Charged Core-Shell Nanolatexes Asa Jerlhagen[1,2], Alexandros E. Alexakis[1], Rosella Telaretti Leggieri[1], Adrian Eliasson[1,2] and Eva Malmström[1,2]; [1]KTH, Sweden; [2]FibRe; A Vinnova Competence Centre, Sweden

Cellulose nanofibrils (CNFs) are one of the most promising lignocellulosic feedstocks for the design of sustainable and advanced materials to meet the challenges of the future. CNFs are produced as aqueous colloidal dispersions of fibrils with diameters of a few nanometers and aspect ratios of several hundred. These dispersions can be dewatered in different processes to give foams, membranes, nanopapers, and nano-reinforcements, to name a few. The mechanisms for dewatering, and the impact of additives upon the assembly of nanofibrils, remains a challenging topic with great potential for tailoring the material to new properties and applications.
The exploration of core-shell polymeric nanolatexes as CNF additives is still just in its infancy. In this project we combine CNFs with a nanolatex synthesized through reversible addition−fragmentation chain-transfer (RAFT)-mediated polymerization-induced self-assembly (PISA) in water. The PISA process makes for a flexible platform in the synthesis of functional nanolatex with tunable size, surface charge and functionality. These nanoparticles have already shown great promise as compatibilizers when adsorbed to CNFs [1], and early work has indicated the introduction of interesting mechanical behavior to CNF materials [2].
In this project we investigate structures formed between anionic CNFs and small additives of a cationic nanolatex. We look at the impact of nanolatex charge and size as nanolatex is adsorbed to CNFs in dispersion and dewatered to give hybrid structures. The addition of nanolatex affects the mechanical properties, water sensitivity and response to heat treatment of these materials. The current work is an indication that nanolatexes can act as efficient compatibilisers for CNF networks, and that these hybrid structures deserve further systematic investigation.

Molecular Engineering of Biorefining Lignin Waste for Solid-State Electrolyte Hongli Zhu; Northeastern University, United States

Current global energy sector is still dominated by the fossil-based energy. Renewable energies, especially these derived from Nature have been extensively sought after as a sustainable solution for emerging energy needs. Among them, wood-derived energy and erengy storage devices come of the age in recent years. However, current convertion of wood and other plant as well into energy, either the energy storage devices or biofuel production, heavily depends on the delignification, which is a process to remove the lignin polymer exsited in plant cell wall. In fact, lignin is the second most abundant biopolymer on earth next to cellulose but a massive industrial waste produced both in paper industry and biofuel manufacturing. Our concept in this research is to convert this industrial lignin waste from biofuel production (also known as biorefining) into solid-state electrolyte (SSE) to enable its application in next generation lithium battery.
The rationale of our experimental design lies in the abundant hydroxyl groups in the lignin polymer, which provides grafting sites for bonding polyethylene glycol (PEG), a most efficient polymer for the SSE of the ASSLBs. Moreover, lignin polymer itself contains plentiful aromatic rings and rich electron-donor groups such as ether type linkages, methoxyl groups (-OCH3), and aromatic and aliphatic hydroxyl groups. These chemical structures of lignin facilitate its interactions with Li salt and improve ion conduction at the interface when ceramics were added into the SSE. We prepared two types of SSE by using the synthesized PEG-g-lignin. The first one was solid polymer electrolyte (SPE), which was prepared by mixing PEG-g-lignin with poly(vinylidene fluoride)-co-hexafluoropropylene (PVDF-HFP) and lithium bis(trifluoromethanesulfonyl)imide (LiTFSI). The resultant SPE had an ionic conductivity of 2.5 × 10-5 S cm-1 at 25oC. The second one was composite polymer electrolyte (CPE), which was prepared by adding Li6.4La3Ga0.2Zr2O12 (LLGZO) into the PEG-g-lignin and PVDF-HFP composite. The ionic conductivity of the resultant CPE was further enhanced to 6.5 × 10-5 S cm-1. This ionic conductivity represents 2.6×105-fold and 2.8×103-fold higher than that of pure PVDF-HFP (9.7 × 10-11 S cm-1) and pure PEO (9.0 × 10-9 S cm-1) based SSE, respectively. Mechanistic study by using 2D HSQC NMR revealed that PEG-g-lignin has increased ether type β-O-4 linkages that can promote the interchain hopping of Li+ between lignin polymer chains, and 31P NMR revealed that lignin phenolic end can be associated by Li+.
The research has both significant novelty and broad impact. 1). The study converted a largely overlooked biorefining waste into the solid-state electrolyte, which opened up a new avenue for industrial waste valorization toward a thriving billion dollars market of next generation lithium battery. 2). By substituting petroleum-derived PEO and other synthetic polymers for SSE, plant-derived lignin polymer will indeed transform the sustainability of current ASSLBs. 3). The study also informed a broader research community and opened new avenues for building up a holistic bio-based energy system. The integration of a sustainable energy storage manufacturing with biofuel production platform will transform current energy sector by simultaneously enhancing biofuel production and promoting the biopolymers from Nature into high energy density, high cycling performance and safe ASSLBs.

11:15 AM SB02.06.06
Injectable Lignin Based Cryogels with Antioxidant and Antibacterial Properties for Biomedical Applications Adnan Memic[1], Turdimuhammed Abdullah[1], Thibault Colombani[2] and Sidi A. Bencherif[2]; [1]King AbdulAziz University, Saudi Arabia; [2]Northeastern University, United States

Hydrogel-based biomaterials, especially those derived from natural polymers, have been regarded as one of the most promising scaffolds for biomedical research. These multifunctional scaffolds can exhibit high water adsorption capacity, biocompatibility, and biomechanical properties that can match native tissues. Cryogels are a special type of hydrogels in which polymers are cross-linked around ice crystals. As a result, cryogels exhibit unique physical features, including a macroporous and interconnected network, flexibility, shape-memory properties, and syringe injectability. Herein, we developed a multifunctional, i.e., antibacterial, antioxidant, and injectable cryogel by combining lignin with gelatin. The cryogel with 0.2% lignin showed a compressive modulus of 25 kPa and a compressive stress of 140 kPa at 80% strain, which is, respectively, 1.8 and 7 times higher than those of the pure gelatin cryogels. Meanwhile, such a cryogel formulation could completely recover its shape after compression up to 90% and was needle-injectable. Additionally, the lignin-*co*-gelatin cryogel inhibited the most common surgical site infection-associated pathogenic bacteria. Furthermore, lignin-*co*-gelatin cryogel was found to scavenge free radicals and have good cytocompatibility, and the cryogels with up to 0.2% lignin minimally activate naïve mouse bone marrow-derived dendritic cells. Overall, the current approach shows great promise for the design of bioresource-based multifunctional cryogels for a wide range of biomedical applications.

11:30 AM SB02.06.07
Utilization of Ultrasonication and Plasticizers to Increase the Thermo-Processability of Lignocellulose Adrian Eliasson[1,2], Eva Malmström[1,2], Lars Wagberg[1,2], Mikael Hedenqvist[1,2] and Anette Larsson[3,2]; [1]KTH The royal institute of technology, Sweden; [2]FibRe Lignocellulose-based Thermoplastics A VINNOVA Competence centre, Sweden; [3]Chalmers University of Technology, Sweden

Polymeric materials are essential in today's modern society and their production has increased exponentially since their commercialization in the 1940s. One of the largest industrial sectors is packaging, estimated to 146 million tons in 2015 [1]. A large fraction of the packaging material is single use and ends up in landfill or is incinerated, as most plastics used are non-degradable and recycling is still challenging in large parts of the world. Material research has focused on decreasing the environmental impact of these kinds of materials by reducing and replacing them with, for example cellulose-based materials like cardboard, but also more innovative materials like bio-based foams. Cellulose is an abundant biopolymer already widely used, while also being bio-degradable and recyclable. One limiting factor for conventional cellulose-based materials is the limitations when shaping cardboard and paper-based materials. Although cellulose is a polymer it does not show typical polymeric behaviors such as thermo-processability which most synthetic polymers do. Our approach, inspired by plasticization of gluten [2], is to incorporate a small amount of plasticizer into the lignocellulose matrix. Our hypothesis is that the small plasticizing molecules will reduce the strong intermolecular interactions within cellulose and enhance the molecular mobility. Successful implementation will increase the lignocellulose's thermo-processability and yield a material which can be processed through conventional thermo-processing such as extrusion or injection moulding allowing more advanced shaping opportunities than existing methods.

A step on the way has been the incorporation of different bio-based plasticizers through ultrasonication as a means to open up the fibers, aiding the sorption of glycerol, urea, and citric acid. The formed materials have been evaluated in regard to plasticizer content, thermal behavior, mechanical properties, degree of crystallinity and interaction with water. In this work, the primary focus was to understand the effect of ultrasonication on plasticizer sorption and its correlation to the highly improved physical properties of the formed materials. The sonication itself, a high energy treatment, peels off fibrils from the fiber surface, breaks down the crystal region and exposes hydroxyl groups which in turn increase the ductility and ultimate strength compared to the reference material [3]. The combination of plasticizer and sonication aids the sorption of urea and glycerol which leads to an increase in the ductility and ultimate strength further. As a result, a 100% bio-based material consisting of more than 75 % lignocellulose is under evaluation as an extrudable material for packaging applications with the potential to be bio-degradable and/or recyclable.

Using renewable resources to produce a thermo-processable lignocellulosic material as a potential alternative to single use plastics in the packaging industry has the potential to reduce our need for fossil-based materials, promote circular materials and reduce CO_2 emissions. This in turn contributes towards the fulfillment of circular bioeconomic principles and the United Nations Sustainable Development Goals 2030.

Pharmaceutical Manufacturing on Reconfigurable Paperfluidics Josselyn Mata-Calidonio[1], Jose Gomez-Marquez[2] and Kimberly Hamad-Schifferli[1]; [1]University of Massachusetts Boston, United States; [2]PopUp Labs, United States

We discuss the use of paperfluidic devices for the synthesis of molecules and nanoparticles using Asynchronous Modular Paperfluidic Linear Instrument-free (Ampli) blocks, which are paper membranes on blocks that can be interlocked together in different configurations. Reagents are embedded into the paper membranes of each block, and blocks are snapped together in a desired sequence for a chemical reaction. The reaction is initiated by adding solvent to the first block, which allows the reagents to flow from one block to the next. We synthesized both gold nanoparticles and pharmaceutically relevant small molecules. Extracted reaction products were characterized using Raman, optical absorption, and dynamic light scattering spectroscopies. Kinetics of reactions and parameters for reaction optimization will be discussed. Ampli blocks allow small scale, on-demand synthesis of molecules and thus can potentially enable de-centralized chemical production, which has the potential to address the challenges associated with supply chains in pharmaceutical distribution. Furthermore, because Ampli blocks can be easily reconfigurable by the enduser, it can be deployed in extreme environments by non-trained experts.

SESSION SB02.07: Lignocellulose Processing and Application II

Cellulose Based High Performance Ambient Water Harvesting Tian Li; Purdue University, United States

Emerging atmospheric water harvesting (AWH) technologies promise water supply to underdeveloped regions that have no access to liquid water resources. The prevailing AWH systems, including condensation- or sorption-based, mostly rely on a single mechanism and thus have a limited range of working conditions and inferior performance. We synergistically integrate multiple mechanisms, including thermosorption effect, radiative cooling, and multiscale cellulose-water interactions, and demonstrate a low-cost (~ 4 USD kg− 1) and high performance (up to 6.75 L kg− 1 day− 1 in field tests) AWH system requiring zero active energy input. The proposed system consists of a highly scalable and sustainable cellulose scaffold impregnated with hygroscopic deliquescent lithium chloride (LiCl) salt. Cellulose scaffold and coated LiCl synergistically interact with water at different scales from molecular, to nanometer, and micrometer scales, providing a fast harvesting rate and high yield over a wide operation range. Iterating radiative cooling and solar heating workflow achieves simultaneous enhancement of water capture and release through the so-called temperature-swing strategy. The captured water in return facilitates radiative cooling due to the intrinsically high infrared (IR) emissivity of the LiCl-cellulose composite. With our simple yet effective material design, the AWH working range extends to lower than ~ 10% relative humidity (RH), and the water uptake in the controlled lab test reaches 16 kg kg− 1 at 90% RH (sample at 19°C, i.e. 6°C below 25°C ambient temperature). In addition, we propose a theoretical model capable of elucidating the experimental water uptake curves and demonstrating the synergy among cellulose-LiCl-water-energy interaction. The promising performance emphasizes the potential of involving multiple AWH mechanisms and points to an alternative pathway to stimulate future improvement.

2:00 PM SB02.07.02
Chitosan-Based N-, S-Doped Nanostructured Carbon/Graphene Oxide Composite as a Sulphur Host in the Lithium-Sulphur Batteries Kirill Murashko, Sara-Maaria Mesceriakove, Anna Lähde and Jorma Jokiniem; University of Eastern Finland, Finland

Among the all next-generation batteries the lithium-sulphur battery, which uses extremely cheap sulphur as the positive electrode and the ultra-high-capacity lithium metal as the negative electrode, is at the forefront of emerging battery technologies by offering higher specific energy, at a lower price and lower CO_2 footprint compared to today's lithium-ion (Li-ion) batteries. Because of the complex, multi-electron chemical reaction the theoretical gravimetric energy density of the Li-S batteries is 2 567 Wh/ kg, which is 4.5-fold higher than the conventional lithium-ion technologies have. However, the instability of the sulphur cathode and lithium metal anode, which results in the poor cycling stability of the battery are the main factors that have limited the successful commercialization of this technology. In Li-S batteries, the liquid electrolyte and the sulphur cathode act like a couple to form the highly soluble lithium polysulfides (LiPS), which causes the well-known “shuttle effect” and lead to the loss of active material, Li metal anode corrosion, and low coulombic efficiency during interaction of the LiPS with Li metal anode. Moreover, the sulphur by itself has a high-volume change over the cycling and low conductivity that also have a negative effect on the electrochemical performances of Li-S batteries. Currently, the most perspective solution to address the above drawbacks is incorporating sulphur with a porous carbon host, which will tolerate sulphur volume expansion, improve the conductivity of the electrode, prevent the shuttle effect and allow reversible lithium-ion migration during charging and discharging. The high conductive carbon materials such as graphene and graphene oxide were suggested as one of the best options as hosts for sulphur in the Li-S battery cathode. These materials not only have a high electrical conductivity but may be doped with different functional groups, which improve the electrochemical properties of the Li-S battery cathodes. However, the currently available synthesis methods for these materials are complex, expensive, and usually require using of the highly toxic chemical. Moreover, the sulphur loading in such a host is limited by the material porosity and restacking possibility of the graphene or graphene oxide sheets.
In our current work, we investigated the possibility to decrease the amount of graphene oxide during the creation of the sulphur-graphene oxide composite material. We proposed a one-step carbonization method to prepare 3D nanostructured porous nitrogen and sulphur dopped carbon materials where graphene oxide is used as the conductive support for the carbon. Such 3D nanostructured carbon materials were created by using chitosan hydrogel as the main carbon source. Chitosan is mainly produced by the deacetylation of chitin which is the second most abundant and renewable biopolymer after cellulose. The chitosan has large amounts of amino groups, which leads to the creation of the self-nitrogen-doped carbon after the pyrolysis process. In addition, thiourea and potassium carbonate are introduced into the chitosan hydrogel and play key roles in optimizing the structure of the carbon material. Thiourea not only generates gas through pyrolysis to form pores, but its own rich nitrogen and sulphur elements can be partially retained in the finally obtained carbon material. The structural, compositional, and morphological properties of the created material were investigated using SEM, EDS, Raman spectroscopy, FTIR and TGA techniques. The produced N,S-doped nanostructured materials have a high surface area of up to 1500 m^2/g and because of the heteroatom doping allow to improve the electrochemical performance of the Li-S battery cathode, when the developed material is used as the sulphur host.

2:15 PM SB02.07.03
The Secret Ingredient, Cellulose—Exploring Its Potential in Desalination Membranes Raed Hashaikeh; New York University Abu Dhabi, United Arab Emirates

Seawater desalination by utilizing a membrane-based technology is a crucial step to overcome the freshwater shortage in some regions of the world. However, the durability and performance of membranes rely on the type of materials and fillers utilized for the fabrication of the membrane. In the efforts towards sustainable, biocompatible, low cost and economical materials, cellulose-based materials or derivatives are the main focus to develop membranes for water desalination. Herein, cellulose is explored as:
Novel material with unique structure to control swelling of reverse osmosis membranes.
Innovative entrapping media for better electrically conductive desalination membranes.
Coating layer to create hydrophilic surface for better desalination of oily wastewater.
Anti-swelling desalination membranes. Novel networked cellulose (NC) material is prepared via combination of controlled sulfuric acid hydrolysis and calculated ethanol regeneration of microcrystalline cellulose (MCC). While acid concentration was kept constant at 70%, factors such as hydrolysis time and temperature were varied to obtain the unique structure. The high-yield material has interesting mechanical integrity with tangled networked fibers that make it suitable for improving materials properties. NC was employed as an anti-swelling material that improved the performance of polyvinyl alcohol (PVA) reverse osmosis (RO) membranes. The open structure of NC entraps the PVA polymer inside and restrict PVA from expanding. This in turn imparts it stability against swelling. In addition, the hydrogen bonding formed provides a compact structure and thus prevents the membrane from swelling. The swelling capacity of PVA was reduced from 340% to 150% without compromising desalination performance. In addition, the tensile strength of wet PVA improved 1520% and the elastic modulus improved 1400% upon blending with NC.
Electrically enhanced fouling control nanofiltration/RO membranes. Electrically conductive membranes based on NC and carbon nanostructures (CNS) were fabricated via vacuum filtration. The hydrolysis process of cellulose was exploited to better incorporate and entrap CNS within the NC structure. High surface area multi-walled CNTs become trapped in the structure of networked cellulose. Membranes were tested and analyzed for their electrocatalytic activity and explored for their potential in fighting fouling issue. Furthermore, the compaction of pores via incorporation of NC resulted in promising results with respect to nanofiltration of divalent ions, with a rejection of 60% for $MgSO_4$ and 47% for $CaCl_2$, while maintaining a high flux of $\geq$ 100 L m^{-2} h^{-1}. Furthermore, NC/CNS/PVA membranes demonstrated enhanced electrocatalytic activity. The RO membranes were tested with 25,000 ppm NaCl as feed, and exhibited 99.8% salt rejection with 93% increase in flux compared to PVA-NC with no CNS implying homogenously mixed CNS. The membrane surface was recovered after fouling via electrolytic cleaning where the membrane was used as the cathode and a potential of −5 V was applied for 20 min.
Improved distillation membranes (MD). A novel concept of stacking two membranes with different wettabilities to obtain a dual-layered membrane was developed. The hydrophilic top layer composed of electrospun PVDF-HFP impregnated with regenerated MCC cellulose while the bottom layer kept hydrophobic. Top layer acted as a hydrophilic barrier preventing oil from passing to the hydrophobic bottom layer during MD process. When tested with saline feed containing 1000 ppm of oil, the stacked dual-layered membrane yielded fresh water flux up to 12.8 kg m^{-2} h^{-1} with complete salt rejection revealing a simple and scalable method for oily wastewater treatment using relatively inexpensive, abundant and ecofriendly materials.

2:30 PM BREAK

3:30 PM *SB02.07.04
Molecular Engineering of Cellulose-Based Materials for Advanced Applications Qi Dong and Liangbing Hu; University of Maryland, United States

The natural abundancy, sustainability, and hierarchical structure of cellulose-based materials make them a promising platform for developing new functionalities. In particular, molecular engineering of cellulose-based materials holds great promise in constructing tailored nanoscale structures and therefore unique properties. In this talk, we will first introduce a general design strategy for achieving one-dimensional (1D), high-performance ion conductors through molecular engineering of cellulose nanofibrils by Cu^{2+}-coordination. The cellulose nanofibrils by themselves are not ionic conductive; however, by opening the molecular channels between the cellulose chains through Cu^{2+} coordination we are able to achieve high ionic conductivities. This enhanced ion transport is enabled by a unique cation hopping mechanism that is decoupled from the polymer segmental motion. As a proof-of-concept demonstration, we show that such decoupling gives rise to multiple advantages of the cellulose-based Li-ion conductor, including a high transference number (0.78 vs. 0.2–0.5 in other polymers), low activation energy (0.19 eV), and a wide electrochemical stability window (4.5 V) that accommodate both Li metal anode and high-voltage cathodes. We further demonstrate this 1D ion conductor not only as a thin, high-conductivity solid-state electrolyte but also as an effective ion-conducting additive for the solid cathode, providing continuous ion transport pathways with a low percolation threshold, which allows us to enable the thickest $LiFePO_4$ solid-state cathode ever reported for high energy density.
In a separate topic, we will discuss a Cu^{2+}-crosslinked chitosan (chitosan-Cu) material as a stable and high-performance hydroxide exchange membrane. Similar to the structure of the Cu^{2+} coordinated cellulose, the Cu^{2+} ions are coordinated with the amino and hydroxyl groups of chitosan to crosslink the chitosan chains, forming hexagonal nanochannels (~1 nm in diameter) that can accommodate water diffusion and facilitate fast ion transport. The chitosan-Cu exhibits a high hydroxide conductivity of 67 mS cm^{-1} at room temperature, which is among the highest compared to other hydroxide exchange membranes. In addition, the Cu^{2+} coordination also enhances the mechanical strength of the membrane, reduces its permeability, and most importantly, improves its stability in alkaline solution. These advantages make chitosan-Cu an outstanding hydroxide exchange membrane candidate for fuel cells and electrolyzer, which we demonstrate in a direct methanol fuel cell that achieves a high power density of 305 mW cm^{-2}.

4:00 PM SB02.07.05
Direct Laser Writing of Laser-Induced-Graphene (LIG) on Recycled Wood for Smart Furniture Applications Han Ku Nam[1], Dongwook Yang[1], Truong-Son D. Le[1], Younggeun Lee[1], Byunggi Kim[2], Young-Ryeul Kim[1], Seung-Woo Kim[1] and Young-Jin Kim[1]; [1]KAIST, Korea (the Republic of); [2]The University of Tokyo, Japan

About 30% of the earth's land is covered by forests, which are mostly composed of trees. As such, wood is naturally abundant and inexpensive; thus, it has been used for a variety of purposes, including furniture, paper, buildings, and vehicles for thousands of years. Today, it is mainly utilized in thermal power plants as a fuel material. Recently, strong interest in green technology has risen around the world, so extensive studies are being conducted on transparent wood formation and wood-based carbonization filter production. Since recycling is more spotlighted for carbon naturalization to save the earth, the global wood recycling market also keeps expanding. However, the key applications of recycled wooden biomass or waste woods have been limited to manufacturing the packaging boxes, fuel biochips for cogeneration plants, fertilizers, and synthetic woods. Biochip production is the largest portion of the wood recycling market, but substitute renewable energy sources, such as solar power, wind power, and tidal power technologies are being actively developed. Therefore, more attractive wood recycling technology needs to be developed. Direct laser writing of Laser-Induced-Graphene (LIG) is considered as one of the technology candidates for taking eco-friendly and economical benefits of waste woods into new markets. Our group reported that high-quality three-dimensional porous multilayer graphene can be formed by illuminating femtosecond laser pulses in ambient air without additional fire-retardant treatment or an inert gas environment. Here, we report femtosecond-laser-direct-writing (FsLDW) of LIGs on recycled waste wood for realizing smart furniture. We tested the LIG formation on particleboards, medium-density fiberboards, and oriented strand boards, as the recycled wood examples.

Ytterbium-doped fiber femtosecond laser with a 250-fs pulse duration, a 1040 nm center wavelength, and a 200 kHz repetition rate was used as the light source with a beam-scanning Galvano scanner with a maximum scanning speed of 2.0 m/s. Various combinations of laser power, wavelength, and beam scanning speeds were delivered onto the recycled wood samples for optimizing the LIG quality then monitored the resulting chemical composition and electrical conductivity. A low sheet resistance of 5.8 Ω/sq was attained on a medium density fiberboard; this is the best value to our best knowledge. A series of chemical composition tests, including SEM (Scanning Electron Microscope), TGA (Thermogravimetric analysis), XRD (X-ray diffraction), XPS (X-ray Photoelectron Spectroscopy), and Raman spectroscopy were performed, which confirmed the successful graphene formation. This LIG electrode will be applied to a joule heating-based heater for a stove warmer on a dining table application, a pulse sensor installed on chair armrests, and power switches without electrical metal-wire interconnects for green and smart furniture applications

4:15 PM SB02.07.07
Multifunctional Composite Paper Adaptable to Industrial Papermaking Alireza Hajian; MIT, United States

Paper lacks functions such as heat, electrical or ion conductance required for various engineering applications. For this reason, various approaches have been used to add such functions in the form of inks, nanoparticles, or biopolymers onto a prefabricated paper. These processes include screen or digital printing, and roll-to-roll press, resulting in two main categories of multifunctional paper: Printed electronics and paper microfluids analytical systems. In either of these, pulp fibers are in dry state and full-exploitation of the fiber adsorption is not possible, furthermore, it requires an added step/cost in the paper industry and devices that are coated/fabricated onto the paper, and makes the recycling process more complex.
We hereby advance papermaking by an industrially scalable chemical modification of pulp that can subsequently adsorb numerous functional materials ranging from conducting polymers to nanoparticles to turn the wet pulp into functional pulp. The functionalized pulps can then be used alone or in mixtures in industrial paper-making to form a fundamentally new form of functional paper at scale. As an example, we show a paper battery that is stable more than 1400 charge-discharge cycles.

4:30 PM SB02.07.08
Porous Silicon Nano-Quill Anodes for Lithium-Ion Batteries Nancy Chen[1], Morteza Sabet[1], Nawraj Sapkota[1], Shailendra Chiluwal[1], Craig M. Clemons[2,1], Apparao M. Rao[1] and Srikanth Pilla[1]; [1]Clemson University, United States; [2]Forest Products Laboratory, United States

The growing population and increasing energy demands are overwhelming our fossil fuel supply and limiting future generations' availability. With the rapid electrification of the transportation sector, rechargeable lithium-ion batteries (LIBs) are emerging to replace conventional fuel-based technologies. LIBs continuously evolve due to demands for higher energy density and long cycling life. Among the recent developments in anode electrode materials, silicon (Si) is regarded as the most promising replacement for graphite due to its high theoretical specific capacity (~4200 mAh g^{-1}), which is over 10 times greater than that of graphite anodes (~372 mAh g^{-1}). Despite the advancements, persisting challenges hinder the commercialization of Si for LIB anodes. Si-based electrodes are susceptible to rapid degradation due to the large volume change (approx. 400%) of Si particles during lithium insertion and extraction. The repeated volume change leads to the pulverization of the Si material, ultimately leading to decreased cycling stability from the loss of contact with the current collector. To overcome this obstacle, 3-dimensional (3D) porous and hollow nanostructures have been employed to provide sufficient void space to accommodate the volume change during electrochemical cycling. However, with the demands for material cost-reduction from industry, Si structures' strategic engineering must be cost-effective for commercial viability.
Our team has developed a patent-pending methodology for utilizing bio-renewable templates to synthesize a 3D Si architecture called Si nano-quills (SiNQs). We innovated a two-step, cost-effective process that yields SiNQs with a porous morphology and hollow interior structure. First, in a scalable sol-gel process, silica gel particles were prepared using low-cost chemicals. A unique mesoporous morphology was engineered using surfactant-modified cellulose nanocrystals as a sacrificial template. The templates were removed via thermal treatment to form silica nano-quills (SilicaNQs), which possess a 3D bulk structure comprised of hollow quill-like arms and a high degree of porosity. In the second step, we employed a low-temperature magnesiothermic reduction method to convert SilicaNQs into SiNQs with a relatively large surface area. A water-based slurry was prepared using a combination of SiNQ and graphite as the active materials. The slurry with 73 wt% MCMB graphite, 15 wt% SiNQ, 2 wt% carbon black, and 10 wt% LiPAA binder was cast onto the commercial copper foil. After room-temperature drying, the electrode was calendered, and vacuum dried. We also prepared batteries using commercial Si nanoparticles (100nm, spherical) with the same slurry composition. The 2032-type coin half cells were assembled for battery testing using SiNQ-graphite and Si-graphite electrodes (with an active mass loading of 3 mg cm^{-2}). The coin cells underwent a formation cycle at a current rate of 0.05C, followed by continuous cycling at a current rate of 0.1C (90 mA g^{-1}) over the potential range of 0.005 – 1.5 V at room temperature. The SiNQ-graphite anode offered an initial reversible capacity of 587 mAh g^{-1} and superior capacity retention of 91% after 90 cycles. In comparison, the commercial Si-graphite battery exhibited an initial capacity of 375 mAh g^{-1} and capacity retention of 61% after 90 cycles. The SiNQs possess a BET surface area of 399 m^2 g^{-1}, and a total pore volume of 0.64 cm^3 g^{-1}. The superior performance of SiNQs is due to their unique morphology that offers high surface area and porosity for effective diffusion of lithium ions and their electrochemical interactions with NQs, leading to a higher reversible capacity. Moreover, the porous architecture of SiNQs can effectively mitigate the volume change during lithiation and delithiation, thus providing a good cycling performance.

SESSION SB02.08: Virtual Session I: Lignocellulose Understanding, Processing and Application
Session Chairs: Chaoji Chen and Yuan Yao
Tuesday Morning, December 6, 2022
SB02-virtual

8:00 AM *SB02.08.02
Functional Wood Materials Ingo Burgert[1,2] and Guido Panzarasa[1]; [1]ETH Zurich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The lecture reports on new developments in the field of functional wood materials. The sophisticated and highly porous hierarchical structure of wood provides a versatile scaffold for functionalization treatments, and the mechanical properties, outstanding in view of its low density, make wood a biomaterial of choice to develop high-performance hybrid materials and composites. Structure-retaining modification and functionalization in top-down approaches allows to profit from these intrinsic features of the wood structure. Moreover, the CO_2-storing capacity and the renewable nature of wood are highly beneficial characteristics, but the potential of functional wood materials to substitute less eco-friendly engineering materials for a transition toward circular economy highly depends on processing conditions and achievable performances. In this talk, various approaches to utilize the hierarchical wood structure will be discussed along with strategies to address essential remaining challenges, including large-scale production and adherence to green chemistry principles.

8:30 AM *SB02.08.04
Supramolecular Engineering of Cellulosic Materials Chaoji Chen; Wuhan University, China

Natural polymers derived from biomass such as cellulose have emerged as a sustainable group of materials widely used in consumer products and functional devices. The renewable and sustainable features of cellulose have made it extremely attractive when competing with the petrochemical-based counterparts. Through engineering cellulosic materials at the supramolecular scale, we are able to regulate their supramolecular structure, configuration and their mechanical, electronic, ionic, fluidic, optical and thermal properties, imparting them with improved or even new functions for potential uses in multiple sustainable devices. In this talk, I will discuss the supramolecular engineering strategies of cellulosic materials and their potential uses in various sustainable devices.

9:00 AM SB02.08.05
Carbon Spheres Incorporated Cellulosic Sensing Paper for Detection of Phthalic Acid Esters in Solutions Hansini Abeysinghe[1,2], Thusitha N. Etampawala[1,1,2], Niluka Sewwandi[1], Panchali Anuchani[1] and Asurasinghe Rajamanthrilage Kumarasinghe[1]; [1]Faculty of Applied Sciences, University of Sri Jayewardenepura, Sri Lanka; [2]Faculty of Applied Science, University of Sri Jayewardenepura, Sri Lanka

Phthalic acid esters (PAEs) or phthalates are one of the ubiquitous environmental pollutants that seem to have a considerable impact on human and biological bodies. After discovering their potential to cause health disorders like endocrine disruption, various PAE detection techniques were developed. Most of them rely on sophisticated instruments and lengthy laboratory procedures. The lack of simple, rapid, in-situ, and real-time techniques to monitor the presence of PAEs seems to be a significant issue, with more attention placed on energy saving, sustainability, and green chemistry. Therefore, this study focuses on developing a quick and easy PAE detection technique that facilitates low energy and low time consumption while promoting green chemistry. Specifically, a novel carbon sphere (CS) incorporated cellulose composite was developed as a PAE sensing paper, where the presence of PAEs in a solution was directly detected based on the conductivity reduction of the composite paper. Though a similar concept of detecting PAEs using the conductivity reduction of the sensing paper was tested using both Multi-Walled Carbon Nanotube (MWCNT) buckypaper and MWCNT/cellulose composite paper, their limited sensitivity remains a challenge. Therefore, in this study non-catalytic CSs synthesized using acetylene pyrolysis were used instead of MWCNTs with the intention of increasing the sensitivity limit past 1000 (v/v) ppm.
The CSs are highly electrically conductive due to a continuous π-electron cloud around the sphere-shaped network of aromatic carbon rings. CSs show potential at adsorbing PAE molecules by primarily forming π-π electron donor-acceptor interactions since both the donor and the acceptor have aromatic rings. However, the PAE molecules are dielectric since they have no continuous π-electron cloud across the molecules containing an aromatic ring with two ester-linked alkyl chains. It was assumed that the adsorption of dielectric PAE molecules with bulky side groups onto the CS would increase the tunneling distance between the CSs, resulting in a disruption in their conductivity network, which in turn reduces the conductivity of the composite. Therefore, a reduction in the overall conductivity of the sensing paper is expected if the PAE molecules are adsorbed from the sample solution. It cannot make a paper consisting of entirely CSs for many reasons.
Consequently, a suitable matrix is needed to support the assembly of CSs. The matrix should have high water absorptivity showing potential for creating passages through the material, such that the PAE molecules present in the solution could direct to the carbon spheres incorporated inside. Therefore, in this study, cellulose, a biologically originated, cheap, and easily accessible polymer, was chosen as the matrix over the other suitable fossil-originated synthetic polymers. The CS-Cellulose composite was developed by compressing the filter cake obtained by vacuum filtering a homogenized solution of carbon spheres in cellulose pulp. The specificity of this study is that the recycled cellulose papers obtained from the local market were used as the source of cellulose. Here, the conductivity variation of the cellulosic sensing paper was measured using a four-probe conductivity meter, where the supplied voltage was varied from 0 – 10V until the target current was achieved. The overall conductivity decrement of the cellulosic paper in the presence of adsorbed PAEs could be easily identified by observing the current variation change. This conductivity decrease could be quantitatively detected by considering the sheet resistance, resistivity, and conductivity values. Using this technique with novel 10% CS-cellulose sensing paper, the presence of DPHP (di(2-propylheptyl) phthalate) in a series of 100000 – 1 (v/v) ppm solutions was detected. The simplicity and easy-to-handle nature of the developed method show potential for developing a portable, in-situ, and real-time PAE monitoring system.

9:15 AM SB02.08.06
Nanoscale Insight in Moisture Adsorption in Lignin, Amorphous Cellulose, and Their Mixtures Investigated with Monte Carlo and Molecular Dynamics Simulation Ali Shomali[1], Chi Zhang[1], Wenqiang Liu[2], Benoit Coasne[3], Eleanor J. Schofield[4], Dominique Derome[2] and Jan Carmeliet[1]; [1]ETH Zurich, Switzerland; [2]Université de Sherbrooke, Canada; [3]CNRS, LIPhy, France; [4]HM Naval Base, United Kingdom

Second to cellulose, lignin is the most abundant renewable polymer on the planet. Majorly found in plant cell wall composite, cross-linked to hemicellulose, and acting as the cohesive matrix that surrounds the wood holocellulose and provides increased hydrophobicity and chemical stability to the composite, Lignin is an exceptional source for different monomers and novel materials, biofuel feedstock and chemicals. In addition, Due to its less susceptibility to biological attack and high compatibility with holocellulose, synthesized lignin-based oligomers and lignin nanoparticles have been considered as potential consolidation material for archaeological wood. Due to the highly heterogeneous structure of lignin and complications of its extraction and separation in experimental approaches, relatively little evidence exists on lignin and cellulose interaction and its response to water adsorption on the molecular level. In this study, a molecular model is used to investigate hygromechanical properties of lignocellulose mixtures and to provide insight into the role of lignin and its derivatives as consolidation agents in wood composites with the aim of finding a mixture model that accurately describes the behavior of lignocellulose mixtures. Molecular models studied include an amorphous cellulose model composed of cellobiose units, various models for lignin from linear lignin composed of guaiacyl (G-type) and syringyl (S-type) units together with more complex models of softwood (spruce) and hardwood (birch) built using a stochastic method to accommodate more complex arrangements of units and linkages and mixtures of amorphous cellulose and uncondensed G-type lignin of different mass ratio. Hydrated samples equilibrated at relative humidity ranging from fully dry to saturation pressure are prepared by employing an iterative hybrid all-atom molecular dynamics and grand canonical Monte-Carlo (GCMC) simulation. The hybrid GCMC/MD technique provides an excellent tool to capture the highly coupled nature of sorption-induced swelling in the lignocellulose mixture by enabling us to capture the sorption by applying relative humidity in GCMC and allowing the resultant swelling during relaxation in the MD stage of the simulation. By applying the mechanical tests to hydrated samples role of lignin in adsorption-induced mechanical softening in wood-polymer is also studied. MD results for different lignin components show linear G-type lignin as the least hygroscopic and the linear S-type lignin, with the higher number of methoxy group, as the most hygroscopic lignin model examined. Amorphous cellulose shows considerably higher adsorption and swelling compared to all lignin models due to its hygroscopic nature and the high number of hydroxyl groups hosting many sorption sites. Looking at mixtures of the two components, as the lignin content increase, The sorption isotherms, swelling curves and mechanical data reveal reduced moisture adsorption and swelling together with mechanical softening signifying the effect of the polymer interaction, which is further characterized by measuring porosity pore size distribution and hydrogen bonding network. The rule of mixture is introduced as an analysis tool to elicit the role of polymer interphase. Comparing the mixture rule to MD data reveals the mixture rule as an acceptable but overestimating approximation of moisture content and swelling, the difference is then taken into account as the properties of cellulose-lignin interphase. The underlying molecular mechanism describing the lignocellulose hygromechanical response is compared to what we learned in our recent studies regarding molecular phenomena involved in polyethylene glycol consolidation of wood in order to unravel molecular characteristics of an inspired wood cell wall consolidant. Although lignin induces less softening in a mixture with amorphous

cellulose, the moisture reduction and anti-swelling effects are less significant.

10:30 AM *SB02.09.01
Biomimetic Colour Engineering From Nature to Applications Silvia Vignolini; University of Cambridge, United Kingdom

In a changing world, Nature must serve as a source of inspiration to develop more sustainable materials. For instance, plants' most brilliant and striking colours result from the helicoidal arrangement of cellulose nanofibrils. Interestingly, similar helicoidal architectures with analogous optical responses can be obtained in vitro by self-assembly of cellulose nanocrystals (CNCs) derived from biomass.
CNCs are rod-like colloids capable of arranging into a liquid crystalline phase above a critical concentration in suspension, which upon complete removal of the solvent, lead to photonic films. So far, this process has been explored and studied only on a relatively small scale, neglecting the limitations and challenges posed by the use of large-scale and continuous processes which are required in any industrial context.
In this presentation, I will address these limitations by demonstrating how the self-assembly of CNCs can be controlled to produce meters-long films using a roll-to-roll (R2R) technique. Particularly, we demonstrated how the suspension properties, the casting parameters and drying conditions relate to the optical properties of the produced films.
To validate the use of this technique and material for pigment preparation, we developed a protocol to prepare coloured microparticles from R2R-cast CNC films. The optical properties of the CNC microparticles were then assessed in various environments and finally benchmarked against other commercial effect pigments and glitter. The prepared microparticles are compatible with a wide range of formulations, making them ideal to replace controversial mineral pigments based on mica and titanium dioxide as well as non-biodegradable glitters.

11:00 AM SB02.09.02
An Overview of Criteria of Lignocellulosic Waste and Residues for Packaging Production Leading to Circular Bioeconomy Samantha Islam and Jonathan M. Cullen; University of Cambridge, United Kingdom

Extensive use of petrochemical plastic packaging, coupled with the lack of systematic collection and disposal, leads to a major contamination in soils and aquatic environments. In response, widespread research is taking place to replace petrochemical plastics with biodegradable polymers i.e. substances capable of being decomposed avoiding environmental pollution. Lignocellulose (LC), the most abundant biomass composites from forest and agriculture, can produce cellulose nanofibrils (CNF), a biodegradable packaging material with significant mechanical, barrier and colloidal properties, low density and renewability. However, the cost of production and the negative environmental impact of agricultural expansion are two major obstacles for commercial upscaling of CNF production. Compared to primary resources, CNF extracted from lignocellulosic wastes and residues (LCW&R) e.g. primary forestry and agricultural residues, and municipal and industrial LC- based wastes, not only lowers the production cost but also removes the need for cropland expansion. Moreover, the use of LCW&R in CNF production, indicating material recovery and recycling in the Waste hierarchy (i.e. the ranking of waste management options), provides a more profitable, environment friendly biowaste treatment compared to incineration and landfilling. Various feedstock criteria influences the properties, performance, processing efficiency and production cost of CNFs. Understanding of how the feedstocks perform across these criteria is required for the optimal feedstock selection in commercial CNF production. However, a consolidated overview of criteria defining the suitability of LCW&R for optimal CNF production is absent in the literature. Therefore, this study performs an iterative literature review and presents an overview of the LCW&R characteristics to consider for the successful commercial production of CNF as a packaging material. The 14 criteria of LCW&Rs identified in this study are: availability; elemental composition; cellulose content; hemicellulose content; lignin content; ash content; cell wall thickness; price, seasonal variability; durability; bulk density; environmental impact; land impact; and biodiversity impact. The results of the study can be used to support decisions on managing lignocellulosic waste and producing bioplastic packaging that can enable circular bioeconomy.

11:15 AM SB02.09.03
Nanostructure and Interfacial Mechanical Properties of PEG-Treated Nanocomposites Studied with Molecular Dynamics Simulation Wenqiang Liu[1], Ali Shomali[2], Chi Zhang[2], Benoit Coasne[3], Jan Carmeliet[2] and Dominique Derome[1]; [1]Université de Sherbrooke, Canada; [2]ETH Zurich, Switzerland; [3]Univ. Grenoble Alpes, CNRS, LIPhy, France

Polyethylene glycol (PEG) is widely used in the treatment of archeological wood to reinforce the decayed wood structure[1]. Understanding the mechanisms that allow PEG to strengthen archeological wood can provide fundamental insights into wood hygromechanical behavior. Inspired by the structure and components of the wood S2 cell wall layer, the composites composed of crystalline cellulose and PEG-treated amorphous cellulose are used to study the interfacial mechanical behavior of the fiber-matrix with the aim to reveal the impact of PEG molecules on the stick-slip behavior. GROMACS package[2] and the OPLS force field[3] are used for the MD simulations. The composites in the dry state are composed of infinitely long crystalline cellulose fiber embedded in a PEG-impregnated amorphous cellulose matrix. Seven levels of PEG loading and eleven levels of moisture loading are constructed resulting in a total of 77 initial configurations. The pulling-out test simulations are carried out to study the interfacial mechanical properties of the composites while recording the shear stress and the displacement of the crystalline cellulose.
The initial densities of the dry systems range from 1.4 g/cm^3 to 1.44 g/cm^3 depending on the given PEG mass ratio. Three factors including, the atom number densities of the matrix atoms all exhibit peak values at certain distances to the surface of crystalline cellulose, a linear correlated relationship between the number density peak values of water atoms and hydrogen bond numbers between crystalline cellulose and water molecules with increasing the moisture content, and the chains of amorphous matrix near the fiber-matrix interface tends to be more aligned revealed by Herman orientation functions, all demonstrate that the ordered structure of crystalline cellulose has a significant impact on the distribution of matrix atoms. The pure amorphous cellulose swells linearly with PEG variation, which indicates that PEG molecules behave like integrated with the amorphous matrix. The swelling coefficients concerning the moisture content variation are found to be larger for the composites with a higher PEG mass ratio.
The maximum shear forces are extracted from the pulling-out simulations which span all PEG mass ratios and moisture content constructed. The shear force map shows that the maximum shear force appears at around 10%-15% PEG mass ratio and 3%-6% moisture content, which indicates the consolidation of the interfacial mechanical property at low moisture content.

Electrochemical Osmotic Hydrogel Actuators—A Fundamentally New Soft Material with Many Possibilites Mahiar M. Hamedi[1], Christoph Keplinger[2] and Tobias Benselfelt[1]; [1]KTH, Sweden; [2]Max Planck Institute for Intelligent Systems, Germany

Intelligent systems combine sensing, actuation, and computation to achieve complex tasks and functions. Soft electrically controlled multifunctional materials, especially hydrogels, are the most promising materials for such systems as they are as adaptable as biological systems yet compatible with advanced systems through electronics. There are however no reports on such soft multifunctional materials and not even hydrogel acuators with direct electric control.

We show an electroactive hydrogels fabricated from two components: a hydrophilic, ionically charged nanofibril (cellulose nanofibrils from trees), and carbon nanotubes. These nanoparticle composite networks are mechanically robust, yet they have an open mesoporous structure that can holds lots of water and be highly permeable to substances in their surroundings. The anisotropy of the network allows high expansion in one direction while maintaining high strength and electric conductivity in the other. These hydrogels are fundamentally different from polymer hydrogels, and their behavior is not described by classical polymer physics: e.g., polymer gels have entropy elastic deforamtion, while nanowire hydrogels deform plastically via a stick-slip-stick behavior. As a result, they show emergent properties not present in any previously known soft material. In particular, they possess two unique properties which are immediately suitable in the area of soft intelligent systems:

The electrochemical charge/discharge of the carbon nanotubes in the hydrogels controls the internal salt concentration and consequently their osmotic swelling. This allows direct electrically controlled actuation where around 700 water molecules expand/contract the structure for each ion/electron pair inserted/de-inserted at only ±1 volt, resulting in up to 300% electroosmotic expansion. This mode of electronic actuation has not been shown before, and is a fundamental advancement for soft materials.

The coupling between expansion and electric resistance allows self-sensing and possible feedback to control and lock a particular expanded state. The relation between expansion and pore size further allows for electrically tunable membranes with a mesoporosity relevant for permeability to larger molecules. These tunable membranes are the first example of electrically controlled mesoporosity suitable for larger molecules such as drugs or proteins. No such active membrane has been presented before, and the best current tunable membranes are dense graphene or conducting polymer membranes for controlling the permeability of gases or water.

Our hydrogels are a new form of soft material and groundbreaking as they monolithically integrate actuation with other functions, not easily achieved with other material systems. They can further be made in any lab using available cheap bulk materials, and shaped into various forms ranging from sheets to fibers, to advanced 3D printed sturctures.

Systems Modeling Approaches for Sustainable Material Development: Techno-Economic and Environmental Considerations Yuan Yao; Yale University, United States

Developing sustainable materials requires a comprehensive understanding of the potential environmental, economic, and societal implications of different material, process, and design strategies. Life Cycle Assessment (LCA) and Techno-Economic Analysis (TEA) have been widely used to assess the potential environmental impacts and economic feasibility of various materials. However, applying LCA and TEA to new materials is challenging due to the lack of large-scale data and limited knowledge of systems effects. Furthermore, the impacts of biomass utilization on ecosystems depend on many complex spatial and temporal factors (e.g., land management, climate and soil conditions), most of which are difficult to be considered in LCA for early-stage material development.

This talk will present several innovative systems modeling frameworks that we have been developing to address this challenge. Our frameworks integrate engineering simulations with advanced modeling approaches in different disciplines, such as LCA, TEA, machine learning, supply chain analysis, ecosystem modeling, and system dynamics. In addition, our frameworks help understand the potential environmental or economic implications of new biomass-derived materials at product-, process-, and industry-wide scales. By the crucial integration of those modeling techniques from engineering, industrial ecology, and data science, our research has demonstrated how interdisciplinary approaches can support sustainable material development.

Several examples will be presented to show how these integrated systems analyses can enhance engineering, process, supply chain, and policy design for sustainable biomass-based materials. The examples will focus on wood-based materials, including mass timber for large-scale building applications, as well as materials derived from forest residues (a waste, under-utilized resource) as carbon-negative technologies. These case studies will highlight the potential of lignocellulosic materials in mitigating climate change and other environmental impacts such as eutrophication, and identify the main process-, supply-chain, and socioeconomic factors determining these potentials. In addition, the presentation will discuss how material manufacturing and land management can be optimized simultaneously for maximum environmental benefits.

Intrinsically-Soft Conductors for Conformal Tissue-Device Interfacing Dae-Hyeong Kim; Institute for Basic Science, Korea (the Republic of)

Recent advances in flexible and stretchable electronics have attracted great attention due to its potential applications in personalized bio-integrated healthcare devices. The mechanical mismatch between conventional rigid electronic devices and soft human tissues oftentimes causes various issues, such as a low signal-to-noise ratio of biosensors, inflammations on the tissue interfacing with the bioelectronics, skin irritations in the case of long-term wearing of the device, and ineffective electrical stimulations in feedback therapies. Ultra-flexible and stretchable bioelectronic devices have a low system modulus and intrinsic softness, and thereby have a potential to solve these issues. Nanomaterials and their composites with the elastomeric matrix are a particularly promising material candidate for realizing this soft bioelectronics concept. In this talk, the unique strategies in the synthesis of nanmaterials, processing as stretchable functional nanocomposites, seamless integration into soft bioelectronics, and their wearable and/or implantable device applications are presented. These efforts have combined recent breakthroughs in nanomaterials and soft electronics, and are expected to address unmet clinical challenges.

11:00 AM SB03.01.02
Reconfigurable 3D Microelectronic Interface via Deterministic Microfolding Wubin Bai; University of North Carolina at Chapel Hill, United States

DNA and proteins fold in three dimensions (3D) to enable functions that sustain life. Emulation of such reversible folding schemes for functional materials can create promising opportunities for advancing a wide range of technologies. In particular, morphing 3D mesostructures via multiple dimensions for high-performance materials including monocrystalline silicon can enable unconventional designs in sensory robotics, biomedical devices, microelectronics, and microelectromechanical systems. Existing approaches to morphing functional materials mostly rely on planar processes, which often complicates needed mechanisms for structural reconfiguration and limits the choice of materials composition and dimension. This presentation will introduce a bioinspired microfolding strategy to realize 3D reconfigurable microelectronic systems in freestanding forms with various advanced materials and complex architectures. The microfolding mechanism allows access to any transitional states of the folded 3D structures in a reversible fashion, to modulate functionalities on demand. Demonstrations on microantennas for telecommunication, wearable accelerometers for tremor monitoring, and epicardial bioelectronic probes for cardiac mapping, all of which are achieved via the microfolding strategy, further highlight the high potential for a broad range of applications in healthcare and communications industry.

11:15 AM *SB03.01.03
Bioadhesive Electronics and Ultrasound Xuanhe Zhao; Massachusetts Institute of Technology, United States

This talk will focus on two technologies developed at MIT Zhao Lab: 1. bioadhesive electronics that can adhere to diverse wet dynamic organs in the body without the formation of fibrotic encapsulation on the tissue-device interfaces, and 2. bioadhesive ultrasound capable of wearable imaging diverse internal organs continuously over days. I will first discuss a set of general principles for designing bioadhesive interfaces. I will illustrate the impacts of bioadhesive electronics and ultrasound on health and biology. I will conclude the talk with a vision of merging human-machine intelligence for a better world.

SESSION SB03.02: Bioelectronic Materials and Structures II
Session Chairs: Alex Chortos, Jia Liu, Alina Rwei and Lizhi Xu
Monday Afternoon, November 28, 2022

1:30 PM SB03.02.02
Villi Inspired Elastomeric Interlocking Device for Intestinal Retentive Applications Durva A. Naik, Gaurav Balakrishnan and Christopher J. Bettinger;

Carnegie Mellon University, United States

Achieving prolonged retention of medical devices in the small intestine while mitigating tissue trauma remains a significant clinical challenge. Tissue-piercing microneedles harm intestinal epithelium inducing inflammation while reactive mucoadhesives are susceptible to fouling. Inspired by morphology of the intestinal villi, a mechanical interlocker laminated with high-aspect-ratio elastomeric microposts, that mimic dimensions of the villi, is investigated to develop intestinal retentive platforms. Effectiveness of the interlockers to resist peristalsis is characterized by performing mechanical simulations on Autodesk Fusion 360 and by determining the resistive force applied by villus when it collides with mobile micropost using Euler-Bernoulli beam theory for large deflections.
The interlocking properties are optimized by studying two simulation models that investigate the influence of device material properties (50kPa < E_m < 1GPa, Poisson's ratio = 0.49), micropost pitch (20,16,12,9 microposts per mm^2), arrangement (cubic/hexagonal) and tip geometry (round/cubic) on the resistive force as the microposts interaction with villi under peristaltic shear (0.01N/cm^2) and contraction (2666.45Pa). Digital Light Processing (DLP) 3D printing in tandem with a multi-step replica molding technique is used to fabricate the microposts and artificial villi (E_v= 50kPa). Dimensions of the microposts are optimized to address shrinkage post UV curing to achieve desired aspect ratio of ~5:1 (length = 1500um) and scanning electron microscopy is used to characterize the microposts (surface roughness = 20um). Work of interlocking between fabricated microposts and villi under varying preload and drag velocity is then evaluated through in vitro lap-shear tests performed on customized equipment to validate simulation results.
It is demonstrated that the ability of individual villus to resist movement of a mobile micropost is directly proportional to the elastic modulus of the micropost and preload (F_{sim} upto 812uN, E_m = 10MPa). In vitro studies comply with simulation results permitting use of computational approach for future study of elastomeric mechanical interlocking systems (F_{sim}/F_{exp} = 1.06, E_m = 2.05MPa, degree of overlap = 95%). Additionally, interlockers seating 20 round tipped microposts per mm^2 arranged hexagonally can effortlessly consolidate within villi (>95% degree of overlap) through peristaltic contraction thereby eliminating the need for external stimulation and optimally resist peristaltic shear via mechanical interlocking (Experimental Work of Interlocking = 64uJ per mm^2).
These interlockers present a compliant non-penetrative method to develop minimally invasive intestinal retentive platforms for applications in gut diagnostics by indwelling sensors, neuromodulation and oral drug delivery.

1:45 PM SB03.02.03
Mechanically Robust and Electrically Conductive Hydrogels with Hybrid Nanofibrous Network Huimin He and Lizhi Xu; The University of Hong Kong, China

Conductive hydrogels are promising candidate materials for the construction of soft bioelectronics. Their mechanical flexibility, water content, and porosity approach those of biological tissues, providing a compliant interface between the human body and electronic hardware. However, most of available conductive hydrogels exhibit poor mechanical properties, which hinders their application in durable bio-integrated systems. This presentation will highlight our recent works on aramid-nanofiber-based multifunctional hydrogels, which provide a combination of high strength, elasticity, and electrical conductivity. Highly branched aramid nanofibers afford a robust 3D framework resembling those in load-bearing soft tissues. When interlaced with polyvinyl alcohol and crosslinked with both non-covalent and covalent interactions, the nanofiber composites exhibit a high water content of ~80 wt%, strength of ~10 MPa, ductility of ~400%, and shape recovery of ~99.5% under 0.3 MPa of cyclic tensile stress. Mobile ions or conducting polymers infiltrated in the nanofibrous network impart a high electrical conductivity, enabling bioelectronic interfaces and large-strain sensors with stable operation. In addition, embedded silver nanoparticles could afford broad-spectrum antimicrobial activities, which is favorable for medical devices. The versatility of aramid-nanofiber-based composites suggests their further possibilities for functionalization and scalable fabrication toward sophisticated bioelectronic systems.

2:30 PM *SB03.02.05
Biocompatible Composites or Heterojunctions for Living Composites Bozhi Tian; University of Chicago, United States

The use of biocompatible and biodegradable devices for the modulation of cells and tissues has many potential implications for medical and industrial technologies. This presentation will showcase several recent projects in this area. First, I will discuss the construction of a soil-like material from nanostructured minerals, starch granules, and liquid metals, designed to mimic immobile inorganic and organic materials and mobile phases in soil. This soil-like material is biocompatible and recyclable. It possesses chemical, optical, or mechanical responsiveness to yield write-erase electrical functions. Using soil-like materials, we demonstrate enhanced microbial metabolism and biofuel production in vitro. In addition, it can enrich gut bacterial diversity under pathological conditions and remedy bacterial dysbiosis in vivo. Afterwards, I will present a class of granule-enabled hydrogel composites that contain a range of biopolymers and synthetic hydrogels. The composites have many tissue-like properties, such as strain-stiffening behaviors. Using granular tissue-like materials, pneumatically actuated bioelectronic device applications have been developed, such as recording the electrocardiogram signal of the heart ex vivo. Additionally, I will present a recently developed nanoporous/non-porous heterojunction for improved actuation biointerfaces. At the end of my presentation, I will discuss future composite or heterojunction developments towards living machines.

3:00 PM SB03.02.06
Fishbone Nanowires for *In Vivo* Intracellular Recording Across the Depth of an Intact Brain Youngbin Tchoe[1], Jihwan Lee[1], Karen Tonsfeldt[1,1], Guy Bouvier[2], Andrew Bourhis[1], Keundong Lee[1], Ritwik Vatsyayan[1], Samantha Russman[1], Grace Lykins[1], Massimo Scanziani[2] and Shadi Dayeh[1]; [1]University of California, San Diego, United States; [2]University of California, San Francisc, United States

Intracellular recordings have long been the gold standard for neurophysiological investigations, but their technical requirements have severely limited their scalability to large populations of neurons, especially in intact brains. Here, we developed fishbone intracellular nanowire electrode (FINE) that is composed of ultra-sharp tip nanowire electrode arrays integrated at a slanted angle on the sides of an implantable shank to record the intracellular potentials from ensembles of neurons *in vivo* across the depth of an intact brain.
FINE was designed to deliver ultrasharp nanowires into the depth of the brain that could subsequently form intracellular interface with individual neurons. To deliver the ultrasharp nanowires undamaged into the depth of the brain, the nanowires were designed to point backward at an angle from the insertion direction and sturdy polycrystalline platinum silicide (PtSi) was used for the body of the nanowires. Once the implantation was completed, sub-micron scale small retractions of FINE resulted in intracellular-like potentials. The mechanical retraction most likely caused the ultrasharp nanowires to push against or penetrate through the surrounding neurons' cell membrane, leading to intracellular-like nanowire-neuron interface. We also compared the distinctive recording characteristics of nanowire probes compared to the extracellular recording using the planar probes (30 μm) on FINE which were placed in close proximity to the nanowire probes. The FINE's capability of recording intracellular-like potentials from neural ensembles will potentially enable us to answer fundamental neuroscience questions.

3:15 PM SB03.02.07
Highly Flexible Thread-Based Eutectogel Organic Electrochemical Transistors Rachel E. Owyeung, Wenxin Zeng, Matthew Panzer and Sameer R. Sonkusale; Tufts University, United States

Electronic devices made from organic materials and polymer systems have attracted much attention across bioelectronic applications that interface closely with the human body, ranging from health monitoring devices to consumer wearables. Versus conventional silicon, organic transistors and electronics realized on flexible substrates can more closely resemble the mechanical properties of the underlying human skin, for improved comfort and accuracy when recording biosignals. Particularly, organic electrochemical transistors (OECTs) have emerged as promising bioelectronic active components, due to their biofriendly composition, facile processing, and high transconductance. Often aqueous electrolytes are used for gating through formation of electrolytic double layers. However, such transistors are volatile and prone to degradation from dehydration over time.
In this work, we utilize a two-prong approach to address this challenge. Firstly, the electrolyte used is a gelatin-supported deep eutectic solvent gel electrolyte or "eutectogel," rather than an archetypical aqueous electrolyte solution. The eutectogel, comprised of choline chloride and ethylene glycol supported by 20 wt.% gelatin, provides a nonvolatile electrolyte for long term device usage without further encapsulation, and the gel support scaffold provides mechanical stability (ie can act as the substrate itself) and leakproof operation of the device. The resulting OECT devices show excellent device performance and stability of transistor operation in ambient conditions without further coatings over several days or weeks. Further, experiments suggest excellent water vapor permeability, which would allow the gel to sit on-body and still allow for the underlying skin to breathe. The second factor in our design is an active channel fiber, which contains PEDOT:PSS between source and drain electrodes deposited via a novel cleanroom-free electroless deposition approach. The fiber adds additional geometric freedom, such that the active channel can be placed anywhere within the eutectogel for transistor action, for more conformal electronics.
The presented transistors operate at low voltage (within ~1 V), exhibit a maximum transconductance and ON/OFF ratio of 16 mS and 10^3, respectively, for the champion device, and an average transconductance efficiency of $4.7\pm1.2\ V^{-1}$ at the applied biasing point of 0 V. A hydrogel equivalent OECT was fabricated and compared with the eutectogel OECT. The hydrogel OECT lost 75% volume over 72 hours and the max transconductance exhibited a 94% change after 24 hours. Conversely, the eutectogel OECT observed no measurable change in volume and only a 12% change in max transconductance over 7 days, likely due to the instability of PEDOT:PSS in ambient conditions itself. This novel device design and construction of 3D electronic circuits could lead to future implementations of smart wearables that better resemble the body it interfaces with.

3:30 PM SB03.02.08
3D Printing Piezoelectric Materials for Smart Tissue-Mimetic Bioelectronics Jun Li; University of Wisconsin--Madison, United States

Piezoelectric materials are an ideal selection for advanced bioelectronic applications including human-machine interfacing, revolutionary therapeutic strategies, and self-sustainable energy solutions. Recent advances in additive manufacturing opened up the possibility of creating complex piezoelectric structures that can seamlessly integrate with bodies to modulate biological activities. Nevertheless, currently printed structures only has fair electromechanical couplings and poor mechanical properties. It demands long-time and energy-intensive post poling to enable piezoelectricity, which significantly increases fabrication time and limits structure designs. Therefore, concurrent 3D-printed piezoelectric materials could hardly meet practical requirements. We developed electric field-assisted 3D printing technologies that enable fast printing of complex and polarized ferroelectric materials with high fidelity and superb piezoelectric performance. Leveraging these technologies, we were capable of realizing smart artificial organs with build-in piezoelectricity and biomimetic properties.

We first directly printed a 3D sinusoidal artificial artery of biocompatible piezoelectric composites. The prints consisted of ferroelectric potassium sodium niobate (KNN) particles embedded within a ferroelectric polyvinylidene fluoride (PVDF) polymer matrix, which can be poled during printing within a few seconds. The synergistic effect from the KNN particles and the PVDF matrix yields a superb piezoelectric performance (bulk-scale d33 > 12 pC N−1). The sinusoidal architecture brings the mechanical modulus close to the level of blood vessels. The desired piezoelectric and mechanical properties of the artificial artery provide an excellent sensitivity to pressure change (0.306 mV mmHg−1, R2 > 0.99) within the range of human blood pressure (11.25–225.00 mmHg). The high pressure sensitivity and the ability to detect subtle vessel motion pattern change enable early detection of partial occlusion, allowing for preventing grafts failure.

We further developed a 3D printed ferroelectric metamaterial that offers simultaneous ceramic-like high piezoelectric properties and bone-like high mechanical toughness. In this work, we adapted the nacre architecture in the design of a lamellar ferroelectric metamaterial to improve its mechanical toughness, where alternating soft ferroelectric and hard electrode layers are directly printed in bulk with an in situ poling function through low-voltage-assisted 3D printing. The principle for piezoelectricity enhancement was adapted from commercial piezo-stacks and enabled by the development of processable and printable ferroelectric and conductive composites. High-fidelity multilayered 3D ferroelectric metamaterial was printed and poled in one step at a constant low voltage. The as-printed material exhibited a significantly enhanced bulk-scale d33 of over 150 pC N−1, as well as a superior mechanical toughness of ~5.5 MPa m1/2, more than three times higher than those of conventional piezo-ceramics. The excellent printability together with the combination of both high piezoelectric and mechanical behaviors allowed for the creation of artificial bone with tunable anisotropic piezoelectric responses and bone-comparable mechanical properties.

SB03.03.01
Porosity-Permeability-Mechanics Relationship of Porous Silicone for Interface with Skin Ruohan Xu and Zhao Qin; Syracuse University, United States

Silicone is currently used in a variety of skin-related applications, including wearable electronic devices and medical devices such as aspirators, breast prostheses, and cosmetic fillers. Its low modulus and nonlinear mechanics make it suitable for making flexible devices that adapt well to the body and skin profiles and wear with comfort. However, a thick silicone layer has poor breathability, heat conductivity, and oxygen permeability, causing an immune response to the skin after a long-time wearing. The symptom becomes more serious with accumulated heat. Adding sacrificial particles, including salt and dissolvable polymers, can effectively make the material porous and more permeable to air, but the porosity-permeability-mechanics relationship of the material is not clear. In this study, we prepared porous silicone and tested it to find different porosity in the air permeability and oxygen passing rate of silicone. We found that the porous silicon is permeable to oxygen, which significantly increases the comfort to wear. Our study serves as a reference to reveal the trade-off between the permeability of silicone and its mechanical properties, making it rational to design flexible products that interface with different human tissues.

SB03.03.02
Flexible, Sticky and Biodegradable Wireless Device for Drug Delivery to Brain Tumors Gi Doo Cha[1], Seung Hong Choi[1] and Dae-Hyeong Kim[2]; [1]Seoul National University Hosptial, Korea (the Republic of); [2]Seoul National University, Korea (the Republic of)

Implantation of biodegradable wafers near the brain surgery site to deliver anti-cancer agents which target residual tumor cells by bypassing the blood-brain barrier has been a promising method for brain tumor treatment. However, further improvement in the prognosis is still necessary. We herein present novel materials and device technologies for drug delivery to brain tumors, i.e., a flexible, sticky, and biodegradable drug-loaded patch integrated with wireless electronics for controlled intracranial drug delivery through mild-thermic actuation. The flexible and bifacially-designed sticky/hydrophobic device allows conformal adhesion on the brain surgery site and provides spatially-controlled and temporarily-extended drug delivery to brain tumors while minimizing unintended drug leakage to the cerebrospinal fluid. Biodegradation of the entire device minimizes potential neurological side-effects. Application of the device to the mouse model confirms tumor volume suppression and improved survival rate. Demonstration in a large animal model (canine model) exhibited its potential for human application.

SB03.03.03
3D Protruded and Soft Cuff-type Electrode for Reliable Peripheral Neural Interface Electronics Hee-Jeong Jin[1], Yoo Na Kang[2] and Min-Ho Seo[1]; [1]Pusan National University, Korea (the Republic of); [2]Korea Institute of Machinery & Materials, Korea (the Republic of)

Cuff-type (or curvy-type, equivalently) electrodes have gained great interest in the field of the peripheral nerve systems, because their 3D cylindrical structure can make reasonably effective contact with peripheral nerve tissues without damage. Conventionally, the cuff-type neural interface electrodes have been developed using metals, such as gold and platinum, however, the rigid metal electrodes still suffer from the low signal-to-noise ratio(SNR) issue for recording since a tight cuff for achieving close contact to a nerve could cause eventual nerve damage during long-term implantation. To address the contact problem, various studies, for example, coating a conductive polymer or a nano-composite on the metal surface, have been actively performed, but there is a fundamental limitation to the metal-based cuff to reduce its mechanical stiffness. More recently, a hydrogel-based soft cuff type electrode has been developed, but the unacceptably high impedance of the electrode still limits its applications.
Here, we developed a mechanically soft cuff-type neural interface device that includes a 3D-protruded elastic electrode for reliable contact. The developed device is not only composed of a thin and small polydimethylsiloxane (PDMS) cuff (inner diameter=~1 mm), but also has ~100 μm-thick carbon-black based conductive elastomeric electrodes in the cuff, realizing excellent electrical conductivity and low mechanical modulus. To demonstrate the proposed device, we developed advanced micro-fabrication, combining UV-laser ablation, screen printing, and pre-strain PDMS bonding technique. The fabricated device does not only show elastic stretchability and flexibility by >30% with a mechanical modulus (826.60±2.23 kPa), similar to that of human peripheral nerve, but it also shows 99.84±1.98 kΩ of impedance (@1 kHz) that is comparable to that of conventional metal electrodes. Moreover, the developed device shows a negligible mechanical modulus changes in the cyclic strain (ε) test (1.3%-change for 10000-cycle of ε=35%) and an insignificant resistance change for 7-day in PH7.4 phosphate buffer saline (PBS) solution (7.8%-change). Finally, we performed a bio-compatibility of the developed electrode using the dilution extraction method, and confirmed the >80% cell viability. From the conducted tests, we experimentally confirm that the developed cuff-type device unprecedentedly shows high mechanical softness, electrical conductivity, and bio-compatibility. Moreover, the shape and dimension of the electrodes can be easily changed owing to the high design-freedom of the developed fabrication method. Thus, we expect the proposed device can be widely used for various peripheral neural interface applications, such as neuro-modulation and pain-control.

1024-Channel, Ultra-Sharp, Individually Addressable Silicon-Based Nanowire Arrays for Natively Recording Intracellular Activity in Neuronal Networks Jihwan Lee[1], Youngbin Tchoe[1], Ren Liu[2], Deborah Pre[3], Karen Tonsfeldt[1], Andrew Bourhis[1], Agnieszka D'Antonio-Chroska[1], Gaelle Robin[3], Sang Heon Lee[1], Yun Goo Ro[1], M. Lisa Phipps[4], Jinkyoung Yoo[4], John Nogan[4], Jennifer Martinez[5], Kelly Frazer[1], Anne G. Bang[3] and Shadi Dayeh[1]; [1]University of California, San Diego, United States; [2]Harvard University, United States; [3]Sanford Burnham Prebys Medical Discovery Institute, United States; [4]Center for Integrated Nanotechnologies, Sandia National Laboratories, United States; [5]Northern Arizona University, United States

Introduction
Intracellular access with high spatiotemporal resolution and minimal invasiveness is imperative in understanding how neurons regulate and orchestrate network activity, and how such activity can be influenced by pharmacology or other interventional methods. The gold standard technique to achieve high-fidelity intracellular recordings involves patch clamp electrophysiology, but it only permits short recording duration and can potentially damage cell health. Other research primarily focuses on vertical, nanoscale interfaces and often employ electroporation or optoporation to permeate the cell membrane and obtain intracellular potentials; however, such methods tend to lead to attenuation of recorded potentials. In our research, we report 1024-channel, vertical, ultra-sharp, silicon-based nanowire arrays to allow long-term, native recordings of intracellular potentials without any electroporation treatment.

Methods
Fabriation of these ultra-sharp tip nanowires were processed with techniques that could provide scalability up to 1024 channels to achieve simultaneous recordings over extended areas, with each single nanowire electrode individually addressed to each channel. We employed top-down etching and successive thermal oxidation on silicon substrate to realize sub-10 nm nanowires, which were subsequently coated with platinum for electrical connection. The nanowire arrays were passivated with dual layer of silicon oxide and plasma-treated parylene C to promote neuronal cell culture adhesion and prevent delamination of metal interconnects.

Results
Previously fabricated nanowires have shown stable amplitudes of intracellular potentials from 3D tissue-like networks of rat cortical neurons across long culture times up to 19 days *in vitro*. Sequential cross-sectional microscopy have revealed intimate nanowire and neuron soma interface. Modulation of electrophysiological activities are demonstrated clearly with pharmacological drugs (picrotoxin and tetrodotoxin) to either stimulate or inhibit neuronal activities. We detected graded membrane potentials prior to recorded action potential from neuronal recordings, exhibiting ability of our platform to record subthreshold potentials and observed synaptic network activities between neurons. Our experiments and simulations demonstrate that as the number of

nanowires per channel decreased, the peak-to-peak amplitude of intracellular signals increased, revealing the importance of individual addressability.

Conclusion
Individually addressable nanowire arrays with height exceeding ~6 um can naturally permeate neurons and record intracellular potentials over extended durations of time. Overall, this study advances our understanding of and control over high-quality multi-channel intracellular recordings, and paves the way toward predictive and high-throughput electrophysiological drug screening platforms.

A Scalable, Rapidly Reconfigurable Microfluidic Platform Enables Dynamic Flow Conditions 'On-Chip' Bryan Schellberg, Ryan Koppes and Abigail Koppes; Northeastern University, United States

Microfluidic devices, or "organ-chips", are an emergent technology that bridges the gap between in-vitro and in-vivo models. With growing pressure from the EPA and other government agencies to reduce or eliminate the use of animals in research, microfluidics offer a robust alternative. However, the most common production method (soft lithography) is expensive and requires specialized equipment, preventing widespread use and adoption of this technology. With recent advances in three-dimensional (3D) printing technology, the chip fabrication process may be simplified considerably without sacrificing the micron-scale resolution required to simulate physiological environments in-vitro.

In this work, a scalable and rapidly reconfigurable chip platform is realized by interfacing our previously validated laser-cut and assembly-based method with 3D printing technology [1]. Laser-cut poly (methyl methacrylate) (PMMA) sheets are used to build the culture and flow compartments of the chip, and stereolithography (SLA) 3D printed resin "tops" provide the described functionality. The chip is built layer-by-layer with 1.6 mm PMMA sheets and a 4.8 mm resin upper layer. Each layer has uniform rectangular dimensions of 22 mm by 40 mm. 50 µm double-sided adhesive tape is sandwiched between each PMMA sheet to bond the lower layers together. Magnets compress a 0.4 mm thick fluoroelastomer rubber gasket at the resin-PMMA interface, forming a reversible seal for removal and re-use of chip tops. Leak tests conducted using water and a 1 mL syringe show complete sealing at pressures well above standard operating conditions.

The chip top features 3 mm by 10 mm dovetail style joints that interlock, like puzzle pieces, with up to four independent 3D printed "chip connectors". Joints between tops and connectors fit together with a simple 'push-to-fit' action, enabling rapid setup and reconfiguration of scalable chip arrays. Internal microchannels pass through the center plane of both the top and connector, allowing fluid flow from one chip to another via in/outlets at each of the joint faces. Fluoroelastomer O-rings embedded in the face of each top-connector joint reversibly seal, preventing leakage. Fluid flow within, and across, chips is directed using 3D printed hand-operated valves. The integrated valves enable flow path customization by simply redirecting or blocking off flow at set points on the chip top or connector. With all individual components prepared, an array of chips may be assembled, or rearranged from a previous configuration, in minutes. Overall, we propose a microfluidic platform that is scalable, modular, and enables dynamic control of microfluidic flow conditions on-chip without the need to adjust offline components such as syringe pumps or reservoirs. Ongoing work is focused on leveraging the current platform to include integrated characterization on-chip towards spatiotemporal data collection. Interfacing SLA 3D printing with established chip fabrication methods opens opportunities for full customization of in-vitro models to recapitulate physiologically relevant conditions on-chip.

Development and Characterization of Directed Biosurface-Active Polymerizable Thiophenes Quintin Baugh, Chun-Yuan Lo, Yuhang Wu, Junghyun Lee, Laure V. Kayser and David C. Martin; University of Delaware, United States

A promising new candidate for bio-electronic interfacing has been developed in the form of a hybrid 3,4-ethylenedioxythiophene/phospholipid monomer, EDOT-phospholipid. The hybrid nature of this molecule covalently fuses together the chemical functionality and specificity of biologically derived lipids to electrochemically active thiophenes in a manner that is intended to promote biological surface-directed electrochemistry. The thermal and electrochemical properties of EDOT-phospholipid have been investigated over biologically relevant conditions using a variety of methods. Thermogravimetric analysis (TGA) and differential scanning calorimetry (DSC) defined the melting point at 75.8 C with a degradation onset temperature of 180 C. The thermal stability and morphology have been investigated using hot-stage optical microscopy coupled with thermally controlled wide-angle x-ray diffraction (XRD) tuned to the thermal profiles determined by TGA/DSC. Diffusion couple experiments show the phases of EDOT-phospholipid across the full spectrum of aqueous concentrations, reinforced with surface infrared-mapping. The capacity for electrochemical polymerization was also investigated using electrochemical impedance spectroscopy (EIS) at varying aqueous concentrations and using alternate counterions. The biological interactions with human neural cells have also been investigated through the exposure of SH-SY5Y human neuroblastoma cell lines to EDOT-phospholipid and exposure to similar electrochemical conditions.

SB03.03.07
Conformal Esophageal Catheter Balloon with On-Surface Fully Printed Electronics Fabricated by Cylindrical Coordinate-Based Aerosol Jet Printing Hansel A. Hobbie, Paolo Maccarini and Aaron D. Franklin; Duke University, United States

Barrett's Esophagus (BE), a precursor to esophageal cancer (EsC), is a condition of the lower esophagus that causes the esophageal lining to inflame and thicken as the normal epithelial tissue is replaced with metaplastic intestinal tissue. BE is caused by stomach acid reflux into the esophagus, occurring as a complication of gastroesophageal reflux disease (GERD), which affects ~30 million people in North America. If left untreated, BE can continue to spread by causing more tissue erosion and the formation of precancerous lesions at both the epithelial surface and within the nonvisible mucosal layer. These lesions can then further deteriorate into adenocarcinomas, which have become the most common form of EsC with a 5-year survival rate of only 20%. Currently, the most prominent treatment for BE involves the use of an esophageal catheter to radiatively ablate affected tissue; however, this technique lacks precision in localized heating and control in terms of monitoring thermal impact on the tissue during treatment. These issues can easily lead to incomplete treatment of the BE lesions, especially those deep in the mucosal layer, requiring the endoscopic procedure to be repeated. Consequently, it is of great importance to develop an esophageal catheter that overcomes these deficiencies to provide precise ablation with tissue temperature dosimetry to ensure full treatment with minimum procedures.
In this work, we demonstrate the design, fabrication, and testing of an esophageal catheter system that is capable of high precision radiative heating and real-time temperature monitoring of surrounding material. These advanced capabilities are achieved by the design of a dual-mode antenna that can create localized heating when radiating and can measure thermal body radiation when receiving. By transmitting higher frequency microwave energy, as opposed to typical radio frequency-based ablators, our device offers more precise heating due to the smaller resolution of the applied wavelength. This precision is then reciprocally utilized in the receiving mode of the antenna to accurately quantify the volume-averaged temperature of encompassing materials. To accomplish the fabrication of this antenna and accompanying sensors onto the complex 3D surface of our soft-material catheter, we developed a custom aerosol jet printer attachment for converting rectangular coordinate-based planar printing to a cylindrical coordinate-based printing approach. This

innovative mechanism enables material deposition onto nonplanar surfaces of revolution, thus providing a simple platform to manufacture and rapidly prototype the design of printed bioelectronics directly on the curved surface of our catheter. The main body of the catheter, which is made of polyurethane, is a balloon that inflates to the shape of the esophagus ensuring conformal contact with the esophageal lining. Using our cylindrical coordinate-based printing method, we print highly conductive silver nanowire and graphene inks onto the circumference of this balloon in an inflated state to fabricate a temperature sensor, a pressure sensor, and the ground plane for our dual-mode microwave antenna. Both sensors utilize the environmentally sensitive properties of graphene to individually monitor temperature on the tissue lining and pressure as the inflated balloon achieves contact with the esophagus. The printed ground plane, which wraps around the circumference of the balloon, operates in tandem with a coaxially mounted monopole in the center of the balloon as the dual-mode antenna. Then as a final step, these surface mounted bioelectronics are covered in a biocompatible encapsulation layer to protect the patient as well as the deposited material. Ultimately, with real-time quantification of tissue temperature and the ability to precisely tune ablation, our esophageal catheter system will enable innovative endoscopic treatment to treat BE fully from the epithelium down to the mucosal tissue layer.

SB03.03.08
Surface-Embedding of Microparticles for Biodegradable Fiber Electrodes in Implantable Electronics Jinho Kim[1], Seohyun Woo[1], Jaehong Lee[1], Congqi Yang[2] and Seongjun Park[2]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Biodegradable materials, which can dissolve by body fluid after use, have been recently highlighted in the field of implantable sensors. The biodegradable sensors can monitor various biosignal and eliminate the need for surgical extraction of implanted sensors after their usage. However, previously reported biodegradable sensors are generally in planar structure that requires additional suturing for stable fixation of the sensors onto target organs or tissues in human body1,2. The additional suturing can damage the sensors which mainly consist of soft materials. Although a few 1-dimensional (1D) implantable sensors have been developed to overcome this limitation, the 1D implantable sensors composed of biodegradable materials have been barely studied3,4. To fabricate the biodegradable 1D sensor, the development of high-performance 1D electrodes is fundamentally essential5,6.
In this work, we developed a biodegradable fiber electrode with high electrical and mechanical performance for implantable electronic devices. The biodegradable fiber electrode is composed of Polycaprolactone (PCL) core and conductive composite layer of PCL and Molybdenum (Mo) microparticles. The fabrication process for the biodegradable fiber consists of three steps: Melt-drawing7 and cold drawing of PCL fibers, and surface-embedding of Mo microparticles. The fabricated biodegradable fibers simultaneously showed outstanding electrical resistance (42 Ω/cm) based on dense electrical connections between the large number of Mo microparticles and high mechanical stability due to the intact PCL core. In addition, the fiber electrodes exhibited electrical stability and durability under repeated bending deformations (4000 cycles). The biocompatibility and biodegradable properties of the fiber electrode is also verified. We demonstrated that the developed biodegradable fibers could be applied to develop biodegradable fiber-based drug-release monitoring sensors, electrical stimulators, and interconnectors.

Universal Sustainable Adhesive Bioelectronics Enabled by Hierarchical Architectures Da Wan Kim, Yeon Soo Lee, Seung Hwan Jeon, Dohyun Lim and Changhyun Pang; Sungkyunkwan University, Korea (the Republic of)

Recent studies on soft adhesives have sought to deeply understand how their chemical or mechanical structures interact strongly with living tissues. The aim is to optimally address the unmet needs of patients with acute or chronic diseases. Synergistic adhesion involving both mechanical interactions (capillarity-assisted suction stress) and electrostatic (hydrogen bonds) seems to be effective in overcoming the challenges associated with long-term unstable coupling to tissues. Here, we developed the electrostatically and mechanically synergistic mechanism of sustainable tissue adhesion with minimal residue by implementing hybrid multiscale architectures.[1] By investigating various geometric parameters of microchannels on the adhesive surface, we develop a simple model to maximize adhesion strength via a time-dependent zig-zag profile and an arresting effect against crack propagation.[2] In addition, a thermodynamic model based on a tailored multiscale combinatory adhesive was proposed. The model supported the experimental results that the thermodynamically controlled swelling of the porous hydrogel embedded in the hierarchical elastomeric structure enhances biofluid-insensitive sustainable in situ adhesion to diverse soft, slippery, and wet organ surfaces, as well as clean detachment in the peeling direction. Based on the robust tissue adhesion capability, we successfully demonstrated universal reliable measurements of electrophysiological signals generated by various tissues ranging from rodent sciatic nerve, the muscle, brain, and human skin.

SB03.03.10
Wireless, Battery-Free Push-Pull Microsystem for Membrane-Free Neurochemical Sampling in Freely Moving Animals Guangfu Wu and Yi Zhang; University of Connecticut, United States

Extensive studies in both animals and humans have demonstrated that high molecular weight neurochemicals, such as neuropeptides and other polypeptide neurochemicals, play critical roles in various neurological disorders. Despite many attempts, existing methods are constrained by detecting neuropeptide release in small animal models during behavior tasks, which leaves the molecular mechanisms underlying many neurological and psychological disorders unresolved. Here, we report a wireless, programmable push-pull microsystem for membrane-free neurochemical sampling with cellular spatial resolution in freely moving animals. In vitro studies demonstrate the sampling of various neurochemicals with high recovery (>80%). Open-field tests reveal that the device implantation does not affect the natural behavior of mice. The probe successfully captures the pharmacologically evoked release of neuropeptide Y in freely moving mice. This wireless push-pull microsystem creates opportunities for neuroscientists to understand where, when, and how the release of neuropeptides modulates diverse behavioral outputs of the brain.

Wearable Label-Free Electrochemical AMH Immunosensor Based on Flexible Conductive Fiber Hyeji Ryu, Seohyun Woo, Minji Jeong and Jaehong

Lee; Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

According to the World Health Organization, Infertility has affected the lives of 48 million couples of people globally. Early diagnosis of infertility can play a critical role in its successful and effective treatment. Menstrual blood is one of the biofluids which contains several biomarkers for monitoring female infertility patients. Among the menstrual blood biomarkers, Anti-Müllerian hormone (AMH), a glycoprotein hormone produced by the primordial follicles that can regulate the primordial follicle recruitment, is highly important for monitoring ovarian reserve in females [1]. To monitor the level of AMH in the body, Enzyme-linked immunosorbent assay (ELISA) has been typically used to detect serum AMH concentration. However, practical drawbacks of the ELISA include the need for blood-taking, long analysis time, labeling process, and bulky sensing instrument [2]. Wearable biosensor can be the powerful approach for the early diagnosis due to its advantages in terms of continuous real-time health monitoring, noninvasiveness, portability, and simplicity [3].
Here in, we developed a wearable electrochemical AMH immunosensor based on flexible conductive fibers for real-time AMH monitoring in menstrual blood sample. Polyurethane (PU)-coated polyethylene terephthalate (PET) fiber was used as a substrate to fabricate the flexible fiber electrode. Gold (Au) precursors were efficiently absorbed into the PU layer and then directly reduced to Au nanoparticles (AuNPs), forming a conductive composite of AuNPs and PU on the fiber. The AuNPs-based conductive fiber showed highly flexibility, stability against bending deformation (1000 repeated cycles), and excellent biocompatibility. Anti-AMH was immobilized on the AuNPs on the conductive fiber electrode by using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and N-hydroxysulfosuccinimide (NHS) coupling agents. Electrochemical characterization of the layer-by-layer assembly of the immunosensor was obtained by electrochemical impedance spectroscopy (EIS) and cyclic voltammetry (CV). To characterize the AMH detection, the performance of the sensor was investigated by using square wave voltammetry (SWV). In addition, we demonstrated that the fiber-based flexible AMH sensor can be successfully applied to textile-based wearable AMH sensors which monitor the AMH level in menstrual blood. This sensor can be appropriate to apply to integrate textile as a wearable electrochemical sensor for menstrual blood AMH.

Use of Laser Induced Graphene (LIG) Electrodes for Hydration Status Monitoring in Artificial Urine Through Electrochemical Impedance Spectroscopy (EIS) Julio Fajardo[1], Andrea Lara[1], Andres Cazali[1], Marcelo Del Aguila[1], Victor Tzorin[1], Douglas Lira[1], Ariel Gonzalez[1], Maria Asplund[2,2,3] and Jose A. Leal Ordonez[2,2,1]; [1]Galileo University, Guatemala; [2]University of Freiburg, Germany; [3]Chalmers University of Technology, Sweden

Water is known as the source of life as it constitutes over 60% of cellular and body composition. It is fundamental for the proper functioning of all organs to keep a constant water content; otherwise, the risk of deterioration and sub-optimal performance increases. Under normal circumstances, a glass of water can reverse the effects of momentary dehydration, as well as a balanced diet, can ensure the correct electrolyte concentrations required for homeostatic maintenance in the body. However, this is not the case for several people in the world, which are at risk of sustained or even chronic dehydration. The latter can be due to poor access to water and food (e.g., developing or war-stricken countries), labor in harsh environments (e.g., field workers at coffee or sugar cane plantations, soldiers, construction workers), or as a result of the physiological aging process. Moreover, chronic dehydration is associated with several dangerous health conditions (e.g., hypertension, renal failure, diabetes, cancer, heart infarction, dementia, etc.) and should be prevented. Unfortunately, in most situations, the first signs of dehydration are mistaken or ignored by patients, which makes the early detection of this process of the utmost importance.

For people within the aforementioned risk groups, it is recommended to be aware of changes in the body throughout the day to recognize the early symptoms of dehydration such as thirst, loss of perspiration and darker-colored urine. Nonetheless, this can't be considered as a reliable, reproducible diagnostic tool, as it does not provide absolute water content and does not consider the loss of essential electrolytes. These people should have access to simple, cheap and reliable diagnostic tools to prevent any critical condition. Current laboratory based solutions like urine specific gravity and osmolality measurements provide clear insight into critical water and electrolyte concentrations and allow to take countermeasures when dehydration, hypo- or hyperkalemia, or -natremia are happening. Nevertheless, this is always a reactive solution to an ongoing problem and would not be feasible as a continuous preventive measure.

As an alternative, we propose the use of cost-effective laser-induced graphene (LIG) electrodes in combination with an AD5940 (Analog Devices, USA) impedance analyzer to perform electrochemical impedance spectroscopy (EIS) of urine samples. The data can then be analyzed through machine learning algorithms to determine the sample's relative water, sodium, and potassium concentration. With this approach, we can bring hydration monitoring to any place in the world.

Kapton sheets were pyrolyzed using a CO_2 laser to fabricate the LIG electrodes. These were then connected through 3D printed holders to the AD5940 impedance analyser and submerged in carefully prepared artificial urine solutions of varying water, sodium and potassium concentrations. The measurements were conducted with several electrodes and repeated until an appropriate set for machine learning training was obtained. During the experiments, the concentration changes could be measured as a change in the EIS spectrum of the solution, which could be then translated to the adequate proportion of water, sodium or potassium. We conclude that LIG electrodes and the AD5940 impedance analyzer are suitable for bioimpedance spectroscopy analysis. Furthermore, combination of these measurements with machine learning can be used for preliminary detection of dehydration in urine, and could be implemented in situations where constant monitoring with limited resources is necessary. Furthermore, the results obtained herein, pave the way for the use of LIG electrodes and EIS for the observation and quantification of biological processes in which bioimpedance plays a significant role such as wound healing monitoring, early cancer detection, live cell monitoring, impedance cardiography, impedance tomography, and many more.

SB03.03.13
Bioinspired Stretchable Water-Repellent Carbon Nanotube-Implanted Adhesive Electronics Patches Hyeongho Min[1,2], Gui Won Hwang[1], Jinhyung Kim[1] and Changhyun Pang[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Korea Research Institute of Standards and Science, Korea (the Republic of)

For reliable real-time diagnosis of dynamic human body, wearable devices with adhesive interfaces for vertical/horizontal directions of dry/wet biological surfaces and water-repellent stretchable electrical performance are in high demand. Here, we present an electrically adhesive patch inspired by a diving beetle with a conductive multi-scale architecture, mechanical-stably implanted with nanowires that provides a skin-adaptable, isotropic stretchable interface for a multi-biometric signal monitoring device. Using a facile all-solution-based process, a hydrophobic, stretchable carbon-nanotube-implanted conductive

composite electrode on insect-like adhesive architectures is fabricated. The conductive adhesive patch with bioinspired wrinkled microsuction cups exhibits remarkable enhanced wet adhesion with sweat-drainability, as well as high stretchable electrical performance under tensile strain in dry and wet conditions. Furthermore, this unique structure exhibits multidirectional bonding (i.e. normal and shear directions) through enhanced horizontal bonding as well as conventional vertical bonding. Due to the high durability and softness of the biomimetic electro-adhesive patch, its performance is successfully maintained even after repeated attachments (<1000 cycles) and mechanical stretching. In order to demonstrate a multiplexed wearable device by minimizing discomfort and signal noise, ECG and temperature measurement on soft skin can be performed simultaneously in a dry and humid environment

SB03.03.14
An Intelligent Skin Patch with Bio-Inspired Architectures for Diagnostics and Treatment Jihyun Lee, Sangyul Baik, Hyoung-Ki Park and Changhyun Pang; Sungkyunkwan University, Korea (the Republic of)

Recent advances in bio-inspired architectures have received attention as promising approaches with which to implement smart skin-interfacial devices for personalized healthcare. In situ skin diagnosis requires adaptable skin adherence and rapid capture of clinical biofluids. Here, we report a simple, all-in-one device consisting of bio-inspired architectures and hydrogels that can rapidly capture biofluids and conformally attach to skin for stable, real-time monitoring of health. Inspired by the male diving beetle, the skin patch achieves repeatable, enhanced, and multidirectional adhesion to human skin in dry/wet environments, revealing the role of the cavities in these architectures. The hydrogels within the microplungers instantaneously absorb liquids from the epidermis for enhanced adhesiveness and reversibly change color for visual indication of skin pH levels. In addition, our hybrid skin patch system demonstrated reversible and directional adhesion to the complex skin surface, while allowing the drug-containing hydrogel to be in ultra-intimate contact with the non-flat skin with hierarchical roughness. With the aid of diving beetle-inspired adhesive, this extraordinary conformal hydrogel interface provides an efficient strategy for the diagnostics and treatment of skin diseases.

SB03.03.15
Mechanically Transformative Electronics Integrated with Soft, Stretchable Radiative Cooler for Reliable Rigidity- and Shape-Tuning in Hot Outdoors Sang-Hyuk Byun[1], Joo Ho Yun[2], Se-Yeon Heo[2], Chuanqian Shi[3], Gil Ju Lee[4], Karen-Christian Agno[1], Kyung-In Jang[5], Jianliang Xiao[3], Young Min Song[2] and Jae-Woong Jeong[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of); [3]University of Colorado Boulder, United States; [4]Pusan National University, Korea (the Republic of); [5]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of)

The integration of a mechanically tunable gallium-based platform with soft electronics, referred to as a transformative electronic system (TES), provides an optimized mechanical interface of electronic devices intended for specific use. The stiff and flat interface of rigid electronics, such as smartphones and laptops, allows robust and convenient handling, while the compliant and deformable nature of soft electronics favors wearable and implantable applications. However, the mechanical properties of each electronics are fixed, restricting their applications beyond the original target use. The stiffness-tuning ability of TES can overcome the inherent constraints of both rigid and soft electronics owing to their fixed rigidity. Through the liquid-solid phase transition of gallium, the TES can exploit the key features of both rigid and soft electronics. While the low melting point of gallium (T_{melt}; 29.76 °C) makes the softened TES appealing for wearable and implantable applications, however, it can also inhibit the stable rigid-mode operation of TES, especially in a hot outdoor environment due to unwanted liquefaction of gallium. Therefore, proper thermal management is required for the gallium-based TES to prevent undesired softening during the rigid-mode operation. Previous approaches to managing excessive heat of electronics involve either enhancement of the device's thermal conductivity for effective heat dissipation or integration of an active cooling system (e.g., coolant circulator and thermoelectric device). However, these strategies are not suitable for TES in preventing unwanted softening due to insufficient cooling capability and high power consumption, respectively.
Here, we present an advanced design of TES that incorporates a stretchable radiative cooling system for a reliable rigid-mode operation in the hot outdoors. The stretchable radiative cooler provides enhanced reflectivity in the solar spectrum and thermal emissivity in the atmospheric window for zero-power cooling of TES. The outstanding optical characteristics are attributed to our unique design of the radiative cooler, which is a multi-layered structure of porous styrene-ethylene-butylene-styrene (SEBS) to maximize multiple Mie scattering, and provide sufficient cooling capability even under strong sunlight. Therefore, the integration of the radiative cooler with TES effectively prevents the undesired rigid-to-soft mode conversion in the hot outdoors. The radiative cooler shows sub-ambient cooling of ~4.5 °C under peak solar power of 927 W/m^2, maintaining the desired high rigidity of TES in a hot environment under sunlight. When the radiative-cooler-integrated TES is mounted on the skin (33–35 °C), the system becomes soft and available for use as a wearable device. Due to the flexible and stretchable properties of the radiative cooler, our proposed TES design allows 3-dimensional conformal integration on the skin with natural deformations. Furthermore, the proof-of-concept demonstration of the radiative-cooler-integrated TES, which can convert between a rigid handheld form and a soft wearable form, verifies the reliable rigid-mode operation in a hot outdoor environment when desired, suggesting that the radiative cooler is a highly favorable option for thermal management of a gallium-based TES owing to its zero-powered sub-ambient cooling capability.

Wearable Ultrasonic Technologies for Deep Tissue Sensing Sheng Xu; University of California, San Diego, United States

Wearable electronic devices that can noninvasively and continuously acquire vital signs from the human body represent an important trend for healthcare. Combined strategies of materials design and advanced microfabrication allow the integration of various components and devices on a soft wearable platform, resulting in functional systems with minimal constraints on the human body. Physiological signals in deep tissues are particularly valuable, because they have a stronger and faster correlation with the events in the human body than those signals on the skin surface. In this presentation, I will demonstrate a wearable ultrasonic technology that can noninvasively and continuously acquire dynamic information about our deep tissues and central organs. I will demonstrate use cases of this wearable ultrasonic technology in recording hemodynamics in central vessels, blood vessel distributions, cardiac chamber activities, and deep tissue biomechanics. The wearable ultrasonic technology represents a platform that holds profound implications for a wide range of applications in consumer electronics, defense medicine, and clinical practices.

Correlation Analysis between Blood Glucose and Tear Glucose in Animal Models Using Smart Contact Lenses Wonjung Park, Byungjun Joo and Jang-ung Park; Yonsei University, Korea (the Republic of)

With the development of a healthcare system, studies regarding the diagnosis of diabetes non-invasively by monitoring the glucose level in various body fluids such as tear, saliva and ISF are ongoing. Among them, tear is emerging as the one of the most promising body fluids for monitoring health conditions and many studies are underway to measure the tear glucose level through various biomedical platforms including contact lenses. For these platforms to be reliable for diagnosing diabetes, it is essential to clarify the correlation between blood glucose and tear glucose which remains controversial. To address this controversial issue, studies that present the relationship between blood glucose and tear glucose using smart contact lens were reported. However, previous smart contact lenses were operated only at specified time which is non-continuous and have failed to identify the exact correlation.
Herein, we present an in-depth investigation of the correlation between blood glucose and tear glucose. Our smart contact lenses are capable of continuous and long-term measurements at short time intervals which enables exact comparative analysis. The developed smart contact lenses were applied to normal and diabetic animal models for authentic clinical investigation of the correlation between blood glucose and tear glucose. This approach can offer unprecedented prospects for applications of the advanced biomedical platforms in further clinical trials.

Wireless Non-Invasive Monitoring of Cholesterol Using A Smart Contact Lens Hayoung Song, Haein Shin and Jang-ung Park; Yonsei University, Korea (the Republic of)

Excessive cholesterol levels in the human body can cause an accumulation of plaques in an artery, which can induce hyperlipidemia. For diagnosing hyperlipidemia, it is important to continuously detect cholesterol levels. In recent years, the smart contact lens platform has emerged as a promising wearable healthcare device platform that measures non-invasive physiological signals in the human body. Herein, we present a soft smart contact lens that can detect cholesterol levels in tear fluids for monitoring hyperlipidemia patients using a smartphone. This smart contact lens incorporates an electrochemical biosensor for the detection of cholesterol concentrations, a stretchable antenna, and a near-field communication chip for wireless communication, which makes a smartphone the only device required to operate this smart contact lens wirelessly. The hyperlipidemia rabbit model was utilized to confirm the correlation between cholesterol levels in tear fluid and blood and to verify the feasibility of this smart contact lens for the diagnostic application of cholesterol-related diseases. Moreover, in-vivo studies with human subjects demonstrated high potential as a non-invasive healthcare device with good wearability and reliability as a non-invasive healthcare device.

Designing Bioelectronic Materials for Regenerative Medicine and Biosensing Molly Stevens; Imperial College London, United Kingdom

This talk will provide an overview of our work on chemical modification and functionalisation strategies to obtain designer materials for bioelectronic applications in regenerative medicine and biosensing. I will discuss how we introduce moieties to the polymer backbone to obtain tunable properties such as semi-conductivity [1], self-immolation [2] and light sensitivity [3]. We design, synthesise and fabricate conjugated polymer-based scaffolds presenting complex electrical and topographical cues to support neural stem cell adhesion, growth and differentiation [4]. I will also discuss the opportunities presented by organic bioelectronics that can be applied as powerful tools for disease diagnostics and cellular monitoring and interfacing [6]. Finally, I will talk about how we are establishing effective translational pipelines to drive our innovations to clinical application.

Mechanics of Bio-Conformable Devices Nanshu Lu; The University of Texas at Austin, United States

Noninvasive or invasive body-conformable devices include epidermal electronics, smart contact lenses, implantable artificial retina, integumentary cardiac membranes and so on. They provide functionalities from biometric sensing to therapeutics, from prosthesis to augmented capabilities. As human organs are soft and curvilinear but electronic devices are conventionally rigid and planar, it is important to understand their mismatch and develop mechanics models to guide the design of the material, structure and interface of body-conformable devices. This talk will present an overview of the field [1] and a few examples related to epidermal electronics [2, 3] and artificial retina [4]. Analytical and numerical models have been established and experimentally validated. In particular, a scaling law has been derived for non-stretchable circular sheets conforming to spherical surfaces with and without cuts [5].

Multi-Variable Biosensing Platform Based on Aerosol Jet Printed Organic Electrochemical Transistors (OECTs) for Diabetic Wound Care Paul Lavryshyn, Jiaxin Fan, Sheldon Parr, Matt Larouche, Michael Lanyon, Douglas Zochodne and Manisha Gupta; University of Alberta, Canada

Diabetic patients have an increased risk of developing chronic foot ulcers/wounds that may lead to severe consequences, including lower-extremity amputation and mortality. Studies have shown that specific parameters, such as pH, pressure, moisture, and temperature, are related to wound infection and healing phases [1]. However, in conventional wound management physicians have limited access to the real-time monitoring of these parameters and can

only assess wound status by removing the dressing, which often leads to patient discomfort and may disrupt the healing process [1]. Continuous monitoring of the wound environment with embedded wound dressing biosensors provides real-time wound status to physicians, which can aid wound care decision-making to reduce severe outcomes.

Here, we have developed a multi-variable biosensing platform to achieve *in situ* continuous monitoring of glucose and temperature levels on chronic diabetic mice wounds. Organic electrochemical transistors (OECTs) were selected for enzymatic glucose sensor development due to their high intrinsic signal amplification, low operation voltages, and compatibility with aqueous environments. We have previously reported functionalization optimization of aerosol jet printed glucose sensors[2]. In this work, the OECTs were fabricated using an Optomec Aerosol Jet 5X printer on flexible Kapton substrates with Au nanoparticle ink for the source and drain electrodes, Pt nanoparticle ink for the gate electrode, a PEDOT:PSS channel, and polyimide as the insulator. Glucose sensing was achieved by functionalizing the printed Pt gate with glucose oxidase, chitosan, and Nafion. The glucose sensor was first optimized in simulated wound fluid to achieve a desired detection range of 0.1mM – 50 mM with an average sensitivity of 0.17NR/dec.

The resistive temperature sensor was developed from a thermoplastic and carbon nanotube nanocomposite mixture. The nanocomposite was drop casted and annealed on printed Au traces and demonstrated a high linearity in its resistance change for the temperature range of 20°C to 55°C. Currently, the sensitivity is approximately 20 **Ω**/°C with an average negative temperature coefficient of -0.001 K^{-1}. The ease of fabrication coupled with extremely high linearity ($R^2 > 0.999$) makes this an ideal candidate for temperature detection to include with our OECT devices on one substrate.

We developed a custom-designed circuit with signal processing hardware for data collection during *in vivo* wound monitoring. It includes low-noise biasing circuitry to enable OECT operation as well as a multi-channel analog to digital converter for the measurement of OECT voltage and current characteristics. Raw 32-bit data is logged to an on-board high-capacity SD card for long-term operation and further data processing is done off-board using a custom MATLAB program. Preliminary results of our glucose and temperature level measurements using our biosensing platform on healthy and diabetic mice animal model wounds will be presented.

Optimization of Polyaniline based Flexible pH Sensor for Diabetic Wound Sensing Michelle Livojevic, Anoushka Ganguli and Manisha Gupta; University of Alberta, Canada

pH is a very important parameter for many different applications where the acidic or basic nature of the media can affect the outcomes. One such application is continuous real-time monitoring of the pH of a diabetic wound is of great importance along with other parameters like glucose, lactate etc. pH of the diabetic wound also provides the information about whether the wound is infected. In addition, the sensing of other parameters like glucose and lactate typically rely on enzymatic reactions which are affected by the pH of the wound exudate. Also, the pH of a wound can give an idea of how well it is healing. Thus, pH sensing is important by itself and also to calibrate the other readings of biosensors in the wound environment. The reliance on pH to determine the outcomes of processes and to establish baselines for sensors is the motivation behind the development of the flexible miniature pH sensor reported here. Due to the small size and flexibility of the pH sensor it can easily be integrated for use in many different situations.
In this work, an electrochemical pH sensor was developed using polyaniline (PANI) as the pH sensitive material. PANI was selected due to its ability to reversibly undergo protonation and deprotonation from its emeraldine base (EB) form to the emeraldine salt (ES) form and back, in the presence of acidic or basic media. This is utilized as the sensing mechanism as the EB form is less conductive than the ES form. Thus, based on the pH of the sample the conductivity of the PANI thin film will change. Another reason that PANI was chosen is that it is sensitive to the physiologically relevant pH range of 4 - 9.[1] One issue with PANI is that pristine PANI thin films are very fragile - therefore, polyvinyl alcohol (PVA) is added to increase the mechanical durability and flexibility of the pH sensor. The sensors were fabricated using an Optomec Aerosol Jet 5X printer to print gold electrodes on a flexible Kapton substrate, followed by a passivation layer of polyimide (PI) to prevent shorting of the device. Next the device was treated with oxygen plasma to enhance the adhesion of the PANI/PVA film to the Kapton substrate. Finally, a PANI/PVA thin film is spin coated on the device to create the pH sensitive film. Devices will be optimized by varying the geometry and composition. Results of pH measurements in different artificial buffers will be presented. To improve the signal to noise quality the developed PANI/PVA thin films will be used in organic electrochemical transistors (OECT) as the gate or channel material.

Rapid Meniscus-Guided Printing of Stable Semi-Solid-State Liquid Metal Microgranular-Particle for Soft Electronics Gun-Hee Lee; KAIST, Korea (the Republic of)

Liquid metal is being regarded as a promising material for soft electronics owing to its distinct combination of high electrical conductivity comparable to that of metals and exceptional deformability derived from its liquid state. However, the applicability of liquid metal is still limited due to the difficulty in simultaneously achieving its mechanical stability and initial conductivity. Furthermore, reliable and rapid patterning of stable liquid metal directly on various soft substrates at high-resolution remains a formidable challenge. In this work, meniscus-guided printing of ink containing polyelectrolyte-attached liquid metal microgranular-particle in an aqueous solvent to generate semi-solid-state liquid metal is presented. Our liquid metal microgranular-particle printed in the evaporative regime is mechanically stable, initially conductive, and patternable down to 50 μm on various substrates. Demonstrations of the ultrastretchable (~500% strain) electrical circuit, customized e-skin, and zero-waste ECG sensor validate the simplicity, versatility, and reliability of this manufacturing strategy, enabling broad utility in the development of advanced soft electronics.

1:30 PM SB03.05.01
Conformable Microneedle Interstitial Fluid Accessing Platform for Biochemical Sensing Wonryung Lee; Korea Institute of Science and Technology, Korea (the Republic of)

Conformable sensing platforms are widely used as medical device platforms because of their ability to adapt well to complex biological structures. In particular, due to its flexibility and biocompatibility, it is used to measure bioelectrical signals in organs (eg brain, heart, muscle). In recent research, using this conformable sensing platform, many research groups are trying to access biofludics in various ways to measure biochemical signals as well as bioelectrical signals. As an example, there is a method using sweat to access biofludics. However, it has limitation to long-term monitoring of the disease, since it must be generated through electrical stimulation.

The microneedle platform is one candidate to access Interstitial fluid as penetration. To provide skin penetrability and conformability to skin simultaneously, the integrated substrate for this device must offer both a high Young's modulus microneedle (10^{2}~10^{3} μm) and a sub-micron-thick conformable substrate (~10 μm). A sub-micron-thick substrate can make high mechanical stress by wrinkling or crumpling, which causes damage to the interface between needle and substrate.

In the work reported here, we developed a novel multi-microneedle pH sensor array on soft substrates by integrating two siloxane-based polymers, each with a different Young's modulus. The device could have two advantages through these integrated substrates, including skin penetrability of low Young's modulus PDMS and conformability to the skin of high Young's modulus epoxy siloxane, respectively. The medical applicability of these conformable microneedle pH sensors was demonstrated by measuring the pH distribution on the dermal layer of a peripheral-vascular-disease rat model. Furthermore, glucose sensing was also demonstrated.

Gelatin-Based Ingestible Impedance Sensor for Diagnosing Eosinophilic Esophagitis Gaurav Balakrishnan, Durva Naik, Arnav Bhat, Julie Shin Kim, Sona Marukyan, Aditya Khair and Christopher J. Bettinger; Carnegie Mellon University, United States

Eosinophilic esophagitis (EoE) is an allergen-induced esophageal inflammatory condition that affects over 200,000 patients in the United States, causing symptoms such as dysphagia, chest pain, and heart burn. With a lack of effective treatment options, early diagnosis and allergen identification is key in managing EoE. Current diagnostic protocols involve frequent endoscopies and tissue biopsies, creating an inconvenient and painful experience for patients. Research has shown that electrical impedance can be used to diagnose EoE because of intercellular dilation. Here, we design, fabricate, and test a gelatin-based ingestible impedance sensing capsule using both *in vitro* and *ex vivo* test beds.
Impedance sensing capsules were fabricated by integrating microfabricated thin-film electrodes with soft gelatin-based structural materials via a custom aqueous-phase transfer printing method. Through controlling the addition of a non-volatile solvent glycerol (50% v/v) and cross-linking agent genipin (10% crosslinking), the mechanical properties of the gelatin substrate were optimized (E ~25kPa, ε_{max} ~200%). The transferred devices on a 0.5 mm gelatin substrate demonstrate a low bending stiffness of 1.5×10^{-8} Nm^2, allowing for the structures to be easily wrapped around a cylinder of 1 cm to form a capsule.
The microfabricated sensors were first tested using a synthetic electrochemical tissue phantom comprising varying volume fractions of 20μm dielectric polystyrene (PS) microparticles dispersed in ionic agarose hydrogels to mimic changes in intercellular spacing. The impedance spectra show that composites with higher PS volume fractions display higher impedances and effective solution resistance values. Furthermore, normalized experimental impedance spectra show strong agreement with predicted spectra calculated using a Poisson-Nernst-Planck model of the composite system.
An *ex vivo* disease model was generated by treating porcine esophageal explants in 0.1 M HCl. Histology was performed to show that there is damage induced to the epithelial layer, causing an increased intercellular spacing. Microfabricated sensors interfaced with planar tissue section show that they are capable of distinguishing between the healthy and damaged tissues, with an over three-fold difference between the impedance of healthy and diseased tissue at 10kHz ($Z_{healthy}$ = 10kΩ, $Z_{diseased}$ = 3kΩ). Following this, 8-channel multiplexed impedance measurements were performed using the gelatin-based sensing capsules linearly translated through a porcine esophagus to obtain impedance heat maps. It is observed that the electrodes have sufficient contact with the epithelial tissue, with a significant increase in impedance on exit from the esophagus ($Z_{in\ eso}$ = 15kΩ, $Z_{out\ eso}$ = 200kΩ; @ 10kHz). Additionally, the sensors provide accurate impedance measurements through healthy and diseased esophagi at translation velocities similar to the rate of swallowing (v = 8 cm/s).
In conclusion, ingestible impedance sensors are a promising non-invasive and reliable platform to diagnose eosinophilic esophagitis. The presented transfer printing method is a versatile technique that can be useful in fabricating soft, hydrogel devices for a wide range of soft bioelectronic applications. Lastly, the *in vitro* synthetic model is a promising testbed for conditions that result in the impeded barrier function of epithelial tissues.

2:00 PM SB03.05.03
Bioelectronics Integrated on 3D Skin Surfaces via Kirigami-Structured Nanofibrous Membranes and Transfer-Printed Microsensors Hegeng Li, Liu Hongzhen, Sun Mingze and Lizhi Xu; The University of Hong Kong, Hong Kong

Skin-integrated soft electronics have attracted extensive research attention due to their potential utility for fitness monitoring, disease management, human-machine interfaces, and other applications. Although many materials and device components were explored for the construction of skin-integrated systems, achieving multifunctional sensor platform combined with good breathability, conformability and robustness on the skin remains difficult. Herein, two platforms were built for 3D interfaces between bioelectronics and the skin. Firstly, breathable and conformal electronic membranes (BCEMs) were manufactured with hybrid integration of microfabricated multifunctional sensors and kirigami-structured nanofibrous substrates. The resulting membrane devices exhibit tissue-like mechanical properties with high permeability for vapor transport. In addition, kirigami structures can be introduced into these membranes, providing high stretchability and 3D conformability for large-area integration on the skin. In the second scheme, tough and permeable aramid nanofiber- polyvinyl alcohol (ANF-PVA) membranes were introduced to build robust kirigami electronics. The nanofiber composite endows high fracture toughness of kirigami membranes, which can prevent failure of kirigami membranes upon stretching due to crack propagation. Energy release rate were calculated by finite element analysis (FEA) to evaluate the robustness of kirigami membranes. Microfabricated sensors and conductive polymers were employed to be the electronic components of kirigami electronics. The multifunctional sensors array from these two platforms allowed for spatiotemporal measurement of bioelectrical signals, temperature, skin hydration, and potentially many other physiological parameters. The robust performance and manufacturing scalability provided by these multifunctional skin electronics may create further opportunities for the development of advanced wearable

systems.

2:15 PM *SB03.05.04
Electronic and Tissue Interactions SuPing Lyu; Medtronic Incorporated, United States

Integration of medical devices into the patients is a must-pass step for the devices to function as intended. Obviously, it can be easier for devices that are intended to work for hours or days than those intended to function for years. Mechanical forms, fit and placement, electrical, chemical, and/or optical communications, and biological interactions are among the factors that need be considered. For certain devices and applications, the changes of devices over time are parts of the intended designs such as those with resorbable devices. More factors need be considered for them.
This talk is focused on how the tissues of the patients may impact the devices' placement and their functions. Specific examples would include how the patient tissues mechanically and biologically affect the electric and /or electronic devices, causing the functions to be different than observed in vitro. One example is electrodes of electrical stimulation devices such as cardiac pacemakers. The electrodes inserted in the tissues must have certain electric and chemical properties in order for them to deliver the electric signals to the tissues. Another example is implanted electronic devices that must be protected from being damaged by the body fluids of the patients. Water diffused into electronics can easily lead to loss of functions. This is one of the most critical questions that need be answered to make devices for long term implantable applications for the patients. Biocompatibility of devices will also be discussed briefly.

3:45 PM SB03.05.06
Bioadhesive Electronics for Atraumatic Cardiac Monitoring and Pacing *In Vivo* Jue Deng and Xuanhe Zhao; Massachusetts Institute of Technology, United States

Existing clinically-adopted bioelectronic implants mostly rely on surgical suturing or insertion of electrodes to the target tissue for diagnostic and therapeutic applications. However, these approaches can cause tissue trauma during the application and/or retrieval of the bioelectronic implants, potentially causing detrimental complications such as bleeding, tissue damage, and/or device failure. Here, we report a bioadhesive electronic device for atraumatic epicardial monitoring and pacing of the heart in vivo to overcome the limitations of existing bioelectronic implants. We use multi-material 3D printing to fabricate the bioadhesive electronic device, which offers rapid atraumatic application and retrieval as well as robust mechanical and electrical interfacing with the heart. We systematically validate the mechanical and electrical properties, biocompatibility, continuous epicardial monitoring and pacing capability, and rapid on-demand atraumatic application and removal of the bioadhesive electronics based on in vivo rat and porcine models. These findings may offer a promising platform for atraumatic bioelectronic diagnosis and treatment and inspire the future development of bioadhesive electronics.

4:00 PM SB03.05.07
Liquid 3D Bioelectronics for Diagnosis and Therapeutic Stimulation in Cardiovascular Disease Sumin Kim and Jang-ung Park; Yonsei University, Korea (the Republic of)

Accuracy in recording the electrocardiograms (ECGs) is essential for the diagnosis and treatment of cardiovascular diseases such as arrhythmia, bradycardia, or atrial fibrillation. Previous studies have been conducted for accurate monitoring of ECGs, but existing devices using planar, rigid materials with high moduli (>1 GPa) have a mechanical mismatch in interface with the biological tissues (~100 KPa). This causes various problems such as lowering the quality of ECGs, resulting in immune responses and damaging the tissue during long-term recording. Additionally, the epicardium layer of the heart adjoining the myocardium, where most planar devices are attached, restricts the clear recording of the ECGs. Therefore, for precise and long-term recording, the development of a tissue-like and injectable three-dimensional (3D) device that can reach the myocardium to reduce undesirable noise levels is important. Here, we demonstrate the liquid 3D bioelectronics based on microneedle structure for both functions of cardiac diagnosis and therapeutic stimulation, with their tattooable, injectable, and biocompatible properties. The fluidity of these liquid 3D microneedles is beneficial in preventing tissue injury by offering reliable operations. Through an in-vivo experiment with a rabbit model, we confirmed that the liquid 3D microneedles are capable of monitoring clearer signals compared to the conventional planar electrodes, and of transmitting electrical stimulus to a live heart for recovering from cardiac disorder to a normal rhythm.

Implantable Bioelectronic Scaffolds Laden with Therapeutic Schwann Cells for Nerve Repair Ryan P. Trueman, Owein Guillemot-Legris, Henry Lancashire, Alethea Tabor, Bob Schroeder and James B. Phillips; University College London, United Kingdom

Nerve injuries can occur following physical trauma and, in severe cases, the nerve is completely severed (full transection of the axons), creating a gap that requires surgical intervention to allow regeneration. The current gold standard of treatment for severe nerve injuries is to obtain nerve tissue from elsewhere in the patient's body and use it as a graft to bridge the gap. This presents various problems including loss of nerve function at the donor site, limited availability of donor tissue, and poor functional recovery. Electrical stimulation has shown promise in both direct applications to less severe nerve injuries[1] and to the cells responsible for nerve regeneration[2]. This work aims to create a bioelectronic, cell laden construct that can be used to replace, and potentially surpass, the current gold standard autograft for treatment for nerve injuries.

The artificial bioelectronic scaffolds are comprised of a composite material of temperature controlled, templated oxidative polymerized polypyrrole (PPy)

nanoparticles combined with fibrillar collagen to create a homogenous hydrogel. These gels were then processed using a technique known as gel aspiration-ejection (GAE). GAE aligns the material within the hydrogel, whilst removing the bulk of the entrapped water. Furthermore, our work investigates Schwann cells, a therapeutic cell type for nerve regeneration, and the effect of electrical stimulation through gene analysis of key repair phenotype genes.

This results in dense, aligned conductive scaffolds suitable for implantation in cases of severe nerve injury. An advantage of the GAE technique is that during the manufacturing process, therapeutic cells, such as Schwann cells[3], can be directly incorporated and distributed throughout the composite hydrogel, creating a cell laden, bioelectronic construct.

Monolayer Schwann cell cultures were investigated to detect gene expression changes caused by a single application of electrical stimulation. This experiment revealed significant upregulation of pro-regenerative gene expression due to the external stimulation, and importantly, a significant upregulation of c-Jun, often cited as the key transcription factor of Schwann cell repair phenotype[4]. Furthermore, upregulation in gene expression of neurotrophic factors was also shown following electrical stimulation. Our work has shown that it is possible to create these cell laden bioelectronic scaffolds. Therapeutic cells within the constructs do not have altered viability, indicating that the material is biocompatible, and the fabrication process is suitable.

By developing bioelectronic cell laden tissue engineered constructs for peripheral nerve repair, we aim to enhance both the therapeutic cells within the construct, and the body's endogenous nerve repair program. Through the process of implanting a bioelectronic scaffold, subsequent applications of electrical stimulation following surgical repair may be used throughout the regenerative process, to further augment the nerve regeneration process. Future work involves conducting the same gene analysis experiment on the therapeutic cell laden bioelectronic constructs to assess if conductive material augments the benefits shown within monolayer cultures.

Flexible Electronics Enable New Insight Into Neuronal Network Dysfunction That Progresses with Aging and Alzheimer's Disease Theodore J. Zwang[1,2], Noah Pettit[2], Chris Harvey[2], Charles M. Lieber[3] and Bradley T. Hyman[1,2]; [1]Massachusetts General Hospital, United States; [2]Harvard Medical School, United States; [3]Harvard University, United States

A major challenge in studying aging processes is that they occur over long time scales and across brain regions, yet they involve changes in individual neurons with millisecond activity. Recent advances in the design of implantable flexible electronics allow them to study the same individual neurons and circuits over multiple months. These properties enable the study of functional changes in brain processes that occur over long periods of time, such as the onset of dementia associated with Alzheimer's disease pathology. In this presentation I will describe the design and use of flexible electronics implanted into the brains of mice that progressively accumulate Alzheimer's disease pathology with age. I will show how flexible electronics enable unique insight into cellular and circuit-level changes over long periods of time. Specifically, two flexible electrophysiology probes with neuron-like design were implanted into a single hemisphere of ThyTau22 or WT mice. One probe was targeted to the hippocampus, and the other to the medial entorhinal cortex. Recordings were made with each probe once per week over 6 months while mice run along a linear track in virtual reality. These data show the progression of an aging and tau-pathology correlated decrease in neuronal network integrity that occurs both within and between the hippocampus and entorhinal cortex at different rates.

9:00 AM SB03.06.03
A Bidirectional Neural Probe for Optical, Electrical and Chemical Probing of Neural Dynamics Nicolette Driscoll, Marc-Joseph Antonini, Atharva Sahasrabudhe, Anthony Tabet and Polina Anikeeva; Massachusetts Institute of Technology, United States

Within the brain, billions of neurons communicate via diverse electrical and chemical signaling mechanisms. To begin to unravel how the function of specific neuronal subtypes within neural circuits gives rise to behavior, methods of recording and modulating neural activity across electrical, optical, and chemical modalities have been developed. Each technique has its own set of advantages and constraints, especially regarding spatial and temporal resolution, cell-type specificity, and the necessity of genetic manipulation. Combining multiple neural interfacing modalities into a single probe can leverage their unique advantages to reveal new insights into neural circuit dynamics. Here, we report a bidirectional, multifunctional neural probe that, for the first time, combines six modalities of neural interfacing: electrophysiology, electrical stimulation, fiber photometry, optogenetic stimulation, fast-scanning cyclic voltammetry (FSCV), and drug/gene delivery. We employed convergence thermal drawing to fabricate meters-long 300 µm diameter flexible fibers containing a polymer optical waveguide for fiber photometry and optogenetics, a microfluidic channel for drug/gene delivery, and carbon nanotube (CNT) electrodes for electrophysiology, electrical stimulation, and FSCV recording of a neurotransmitter dopamine (DA). Polymeric components with similar glass transition temperatures (T_g) were first machined into a macroscale preform containing the optical waveguide, a microfluidic channel, and hollow channels for CNT yarn electrodes. During the draw, the polymer preform was heated above its T_g and stretched such that the hollow channels shrank and converged around high T_g CNT yarns, which were thus integrated into the microscale fiber. This resulted in a multimaterial microscale fiber with conserved cross-sectional geometry compared to the preform. We demonstrate the use of our multimodal neural probe *in vivo* by implanting probes into the ventral tegmental area (VTA) and nucleus accumbens (NAc) of adult mice and investigating mesolimbic dopaminergic reward pathways. During implantation, the embedded microfluidic channel was used to deliver opsins (ChrimsonR) and optical reporters (dLight1.1) to the target brain regions. Following recovery, we performed combinations of electrical and optical stimulation, coupled with fiber photometry, electrophysiology, and FSCV recording to illustrate the utility of our multimodal probe for studying circuit level neural dynamics.

9:15 AM *SB03.06.04
Soft Subdural Electrode Arrays Tailored to Monitor Slow and Fast Neural Activity Stephanie P. Lacour; Ecole Polytechnique Federale de Lausanne, Switzerland

Brain signals arising from neuropathologies can include both fast (e.g. fast ripples, up to 1kHz) and slower signals (e.g. spreading depolarization (SD) below 1Hz). Building interfaces that can monitor the full bandwidth of neural signals is thus crucial for a deeper understanding of the possible links

between the two electrophysiological signatures in brain diseases.
We report on our efforts to engineer soft subdural electrode arrays scaled to large animal models and chronic studies. Such translation requires high manufacturing reproducibility and performance stability of the soft device materials and devices. We verify the functional integrity and stability of the soft brain implants in vivo over time using *in-vivo* electrochemical spectroscopy measurements.
We implemented the soft neurotechnology to monitor seizure episodes and slow depolarization (SDs) in a middle cerebral and anterior artery occlusion (MCA and AA) pig model of ischemic stroke. The electrode array was designed to cover a large surface of the cortex (5.2 cm^2) from 32 electrodes of 250 µm radius, in order to follow the spread of SDs over a large portion of the occluded hemisphere. Electrodes are coated with a soft platinum-based composite to guarantee low electrode impedance. We monitor continuously cortical activity using a wireless amplifier system at 1kHz sampling starting from the healthy cortex pre-occlusion, during the occlusion itself and post-occlusion over a timespan of 18 to 26 hours.
Slow patterns (SDs) and faster activity resembling focal seizures were successfully recorded in three animals indicating the soft electrode arrays are a promising interface to help decipher pathological activities for neurological diseases.

Peripheral Neural Interfaces to Restore Sensory, Motor and Autonomic Functions Silvestro Micera[1,2], Eugenio Redolfi Riva[2], Ciro Zinno[2], Alice Giannotti[2] and Melis Özkan[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Scuola Superiore Sant'Anna, Italy

Neuroengineering is a novel discipline combining engineering including micro and nanotechnology, electrical and mechanical, and computer science with cellular, molecular, and cognitive neuroscience to increase our basic knowledge of how the nervous system works and to develop systems able to restore functions in people affected by different types of neural disability.
Here we are going to present our recent activities to develop new and more effective peripheral interfaces for different applications. First, we are going to show how a new regenerative interface can allow to re-connect the vagus nerve with cardiac functions. Then, we are going to show how a three-dimensional intraneural interface can be used for recording and stimulation to restore bladder functions. Finally, we are going to show how new epineural interfaces can be developed for bidirectional prosthetic systems.

Printing of Soft Neural Interface Systems on the Cranium for Wireless Neural Recording Yong Won Kwon, Young-Geun Park, Dong Ha Lee and Jang-ung Park; Yonsei Uuniversity, Korea (the Republic of)

Unveiling the mechanism of the functional connectivity of the brain can help reveal the treatments for brain dysfunction causing brain disorders and neurodegenerative diseases. Thus, long-term monitoring of brain activities with high-spatiotemporal resolution in natural conditions of subject is necessary. Moreover, current approaches for wireless neural recording based on battery-powered or battery-free systems, deteriorate integration to the biological system by requiring replacement of intermittent batteries and heavy batteries mounted on the head, or additional bulky stages for wireless power transfer and data acquisition system.
To overcome these limitations, we report a soft, conformable, and printable neural interface system on the cranium for wireless neural recording that can be conformally integrated within the subject's head, with the high-resolution printing of eutectic gallium-indium alloy (EGaIn; 75.5% gallium, 24.5% indium by weight), which is a representative gallium-based liquid metal. The printed neural interface system comprises soft neural probes, cranial circuits, and form factor-free batteries. First, liquid metal-based neural probes are fabricated structurally and mechanically similar to neurons (~ 5 um), minimizing the formation of inflammation and immune responses. Second, liquid metal-based cranial circuits are directly printed on the surface of the cranium for electrical connection to neural probes, which are implanted in multiple brain regions of a single subject, with adaptable geometries. Third, liquid metal-based electrical interconnections with subsidiary electronics form miniaturized and conformal circuits on the cranium within the subject's head, which maximizes the integrity of electronics to biological systems, minimizing bulky head-mounted configurations. Furthermore, in-vivo recording using our device in freely moving mice demonstrated the simultaneous recording of local field potentials (LFPs) and single-unit spiking in multiple regions of the brain, as well as its biocompatibility and stability for the long term (~ 33 weeks), and these results suggest its broad and practical applications for various bioelectronics and neuroscience research.

11:00 AM SB03.06.07
Fully Injectable Tissue Engineered Bioelectronics for the Brain Alexander J. Boys, Alejandro Carnicer-Lombarte, Ana Fernandez-Villegas, Gabriele Kaminski Shierle, George G. Malliaras and Roisin Owens; University of Cambridge, United Kingdom

Stable, long-term integration between implanted devices and the brain remains a challenge. Properly interfaced neural implants provide the potential for recording brain activity, enabling the generation of neurally-driven prosthetics, treatment of neuroses, and a deeper understanding of brain function, among other applications. One of the major issues inhibiting long-term recordings of the brain is the lack of integration between an implant and surrounding tissue. This lack of integration often results in an inflammatory and subsequent scarring response driven by mechanical mismatches between the probe and adjacent tissue, as well as damage caused during implant placement. Tissue engineered implants provide a solution to this problem through their superior integrative capacity *in vivo* but traditionally lack any interactive components. To generate a tissue engineered neural probe, we have combined the recording capabilities of bioelectronic devices with the regenerative capacity of cellularized, tissue engineered implants to create a new implant system. Here, we developed a fully injectable bioelectronic, tissue engineered implant system for integration with the brain.

We constructed a bioelectronic device with a minimized cross-section and individually articulable leads (32 leads, each 8 x 4 µm in cross-section) to reduce the footprint of the device at the implantation site. We utilized a needle to place the device and to inject a tissue engineered matrix containing primary neurons to assist in implant placement and integration between the device and surrounding tissue. After 3 weeks, the tissue engineered insertion site was well-integrated into surrounding tissue with no clear boundary between the insertion site and brain. The interior of the implant site is entirely cellularized, primarily with neurons. A minimal microgial response was noted at the insertion site. Astrocytes were visible within the boundaries of the implant site as well. Astrocytes were also surrounding the implant site but not in conjunction with microglia, likely indicating remodeling of the insertion site. Conversely, in the control, a large boundary, consisting of astrocytes and microglia, is visible, and the interior of the implant site contained fragmented tissue.

We show the design and implementation of a fully injectable system for placing tissue engineered bioelectronic implants into the brain. This system allows for the placement of viable cell populations along with functional bioelectronic recording devices that integrate into surrounding tissue. We are now examining the long-term implications for this system and recording efficacy for neural signals over this period. Overall, we have generated a new, injectable implant system for placing bioelectronic tissue engineered brain implants. This system has potential to promote long-term recordings and integration, while causing minimal damage at the insertion site, and provides a means for new therapeutic approaches in the brain.

11:15 AM SB03.06.08

A Flexible and Scalable Neurophysiological Acquisition Array for High-Definition Brain Mapping Andrew Bourhis, Ian Galton and Shadi Dayeh; University of California, San Diego, United States

For decades, neurophysiologists have relied on electrophysiological recoding arrays to investigate cortical function. Electrocorticography (ECoG) grid arrays are routinely placed on the cortical surface for mapping of functional and diseased cortical tissue and have improved patient outcomes. However, clinically used ECoG arrays have low spatial resolution and have seen little innovation until recently. Owing in part to advances in materials science and semiconductor devices, the field of neural interface technology is now exploding, with different approaches demonstrating improvements in spatiotemporal resolution, coverage, implantability, and scalability towards higher channel counts. Despite these recent strides, many problems in this field remain unsolved. One of these challenges is the scalability of systems towards ultra-high channel counts where wiring within the arrays and toward the outside world remains a major bottleneck. Integrated circuits fabricated using conventional lithographic techniques can significantly simplify routing and reduce the number of connecting wires, but rigid and brittle silicon-based acquisition electronics are incompatible with soft neural tissue.

Toward this end, we have developed a flexible neural interface that incorporates dual-gate indium gallium zinc oxide (IGZO) thin-film transistors (TFT) as active amplifying and multiplexing elements for neurophysiological sensors. These TFTs are optimized for bio-interface applications, generating low heat densities during normal operation while maintaining high sensitivity, with electron mobilities up to 30cm^2/Vs and transconductance per unit drain current comparable to silicon technologies. The TFTs are built with a low-temperature monolithic fabrication process which is compatible with polymer substrates, incorporating a novel multi-layer ceramic-polymer hermetic sealing which acts to protect the system against fluids and charged ions. We have demonstrated that this strategy protects traces from undergoing any electrochemical reaction while immersed in phosphate-buffered saline for 24 hours and driving them with +-6V amplitude square waves, and we plan on conducting accelerated aging tests with single TFT devices under various bias conditions. We have also fabricated 256-channel multiplexed ECoG arrays and have fine-tuned the device characteristics and fabrication flow to be able to conduct benchtop experiments in PBS prior to conducting an in-vivo whisker-barrel stimulation experiment in a rat model.

11:30 AM SB03.06.09
Adaptable Liquid Metal Neural Probes for Neural Recording and Localized Stimulation Dong Ha Lee, Yong Won Kwon, Young-Geun Park and Jang-ung Park; Yonsei University, Korea (the Republic of)

Monitoring neural activities and stimulating deep regions of the brain are the essential method to diagnose and treat neurological disorders such as Parkinson's disease, tremor, and dystonia. Recently, neural probes that can monitor neuronal signals and stimulate deep brain regions, have been researched as implantable bioelectronics for deep brain interface. However, current neural probes are based on solid metals or silicon, which cause inflammation and glial scars at tissue-electrode interfaces during micromovements of the brain with complicated nanofabrication methodologies. For long-term, stable recording and stimulation of the brain, which is essential for the neural probe as a device for the treatment of chronic neurological diseases, such bioelectronic devices require softness as a tissue, high conductivity, and long-term biostability. Gallium-based liquid metals have low Young's modulus compared to rigid metals while maintaining high conductivity and also show great biocompatibility, making them a potential applicant to neural probes.
Herein, we present the adaptable, facilely fabricated liquid-type neural probes applicable for both neural recording and electrical stimulation. The liquid form of our neural probe has comparable Young's modulus to the neural tissues compared to former neural probes using rigid metals, minimizing the formation of inflammation and glial scars on the brain tissues when implanted. A porous nanostructure was formed on the electrode-tissue interface, improving the electrochemical properties such as the impedance, charge storage capacity, and charge injection capacity for effective recording of neural signals and charge injection during electrical stimulation. Moreover, the liquid extrusion resulting from the electrical stimulation-induced current was effectively controlled, and biostability was improved due to this porous biocompatible nanostructure. We also demonstrate *in-vivo* tests for electrical stimulation and recording of neuronal signals from the rat's brain. Through electrical stimulation to the rat's brain, the rat's behaviors were controlled to a stable and manageable level, furthermore, significant changes in recorded neural signals were detected with different behavior conditions. These effective recording and stimulation results using our liquid-type neural probes are expected to play a role in the treatment of neurological disorders.

Human Brain Mapping with Multi-Thousand Channel PtNRGrids Resolves Spatiotemporal Dynamics Youngbin Tchoe[1], Andrew Bourhis[1], Daniel R. Cleary[1], Brittany Stedelin[2], Jihwan Lee[1], Karen Tonsfeldt[1,1], Erik C. Brown[2], Dominic Siler[2], Angelique C. Paulk[3], Jimmy C. Yang[3], Hongseok Oh[1], Yun Goo Ro[1], Keundong Lee[1], Samantha Russman[1], Mehran Ganji[1], Ian Galton[1], Sharona Ben-Haim[1], Ahmed M. Raslan[2] and Shadi Dayeh[1]; [1]University of California, San Diego, United States; [2], Oregon Health & Science University, United States; [3]Massachusetts General Hospital, United States

Electrophysiological devices are critical for mapping eloquent and diseased brain regions and therapeutic neuromodulation in clinical settings and are extensively utilized for research in brain-machine interfaces. However, the existing devices are often limited in either spatial resolution or cortical coverage, even including those with thousands of channels used in animal experiments. Here, we developed scalable manufacturing processes and dense connectorization to achieve reconfigurable thin-film, multi-thousand channel neurophysiological recording grids using platinum-nanorods (PtNRGrids). With PtNRGrids, we have achieved a multi-thousand channel array of small (30 μm) contacts with low impedance, providing unparalleled spatial and temporal resolution over a large cortical area. The 7" long cortical electrodes together with our sterilizable compact connector overcome challenges associated with the required large separation between the sterile surgical field and the non-sterile acquisition electronics enabling reliable intraoperative recordings from patients undergoing neurosurgical resections.
The spatiotemporal recording capability of the PtNRGrids is investigated first with anesthetized rat model undergoing whisker air-puff stimulations using high-density 32 × 32 array electrodes with 150 μm pitch and 4.8 mm × 4.8 mm coverage. The spatial mapping of stimulation evoked high gamma activity (HGA) measured from the electrode clearly distinguished functional boundaries of individual whisker barrels at 150 μm resolution that captured the histochemically-demonstrated structure.
In the clinical setting, PtNRGrids resolved fine, complex temporal dynamics from the cortical surface in an awake human patient performing grasping tasks. HGA showed distinctive neural correlates of hand movements when compared to baseline. Furthermore, we recorded phase reversal boundaries during motor mapping to precisely localize the central sulcus in sub-mm scale resolution. These results with our high-density grids offer an unprecedented view of the functional organization and coordination of motor function over large brain regions in the human cortex. Additionally, the PtNRGrids

identified the spatial spread and dynamics of epileptic discharges in a patient undergoing epilepsy surgery at 1 mm spatial resolution, including activity induced by direct electrical stimulation. Collectively, these findings demonstrate the power of the PtNRGrids to transform clinical mapping and research with brain-machine interfaces and highlights a path toward novel therapeutics.

1:45 PM SB03.07.02
Direct-Print 3D Electrodes for High-Resolution and High-Multiplexity Neural Interfaces Pingyu Wang[1], Eric Wu[1], Hasan Ulusan[2], A.J. Phillips[1], Sasidhar Madugula[1], Ramandeep Vilkhu[1], Eric T. Zhao[1], Andreas Hierlemann[2], Guosong Hong[1], E.J. Chichilnisky[1,1] and Nicholas Melosh[1]; [1]Stanford University, United States; [2]ETH Zürich, Switzerland

With advances in complementary metal-oxide-semiconductor (CMOS) technology, it is now possible to sense or modulate neural activity at an unprecedentedly large scale, through multiple modalities, and at a spatial resolution matching the neuron density. However, most planar and rigid CMOS devices have limited access to regions within neural tissue, limiting our ability to understand or modulate neural activity. To bridge this geometrical gap, researchers have investigated integrating penetrating electrodes onto CMOS devices, yet many critical challenges remain. For example, these penetrating electrodes have low spatial density and their fabrication processes can damage the CMOS electronics.

Here, we leveraged a high-resolution 3D printing technology to directly build high-density penetrating microelectrode arrays onto CMOS devices. We fabricated 6,600 electrodes with varying heights and pitched at 35um. The highly versatile process allows customization of array shape and spatial density to tailor to different tissue shape or neuron density. We characterized the electrical and electrochemical properties of the electrode array, and showed that they can be easily customized. As a proof-of-principle demonstration, we recorded retinal ganglion cell activity ex vivo. With this technology, we hope to achieve neural interfacing at single-cell and single-cell-type resolution, which will be crucial for communicating with neural circuits using their natural neural codes.

2:00 PM SB03.07.03
Electrophoretic Devices for Brain Cancer Therapy Tobias Naegele[1], Johannes Gurke[2] and George G. Malliaras[1]; [1]University of Cambridge, United Kingdom; [2]University of Potsdam, Germany

A fundamental limitation for the success of chemotherapy in brain cancer therapies is the blood-brain-barrier which plays a pivotal role in protecting the central nervous system but also significantly reduces the amount of cancer drugs which can be delivered into a tumour [1]. Bad vascularisation of solid brain tumours further complicates delivery of therapeutically relevant drug doses [2]. Therefore, the off-target toxicity of many common chemotherapeutics places strong constraints on the amount of drugs which can be safely systemically administered.

Here, we present a novel implantable device which allows highly spatially selective delivery of charged drug molecules directly into brain tumours. Our device combines a microfluidic system for drug transport with embedded electrodes which facilitate electrophoretic transport of charged drug molecules into the target tissue. This allows delivery of drug molecules without transport of bulk solvent preventing issues arising from intracranial pressure gradients. We have investigated different electrode reactions in order to overcome limitations arising from limited electrode capacitances. The device is uniquely designed for cranial implantation ensuring minimal damage to healthy tissue when implanted. By employing stereolithographic 3D printing for the device fabrication, we allow easy modification of the design to adapt the device driven by individual tumour morphologies. Our device is not limited to specific drug molecules and can therefore easily be adapted to different cancer therapy schedules. While electrophoretic drug delivery was first described in the early 20th century and has been used since primarily for transdermal drug delivery, we believe that our approach is one of the first times this has been demonstrated for brain cancer therapy. Electrophoretic delivery will facilitate significantly higher drug concentrations in the tumour tissue than when systemically delivered while having minimal systemic impact.

Multiplex Neurochemical Sensing via Electrografting-Enabled Site-Selective Functionalization of Graphene Field-Effect Transistors Yang Song, Zan Gao, Guangfu Wu and Yi Zhang; University of Connecticut, United States

Neurochemicals corelease has received much attention in understanding brain activity and cognition. Despite many attempts, the multiplex monitoring of coreleased neurochemicals with spatiotemporal precision and minimal crosstalk using existing methods is challenging. Here, we report a soft neural probe for multiplex neurochemical monitoring via electrografting-assisted site-selective functionalization of aptamers on graphene field-effect transistors (G-FETs). The neural probes possess excellent flexibility, ultralight mass (28 mg), and a nearly cellular-scale dimension of 50 μm × 50 μm for each G-FET. As a demonstration example, we show that G-FETs with electrochemically grafted molecular linkers (-COOH or -NH_2) and specific aptamers can be used to monitor serotonin and dopamine with high sensitivity (limit of detection: 10 pM) and selectivity (dopamine sensor > 22-fold over norepinephrine; serotonin sensor > 15-fold over dopamine). In addition, we demonstrate the feasibility for the simultaneous monitoring of dopamine and serotonin in a single neural probe with minimal crosstalk and interferences. The developed multiplex neural probes can be used to study the corelease of dopamine and serotonin in the brain, spinal cord and peripheral nerves, suggesting broad applications in neuroscience research. The developed multiplex methodology can also be adapted for monitoring other neurochemicals, such as other monoamines, amino acids and neuropeptides, by simply replacing the target aptamers functionalized on the G-FETs.

3:30 PM *SB03.07.05
Miniature Battery-Free Bioelectronic Devices and Networks Jacob T. Robinson; Rice University, United States

Electronic devices that sense or manipulate biological signals have the potential to improve medical outcomes by directly acting on nerves, brain areas, and organs. However, despite the potential for these “bioelectronics devices” only a handful of implanted bioelectronic devices are currently the standard of care. One reason that implantable bioelectronics are not more widely used is that they typically require a relatively large battery pack roughly the size of a matchbox, and long wires that connect the battery pack to the sensing or stimulation target inside the body.

By creating bioelectronic devices that function without the need for batteries it would be possible to miniaturize these technologies to millimeter-scale dimensions that could easily be implanted with minimally invasive surgeries. This approach would further allow distributed networks of sensors and

actuators to measure and manipulate physiological activity throughout the body to enable precise and adaptive bioelectronic therapies with minimal risks or interference with daily activities. Magnetoelectric materials offer a platform wireless power transfer technology particularly well suited for this goal of miniature bioelectronics.

Here we will discuss how magnetoelectric materials function for wireless power transfer through the body and how they enable millimeter-sized devices that can be implanted through catheters and used to reach nerve targets via blood vessels. We go on to describe new opportunities for creating bioelectronic networks and how advances in magnetoelectric materials can enable even smaller implantable bioelectronic interfaces.

4:00 PM SB03.07.06
Highly Sensitive and Tunable Organic Voltage Amplifiers Based on Inkjet-Printed Organic Electrochemical Transistors for *In Vivo* Recordings of Brain Activity Yongwoo Lee[1], Alejandro Carnicer-Lombarte[2], Sanggil Han[2], Ben Woodington[2], Seungjin Chai[1], Anastasios Polyravas[2], Santiago Velasco-Bosom[2], George G. Malliaras[2] and Sungjune Jung[1,1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]University of Cambridge, United Kingdom

Organic electrochemical transistors (OECTs) exhibit great potential in electrophysiology signal-recording applications. Their mechanism of operation leverages mixed ionic/electronic conduction, and this makes them amplifying transducers that offer a high signal-to-noise ratio. However, the output of OECTs is current and this makes them incompatible with most electrophysiology data acquisition systems. To maximize their utilization, a circuit converting their output to the voltage without bulky back-end connectivity would be highly desirable. Here, we present inkjet-printed organic voltage amplifiers by integrating active and passive electrical components on a single, highly flexible substrate for in vivo brain activity recording. Drop-on-demand printing facilitates fine-tuning of the voltage amplification properties while monolithic integration of the printed circuit achieves significant noise reduction. Finally, we validate the conformable brain-integrated organic voltage amplifiers as electrocorticography devices in a rat in vivo model, showing their ability to record local field potentials in an experimental model of spontaneous and epileptiform activity in rats. Our results pave the way for the use of OECT-based circuits toward the seamless interface between biology and electronics.

4:15 PM SB03.07.07
A Lubricated Non-Immunogenic Neural Probe for Acute Insertion Trauma Minimization and Long-Term Signal Recording Yeontaek Lee[1], Hyogeun Shin[2], Il-Joo Cho[2] and Jungmok Seo[1]; [1]Yonsei University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

Brain-machine interfaces (BMI) are being spotlighted as a tool to help people with extensive clinical disabilities. For example, neural signals recorded from the brain through chronically implanted electrodes can be decoded into a synthesized voice, controlling the movement of computer cursors and robotic limbs. Therefore, it is most essential to seamlessly integrate interfaces between the brain tissue and the implanted neural probe to record and control neurons over long periods of time. In recent decades, a myriad of neural probes with different shapes, materials, multiplexities, and functionalities has been developed for firm integration with brain tissue to record single action potentials stably from neurons. However, clinical BMI has not yet been widely adopted, largely because of the biological inflammatory responses on probe-tissue interfaces that arise from acute insertion trauma and chronic foreign body reaction. Intense insertion trauma not only causes an increase of acute neural loss but also accelerates the initial formation of the glial sheath around the implanted probe. Furthermore, the thickness of this glial sheath increases gradually due to the foreign body reaction, eventually driving neurons away from electrodes beyond effective recording range.
Here, we report a lubricated immune-stealth probe surface (LIPS), a neural probe electrode surface fully combined with a thin lubricant layer that displays frictionless and anti-biofouling properties *in vitro* and uncompromised electrode performance *in vivo*. The simple act of coating extends the lifetime of implantable devices by minimizing both the inflammatory response that arises from probe insertion trauma and the adhesion of inflammatory factors. LIPS can repel the adhesion of various body fluids (artificial cerebrospinal fluid; aCSF, simulated body fluid; SBF, and blood) and maintain its extraordinary anti-biofouling properties. Its exceptional anti-biofouling properties against plasma proteins and glial cells were confirmed *in vitro*, resulting in less than 1% attachment, whereas extensive adhesion occurred on bare probe surfaces. Also, our mechanical analysis confirmed that LIPS could reduce 86% of impulse from probe-tissue interface friction, shortening the acute inflammatory response that follows. Lastly, *in vivo* evaluation of the LIPS applied neural probe's electro-physiological performance was conducted. Compared to the bare probe, LIPS transiently doubled in the number of recording channels and displayed up to 9-fold improvement in signal-to-noise ratio (SNR). Long-term effects of LIPS formation included an electrode lifetime double that of the bare probe, as shown by their ability to record neuronal action potentials over a period of 4 months. This is consistent with the immunohistology results, which revealed minimal foreign body reaction on LIPS. Therefore, LIPS displays potential as a non-immunogenic surface for versatile use in BMI applications – even for the studies of deep brain electro-physiology that require insertion of rigid probes.

4:30 PM SB03.07.08
Miniaturized and Multifunctional Hydrogel Probes for Neuromodulation Sizhe Huang[1], Collin Maley[2], Kayla Felix[1], Weixuan Chen[1], Qianbin Wang[1] and Siyuan Rao[1]; [1]University of Massachusetts Amherst, United States; [2]Boston University, United States

Neural probe technologies have been used in the nervous system to modulate and record neural signaling via different modalities for understanding the mechanisms underlying neurological disorders, yet the long-term stability of such interfaces has been hindered due to the immune response caused by the mechanical mismatch between the tissues and devices. Also, the integration of different modalities within a biocompatible neural probe without increasing its rigidity and dimensions has been unachievable. Here, we report a multifunctional neural fiber probe based on soft and stretchable hydrogel materials (Polyvinyl Alcohol, PVA) via a one-step molding and extrusion method with controllable shrinking manners to address these challenges. The results have demonstrated that the PVA fiber probes can achieve a high shrinking ratio at hydrated states with a high refractive index, low absorbance, and low light loss. Additionally, a microfluidic channel has been integrated into a hydrogel optical core for pharmaceutical delivery via hydrogel shrinking manners. Furthermore, the hydrogel neural probe has been implanted into the social circuit-related brain region (Ventral tegmental area, VTA) of mice which permits chronically optogenetic stimulation, chemical intervention, and behavior studies of neural circuits in moving and socializing animals.

4:45 PM SB03.07.09
Supercapacitor RuO_2-Integrated Optoelectronic Neural Interface for Safe and Efficient Neurostimulation Onuralp Karatum[1], Erdost Yildiz[1], Humeyra Nur Kaleli[1], Afsun Sahin[1], Burak Ulgut[2] and Sedat Nizamoglu[1]; [1]Koc University, Turkey; [2]Bilkent University, Turkey

Fabrication of light-sensitive and safe optoelectronic biointerfaces that have high charge densities is important for non-invasive photostimulation of neurons with low light intensities. Photocapacitive biointerfaces offer a biocompatible charge injection mechanism, but their charge injection densities are mostly limited with the double-layer capacitance at the electrode-electrolyte interface. Here, we integrated supercapacitor ruthenium oxide (RuO_2) into an organic photocapacitive biointerface architecture to overcome the double-layer capacitance-limited charge injection.[1] RuO_2-integrated biointerfaces exhibit more than an-order-of-magnitude enhancement of photogenerated charge densitiy because of high interfacial pseudocapacitance of RuO_2 that results from fast and reversible redox reactions. The improved photoresponse of the biointerfaces enabled light-induced activation of voltage-gated sodium channels

that led to repetitive and high success rate firing of action potentials in primary hippocampal neurons with light intensities below 1 mW mm^{-2}. The reversible faradaic reactions induced by RuO_2 provides a safe charge injection route at the device-electrolyte interface, which was supported via intracellular oxidative stress analysis. We verify the stability of RuO_2 biointerfaces with accelerated ageing and sterilization tests and confirm their in vitro biocompatibility via cytotoxicity analysis. Our findings show that flexible and all-solution-processed RuO_2 biointerfaces can be used for photomodulation of neurons with safe charge injection and low light intensities.

Comparing a Conventional 2D with a 3D Bioelectronic Platform for Studying the Mechanism of Diet on Host-Microbiome Interactions in the Human Gut Verena Stoeger and Roisin Owens; University of Cambridge, United Kingdom

Increasing evidence demonstrates that the gut microbiome plays a significant role in human health and disease. Moreover, a strong association of the gut microbiome with the aetiology of non-communicable diseases such as type II diabetes or inflammatory bowel disease (IBD) exists.[1] Metabolites, synthesized by gut bacteria from the diet, are key for inducing beneficial health effects within host-microbiome interactions. The most prominent metabolites are short-chain fatty acids (SCFA), which are mainly acetate, propionate, and butyrate, predominantly produced by fermentation of dietary-derived fibre by bacteria like *F. prausnitzii*.[2] SCFAs have been shown to induce several favourable health effects in the mechanism of diabetes or obesity, but are also able to improve the functionality of the gut barrier in IBD. These effects induced by SCFAs are suggested to be mediated via activation of G-Protein coupled receptors (GPCR), especially the candidate GPR43, however, full mechanisms are not well understood yet.[3]
The most obvious reasons for that are the limited possibility to study non-invasively host-microbiome interactions in humans as well as a lack of access to human biopsies. Conventional 2D in vitro models are valuable tools for high-throughput screening and animal studies allow to get insights into cause-effect relationships, however, a translation to human physiology is still challenging.[4] Thus, with the recently developed electronic 3D model of the human gut, we are aiming to generate predictions on host-microbiome interactions that are closer to the real human *in vivo* situation. The use of a soft and tissue-like electroactive scaffold (PEDOT: PSS) as a platform for cell hosting, allows to monitor in real-time non-invasively changes of the electrical resistance as a readout parameter of the gut barrier functionality (barrier integrity).[5] Co-culturing of cell lines promotes cell-cell communications and thereby improves the expression of native cell receptor profiles as well as cell signalling processes.[6] In addition, the integration of a bioelectronic sensor enables detection of the overall cell activity after activation of GPR43 by SCFAs instead of single pathway analysis, commonly done in conventional receptor assays.[7] Currently, the effects of SCFAs on markers of the gut barrier integrity are compared in (*i*) traditional 2D Transwell inserts versus the 3D bioelectronic model of the human gut. Moreover, for getting a better understanding of the bioelectrical signature of the 3D platform, (*ii*) electrical readouts are deconvoluted using conventional molecular biological techniques like RT-qPCR.

3D Multifunctional Bioelectronics for Multimodal Charting of the Human Induced Pluripotent Stem Cell Derived Organoids Ren Liu, Qiang Li, Zuwan Lin, Xin Tang and Jia Liu; Harvard University, United States

Induced pluripotent stem cells (iPSCs) technology has created great opportunity for modelling human diseases and offers potential for application of personalized regenerative cell therapies. To fully understand and assess the function and maturation of stem cells-derived tissues and organoids, we need multimodal methods capable of long-term stably recording individual cell electrical activity with high spatiotemporal resolution across three-dimensional (3D) tissues, multiplexed profiling of a large number of genes in electrically recorded cells, and cross-modal computational analysis. However, none of existing technologies can fulfill these requirements. In this talk, I will first introduce the development of soft “tissue-like” stretchable mesh nanoelectronics, which match the physical and mechanical properties of soft tissue. I will also present how to integrate multifunctional sensors into the soft “tissue-like” nanoelectronics to map the multimodal tissue functions. Then I will discuss how to distribute the stretchable tissue-like bioelectronics across the entire 3D organoids by their organogenetic processes. I will discuss the seamless and noninvasive coupling of electrodes to cells, capable of providing long-term stable electrical contacts with progenitor or stem cell, captures the emergence of single-cell action potentials and enables long-term stable, continuous recording from 3D organoids during their development process. Third, I will introduce our efforts to combine the *in situ* single-cell RNA sequencing with soft bioelectronics as a method termed “*in situ* electro-seq”. *In situ* electro-seq enables large-scale single-cell electrical recording and high-throughput single-cell sequencing to systematically and simultaneously investigate single-cell electrophysiology and gene expression across the intact iPSC-CMs organoids. Finally, the future perspective to apply these technologies to both *in vitro* and *in vivo* biosystems for stem cell therapies will be discussed.

Controlled Small Molecule Transport in Nanofluidic Channels Aleksandr Noy[1,2]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Merced, United States

The ability to control and direct specific ion transport across multiple scales is one of the fundamental challenges for bioelectronic applications. While researchers have traditionally focused on organic materials such as conductive polymers for these tasks, recent progress in materials science associated with development of 1D and 2D nanomaterials is beginning to offer some potential alternatives. Precise control over molecular confinement, readily achievable in these materials, provides additional unique opportunities to enhance their performance. I will discuss several examples of controlling ion and small molecule transport in highly confined channels with conductive walls. I will highlight some of the unusual mechanisms that enhance ion transport efficiency and ion transport selectivity in these systems, discuss the energy barriers for transport in these systems, and outline some challenges that we face in translating these unique transport properties into applications.

9:30 AM BREAK

10:00 AM *SB03.08.04
Materials for 3D Mesoscale Bioelectronic and Microfluidic Interface Technologies John A. Rogers; Northwestern University, United States

Three-dimensional (3D), sub-millimeter-scale tissue constructs formed using human stem cells, ranging from spheroids and organoids to assembloids, are of rapidly growing interest due to their ability to reproduce essential features of vital organs in a patient specific manner. These miniaturized, fragile 3D living systems cannot, however, be examined easily using most conventional methods for sensing and manipulation, nor can they be grown to sizes larger than those that can be sustained by passive diffusion to and from surrounding media. This talk describes the essential materials and assembly aspects of a type of compliant, 3D technology framework that can be tailored with shapes, sizes and complex geometries to match those of spheroids, organoids and assembloids. Systematic studies demonstrate various electrical, fluidic, thermal, chemical and optical modes of operation that can be supported by these constructs. Examples include their use in monitoring electrophysiological behaviors and mechanical characteristics of cortical spheroids and in forming complex assembloids from dissimilar collections of spheriods.

10:30 AM SB03.08.05
Adaptive Fibre Organic Electrochemical Transistor for Volumetric Embedded Sensing in Organ-on-a-Chip Yifei Pan, Yaqi Sheng, Yan Yan Shery Huang and Ruishan Liu; University of Cambridge, United Kingdom

Three-dimensional (3D) organ-on-a-chip models, which aim to recreate key in vivo, physio-pathological behaviours of organs on microfluidics, have become an important platform for fundamental research and for pharmaceutical testing. As these in vitro models increase in size and complexity, it is paramount to find means of monitoring the dynamics of tissue states in thick sections. Although various transistors and sensors have been developed to integrate with 3D cell cultures, their pre-set formats limit their adaptation and utilisation in a wide range of organ-on-a-chip contexts. Here, an ultra-flexible fibre organic electrochemical transistor (ufOECT) is fabricated to perform volumetric sensing in diverse formats of 3D cultures and organ-on-a-chips. With a diameter of ~30um, and a length adjustable between millimetres to centimetres, the ufOECT can be twisted, curved, or straightened for embedding into a cell culture device for in situ monitoring of effective tissue matrix impedance. It is envisaged that ufOECT could be developed into a powerful tool for low-cost, scalable, label-free and sustainable monitoring organ-on-a-chip devices.

10:45 AM SB03.08.06
3D Bioelectronic Models of the Human Gut and Microbiome Chrysanthi-Maria Moysidou[1], Douglas van Niekerk[1], Verena Stoeger[1], Lorraine Draper[2], Aimee Whiters[1], Colin Hill[2] and Roisin Owens[1]; [1]University of Cambridge, United Kingdom; [2]University College Cork, Ireland

The implications of gut microbiome in various aspects of health and disease is now a well-established concept in modern biomedicine. Over the past decades, numerous studies have revealed links between host health and microbial activity, spanning from digestion and metabolism to autoimmune disorders and neuroinflammation. However, the exact mechanisms underlying the complex host-microbiome cross-talk remain still a mystery,[1] mainly due to the lack of human clinical models and the challenges of translating data from animal models to human systems. Tissue-engineered constructs represent a highly promising alternative technology, apt for tackling these challenges. Such models have benefited from the use of inert gels and scaffolds as substrates for growing human cells within 3D biomimetic microenvironments, prompting tissue formation. However, monitoring technologies used to characterize cell status and activity, as well as to assess treatment effects are ill adapted to 3D biology.[2]
Here, we report on the establishment of a 3D human intestinal model within e-Transmembranes (patent pending), a novel 3D bioelectronic platform recently developed by our group. We first describe the development of the 3D biological system, comprising intestinal and connective tissue cellular components, on the electroactive scaffolds of the e-Transmembranes, which act both as tissue substrates and as electrodes; tissue formation invokes changes on the scaffold conductivity, which is dynamically monitored via Electrochemical Impedance Spectroscopy. We then implement this bioelectronic tissue construct in a proof-of-concept study, looking at the impact of microbiota on the gut barrier integrity. More specifically, we compare the effect of a cohort of postbiotics (i.e., inanimate microorganisms and/or their components that confers a health benefit on the host)[3], with well-known properties, on the morphology and functionality of the intestinal barrier with the respective effects of live bacterial strains (i.e., probiotics approach), also present in the postbiotic cohort. Thanks to real-time, high-content, comprehensive electrical readouts provided by our platform, we are able to closely follow both the evolution of tissue formation (~1 month) and the intimate interactions between host and microbes/microbial components during the postbiotic/probiotic interventions (~24hours). Optical and molecular biology assays at the end of the respective experimental period validate our findings, establishing the electrical signature i) of the complex tissue and its components and ii) of the impact of postbiotic and probiotic interventions on the 3D gut barrier model, thus revealing valuable information on the host-microbiome cross-talk with unprecedented time-resolution. Currently, we are working on interfacing our bioelectronic platform with more complex biological systems, such as intestinal organoids, immune cells and neurons, to further study host-microbe interactions within multi-tissue platforms. We anticipate that the unparalleled capabilities of our bioelectronic tools, combined with our tissue engineering strategy, will serve as a framework for further studies, including toxicology and drug screening/development applications.

Engineering Flexible Electronics for Monitoring Cellular Systems at the Air Liquid Interface (ALI). Sarah L. Barron[1,2], Sophie Oldroyd[1] and Roisin Owens[1]; [1]University of Cambridge, United Kingdom; [2]AstraZeneca, United Kingdom

Over the past decade there has a been substantial growth in the field of flexible electronics for a wide range of applications including device displays, wearables and *in vivo* implants. However, their use in the pharmaceutical industry for the purpose of *in vitro* drug screening has been neglected, leaving gold standard electronic techniques outdated and unnameable to advanced biomimetic cell models. Air Liquid Interface (ALI) cultures, such as those

representative of the lung or skin, pose an additional challenge where the system can not be submerged in an electrolyte for electrode operation. To date, there is no commercially available sensor capable of continuously and non-invasively monitoring at ALI, meaning valuable mechanistic insights into barrier properties may yet be discovered.[1] Building on our previous work[2] and to address the above limitations, flexible microelectrode arrays have been fabricated using established photolithographic techniques.[3] These devices display high conformability and biocompatibility with 21 day old human ALI culture and are capable of monitoring epithelial barrier formation and disruption in real-time, offering combined optical-electrical readouts. This platform provides new insights into barrier properties for improved understanding and pharmacological targeting of biological barrier systems in health and disease. Future directions including validation in other advanced ALI microsystems such as organoid, tissue engineered and lab-on-chip applications.

11:15 AM DISCUSSION TIME

11:30 AM SB03.08.09
Label-Free Optical Recording of Bioelectrical Signals Harnessing Bio-electrochromic Materials Interface. Yuecheng Peter Zhou[1], Erica Liu[1], Holger Müller[2,3] and Bianxiao Cui[1]; [1]Stanford University, United States; [2]University of California, Berkeley, United States; [3]Lawrence Berkeley National Laboratory, United States

Understanding how a network of neurons receive, store and process information in the human brain is a grand scientific challenge of our time. Neurons encode and communicate information through electrical signals. Traditional electrode-based recording methods such as patch clamp or multielectrode arrays are either highly invasive to cells or inflexible to sense electrical fields of cells at user-selected spatial positions with limited recording capacity. Existing optical methods, on the other hand, rely heavily on inserting voltage-sensitive fluorescent molecules into the cell membrane, which suffer from cell phototoxicity, limited recording duration and signal-to-noise ratio due to photobleaching.

Here, we introduce ElectroChromic Optical REcording (ECORE), a new electrophysiology method that optically reads out the electrical activity of electrogenic cells in a label-free and non-perturbative manner harnessing the unique properties of electrochromic polymers. The ECORE method fundamentally differs from any existing voltage recording approaches in that cell electrical signals are read out optically through voltage-sensitive optical absorption of electrochromic polymer thin films. Changes in optical reflection of the film, rather than fluorescence, are detected to probe cell electrical activities through a home-engineered optical system with a high signal-to-noise ratio. In this way, ECORE does not perturb the physiology of cells without the insertion of any molecular probes. It is also not limited by photobleaching or phototoxicity, making it a suitable tool for long-term recording of cell electrical signals over weeks or months. I will talk about single-color, dual-color, and multi-channel optical recording of electrical signals from heart muscle cells, heart tissue, neurons, and brain slices interfaced with different conjugated electrochromic polymers with high sensitivity and throughput.

SESSION SB03.09: Devices for Cells and Tissues II
Session Chairs: Alex Chortos, Jia Liu, Alina Rwei and Lizhi Xu
Thursday Afternoon, December 1, 2022
Hynes, Level 1, Room 111

1:45 PM SB03.09.01
Cyborg Engineering—Integration of Soft Nanoelectronics with hiPSC-Derived Three-dimensional Tissues and Organoids Qiang Li[1], Zuwan Lin[1], Ren Liu[1], Xin Tang[1], Xiao Wang[2,3] and Jia Liu[1]; [1]Harvard University, United States; [2]Broad Institute of MIT and Harvard, United States; [3]Massachusetts Institute of Technology, United States

Complex organs (e.g., heart and brain) rely on spatiotemporally orchestrated interaction of heterogeneous cells to maintain the whole-organ functions. Thus, understating the development, mechanisms, and diseases of these organs require system-level mapping of cellular activities across entire three-dimensional (3D) volumes. Simultaneously charting single-cell gene expression and electrophysiology in intact tissues across time and space is crucial to understand gene-to-function relationships. Such multimodal methods require stable and continuous recording of individual cell electrical activity, multiplexed profiling of a large number of genes in electrically recorded cells, and multi- and cross-modal computational analysis. In this talk, I will first introduce the cyborg organoid platform, which implanted and distributed soft stretchable nanoelectronics through 2D-to-3D organogenesis triggered by cell-cell interactions, enabling long-term stable and tissue-wide recording of cardiac and brain organoids at single-cell resolution throughout tissue development with minimal impact on growth and differentiation. Then, I will discuss our efforts to integrate cyborg organoid technology with *in situ* RNA sequencing as an *in situ* electro-sequencing (electro-seq) technology to stably map millisecond-timescale electrical activity and simultaneously profile single-cell transcriptomes across 3D tissues. We applied *in situ* electro-seq to human-induced pluripotent stem cell-derived cardiomyocyte (hiPSC-CM) patches, enabling multi-modal *in situ* analysis of CM electrophysiology with gene expression at the cellular level, jointly defining cell states and developmental trajectories. Using machine learning-based cross-modal analysis, *in situ* electro-seq identified gene-to-electrophysiology relationships across CM development and accurately reconstructed the evolution of gene expression profiles based on long-term stable electrical measurements. Finally, I will discuss the future directions to apply these technologies to 3D developing tissues and organoids, creating spatiotemporal multi-modal maps and predictive models to assess the functional and transcriptional maturation of the human organoids for cell therapies.

2:00 PM *SB03.09.02
Toward Multimodality Sense (and Actuate) of Three-Dimensional (3D) Tissues Tzahi Cohen-Karni; Carnegie Mellon University, United States

My team's efforts are focused on the development and engineering of nanomaterials-based platforms to interrogate and affect the electrical properties of tissue and cells such as cardiomyocytes, and neurons, with a specific goal to understand electrical signal transduction in complex 3D cellular assemblies, e.g., organoids or spheroids. Highly flexible bottom-up nanomaterials synthesis capabilities allow us to form unique hybrid-nanomaterials that can be used in various input/output bioelectrical interfaces, i.e., bioelectrical platforms for chemical and physical sensing and actuation. We developed a breakthrough bioelectrical interface, a 3D self-rolled biosensor arrays (3D-SR-BAs) of either active field effect transistors or passive microelectrodes to measure both cardiac and neural spheroids electrophysiology in 3D. This approach enables electrophysiological investigation and monitoring of the complex signal transduction in 3D cellular assemblies toward an organ-on-an-electronic-chip (organ-on-e-chip) platform for tissue maturation investigations and

development of drugs for disease treatment. Utilizing graphene, a two-dimensional (2D) atomically thin carbon allotrope, we can simultaneously record the intracellular electrical activity of multiple excitable cells with ultra-microelectrodes that can be as small as an axon (ca. 2µm). The outstanding electrochemical properties of the synthesized hybrid-nanomaterials allow us to develop highly efficient catalysts, and electrical sensors and actuators. We demonstrated sensors capable of exploring brain chemistry and sensors/actuators that are deployed in a 3D tissue models. Finally, using the unique optical properties of nanocarbons in the form of graphene-based hybrid-nanomaterials and 2D nanocarbides (MXene), we have formed remote, non-genetic bioelectrical interfaces with excitable cells and modulated cellular and network activity with low needed energy and high precision. In summary, the exceptional synthetic control and flexible assembly of nanomaterials provide powerful tools for fundamental studies and applications in life science and potentially seamlessly merge nanomaterials-based platforms with cells and tissue, fusing nonliving and living systems together.

2:30 PM *SB03.09.03
Graphene-Based Autonomous Wearable Sweat Biosensors Wei Gao; California Institute of Technology, United States

Wearable and flexible non-invasive bioelectronics for the continuous monitoring of metabolites in sweat can detect a few analytes at sufficiently high concentrations, typically during vigorous exercise so as to generate sufficient quantity of the biofluid. Here, we report the design and performance of wearable electrochemical biosensors for the continuous analysis, in sweat during physical exercise and at rest, of trace levels of a variety of biomarkers including metabolites, amino acids, and vitamins. The wearable sensors consist of laser-engraved graphene electrodes, functionalized with target-specific receptors such as antibody-like molecularly imprinted polymers, and integrated with modules for iontophoresis-based sweat induction, microfluidic sweat sampling, signal processing and calibration, and wireless communication. The clinical value of our wearable sensors was evaluated through multiple human studies involving both healthy and patient populations toward physiological monitoring, nutritional monitoring, disease diagnosis, mental health assessment, and drug personalization. These wearable and flexible devices could open the door to a wide range of personalized monitoring, diagnostic, and therapeutic applications.

Real-Time Pressure Mapping of Brain Organoids by Active-Matrix Array of Field-Effect Transistor Jakyoung Lee, Hunkyu Seo, Moohyun Kim and Jang-ung Park; Yonsei University, Korea (the Republic of)

Brain organoids are being studied for neurodegenerative disease modeling due to their intrinsic three-dimensional (3D) phenotypic characteristics. They are typically cultured for a long time, with their size growing as each day passes. Interestingly, at the end of their functional lifespan, their size does not change significantly, and necrosis starts from the core decreasing the central density of brain organoids. Therefore, it is important to inspect their core condition for characterization of their age. Generally, the cores of organoids are observed by using a confocal microscope. However, this method tends to be inaccurate as the optical characterization cannot thoroughly examine the inside of the organoid.
Herein, we developed a pressure sensor with an active-matrix array for the real-time monitoring of brain organoids. The sensor consists of an array of field-effect transistors (FET) based on Si channels. The channels are extremely small, 10 µm x 10 µm, capable to detect delicate weight of the brain organoids and represent high-resolution pressure sensing. Recording the pressure signal readouts detected from each channel allows 2D mapping that makes it possible to visualize the pressure distribution of the brain organoids. This distribution correlates to the core density which reflects the condition of the organoids, thus it provides the indicator of age characterization. In addition, the examination of their conditions in real-time is simultaneous with the cultivation of organoids due to the media well placed directly above the top gate of the device. Therefore, real-time monitoring through our active-matrix array sensor is expected to manage the brain organoids effectively and evaluate the unconventional mechano-physiological conditions even during the cultivation phase.

3:45 PM SB03.09.05
An Effective On-Demand Chronic Oxygen Delivery Strategy for Implanted Cells via Electrocatalytic Oxygen Evolution Reaction Inkyu Lee[1], Abhijith Surendran[2], Seonghan Jo[1], Samantha Fleury[3], Abijeet S. Mehta[2], Ian Gimino[1], Georgios Nikifordis[2], Xudong Ji[2], Omid Veiseh[3], Jonathan Rivnay[2] and Tzahi Cohen-Karni[1,1]; [1]Carnegie Mellon University, United States; [2]Northwestern University, United States; [3]Rice University, United States

Immunoisolation device containing therapeutic cells has been regarded as a promising cell therapy technique, encapsulating the cells within size-exclusive immunobarrier without the use of immunosuppression. However, the barrier restricts the diffusion of nutrients for the cells. High cell density needed for minimizing device footprint resulting with innately large oxygen consumption further exacerbates local oxygen deficiency. Moreover, physiological oxygen tensions are insufficient to sustain such densely packed cells. Several approaches were developed to support the cells using exogenous oxygen, for example, periodic oxygen injection and embedding peroxide solids. Nevertheless, their capabilities are limited because of a lack of controllability and the exhaustion of oxygen-generating agents.
Here, we report a miniaturized and chronic on-demand electrochemical cell maintenance platform via electrocatalytic oxygen evolution reaction, employing iridium oxide as an electrocatalyst. The distribution of generated oxygen was manipulated by the geometries of catalytic arrays, supported by diffusion simulation. The actual oxygen-generating capabilities of the system were verified by using an oxygen-sensitive probe, and on-demand oxygen delivery was realized by fine-tuning the applied potential/current. We further demonstrated that our strategy does not produce detrimental side reactions. Importantly, our unique bioelectrical oxygenating system significantly improved cellular viability and functionality of cell capsules (60kcell/mm^3) for up to 21 days in vitro under hypoxic conditions (1 % oxygen). By supporting high cell density, our effective and versatile bioelectronic system opens up broad bioengineering applications from organoid basic research to clinical opportunities for patients who are suffering from chronic endocrine disorders.

4:00 PM SB03.09.06
Monitoring of 3D-Printed Airway Model Integrity with an Printed Organic Electrochemical Transistor Seungjin Chai[1], Yunji Lee[1], Yongwoo Lee[1], Woojo Kim[1], Roisin Owens[2] and Sungjune Jung[1,1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]University of Cambridge, United Kingdom

SARS-CoV-2 pandemic has drawn new attention to virus neutralization assay and neutralizing antibody quantification for drug testing preclinical testing and determining drug testing efficacy over time. Disruption of epithelial barriers is a key clinical turning point that differentiates patients who are likely to develop severe virus outcomes. However, convenient, fast and accurate barrier measurement remains a challenge. Organic electrochemical transistor(OECT) has shown a great potential particularly in capturing ionic signals, therefore extensively employed to probe local ion flux changes that are caused by paracellular flow of soluble molecules controlled by tight junctions. Here, we report inkjet printed PEDOT:PSS-based OECT for barrier measurement platform with inkjet printed 3D-printed airway model. We have developed a reliable printing process for fabricating OECT devices. Volumetric capacitance and transconductance of a device were significantly enhanced as the number of printed layered increased.Transient response in OECT could evaluate 3D-printed airway model. Finally, Influenza A virus infection was monitored in a 3D airway model with OECT. We could be detected barrier integrity with the advantages of a noninvasive process. Our platform show promise for use in vaccine evaluation.

4:15 PM SB03.09.07
A Miniature 3D Electrochemical Biosensor for the Detection of Collagenase Type I Graziele M. Cruzado[1], Geraldine Merle[1] and Ashkan Koushanpour[2]; [1]Polytechnique Montreal, Canada; [2]McGill University, Canada

Breast cancer can occur in women at any age after puberty, and according to WHO accounts for 685,000 deaths globally, in 2020. A variety of carcinogenesis processes are intimately related to the extracellular environment, and because collagenases play an important role in extracellular matrix remodeling, they are found to be commonly associated with cancer pathologies. It is known that collagenase type I is commonly associated with enhanced breast cancer growth and metastasis. The levels of collagenase I in a normal adult body are usually low (1.19 ± 0.7 ng/mL) and an elevated concentration is a predictive marker for future development of an invasive type of breast cancer. There's an urge for rapid and efficient tests to help the early diagnosis and consequently treatment of this type of cancer, so that the survival rates can significantly increase. Current technologies – liquid chromatography-mass spectroscopy, fluorescence resonance energy transfer, surface plasmon resonance and ELISA – are costly, complicated, labour intensive, and time-consuming. Additionally, since molecular diagnostic tests and instrumentation are complex, they require highly knowledgeable and expert scientists to establish benchmarks. Compared to these approaches, electrochemical techniques are simpler, faster, low-cost, and user-friendly.
Here we report a miniature 3D electrochemical biosensor for the detection of Collagenase I. A portable 3D electrochemical system was built using 3D printing. Given the hydrolysis ability of the collagenase, a short peptide sequence was chemically modified with a redox probe and attached to a gold electrode. Improving on the signal to noise ratio and sensitivity without affecting the volume of the electrode was achieved with Au nanospikes. Au nanospikes were first electrodeposited using Pb to guide the Au growth and to increase the deposition rate due to the cathodic depolarisation of the electrode surface. Given the presence of cysteine in the peptide, thiol chemistry was applied by simply immersing the Au surface of the 3D electrode. The successful grafting was well established by FT-IR, electrochemical analysis through cyclic voltammetry (CV) and square wave voltammetry (SWV) and SEM analysis. The cleavage of the peptide by the collagenase, was measured after only 10 minutes via the signal decrease due to the decrease in the tunneling current. The peptide loaded Au nanospike system performance was verified in collagenase type I solution (PBS, pH 7.4) exhibiting linear range of detection of 1 to 500 ng.ml-1 and LOD of 0.07ng/ml The peptide loaded Au nanospikes on an unconventional 3D system showed as a desirable candidate to become an alternative to the conventional and complex assay for the detection of collagenase and can be deployed for mass testing in point-of-care settings.

4:30 PM SB03.09.08
Aerosol Jet Printed OECT-Based SARS-CoV-2 Spike Proteins Disposable Biosensors with n-type Naphthalene Diimide Small-Molecule OMIECs Seongdae Kang, Jiaxin Fan and Manisha Gupta; University of Alberta, Canada

COVID-19 pandemic is still an ongoing issue in our community. The battle against this disease still imposes a heavy burden on hospitals and the healthcare system. Screening asymptomatic and mild case patient is profoundly essential to abate this threat. The development of rapid, accurate, and predictable diagnosis methods will provide huge assistance to public health. The current sample collection method for the nasal antigen test is uncomfortable and has a higher risk of bleeding. Moreover, the South African researcher suggested that the saliva sample is preferred to the nasal one for detecting Omicron, the dominant variant.[1)]
Here, we report all-printed organic electrochemical transistor (OECT)-based single-use disposable biosensors with n-type naphthalene diimide (NDI) small-molecule organic mixed ionic-electronic conductor (OMIEC) channel for SARS-COV-2 spike protein detection.
We developed an all-printed OECT biosensor using an Optomec Aerosol Jet 5X 3D printer onto a flexible polyimide substrate. Gold nanoparticle ink was used for printing the source/drain and gate electrode. The glycolated naphthalene diimide (gNDI-Br_2) small-molecule OMIEC is deposited to form the channel with a width of 600 µm, a length of 100 µm, and an optimized thickness of 2 µm. SARS-CoV-2 spike protein detection was achieved by the functionalization of the printed gold gate electrode with antibodies which are anchored via thiol-based self-assembled monolayers (SAMs).
The 3D printed p-type OMIECs have been applied for the OECT and published[2)], but the n-type has not. We have previously presented the mixed ionic-electronic conduction behaviour of the gNDI-Br_2 n-type small-molecule OMIEC[3)]. In this work, we were able to fabricate all-printed OECT biosensors with NDI channel material because the gNDI-Br_2 is easily processable with common organic solvents that are suitable for printing. This is the first demonstration for the n-type gNDI-Br_2 OMIEC that can be utilized as the OECT channel material.
The SARS-CoV-2 antibodies functionalized OECT antigen biosensors showed a noticeable shift in their transfer characteristics before and after the antibody attachment. The biosensor was tested with different concentrations of SARS-CoV-2 S1 spike protein (1 pg/mL to 10 µg/mL) solution in 1X PBS with 5 min of incubation time. The transfer characteristics were collected after the incubation and demonstrated a clear trend with spike protein concentration. The threshold voltage, V_T, shifted to a higher value as the spike protein concentration increases. To the best of our knowledge, this NDI-based biosensor is the first n-type OECT-based immunosensor. By modifying the gate functionalization, the NDI biosensor can be used for detecting other bio-analytes such as different types of viruses or enzymes. We will present the biosensor geometry optimization, sensing with different SARS-CoV-2 spike protein variants, and preliminary results of detecting SARS-COV-2 spike protein in an artificial saliva buffer.

SB03-virtual

8:00 AM *SB03.10.01
Silicon-Based Optoelectronic Interfaces for Biological Modulations Xing Sheng[1] and Yunxiang Huang[2]; [1]Tsinghua University, China; [2]Dartmouth College, United States

The capability to selectively and precisely modulate biological activities represents a powerful tool for fundamental research and clinical therapeutics. Traditional electrical stimulations associate with bulky and tethered implants, and optogenetic methods rely on genetic modification for cell targeting. Here, we report an optoelectronic, non-genetic strategy for exciting and inhibiting biological activities, accomplished by bioresorbable, thin-film silicon

based 3D structures. Under illumination, these structures establish polarity-dependent, positive or negative voltages at the semiconductor/solution interface. Such photovoltaic signals enable deterministic depolarization and hyperpolarization of cultured neurons and stem cells, upregulating and downregulating intracellular calcium dynamics in vitro. Furthermore, flexible, thin-film Si based devices mounted on the animal tissue selectively activate and silence in vivo activities. We demonstrate that these Si structures can modulate the neural activities as well as the bone regeneration process. Finally, these Si membranes naturally dissolve within the animal body. Such a Si-based material and device platform offers broad potential for biomedical applications.

8:30 AM *SB03.10.02
Bioinspired Self-Adaptive Conformal Electronic Armor, Electronic Tattoo and iFlexSense Skin Yongan Huang and Shan Jiang; Huazhong Univ of Science & Technolgy, China

Conformability plays a ballast role in the final functionality and performance of flexible electronics since it is the basis of superior signal-to-noise ratio and large area mapping capability. It involves flexibility and stretchability, which depends on key factors such as geometry, material, and surface curvature. The interfacial mechanics and adhesion strength at the interfaces determine the nature of this contact. However, conformable integration of flexible electronics on complex 3D surfaces remains to be challenging and costly both from a design and manufacturing perspective.
Bioinspiration has been proved powerful and effective to develop novel materials, devices, and structures from biological systems and biological evolution and refinement which has occurred over millions of years. Historically, many great ideas in science and technology often arise from studying nature. Bioinspired flexible electronics have been widely investigated, the imitated objects range from plants to animals or human, from birds to reptiles, and from terrestrial species to marine species. This presentation mainly introduces bioinspired strategies to design the flexible electronics:
1) **Bioinspired Electronic Armor**: Bionspired by freeform snakeskin composed of rigid scales and connective soft integument, we propose a novel rigid-structure-based electronic armor (E-armor) that reconciles the protectability and conformability while enables stable electronic functions. It can render the rigid, non-stretchable devices fully conformable to arbitrary 3D surfaces. Based on the unique soft-hinge Kirigami regime, it can make use of the supernormal mechanical advantages like auxetic stretchability and high fill factor but overcome the inherent buckling conflict, rendering the stiff, non-stretchable electronics fully conform to arbitrary 3D surfaces. Meanwhile, the conductivity of soft nodes endows the Kiri-MM with electrical connotation and innovative functionalities. The results establish new directions for applied and basic research in the fields of flexible electronics and soft robotics, with relevance to grant challenges in improving the survivability of flexible electronics in complex environments.
2) **Bioinspired Electronic Tattoo**: Bioinspired by the breathable human skin, we have successfully designed, fabricated, compensated, and applied a substrate-free tattoo-like electrode system for large-scale epidermal electrophysiology. Highly stretchable and high-area filling-factor electrodes are designed using Peano curves with transformable topology. The breathability of the substrate-free epidermal electrodes is quantified through thermal and hydration characterizations. Applications of these electrodes include multichannel ECG, accurate ASL recognition, and prostheses control, as well as mapping of neck activities. These low-cost but large-area and high-performance epidermal electrodes have paved the way for future large-area epidermal electronics necessary for personnel health/performance management, disease diagnosis, and human-machine interaction.
3) **Bioinspired iFlexSense Skin**: Bioinspired by the unprecedented sensing abilities (skin, synapse, immune system, and brain) of flying creatures, we innovatively propose an intelligent flexible sensing skin with multifunctional sensor array, data transmission, impact monitoring and artificial intelligence for aerodynamic measurement of complex surface. The skin-like mechanosensation system integrates with five kinds of flexible sensors, including capacitive sensors, piezoelectric sensors, hot-film sensors, temperature sensors, and strain sensors. The synapse-like encoding system is also directly integrated on the sensing skin to convert analog data to digital data to diminish the transmission noise. The brain-like intelligent algorithm is employed to for analyzing the data and making a judgment, such as identifying and localizing the impacts.

9:00 AM SB03.10.05
Novel Ultra-Sensitive Permeation-Measuring Methods for Ultra-High Barrier Encapsulations of Compliant Implantable Bioelectronics Massimo Mariello[1], Kangling Wu[1], Marion Von Allmen[2], Matthias Van Gompel[2], Stephanie P. Lacour[1] and Yves Leterrier[1]; [1]Ecole Polytechnique Federale de Lausanne, Switzerland; [2]Comelec SA, Switzerland

The next generation of implantable bioelectronic devices are soft, compliant and flexible/stretchable and they need to be protected from the body environment through high-barrier coatings. A critical challenge is the design, synthesis and integration of these coatings in order to guarantee simultaneously hermeticity, biocompatibility, flexibility, mechanical integrity, compatibility with microfabrication processes, long-term reliability and stability (at least longer than 5÷10 years in the body). Against standard barrier technologies based on macroscopic rigid capsules made in Titanium or ceramics, or on thick soft silicones, the next generation of barrier coatings relies on thin-film encapsulations (TFE). They can be manufactured through several deposition techniques (ALD, PECVD, thermal growth, etc.), based on organic/inorganic single-layers or hybrid multilayers. The accurate evaluation of their barrier performances is still a challenge, because standard measuring systems are characterized by too high sensitivity limits ($> 10^{-5}$ g/m^2/day) which cannot detect the ultra-low permeation capabilities of the coatings. Hence, novel ultrasensitive (at least 10^{-7} g/m^2/day) quantitative methods to assess the barrier hermeticity need to be engineered.

In this work, we introduce a comprehensive method to quantify ultra-low permeability of TFE engineered for bioelectronic micro-devices. The method relies on magnesium (Mg) thin-film sensors. Corrosion of Mg induced by water diffusion in the barrier coating is observed and analysed in terms of optical, electrical and electrochemical properties of Mg structures. The advantages of this approach are that Mg does not need a fully inert atmosphere and it can be easily integrated in the microfabrication processes of implantable bioelectronic devices. Different methods are presented based on the optical characterization of Mg thin films coated with some standard barriers, the monitoring of their electrical resistance during corrosion, or the analysis of the anticorrosive properties of the encapsulations through electrochemical measurements. Several testing conditions are selected, including exposure to wet air or soaking in a phosphate buffer saline (PBS) solution that mimics the body biofluids. High temperatures are chosen to perform accelerated tests whereas specific analytical/computational models are used to extract from the measurements the water-vapour transmission rates (WVTR) of the barriers. Rigid, flexible and stretchable substrates coated with TFE are used to evaluate the versatility of the measuring system. A record sensitivity of 3.3×10^{-8} g/m^2/day was achieved, which is lower than the other current methods. The integration of this method into real active implants is also demonstrated.
The proposed characterization strategy answers a long-term need to assess thin film hermeticity, reveals tangible prospective applications for the development of thin hermetic customizable packaging for miniaturized implantable electronics, and promise quantitative evaluation of all types of conformal TFE for bioelectronic systems in a reliable way.

9:15 AM SB03.10.06
Surface Modulation of Conducting Polymers for Advanced Organic Neural Interfaces Michele Bianchi[1,2], Alice Lunghi[1,3], Sonia Guzzo[1,3], Anna De Salvo[1,3], Pierpaolo Greco[3], Mauro Murgia[1,4], Michele Di Lauro[1], Luciano Fadiga[1,3] and Fabio Biscarini[1,2]; [1]Italian Institute of Technology, Italy; [2]Università degli Studi di Modena e Reggio Emilia, Italy; [3]Università di Ferrara, Italy; [4]National Research Council, Italy

Surface modulation of conducting polymers (CPs) has attracted great interest in organic electronics due to the possibility of controlling the optical, electrical and electrochemical properties of devices through the introduction of preferential charge transport pathways or by increasing the active area of the material [1,2]. Micro- and nanopatterning techniques such as 3D printing, inkjet printing, plasma etching, nanosphere lithography and soft-lithography

have been exploited in a number of applications, including organic photovoltaic cells (OPVs), field effect transistors (OFETs) and light emitting diodes (OLEDs).
However, surface modulation of CPs for bio-related applications such as multi-electrode arrays (MEA), neural interfaces, neuromorphic devices and tissue engineering, is largely unexplored, despite the rapidly growing role of CPs in these fields [3,4]. At the Center for Translational Neurophysiology of Speech and Communication of the Italian Institute of Technology (IIT), we pursue the design and fabrication of micro- and nanopatterned/modulated CPs that can be easily integrated on flexible substrates in order to design advanced organic neural interfaces.
Multi-electrode arrays with 3D micropillars enable the recording of electrophysiological signals in vitro with higher accuracy and signal-to-noise ratio than planar arrays. I will present a simple approach for the fabrication of flexible interfaces featuring poly(3,4-ethylenedioxythiophene)-poly(styrenesulfonate) (PEDOT:PSS) micropillars on a technologically interesting flexible polydimethylsiloxane (PDMS) substrate [5]. Large-area, isotropic arrays of PEDOT:PSS micropillars with tailored geometric area, surface properties and electrochemical characteristics were fabricated by a combination of soft-lithography and electrodeposition methods. The 3D PEDOT:PSS micropillars were demonstrated to optimally support adhesion, growth and differentiation of SH-SY5Y cells and influence the direction of neurite outgrowth. I will also describe the integration of such micropillar arrays into ultra-flexible surface arrays for neural recording and stimulation.
I will then show the possibility of influencing neuronal polarization and accelerating neurite outgrowth during cell differentiation using PEDOT:PSS nanogrooves, with a potentially major impact in the field of neural tissue regeneration, where synergistic integration of electrical stimulation and topographical guidance is expected to accelerate axonal reconnection and regeneration of damaged tissue.
Organic electrochemical transistors (OECTs) can be integrated into neural interfaces to significantly increase the signal-to-noise ratio during recording [6]. In this context, I will show that the transconductance (a figure of merit of the device directly related to its ability to amplify electrophysiological signals) can be significantly increased by nanomodulating the surface of ultrathin PEDOT channel through a simple stamp-assisted soft-lithography approach.

SESSION SB04.01: Biomaterials and Interfaces I
Session Chairs: Giuseppe Paternò and Teuta Pilizota
Monday Morning, November 28, 2022
Hynes, Level 3, Room 303

10:30 AM *SB04.01.01
Organic Semiconductor Nanoparticles Restore Vision in Blind Retinas Guglielmo Lanzani[1,2]; [1]Italian Inst of Technology, Italy; [2]Politecnico di Milano, Italy

Inherited retinal dystrophies and late-stage age-related macular degeneration, for which treatments remain limited, are among the most prevalent causes of legal blindness. Retinal prostheses have been developed to stimulate the inner retinal network; however, lack of sensitivity and resolution, and the need for wiring or external cameras, have limited their application. Here I report on the use of conjugated polymer nanoparticles (P3HT NPs), showing that they mediate light-evoked stimulation of retinal neurons and persistently rescue visual functions when subretinally injected in a rat model of retinitis pigmentosa. In particular I will report on recent results showing that the organic liquid prosthesis is effective also in retinas that have undergone a process of rewiring caused by the loss of photoreceptor function.

11:00 AM SB04.01.02
Optical Mirroring of Electrical Signals from Non-Electrogenic Cells Rosalia Moreddu[1], Alessio Boschi[1,2], Marta d'Amora[1,3], Giuseppina Iachetta[1], Michele Dipalo[1] and Francesco De Angelis[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]University of Genoa, Italy; [3]University of Pisa, Italy

Cell membrane potential is known to be an essential parameter to monitor the electrical activities of excitable cells, such as neurons and cardiac cells. However, recent data has revealed that it also plays a crucial role in non-excitable cells, such as epithelial cells. Electrical perturbations induce localized bioelectrical changes, which can trigger different cell responses, including migration, mitosis, and mutation.[1]
The directional migration of cells under an electric field is known as galvanotaxis, and represents a dominant mechanism in guiding the behavior of multiple cell populations in mammals, fishes, amphibians, and plants.[2,3] Wound healing is controlled by endogenous electric fields, generated by ion transport across the epithelium, which set a trans-epithelial potential difference (TCPD) of +40 mV in healthy conditions. At the wound, the TCPD falls to zero, but it is maintained at normal levels in its proximity (~ 0.5 mm) to drive epithelial cells to migrate and heal the wound.[4] Bioelectrical cues are also involved in cellular mutation, responsible for the onset of multiple diseases. For example, cell electrical charges are the biophysical manifestation of metabolic patterns in cancer development and metastasis.[5] Cancer cells exhibit the Warburg Effect, resulting in the secretion of lactate anions that produce a high concentration of negative surface charges.[5] The membrane potential is also highly correlated with mitosis, DNA synthesis, cell cycle progression and overall cellular proliferation.[6]
Understanding these mechanisms is the key to unravel precision diagnostic and therapeutic strategies. However, this dynamic information is currently hard to access because existing technologies for electrophysiological recording of resting cell membrane potentials are invasive: they require physical access to the intracellular compartments, which implies the disruption of the cell membrane (known as electroporation).[7] This makes it challenging to perform passive measurements and prolonged recordings under varying conditions.
A variety of alternative or complementary technologies based on optical methods were introduced in the past decades. However, the majority of them are designed to be implemented in electrogenic cells, which transport signals through action potentials (i.e., rapid polarization and depolarization of the cell membrane). Nevertheless, most of the cells in the human body do not fire action potentials, and their mechanisms of communication happen in a narrower signal range.
In this work, we present a novel approach in electrophysiological recording, based on optical mirroring of bioelectric charges. The feasibility of this method was previously demonstrated for the high throughput recording of action potentials in human-derived cardiomyocytes.[7] In this context, the technology was refined and implemented in epithelial cells.
The nano-platform consisted of two chambers separated by a thin membrane. Pass-through electrodes enabled to mirror the cell membrane charge (top) all the way to the optical chamber (bottom), where dispersed fluorophores migrated to balance the charge, generating a dynamic fluorescent signal. Fluorescence was recorded with a camera, while exciting the fluorophores with incident light. Preliminary results on HEK cells yielded a fluorescence intensity increase of the 2.5% in presence of a cell on the microelectrode compared to reference microelectrodes. At present, this technology may be used to evaluate cell-substrate adhesion, monitor cell proliferation, and test novel biomaterials. In the near future, further investigations could allow extrapolating quantitative data on resting membrane potential in dynamic settings to perform cell/tissue studies on wound healing, cellular division, and cancer progression.

Membrane-Targeted Molecules for Cell Optostimulation Arianna Magni[1,2], Matteo Moschetta[2], Giuseppe M. Paternò[1,2], Chiara Bertarelli[1,2], Luca Beverina[3], Fabio Benfenati[2] and Guglielmo Lanzani[2,1]; [1]Politecnico di Milano, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]Università degli Studi di Milano-Bicocca, Italy

Light-driven modulation of cellular activity with both high spatial and temporal resolution is becoming an increasingly active research area. Existing approaches, such as optogenetics, have shown promising results and, as an alternative, we envision the use of light-sensitive molecules that act as photo-actuators avoiding genetic manipulation.
We are interested in investigating the effects of different photo-actuators, such as azobenzene-based photochromic and donor-acceptor molecules. These compounds are designed to satisfy the following requirements: (i) absorb light in the visible or near-infrared window of the spectrum; (ii) spontaneously and efficiently partition into the lipid bilayers owing to their amphiphilicity, (iii) exhibit low toxicity in dark condition and preferentially also under illumination.
We combine the observation of the photoinduced effects on both HEK-293 cells and primary neurons, which are evaluated by exploiting electrophysiology, while steady-state and time-resolved optical spectroscopies reveal their photophysics and functioning mechanism.
Taken together, our data allows us to identify different light-driven mechanisms, responsible for the photoinduced effects observed on cells. These include, for instance, (i) the thinning or thickening of the membrane due to conformational changes in the molecules, (ii) the increase of the membrane permeabilization, and the formation of pore-like structures likely due to the lipid peroxidation following the photosensitization of singlet oxygen within the cell membrane, (iii) the rearrangement of the charges adsorbed to the membrane due to variations in the molecular dipole moment.

11:30 AM *SB04.01.04
Electron-Transporting Conjugated Polymers for Electronic Biohydrids Sahika Inal; King Abdullah University of Science and Technology, Saudi Arabia

Establishing close interactions between biological systems and synthetic materials is the key to forming biohybrid assemblies that find use in sensors, actuators, and robotics. In this work, I will present an electronic platform based on an n-type conjugated polymer that is tailored to form favorable interactions with catalytic enzymes.[1] When this biohybrid is applied in an enhancement mode organic electrochemical transistor (OECT), the device detects glucose and lactate in blood serum or saliva with excellent sensitivity and selectivity over six orders of magnitude wide detection range. The same biohybrid serves as the anode of a glucose fuel cell, extracting enough power from bodily fluids to drive the microscale OECT sensors. While showing the unique characteristics of these devices, I will discuss the possible pathways through which the polymer film generates charges as the enzyme reacts with its metabolites.[2] I will then show how these biohybrids are also responding to visible and NIR light by generating photocurrents in aqueous electrolytes.

SESSION SB04.02: Engineering of Living Components
Session Chairs: Guillermo Bazan and Tanya Tschirhart
Monday Afternoon, November 28, 2022
Hynes, Level 3, Room 303

1:30 PM *SB04.02.01
Programming Bioelectronic Bacteria as Real-Time and Multi-Channel Sensors Xu Zhang[1], Lin Su[1,2], Joshua Atkinson[1,3] and Caroline Ajo-Franklin[1]; [1]Rice University, United States; [2]University of Cambridge, United Kingdom; [3]University of Southern California, United States

Challenged by a changing climate, dwindling natural resources, and a growing global population, we need advanced renewable materials that meld the sustainability of biological materials with the functionality of conventional materials. To help address this need, my research group creates sustainable and environmentally-responsive living materials by seamlessly integrating conventional materials with living systems. One major effort in our group is to co-engineer microorganisms and microelectronics to serve as living bioelectronic sensors that can selectively sense a variety of complex molecules in real-time.

In my talk, I will first describe a collaborative project with the Silberg group at Rice to develop bioelectronic sensors that have minute detection times. We programmed *Escherichia coli* to produce current in response to specific chemicals using a modular, eight-component, synthetic electron transport chain. As designed, this strain produced electrical current upon exposure to thiosulfate, an anion that causes microbial blooms, in two minutes. By incorporating a protein switch into the synthetic pathway and encapsulating the bacteria with conductive nanomaterials, this amperometric sensor could be modified to detect an endocrine disruptor within two minutes in riverine water. Our results provide design rules to sense a variety of chemicals with mass transport-limited detection times and a new platform for miniature, low-power bioelectronic sensors that safeguard ecological and human health.

In the second part of my talk, I will describe how we have created bioelectronic sensors that convey multiple channels of information. Existing bioelectronic sensors can sense a variety of hazards to human and environmental health, however, these sensors transmit information through only a single electrochemical channel. This severely limits the amount of sensing information that can be transmitted. To increase this information content, we developed a multichannel bioelectronic sensor in which different chemicals modulate distinct extracellular electron transfer pathways in *E. coli*. To create an *E. coli* strain with two reporting channels, we introduced a riboflavin synthesis pathway from *Bacillus subtilis* alongside the metal reducing (Mtr) pathway from *Shewanella oneidensis*. We can distinguish whether one or both pathways are active in this strain using either chronoamperometry or a series of amperometric measurements at distinct redox potentials. To demonstrate multi-channel bioelectronic sensing, we regulated the Mtr and riboflavin pathways using arsenic and cadmium responsive promoters. With this strain, we used a series of amperometric measurements at distinct redox potentials to distinguish the presence of the different heavy metals *in situ*. These accomplishments provide a new platform for multichannel bioelectronic sensors that simultaneously detect and report multiple toxins.

2:00 PM SB04.02.02
Bioelectricity in Microalgae Cohorts Paulo R. Rocha[1] and Lode Vandamme[2]; [1]University of Coimbra, Portugal; [2]Eindhoven University of Technology, Netherlands

Diatoms are early Jurassic microalgae, a photosynthetic group with a major environmental role on the planet due to the biogeochemical cycling of silica and global fixation of carbon. However, they can evolve into harmful blooms through a resourceful communication mechanism, not yet fully understood. Harmful algae blooms in water supply reservoirs must be eradicated due to unwanted toxin production and filter blocking at water treatment works. Until now there has been no efficient consensus that harmful microorganisms such as diatoms communicate with each other and no accurate and self-sustained tool to monitor such communication.

Here, we demonstrate the ability to electrically monitor a diatom cohort. The breakthrough is realized by means of a unique measurement setup based on low impedance electrodes that exploit the large Helmholtz-Gouy-Chapman double-layer capacitance. The sensing system comprises a transducer based on a metal/Si/SiO_2/Au electrode. Small extracellular voltages of diatoms adhered to the electrode induce a displacement current that is enhanced by a gain factor proportional to the double-layer capacitance.

The origin is paracrine signalling, which is a feedback, or survival, mechanism that counteracts changes in the physicochemical environment. The intracellular messenger could be related to Ca^{2+} ions since spatiotemporal changes in their concentration match the characteristics of the intercellular waves. Our conclusion is supported by using a Ca^{2+} channel inhibitor. The transport of Ca^{2+} ions through the membrane to the extracellular medium is blocked and the intercellular waves disappear. The translation of microalgae cooperative signalling paves the way for early detection and prevention of harmful blooms and an extensive range of stress-induced alterations in the aquatic ecosystem.

2:45 PM *SB04.02.04
Strategies for Improving Extracellular Electron Transfer Between Microbes and Electrode Materials Shelley Minteer; University of Utah, United States

Over the last two decades, there has been a wealth of research in using microbially modified electrodes for various applications from microbial fuel cells to biosensing to electrosynthesis. The majority of these technologies are limited by slow extracellular electron transfer between the microbe and the electrode material. This talk will discuss chemical, materials, and biological strategies for improving extracellular electron transfer. It will start with a discussion of materials modification strategies for improving the surface area and biotic-abiotic interface to enhance current densities followed by a discussion of chemical strategies for mediating electron transfer. Finally, the use of synthetic biology to genetically engineer microbes to communicate directly with electrode surfaces will be discussed and the talk will compare and contrast the chemical, materials, and biological strategies for improving electron transfer and therefore performance of these bioelectrochemical systems.

3:15 PM SB04.02.05
Solar Power to Electricity—A Photovoltaic Perspective on the Plant Microbial Fuel Cell Thessa Van Limbergen[1], Robin Bonné[2,1], Jeroen Hustings[1],

Roland Valcke[1], Sofie Thijs[1], Jaco Vangronsveld[1,3] and Jean V. Manca[1]; [1]Hasselt University, Belgium; [2]Aarhus University, Denmark; [3]Maria Curie-Sklodowska University, Poland

The keywords solar power and electricity combined evidently point our minds toward photovoltaics. However, plant microbial fuel cells (PMFCs) have a similar working principle. The technology – which emerged in 2008 – combines living plants and microorganisms in an *in situ* fuel cell configuration, also converting sunlight into electricity [1]. But how do these two technologies compare? In this study, PMFCs were approached from a photovoltaic perspective. A rough upper limit for the overall energy conversion efficiency was estimated and compared to various classes of photovoltaics. To this end, each intermediate step in the working principle of plant microbial fuel cells was investigated, and of each step, the maximum efficiency found in literature was used to calculate the maximum power conversion efficiency. This approach estimated the maximum efficiency to be around 1%, more than one order of magnitude lower than traditional and emerging photovoltaics [2].
Going from theory to practice, the corresponding maximum power density was compared to the historical evolution of reported power output values. However, no apparent increase through time could be seen since their emergence. The application of the technology may explain this as the plant microbial fuel cell has many dedicated niche applications ranging from sensing to remediation, where power output might not be of interest [3]. Even though various routes toward increased power output are still being proposed, it is clear that PMFCs are intrinsically limited and dwarfed in comparison to photovoltaics when looking at power output alone. Nonetheless, the various niche applications - together with certain advantages the technology has over photovoltaics, i.e., aesthetics, price, straightforwardness, etc. - provide an added value to the technology.
This critical discussion aids in placing the plant microbial fuel cells, their applications, and expectations in the world of green, and particularly of solar energy-related research.

3:30 PM SB04.02.06
Improving the Photoelectron Transfer from Photosynthetic Proteins into TiO_2 Electrodes for Bio-Sensitized Solar Cell Application Christopher Espinoza-Araya[1,1,1], Jose Daniel Zelada-Ramírez[1,1], Dariana Aguilar[1,1], Alexandra Tames[1,1], Jesse Bergkamp[2], Ernesto Montero-Zeledón[1,1], Venkatesan Renugopalakrishnan[3,4], Barry Bruce[5,5] and Claudia C. Villarreal[1,1]; [1]Instituto Tecnológico de Costa Rica, Costa Rica; [2]California State University, United States; [3]Harvard Medical School, United States; [4]Northeastern University, United States; [5]University of Tennessee at Knoxville, United States

The bio-sensitized solar cell is the architecture with the highest power conversion efficiencies (PCE) amongst photovoltaic devices that integrate natural photosynthetic proteins (1-2%). In these devices, a nanostructured wide-bandgap semiconducting electrode is coated with the protein and used as the photoanode in an electrochemical cell. Our team studies two different biosensitizers that stand out as some of the best performing natural light absorbers in bio-photovoltaic devices: **bacteriorhodopsin** (bR), a light-driven proton pump from archaebacteria, and **photosystem I** (PSI), a chlorophyll-protein complex from cyanobacteria and green plants that catalyzes photoactivated unidirectional electron transfer in oxygenic photosynthesis. Two factors that currently limit the **charge transfer efficiency** from the protein to the TiO_2 are the reduced contact area between the two materials and the non-specific orientation of the protein with respect to TiO_2. The proteins here studied are significantly larger than traditional synthetic dyes, which hinders their penetration into the pores of the TiO_2 nanoparticle layer during impregnation. The use of **TiO_2 nanorods doped with CNTs** is proposed to provide larger contact area where the protein can inject the photoelectrons into the semiconductor. In nature, electron transfer occurs in very specific electrical pathways that have evolved over millions of years, while simple dropcasting of a protein onto the electrode results in random orientations that may or may not connect these natural electrical wires with the electrode surface. Alternative techniques to promote an organized interface with **preferential orientation of the proteins** on the TiO_2 are here explored, so that the electron injection is directional according to the natural function of the biomolecule in the organism. *In situ* crystallization and structural modifications of the protein are proposed to drive a preferential orientation on the electrode. The effect of these variables in photovoltaic performance of devices is determined. The devices here proposed consist on the biosensitized TiO_2 photoanode and a PEDOT/CNT counterelectrode. A gel electrolyte is used to connect the two electrodes, containing the hydroquinone/benzoquinone pair or aqueous-soluble bipyridine cobalt(II/III) complexes as direct redox mediators for bR and PSI, respectively. These work intends to deepen the understading of electron transfer in a bio-hybrid interface for photogeneration of bioelectricity.

SESSION SB04.03: Biomaterials and Interfaces II
Session Chairs: Guillermo Bazan and Teuta Pilizota
Tuesday Morning, November 29, 2022
Hynes, Level 3, Room 303

8:30 AM SB04.03.03
Externally Tunable, Low Power Electrostatic Control of Cell Adhesion with Nanometric High-k Dielectric Films Victor Leon, Baptiste Blanc, Sophia Sonnert and Kripa Varanasi; Massachusetts Institute of Technology, United States

Biological systems are notoriously difficult to control. A major technical issue is controlling where and when bio-adhesion occurs on surfaces in engineered systems. Promoting bio-adhesion may be useful to pattern cells for tissue engineering. Preventing bio-adhesion is useful in micro-algal photobioreactors, where cleaning operations are costly and time consuming.

Current methods to promote or inhibit bio-adhesion depend on directly modifying the surface chemistry (e.g. hydrophobicity, molecular end groups). Here, we study the interaction between micro-algae cells (i.e. freshwater Chlorella vulgaris and saltwater Nannochloropsis oculata), and an engineered surface that can actively change its zeta potential based on the magnitude and polarity of applied voltage without changing its chemistry. Since the studied algae have negative zeta potentials, colloidal DLVO theory suggests that a surface with negative zeta potential should repel algae and a surface with positive zeta potential should attract algae. We observe that algae adhesion is inhibited at negative zeta potentials and enhanced at positive zeta potentials with a power draw of ~nW by applying -/+ 1V. Using microfluidic experiments, we report the effect of varying voltage magnitude, voltage polarity, wall shear, algae species, and solution salinity on bio-adhesion. We also conduct longer term (4 week) bio-adhesion and patterning experiments to observe the effect on practical performance

8:45 AM SB04.03.04
Novel Approach for Precise Measurement of Bioelectronic Interface—Transfer Length Method-Based Interface Electrical Characterization

Jinpyeo Jeung[1], Inyeol Yun[1] and Yoonyoung Chung[1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Center of Semiconductor Technology Convergence, Korea (the Republic of)

Bioelectronic interfaces significantly affect the signal transmission between electronic devices and biomaterials. Therefore, the electrical characterization of bioelectronics interfaces is of paramount importance for designing various bioelectronic devices or biohybrid sensors. Conventionally, the characterization of bioelectronic interface impedance relies on estimation using electrochemical impedance spectroscopy (EIS) data. However, the conventional method possesses a critical limitation in that the results of the electrical characterization are not unique since different estimations can produce identical impedance results.[1] The limitation undermines the reliability of the measurements and can causes errors. Thus, the development of a method that can accurately distinguish and measure the impedance of the bioelectronic interface and bulk is necessary.
In this study, we propose a novel method that satisfies the necessity by applying the transfer length method in an electrode/electrolyte system. Transfer length method-based interface electrical characterization (TLM-IEC) obtains accurate bulk electrolyte impedance by measuring impedance between electrodes at various intervals, and then the interface impedance is obtained by removing the bulk electrolyte impedance from the total impedance. The validity of the TLM-IEC was confirmed, and the method exhibits a superior advantage over the conventional method since the impedances of the interface and bulk are measured, not estimated. The unique electrical characterization of bioelectronic interface by the TLM-IEC can facilitate the optimized design of bioelectronic devices and sensors, and can be utilized for various applications.

Controlling the Resting Membrane Potential of Bacteria—Decoupling Hyperpolarization, Reactive Oxygen Species Generation, Enzyme Activity and Membrane Permeabilization Christine Payne; Duke University, United States

Cells generate a -10 mV to -100 mV electrical potential across the plasma membrane driven by an ion gradient. This resting membrane potential, in comparison to the action potentials of neurons and muscle cells, is present in all cells, including bacteria. A fundamental understanding of bacterial electrophysiology would lead to new methods for the control of engineered living materials, as well as significant advances in synthetic biology, cell growth in industrial bioreactors, and screening of anti-bacterial agents. Recent research in the Payne Lab is aimed at understanding bioelectricity in bacteria guided by questions of heterogeneity and cell growth with applications in materials science.The resting membrane potential of individual cells within a population is highly heterogeneous. In addition to cell-level heterogeneity, we also observe temporal heterogeneity with 2% of individual cells showing short bursts of hyperpolarization, referred to as “spiking.” We have developed methods to image and control resting membrane potential, simultaneously, on the single cell level to determine the underlying source of both the cellular and temporal heterogeneity. We use blue light, which can be patterned, to suppress cell growth in certain regions, creating patterned bacteria, in a way that is not possible using diffusible reagents that affect all cells equally. Blue light-mediated hyperpolarization is coupled with a range of cellular responses including generation of reactive oxygen species, altered enzymatic activity, and changes in membrane permeability, in addition to the inherent heterogeneity of this system. Our experiments are aimed at decoupling these cellular responses to determine what factors drive the associated decrease in cell growth. We hope these experiments will provide new insights in the growing field of bacterial electrophysiology.

Generating Electricity from Ambient Water with Microbial Biofilms or Their Protein Nanowires Jun Yao; University of Massachusetts Amherst, United States

Water sources in both gaseous and liquid forms are ubiquitous. The electrostatic and hydrokinetic energy associated with this water is a large reservoir that potentially could be transformed into a sustainable source of energy for powering electronics. We have found that useful amounts of electricity can be generated from water with microbial materials. For example, protein nanowires harvested from the microbe *Geobacter sulfurreducens* are the functional material in ‘Air-gen’ devices that continuously generate electricity from the ambient humidity that is available literally anywhere on earth. We also found that devices fabricated from microbial biofilms can generate electricity from evaporating liquid water, achieving energy densities higher than those possible with traditionally engineered materials. These two types of devices for generating electricity from water are complementary, closing the loop for broadly harvesting electricity from all distributed water forms on earth. We further demonstrate the practical application of both types of devices for continuous, sustainable powering of wearable electronic devices that monitor important human physiological functions.

Membrane-Targeted Photoswitch Induces Cardiac Cells and Tissue Optical Pacing Vito Vurro[1], Carlotta Ronchi[1], Valentina Sesti[2,1], Silvia Crasto[3,4], Maria Rosa Antognazza[1], Chiara Bertarelli[2,1], Elisa Di Pasquale[3,4], Guglielmo Lanzani[1,2] and Francesco Lodola[5]; [1]Istituto Italiano di Tecnologia, Italy; [2]Politecnico di Milano, Italy; [3]National Research Council of Italy, Italy; [4]Humanitas Clinical and Research Center, Italy; [5]Università degli Studi di Milano-Bicocca, Italy

The study of human-machine interaction is an appealing research area where the developed interfaces find application in robotic,[1,2] biological[3,4] and medical areas.[5] In particular, great interest is rising for the development of a contactless and wireless interaction. Within this context, light represents a clean and spatiotemporal precise tool to achieve such a goal.[6] Conjugated molecules and polymers offer a promising platform to interface with cells and living organisms due to their high optical absorption/emission cross section, chemical synthesis’ easiness and relatively low toxicity.[7,8]
In this work, we focus on cardiomyocytes photopacing, whichare interesting candidates to test the stimulation process due to their excitability, contraction ability and their electrical behaviour. Specifically, we present the use of an azobenzene-derivative that is able to trigger the signalling process in muscle cells at all the physiological levels of the contraction. We characterized the effect of the photostimulation on electrophysiology response, calcium wave generation and contraction activity. Moreover, we test this approach on *in vitro* micro-physiological systems controlling its macroscopic contraction activity.

This last step consists of the realization of a bio-hybrid photoresponsive smart tissue, which is crucial for moving towards a real translational application and achieve the ultimate goal of this project. This can be a breakthrough for future applications in robotics and pharmacology, as well as tissue regeneration.

Designing Bioelectronic Interfaces with Peptidic Assemblies Herdeline Ardoña, Ze-Fan Yao, Yuyao Kuang and Sujeung Lim; University of California, Irvine, United States

Integration of synthetic electronic biomaterials with living systems has emerged as an approach for modulating or probing cellular behavior and tissue function that minimize the need for contact with traditional, bulky, and non-flexible inorganic electrodes. Bioelectronic materials have been demonstrated to effectively integrate with cells, in vitro tissue models, organoids, and even with small model organisms, but the long-term effects of these materials on living systems are rarely considered when designing a material. In this presentation, we present peptide-based structures functionalized with π-conjugated units as designer biomolecules that can be interfaced with excitable cells. We present herein structure-function relationships that demonstrate the dependence of assembly behavior on monomeric structure and assembly trigger used while in completely aqueous environments. First, we show that small molecule coupling agents that allow for anhydride formation generate peptidic π-conjugated conduits that are amenable to disassembly once the fuel is diminished and anhydride hydrolysis predominates. The compliance of a peptide-bearing quaterthiophene monomer to this process is highly dependent on the electrostatic nature of the peptide sequence used. On the other hand, peptide-polydiacetylene conjugates will also be discussed as π-conjugated assemblies that exhibit sequence-dependent photophysical and electrical properties. Our results show the differential impacts of amino acid size and polarity, and the degree that these molecular parameters can influence bulk properties based on the location of the residue substitution. Interestingly, we also show that the interaction of fibroblasts (as a model cell line) with the monomeric and polymeric equivalents of these peptide-polymer also sequence-dependence. Collectively, these findings shed light to the tunability of properties and assembly behavior of π-conjugated peptides under physiologically relevant environments. In the future, we will leverage these design principles for engineering biotic-abiotic interfaces that rely on the properties of these peptides functionalized with π-conjugated units.

3:30 PM *SB04.04.05

Healable, Stretchable and Flexible Bioelectronics Fabio Cicoira; Polytechnique Montréal, Canada

The ability of certain materials to regenerate after damage has attracted a great deal of attention since the ancient times. For instance, self-healing concretes, able to resist earthquakes, aging, weather, and seawater have been known since the times of ancient Rome and are still the object of research. While the field of mechanically healable materials is relatively established, self-healing conductors are still rare, and are nowadays attracting enormous interest for applications in electronic skin for health monitoring, wearable and stretchable sensors, actuators, transistors, energy harvesting, and storage devices, such as batteries and supercapacitors. Self-healing can significantly enhance the lifetime of conducting materials, leading to the improved environmental sustainability and reduced costs.
Conducting polymers exhibit attractive properties, such as mixed ionic-electronic conductivity, leading to low interfacial impedance, tunability by chemical synthesis, ease of process via solution process and printing, and biomechanical compatibility with living tissues, which makes them ideal materials for bioelectronics and stretchable electronics. However, they show typically poor mechanical properties and are therefore not suitable as self-healing materials. Self-healing conductors can be achieved upon mixing with other polymers, such as poly(vinyl alcohol) (PVA) and poly(ethylene glycol) (PEG), which provide the mechanical characteristics leading to self-healing.
My talk will deal with processing and characterization of conducting polymer films and hydrogels and devices for healable, flexible, stretchable and electronics as well as for implantable electrodes. I will particularly focus on processing strategies to fabricate stretchable and self-healing conductors and their applications. [1-9]

SB04.05.01
Photosynthesis Re-Wired on the Pico-Second Timescale Tomi Baikie, Laura Wey, Christopher Howe, Christoph Schnedermann, Akshay Rao and Jenny Zhang; University of Cambridge, United Kingdom

Photosystems II and I (PSII and PSI) are the reaction centre complexes that drive the light reactions of photosynthesis. PSII performs light-driven water oxidation (quantum efficiencies and catalysis rates of up to 80% and 1000 e−s−1, respectively) and PSI further photo-energises the harvested electrons (quantum efficiencies of ~100%). The impressive performance of the light harvesting components of photosynthesis has motivated extensive biological, artificial and biohybrid approaches to re-wire photosynthesis to enable higher efficiencies and new reaction pathways, such as H2 evolution or alternative CO2 fixation. To date these approaches have focussed on charge extraction at the terminal electron quinones of PSII and terminal iron-sulfur clusters of PSI. Ideally electron extraction would be possible immediately from the photoexcited reaction centres to enable the greatest thermodynamic gains. However, this was believed to be impossible because the reaction centres are buried around 4 nm within PSII and 5 nm within PSI from the cytoplasmic face. Here, we demonstrate using in vivo ultrafast transient absorption (TA) spectroscopy that it is possible to extract electrons directly from photoexcited PSI and PSII, using both live cyanobacterial cells and isolated photosystems, with the exogenous electron mediator 2,6-dichloro1,4-benzoquinone (DCBQ). We postulate that DCBQ can oxidise peripheral chlorophyll pigments participating in highly delocalised charge transfer (CT) states after initial photoexcitation. Our results open new avenues to study and re-wire photosynthesis for bioenergy and semi-artificial photosynthesis.

SB04.05.02
Blue Light Patterning for Engineered Living Materials Xu Han and Christine Payne; Duke University, United States

Engineered living materials have many exciting properties such as self-healing, bioresponstivity, and the formation of composite materials with complex structures. One challenge in the advancement of engineered living materials is controlling the growth of single cells to form micro- and nano-scale patterns. We, and others, have reported the use of low intensity blue light to control the resting membrane potential of bacteria at the single cell level. We found that blue light (480 nm, <60 s) can slow the growth of *B. subtilis* and *E. coli* without damaging the cells. The growth rate of bacteria is inversely proportional to blue light exposure time. We have used this method to pattern bacteria by controlled cell growth. This use of blue light provides a low-cost, high-throughput method for patterning biofilms or the deposition of materials by bacteria, such as bacterial cellulose and calcium carbonate. Current research is aimed at characterizing the underlying mechanism for the slowed bacteria growth including hyperpolarization, generation of reactive oxygen species, and enzyme activity.

SB04.05.03
Self-Assembled Hybrid Structure of Natural Photosystems in Bio-Photovoltaic Cells for Enhanced Photoelectric Current Generation Nyeongbeen Jo and Yoon Sung Nam; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In the natural photosynthesis of plant or cyanobacteria, functional proteins and redox cofactors are sophisticatedly self-assembled in the thylakoid membrane, exhibiting nearly 100 % of light-harvesting quantum efficiency. Photosystem I (PSI) is an integrated membrane protein complex that catalyzes the transfer of electrons using light energy. The photon energy absorbed by PSI also provides a proton motive force used to produce organic compounds. This finding has inspired engineers to pursue biomimetic and bio-inspired designs for efficient light-harvesting and charge extraction. However, the efficiency of nano-bio hybrid photosystems is often limited by the poorly-oriented assembly of photosystems with nanomaterials. In this work, we assembled PSI with protonated-carbon nitride (PCN) nanosheets through balanced intermolecular interactions, resulting in linker-free PSI/PCN hybrid nanostructures that generate favorable electronic interfacial structures for charge transfer through a Z-scheme system. Surface-modified carbon nitrides can provide photocatalytic activity under visible light irradiation conditions and a new electron transfer path in the hybrid structure with PSI. Electrostatic hybridization between protonated sites on the PCN nanosheets and the partially negatively charged lumen side of PSs provides a favorable orientation for efficient electron transfer. The PSI/PCN hybrids exhibit a photocurrent density more than 28 times higher than randomly oriented PSI. We also show that when coupling the developed bio-photocathode with a PSII-based photoanode, a photocurrent of 7.7 μA cm^{-2} under bias-free conditions and a cell power up to 0.9 μW cm^{-2} can be achieved. This study provides a vital strategy to construct an efficient biochemical photoelectrode based on natural photosystems coupled with semiconductor carbon nanostructures through simple self-assembly in a favorable orientation for efficient and stable interfacial electron transfer. This work was supported by Nano●Material Technology Development Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Science, ICT & Future Planning (NRF-2017M3A7B4052797).

SB04.05.04
Carbon Nanomaterials to Improve Charge Transfer at the Electrode Interface in Microbial Fuel Cell for Wastewater Treatment and Bioelectricity Generation Denisse P. Murillo, Daniela Zúñiga Rivera, Karina Tellería Chaves, Mónica Carmona Córdoba, Ricardo Esquivel-Isern and Claudia C. Villarreal; Instituto Tecnológico de Costa Rica, Costa Rica

At least 50% of the wastewater from human activities is discharged into the environment without treatment, a practice that compromises the human right to access clean water and sanitation. Microbial fuel cells (MFCs) are devices capable of converting chemical energy into electrical energy through electrochemical reactions, using the electrosynthesis of microorganisms. In this work, a device composed of two chambers is proposed. Biodigester effluent is used as an anolyte and oxidation of organic components is perfomed by bacteria at the electrode surface in the anodic chamber, while the reduction of heavy metals from industrial wastewater takes place in the cathodic chamber. The proposed MFC can simultaneously reduce the load of pollutants in agricultural and metallurgic wastewater and produce renewable energy. The objective of this study is to determine the effect of coating the graphite electrodes in the cathodic and anodic chamber with carbon nanomaterials, including graphene and a seamless hybrid of graphene and carbon nanotubes, both materials obtained by chemical vapour deposition. The nanostructured electrodes provide a larger surface area and increased electron transfer rates to improve the performance of bioelectricity generation. This work improves the comprehension of bioelectrochemical phenomena occurring in biofilm-based microbial devices and analyzes how the electrode surface structure can tune the charge transfer efficiency at the interface of living organism and carbon electrodes.

SB04.05.06
PEDOT:PSS Based Soft, Healable and Highly Adhesive Hydrogels for Monitoring Human Health Xin Zhou[1], Gregory A. Lodygensky[2,3] and Fabio Cicoira[1]; [1]Polytechnique of Montreal, Canada; [2]Sainte-Justine University Hospital Research Center, Canada; [3]University of Montreal, Canada

Flexible, soft, self-healing, and adhesive conductive materials with Young's modulus matching biological tissues (with a moduli of 0.5-500 KPa) are highly desired for applications in bioelectronics. Here, we report self-healing, stretchable, highly adhesive, and conductive hydrogels obtained by mixing polyvinyl alcohol (PVA), borax, and Poly (3,4-ethylenedioxythiophene) doped with polystyrene sulfonate (PEDOT:PSS) screen printing paste. The prepared hydrogels demonstrated remarkable compliance on skin, outstanding plastic stretchability (over 10000% strain), high adhesion on pig skin (1.96

N/cm^2), a good strain sensitivity (gauge factor = 3.88 at 500 % strain), remarkable self-healing properties, and low compressive Young's modulus (~3.7 KPa). Our hydrogels were used to fabricate electrophysiological epidermal patch electrodes, which exhibited high-quality similar to commercial Ag/AgCl gel electrodes for recording of electrocardiography (ECG) and electromyography (EMG) signals.

SB04.05.07
Printable and Self-Adhesive Dry Epidermal Electrodes Using PEDOT:PSS and Polyurethane-Based Composite Pierre Kateb[1], Jinsil Kim[1], Xin Zhou[1], Gregory A. Lodygensky[2] and Fabio Cicoira[1]; [1]Polytechnique Montreal, Canada; [2]Sainte-Justine Mother and Child University Hospital Center, Canada

Monitoring the vital signs of children born prematurely is of paramount importance for their health. Electrocardiography (ECG), electromyography (EMG), heart rate and respiration data are used to assess their well-being and development. These measurements require the placement of electrodes on the skin via an adhesive, which can lead to damage during its removal because the skin of premature infants does not have a protective outer layer. Therefore, alternative monitoring methods are needed to increase comfort and reduce the burden of preterm infants. This can be achieved with flexible, stretchable, and self-adhesive electrodes that can adapt to the shape and movements of the child while maintaining signal quality for a long-term use.
Commonly used biomedical electrodes for on-skin electrophysiological measurements are hydrogel-based and suffer from water loss, therefore degrading and losing signal quality overtime. Long-term monitoring using gels is therefore hindered. On the other hand, electrodes using adhesives often adhere too strongly for sensitive skin and can only be used once. Herein, a conductive polymer, poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS), is mixed with a short chain polyurethane diol (PUD) and printed onto a thin thermoplastic polyurethane substrate to obtain a reusable, wearable and dry electrode for durable electrophysiological signal monitoring. Due to its light adhesivity, the dry electrode can conform to the skin and reduce noise during the signal acquisition without inducing pain during its removal. Furthermore, PUD/PEDOT:PSS electrodes showed stretchability and a Young's Modulus similar to skin, which demonstrates the durability of the electrode and tolerance to repeated mechanical strains, while maintaining high conductivity. Strain-stress, cyclic stress, electrotensile as well as adhesion tests confirm this PUD/ PEDOT:PSS composite's excellent mechanical properties. Weeklong EMG and ECG measurements with the same electrodes also showed its capability for long-term usage.
Such an electrode is more suitable for long-term health monitoring of patients with fragile skin, such as premature infants.

SB04.05.09
Electropolymerized PEDOT Coatings on Penetrating Neural Probes Improve Chronic In Vivo Electrochemical Stability Jeeyeon Yeu[1], Jo'Elen Hagler[1], Guillaume Ducharme[2], Bénédicte Amilhon[2,3] and Fabio Cicoira[1]; [1]Polytechnique Montreal, Canada; [2]Université de Montréal, Canada; [3]CHU Sainte-Justine Research Center, Canada

The conducting polymer poly(3,4-ethylenedioxythiophene) (PEDOT) is a promising material for improving the stimulation efficiency of neural microelectrodes due to its many advantageous characteristics, such as mechanical compliancy, electrochemical stability, and high conductivity. Studies on the long-term in vivo electrochemical stability of penetrating PEDOT-coated electrodes undergoing high-frequency stimulation are not extensively done and the immune response of the brain towards PEDOT-coated stimulating neural probes is not well investigated. In this study, electropolymerized PEDOT doped with tetrafluoroborate (PEDOT:BF4) is selectively deposited on the electrodes of platinum iridium (PtIr) neural probes and implanted for 2 weeks and 2 months to evaluate the effect of implantation on the electrical performance, along with the foreign body response to the probes. Histological analysis after 8 weeks of implantation shows no difference in the degree of inflammation around PtIr and PEDOT probes. Furthermore, PEDOT and PtIr probes are implanted for 60 days, and subject to daily high frequency stimulation while being monitored for changes in electrochemical properties. Impedance measurements confirm an overall lower impedance for PEDOT probes. This study shows that PEDOT:BF4 coatings can contribute to the electrochemical stability of neural interfacing devices for stimulation and recording.

SB04.05.10
Electrodeposition of PEDOT on Nickel-Plated Copper for Biomedical Electrodes Kathel C. Dongnang Ngoula, Sara Ebrahimi, Sally Zhou and Fabio Cicoira; Polytechnique Montreal, Canada

Current approaches in the healthcare field use electrodes as biomedical devices at the interface of biological systems and electronics to either transmit electrical impulses or as sensors to record bioelectric signals. The main hindrance to these measures is the resistance to the flow of the electric signal from the living tissues, called the impedance. Recent advances are proposing organic conducting polymers, mainly poly(3,4-ethylenedioxythiophene) (PEDOT), to improve signal acquisition and lower the impedance at the electrode/tissue interface. In fact, PEDOT has been shown to have a low impedance, a high conductivity due to its mixed electronic ionic conduction, good electrochemical stability, and biocompatibility allowing its use in bioelectronic devices.[1]
The present study proposes using PEDOT as a coating on Nickel plated copper (Ni-Cu) electrodes to design innovative devices with low impedance and high conductivity to record bio-signals for diagnosis, monitoring, and prevention of medical conditions. The nickel coating has been achieved through an electroless plating process in a nickel-plating bath.[2] Afterwards, the PEDOT coating has been achieved through cyclic voltammetry (CV) and a galvanostatic chronopotentiometry (CP) electropolymerization of the 3,4-ethylenedioxythiophene (EDOT) monomer. The bath contained the EDOT monomer and the dopant, lithium perchlorate ($LiClO_4$), dissolved in either water or acetonitrile (ACN). A variety of potential ranges were considered for cyclic voltammetry, but only cycling held constant between -1.0 V and +1.2 V produces the agglomeration of PEDOT on the substrate. The chronoamperometric method resulted in homogeneous/uniform PEDOT films, and by optimizing the electropolymerization conditions, we demonstrated the mechanical and electrochemical stability of PEDOT doped with $LiClO_4$ deposited on Ni-Cu electrodes. The coatings have been analyzed and characterized using electrochemical impedance spectroscopy (EIS) and CV in a phosphate-buffered saline solution (PBS), X-ray photoelectron spectroscopy (XPS), and scanning electron microscopy (SEM). As a result of PEDOT coating's potential electrocatalytic properties, an improvement in the electrode's electrochemical properties was achieved, resulting in reduced impedance and higher performance. Due to their high capacitance and low impedance, PEDOT Ni-Cu electrodes can be used as convenient electrodes for detecting biological signals, improving biomedical devices in the future.

SB04.05.11
All-Printed and Fully-Stretchable Organic Electrochemical Transistors Based on Hydrogel Electrolyte Chi-hyeong Kim[1], Mona Azimi[1], Harini Nagarajan[2] and Fabio Cicoira[3]; [1]Polytechnique Montréal, Canada; [2]Madras Institute of Technology, India; [3]Polytechnique Montreal, Canada

Solution-processable organic materials are desirable for functionalized wearable devices. To maximize that feature of organic polymers, printing is one of

the best methods to cast films or patterns. Herein, we fabricated fully-stretchable organic electrochemical transistors(OECTs) by a conventional PBC printer. To achieve the stretching of the whole body of the devices, a printed planar gate electrode and polyvinyl alcohol(PVA) hydrogel electrolyte were employed. The simplicity of the PCB printer made it possible to print a wide range of viscous inks, from an organic semiconductor to a hydrogel precursor. A Stretchable silver paste provided a soft feature to drain/source, gate and interconnect without any strategies to improve the stretchability of metallic components, such as pre-stretching methods and formation of stretchable patterns. Moreover, unlike reported studies of printed ion-gel electrolytes for transistors, a printed hydrogel electrolyte on OECTs has not been reported yet. The resulting OECTs showed decent performance comparable to ink-jet or screen-printed OECTs; the maximum transconductance and on/off ratio were 1.2mS and around 1400, respectively. The devices were stable in electromechanical behavior until 30% strain which is required for wearable electronics on the skin.

Redox-Linked Synthetic Biology and Electrogenetics Opens Lines of Communication William Bentley, Eric VanArsdale, Sally Wang, Chen-Yu Chen, Eunkyoung Kim, Zhiling Zhao, Jinyang Li, Rahma Zakaria, Chen-Yu Tsao, Kayla Chun, Dana Motabar, Monica Chu and Gregory Payne; University of Maryland, United States

Microelectronics has transformed our lives. It has changed the way we collect, process, and transmit information. The intersection between microelectronics and biology has also been transformative – ionic currents that control cardiovascular and neural systems are detected and even corrected using electronics (e.g., EKG & defibrillators). Yet, the microelectronics world has barely "sampled" the vast repertoire of chemical information in our biological world. Take for example the human immune, endocrine, and gastrointestinal systems – they are largely opaque to the methods of electrical sensing and communication. In biology, information is often contained in the *structure of its molecules* – molecules that move from place to place and based on their structure, convey information and provoke a response.

We envision new processes and deployable products that open the dialogue between biology and microelectronics – that eavesdrop on and manipulate biological systems within their own settings and in ways that speed corrective actions. We view biofabrication and synthetic biology as integral technologies for achieving this vision. Synthetic biology, often visualized as an innovative means for "green" product synthesis through the genetic rearrangement of cells, can also provide a means to connect biological systems with microelectronic devices. Cells can be reprogrammed to close the communication gap that exists between the electrons and photons of devices and the molecules and ions of biology. This is enabled, in part, through redox mediators – biological carriers of electrons that transfer "packets" information to and from electronics. We have suggested the purposeful electronically actuated elicitation of gene expression is "electrogenetics". Biofabrication, the assembly of biological components using biological means or mimics thereof, offers a means to close the fabrication gap – a gap that stems from the disparity between biological systems, assembled of labile components using built-in error correction, and devices, built of potentially toxic materials using error prevention and byproduct exclusion. Here, innovative materials, electronics, biomolecular and cellular engineering strategies can be developed to mediate "molecular" communication - information transfer to microelectronic systems and back. New systems and devices are continually emerging that integrate abiotic and biological components (e.g, animal-on-a-chip devices, chip based manufacturing systems, etc.) at a hierarchy of length scales. New systems may emerge that eavesdrop on and electronically guide cellular consortia, vastly expanding our synthetic biology repertoire while utilizing increasingly complex raw materials.

We suggest that a great many of our society's grand challenges in sustainability, food, energy, and medicine may be addressed by developing tools that open lines of communication between the biological and electronics worlds.

10:30 AM SB04.06.02
Broad Bacteria Biosensing Based on Integration of 3D Organic Transistors in Fluid Flow Cells Jingchu Huang, Daewoo Han and Andrew J. Steckl; University of Cincinnati, United States

A novel approach for bacteria biosensing using organic electrochemical transistors (OECT)[1] has been demonstrated in the sensing of cells and metabolic products (carbohydrates, protein, and cations)[2]. OECTs are attractive for bacteria biosensing due high sensitivity, fast diagnostics, and simpler bacteria handling. The use of OECT enables the detection of bacterial contamination in home-liquid-goods and provide potential real-time monitoring capabilities. Two main requirements for bacteria sensing in liquid products are: (a) non-specific detection (no capture agents) - there are hundreds of common bacteria strains present in daily living that are harmful to humans; (b) high sensitivity – for early detection of liquid goods contamination, at bacteria concentrations as low as a few hundred colony-forming units per mL (CFU/ml). OECTs can respond to bacteria attached to (or near) either the source-drain channel or the gate electrode. Here, we report on universal bacteria sensing using OECTs integrated within a microfluidic flow cell. A conductive microporous filter membrane in the flow cell device was utilized to accumulate the bacteria and serve as a gate electrode for OECT operation ("gate filter"). The device can detect ~ 10^2 CFU/ml bacteria in mixtures of household liquid products and common bacteria growth broths. This is the result of bacteria accumulation on the gate causing a shift in the OECT source-drain channel current (I_{ds}).

The overall sensor consists of a dual PEDOT: PSS gate OECT, a 3D-printed flow cell, and an Au-coated 0.4um PETE filter membrane as the gate electrode. The dual OECTs are integrated into the flow cell device and both channel sensing and gate sensing approaches are evaluated using *pseudomonas fluorescens*, a common Gram-negative bacterium. OECT channel sensing shows good discrimination between bacteria and sterile solutions, with higher bacteria concentration resulting in higher I_{ds} shift and increased peak transconductance (g_m). At $V_g = 0.3V$, compared to sterile solution a solution of 10^5 CFU/ml bacteria results in ~ 43% and 100% increase in I_{ds} (2.51mA) and g_m (7.2mS), respectively. In the flow cell device operation, bacteria trapped on the gate filter results in additional gate-to-electrolyte potential drop on the effective gate voltage. Sterile and bacteria solutions of 10^2 and 10^3 CFU/ml display the same I_{ds} starting point (4.6 mA) at $V_g = 0V$. As gate bias is applied, the higher bacteria concentration samples have a sharper I_{ds} reduction. At $V_g = 0.3V$, the channel current is reduced to 1.7 mA for the sterile solution, 1.3 mA for the 10^2 CFU/ml, and 0.5 mA for the 10^3 CFU/ml bacteria solutions. The higher bacteria concentration results in a smaller voltage required to switch off the OECT of 0.5 and 0.7V for 10^3 and 10^2 CFU/ml, respectively. With the OECT flow cell approach, bacteria detection resolution reached a low value of ~ 10^2 CFU/ml. For continuous real-time detection testing using OECT flow cells, the device maintains $I_{ds} = 3.5mA$ at $V_g = 0.3V$ when flowing sterile solution at 3ml/hr. Introducing 10^3 CFU/ml bacteria solution results in the I_{ds} current decrease with a 1.5mA/hr rate. In summary, the 3D-printed flow cell incorporating OECTs has been used to sense low levels of bacteria present in commercial household liquid products within an hour without the need for amplification, providing a promising approach towards future biosensing

system.

Recording of Intracellular Action Potential of Cardiomyocytes by Means of Organic Electrochemical Transistors Silvia Conti, Rustamzhon Melikov, Giuseppina Iachetta, Michele Dipalo, Francesco Tantussi and Francesco De Angelis; Istituto Italiano di Tecnologia, Italy

The existence of an electronic coupling between electrogenic cells and electronic supports is the bases of any tailored system employed to study biology-driven phenomena. During real-time monitoring of electrophysiological signals (action potentials, APs), the communication typically occurs at the cell (neurons or cardiomyocytes)/transducer interface, whose optimization is fundamental to make the investigation of neurodegenerative and cardiac diseases effective. In the last 20 years, organic materials have been largely used for the fabrication of bioelectronic devices thanks to their biocompatibility, easy processability, tunability of physical properties, stimuli-responsiveness and high conformability [1].
Organic electrochemical transistors (OECTs) using Poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) PEDOT:PSS as active material, present features that make them perfectly suitable for the record of electrophysiological potentials: *i)* the biocompatibility, *ii)* the flexibility, and *iii)* the double ionic/electronic conductivity of the polymer. The cell/transducer interface is, in this case, represented by the active material that interfaces the biological system and dictates the transduction of the ionic transmembrane flows (able to dope/de-dope the polymer) into an electrical readout [2]. Moreover, *iv)* the high source-drain current levels and *v)* the large transconductance values that characterized this type of devices, allow to keep low operating voltages and reduced heat generation, necessary for the system durability in aqueous biological environment [3]. Being a non-invasive measurement, it increases the vitality of the cells, allowing multiple and long-duration recordings, fundamental for chronic studies.
In this work, we report *in vitro* recordings of APs of human induced pluripotent stem cell-derived cardiomyocytes (hiPSC-CMs) by using planar OECTs with spin-coated PEDOT:PSS channel. hiPSCs-CMs were cultured directly on the polymeric surface. Extracellular potential recordings were obtained by simply turning on the transistors at their maximum transconductance and following the variation of both the drain-source and the gate-source currents. Extracellular signals present a typical and predominant negative phase (with amplitude around 0.3 mV) and an expected short duration of around 20 ms [2,4]. Intracellular signals were recording adopting a cell optoporation protocol (large pulse, low current intensity) that enabled the measurement without stimulating the cells [5]. Amplitudes in the range of 3-4 mV were recorded, which is comparable to performance obtained with similar devices that use electroporation [3]. To improve the photocurrent response different formulations of PEDOT:PSS with the addition of gold nanoparticles are tested. Drug screening tests are performed to assess the ability of the devices to detect cardiotoxic effects; live/dead assay and immunofluorescence imaging to evaluate their biocompatibility. In future, additional electronics and biosensing elements could be complemented on the same device paving the way to multifunctional, reliable, and low-cost biosensors.

Wireless Detection of Enzyme-Powered Hydrogel Motor for Autonomous Mobile Biosensors Shogo Himori and Toshiya Sakata; The University of Tokyo, Japan

Electrochemical detection methods are promising for accessible biosensors to all citizens because of their simple principle, and various types of electrochemical biosensors have been developed, including wearable sensors and implantable sensors [1]. However, these sensors cannot reach wide-area spatial information, although they can detect biological information near the electrodes. Therefore, we are proposing a new-type biosensor, an autonomous mobile biosensor that moves in solution and continuously tells us the biological information.
In the Marangoni motor system, the motor releases surfactant from its body, allowing it to move in solution while generating a surface tension gradient around itself [2]. Urease, one enzyme, catalyzes the production of ammonia molecules from the biomolecule urea, and the ammonia reduces surface tension [3]. It suggests that the urease-modified motor can generate driving force in urea containing bio-solution without external energy supply. In addition, conductive polymer hydrogels are suitable for the motor body material because of their conductivity, which mediates electrochemical information, and their porosity, which allows enzymes to be carried in the three-dimensional polymer network. Common electrochemical sensors use wires to connect the sensing electrodes with external measurement systems for the collection of electrical signals, but the wires inhibit the movement of the motors in the autonomous mobile biosensor. In this study, a wireless sensing system was developed to acquire biological signals from the self-propelled conductive hydrogel motor.
The conductive hydrogels were fabricated from a mixture of poly(3,4-ethylene dioxythiophene): poly (styrene sulfonate) (PEDOT: PSS) and dimethyl sulfoxide (DMSO) [4]. Enzyme-based motorization was investigated via modification of urease on a conductive hydrogel by physical cross-linking with glutaraldehyde. In developing wireless motor detection, we examined impedance sensing methods. Two parallel Au electrodes, called direct electrodes (DEs) were placed in PBS and connected to the electrochemical analyzer. In addition, four materials (Au, ITO; indium tin oxide, Gel; conductive hydrogel, glass), called bipolar electrodes (BPE) were placed between the DEs wirelessly, and the impedance changes depending on the material and placement of the BPEs were investigated.
As a result, the urease-modified hydrogel motor began moving in PBS including urea on the basics of the enzymatic reaction. It indicates that urease-modified gel can obtain driving energy from urea and move continuously in bio solution. In addition, the impedance change was studied depending on the wireless BPE material, and it was found that when conductive materials (Au, ITO, Gel) were put between the DEs, the impedance at high frequency become lower than when no material was put in the solution. In contrast, when glass, an insulator, is placed between the DEs, the impedance increases. It indicates that the conductivity of the BPE material alters the current flowing between the DEs. Besides, impedance change dependent on the wireless gel position was also investigated, and it was found that the impedance change became smaller as the gel moved away from the DEs. It indicates that the impedance measurement method provides information on the movement of the gel wirelessly. In the future, we will capture urea concentration-dependent changes in gel motion wirelessly and investigate potential applications in biosensing.

A Living Electronic Biosensor for the Marine Environment Sarah M. Glaven[1], Lina Bird[1], Dasha Leary[1], Judson Hervey[1], Jaimee Compton[1] and Christopher A. Voigt[2]; [1]U.S. Naval Research Laboratory, United States; [2]Massachusetts Institute of Technology, United States

Microbial extracellular electron transfer (EET) by electroactive bacteria can be reprogrammed using bioengineering to enhance existing technologies (e.g. microbial fuel cells) or create entirely new ones (living electronic sensors). A current bottleneck in engineering electroactive bacteria is the selection and development of chassis strains that can both host complex EET machinery and survive under conditions relevant to the application of interest. In this talk I will describe our efforts to develop *Marinobacter atlanticus*, a gram-negative marine bacterium, as an engineered electroactive bacterium for sense and respond in seawater. Genetically encoded sensors optimized for use in *E. coli* were used to control expression of the *Shewanella oneidensis* electron transfer pathway in planktonic and biofilm attached cells. Electrical current production could be induced during biofilm growth in artificial seawater when sensors controlling expression of different components of the pathway were activated by addition of 2,4-diacetylphloroglucinol (DAPG), isopropyl β -d-1-thiogalactopyranoside (IPTG), and tetracycline (Tc). Significant current production also required addition of menaquinone, which *M. atlanticus* does not produce, for electron transfer from the inner membrane to the expressed electron transfer pathway. Electron transfer was also reversible, indicating electron transfer into *M. atlanticus* could be controlled. These results show that an operationally relevant marine bacterium can be genetically engineered for environmental sensing and response using an electrical signal.

SESSION SB04.07: Emerging Applications
Session Chairs: Teuta Pilizota and Tanya Tschirhart

Photosynthetic Microorganisms for Photoconversion Gianluca Maria Farinola[1], Rossella Labarile[1,2], Danilo Vona[1], Gabriella Buscemi[1], Matteo Grattieri[1], Roberta Ragni[1] and Massimo Trotta[2]; [1]Universita' degli Studi di Bari Aldo Moro, Italy; [2]CNR, Italy

Photosynthetic microorganisms and their molecular components represent attractive functional elements for harvesting and conversion of solar energy in bioelectronic devices [1].
We have recently investigated several approaches for addressing the Reaction Center (RC) photoenzyme extracted from the purple non sulfur photosynthetic bacterium *Rhodobacter (R.) sphaeroides* in optoelectronic devices for conversion of solar energy into photocurrent.
We have used polydopamine (PDA) for immobilizing and interfacing RC on ITO electrodes, by simple polymerization of dopamine in aqueous media [2].
We also used polydopamine to directly integrate living cells of photosynthetic bacteria onto electrodes in bio-photoelectrochemical cells. Two different approaches were used for *R. sphaeroides* and its closely related strain *R. capsulatus*, respectively. The encapsulation of entire bacterial cells of *R. sphaeroides* in PDA conductive coating was obtained by addition of dopamine in bacterial growth medium [3]. In the case of the *R. capsulatus* a one-pot procedure was used, which was initiated by oxygenic polymerization followed by electrochemical polymerization of dopamine, including redox mediators [4].
We have also explored the possibility to directly interface photosynthetic microorganisms with electrodes without the use of an additional soft interfacing material. For this purpose, we used the unicellular diatom algae *Phaeodactylum tricornutum*, exploiting their spontaneous biofilm formation.
Our study discloses new concepts for the generation of bio-hybrid materials for sunlight photoconversion and for light-responsive bioelectronics from the combination of photosynthetic microorganisms with tailored functional materials.

2:00 PM SB04.07.02
Machine-Learning-Based Inverse Design for Electrochemically Controlled Microscopic Gradients of O_2 and H_2O_2 Yi Chen, Jingyu Wang, Ben Hoar, Shengtao Lu and Chong Liu; University of California, Los Angeles, United States

A fundamental understanding of the extracellular microenvironments of O_2 and reactive oxygen species (ROS) such as H_2O_2, ubiquitous in microbiology, demands high-throughput methods of mimicking, controlling, and perturbing gradients of O_2 and H_2O_2 at microscopic scale with high spatiotemporal precision. However, there is a paucity for a high-throughput strategy of microenvironment design and it remains challenging to achieve O_2 and H_2O_2 heterogeneities with the microbiologically desirable spatiotemporal resolutions. Here we report the inverse design, based on machine learning (ML), of electrochemically generated microscopic O_2 and H_2O_2 profiles relevant for microbiology. Microwire arrays with suitably designed electrochemical catalysts enable the independent control of O_2 and H_2O_2 profiles with spatial resolution of ~10^1 μm and temporal resolution of ~10^0 sec. Neural networks aided by data augmentation inversely design the experimental conditions needed for targeted O_2 and H_2O_2 microenvironments while being order-of-magnitude faster. Interfacing ML-based inverse design with electrochemically controlled concentration heterogeneity creates a viable fast-response platform towards better understanding the extracellular space with desirable spatiotemporal control.

2:15 PM SB04.07.03
Enhancing Solar-Driven CO_2 Reduction to Multi-Carbon Products via Adapted Whole-Cell Catalysts and a Silicon Nanowire Photocathode Jimin Kim and Peidong Yang; UC Berkeley, United States

Due to the anthropogenic CO_2 emissions, the atmospheric concentration of CO_2 exceeded 413 ppm in 2020, sharply increasing from 270 ppm at the beginning of the industrial revolution. Dramatic climate changes, such as extreme heat waves, wildfires, and droughts, are affecting human societies and ecosystems at such alarming levels that their influence can no longer be ignored. Thus, developing alternatives to fossil fuels and mitigating CO_2 emissions at a necessary scale is more urgent than ever to establish a carbon-neutral society. Catalytic CO_2 conversion to renewable fuels has been the focus of intensive research with the goal of closing the carbon loop. Photosynthetic biohybrid systems (PBSs), in which a photoactive semiconductor directly

interfaces with nonphotosynthetic, CO_2-reducing bacteria, represent a promising approach for the renewable and sustainable production of fuels and chemicals. They combine the best features of semiconducting nanomaterials and biological whole-cell catalysts to power biocatalytic CO_2 conversion with light. Semiconducting nanomaterials can harvest solar energy efficiently. Nature's catalytic machinery enclosed in its cellular environment provides low activation energies and exquisite product selectivity through its cascade reactions. We demonstrate that by tunning the local chemical environment of a silicon nanowire – acetogen *sporomusa ovata* (*S. ovata*) biohybrid, we can maximize the interfacial area between living cells and cathodes and boost the bioelectrochemical CO_2 reduction rate. In addition to optimizing the local environment, the rational design of biocatalysts in PBSs is imperative to reduce CO_2 into valuable chemicals effectively. We introduce a methanol adapted *S. ovata* to enhance the sluggish biocatalytic activity of wild-type microorganisms into our silicon nanowires (Si NWs) photocathodes for efficient solar-to-chemical conversion. Electrochemical impedance spectroscopy (EIS) is exploited to study the biohybrid system and the biofilm cathodes. We illustrate the fundamental charge transfer mechanisms at the biotic-abiotic interface between silicon nanowires and microorganisms. Using adapted *S. ovata* decreases the charge transfer resistance at the cathodes and facilitates charge transfer from directly interfaced solid electrodes. Finally, this new generation of biohybrids with adapted *S. ovata* enables an increase of solar CO_2 fixation under photoelectrochemical reducing environments on the Si NWs photocathode.

3:30 PM SB04.07.04
Enzyme Bioanode with Electropolymerized Thiazine for Formic Acid//O_2 Biofuel Cells Motohiro Kosugi, Yuki Fujii, Ryoichi Tatara and Shinichi Komaba; Tokyo University of Science, Japan

An enzymatic biofuel cell (EBFC) is a type of power generating device where enzymes function as catalysts to oxidize biofuel (saccharides such as glucose or alcohols)[1]-[4] and reduce oxygen molecules.[5]-[7] It can be operated under mild conditions of neutral solution, room temperature and atmospheric pressure. The main advantage of an EBFC is the utilization of renewable energy sources through enzymatic reactions. Among the fuel sources currently available for EBFCs, formic acid is oxidized by formate dehydrogenase (FDH) at a low potential and is expected to high-voltage EBFCs. Most of the previously reported fuel cells with formic acid as the fuel utilize palladium or platinum as catalysts, and there are few reports of enzymes being used as catalysts. Using enzymes has the advantage of being relatively inexpensive compared to other catalysts in EBFCs. In this study, we focused on FDH with nicotinamide adenine dinucleotide (NAD) as the active site and prepared enzymatic bioanodes modified with three different electropolymerized thiazine dyes, methylene blue (MB), thionine (Th), and Azure A (AA), as electrocatalyst and investigated their electrochemical properties.

The bioanodes were prepared as follows: 1) carbon powders (carbon nanotube or sucrose-derived carbon) was dispersed in water with sodium polyglutamate as the binder and dropped on carbon-felt (CF) electrodes (thickness: 2 mm; diameter: 11 mm), then the carbon electrodes were modified with the three electropolymerized films, polyMB, polyTh, and polyAA, and 3) FDH solution was drop-cast on the electrodes. Electrochemical measurements were conducted at room temperature in the phosphate buffer solution (0.1 mol dm^{-3} PBS at pH = 7.0,) containing NAD (10 mmol dm^{-3}) and sodium formate (0.15 mmol dm^{-3}).
At the prepared electrode, formate was anodically oxidized with FDH at the electropolymerized electrode, and the coenzyme NAD was simultaneously reduced to NADH. The oxidation of NADH by the electropolymerized thiazine was expected to proceed rapidly. We successfully observed an oxidation current at −0.05 V (vs. Ag/AgCl), generated by the anodic decomposition of formate ions, in the substrate solution. This confirms that the electrochemically deposited thiazine polymer can act as electrocatalyst for the series of above oxidation reaction as expected. Among three thiazine dyes, it was found that polyMB has the highest catalytic activity for NADH oxidation, yielding the highest oxidation current densities owing to the efficient electron transfer process. The comparison of the electrochemical properties of the bioanode prepared with CNT and pyrolytic sucrose-derived carbon will also be discussed in the presentation.

3:45 PM SB04.07.05
Cable Bacteria—Electrifying Electronic Biological Materials with Record Intrinsic Electrical Properties—From Transistors to Billie Eilish Jean V. Manca[1], Robin Bonné[2], Raghavendran Thiruvallur Eachembadi[1], Koen Wouters[1], Nico Fransaert[1], Roland Valcke[1] and Bart Cleuren[1]; [1]University of Hasselt, Belgium; [2]Aarhus University, Denmark

Cable bacteria, a group of filamentous electroactive bacteria, have developed a unique energy metabolism and parallel fibre structures demonstrating electron transport for conduction lengths up to 1 cm and with fibre conductivities exceeding 10 S/cm. Conduction measurements carried out in high vacuum excluded the possibility of ionic conduction, but the fundamental charge transport mechanisms remain unknown. The observed electron transport in cable bacteria over distances in the order of centimeters is remarkable in the biological world.

Cable bacteria as 'living electrical wires' are of fundamental interest to better understand the underlying biological processes, but are also potentially interesting as alternative organic electronic materials for the emerging field of bioelectronics as *e.g.* biocompatible electrical connections and circuits, conductive composite materials, (nano-) sensors, transistors,... In order to investigate the intrinsic electrical properties and underlying transport mechanisms, our approach is to study them with a range of macroscopic and nanoscale solid state electrical characterisation techniques, in combination with structural and analytical techniques ranging from SEM to ToF-SIMS.

The electrical circuitry in a single cable bacterium is visualized with nanoscopic resolution using conductive atomic force microscopy (C-AFM). Combined with perturbation experiments, it is demonstrated that electrical currents are conveyed through a parallel network of conductive fibers embedded in the cell envelope, which are electrically interconnected between adjacent cells. This structural organization provides a fail-safe electrical network for long-distance electron transport in these filamentous microorganisms.

Impedance spectroscopy provides an equivalent electrical circuit model, which demonstrates that dry cable bacteria filaments function as resistive biological wires. Temperature-dependent electrical characterization reveals that the conductivity can be described with an Arrhenius-type relation over a broad temperature range (-195°C to +50°C), demonstrating that charge transport is thermally activated with a low activation energy of 40-50 meV. Furthermore, cable bacterium filaments can be utilized as the channel in a field-effect transistor.

The measured intrinsic electrical properties result very similar to for instance organic semiconductors, situating them in the context of electrical functional materials between semiconductors and conductors. These electrifying 'bad guy' microorganisms – with from various perspectives behave as they are not supposed to – are attracting growing interest and in the long-term could open novel avenues in emerging domains such as bioelectronics, biodegradable electronics and electronic biological materials (e-biologics). As a proof-of-principle for electrical transmission capabilities through cable bacteria filaments, the music track "Bad Guy" of Billie Eilish is transported through them. Cable Bacteria are rock & roll.

4:00 PM SB04.07.06
Enabling Electron Injection for Microbial Electrosynthesis with n-Type Conjugated Polyelectrolytes Glenn Quek, Ricardo J. Vázquez, Samantha R. Mccuskey and Guillermo Bazan; National University of Singapore, Singapore

Microbial electrosynthesis – using renewable electricity to stimulate microbial metabolism – holds the promise of sustainable chemical production. A key limitation hindering performance are slow electron transfer rates at biotic-abiotic interfaces. Here, we rationally design a water-processible n-type organic semiconducting polymer and demonstrate its use as a soft conductive material to encapsulate electroactive *Shewanella oneidensis* MR-1. The self-assembled three-dimensional living biocomposite amplifies current uptake from the electrode ≈674-fold over controls with the same initial number of cells, thereby enabling continuous synthesis of succinate from fumarate. By demonstrating synergy between living cells with n-type organic semiconductor materials, these results provide new strategies for improving the performance of bioelectrosynthesis technologies.

4:15 PM SB04.07.07
The Impact of Oxygen on Mtr-expressing *Escherichia coli* Xu Zhang and Caroline Ajo-Franklin; Rice University, United States

In bioelectrochemical systems (BESs), anaerobic conditions are used to generate current from microorganisms because oxygen can compete with an electrode as a terminal electron acceptor. However, prior studies have shown that oxygen enhances current production from *Shewanella oneidensis* MR-1 by counterbalancing a modest decrease in current per cell with a substantial increase in the total biomass. This opens the possibility that BESs based on oxygen-tolerant microorganisms might not need anaerobic conditions for maximal current production. Here we investigated this question in the facultative anaerobe *Escherichia coli*, which has been engineered to produce current using the Mtr pathway from *Shewanella oneidensis* MR-1.
To investigate the effect of oxygen on the current production of *Escherichia coli*, we have introduced different oxygen levels to BESs containing Mtr-expressing *E. coli* and monitored current production, biomass, protein expression and metabolic products. Our results showed that oxygen exposure substantially boosted current up to 30-fold relative to anaerobic conditions. With increasing oxygen levels, both the current per cell and total biomass increase. Oxygen enhances the expression of the Mtr proteins relative to anaerobic conditions. Additionally, oxygen levels linearly increased the abundance of the first protein in the Mtr pathway, indicating that this protein is the limiting step in the current production. Additionally, oxygen increased energy flux and substrate utilization.
In summary, oxygen enhances the current production of Mtr-expressing *Escherichia coli*. This work challenges the prevailing paradigm that anaerobic conditions promote current production, suggesting that bioelectronic applications can be performed in oxygen-rich conditions.

SESSION SB04.08: Virtual Session
Session Chairs: Giuseppe Paternò and Tanya Tschirhart
Wednesday Morning, December 7, 2022
SB04-virtual

10:30 AM SB04.08.01
Electrolyte-Gated Transistors Biosensors for Healthcare Applications Matteo Sensi[1], Marcello Berto[1], Carlo A. Bortolotti[1] and Fabio Biscarini[1,2]; [1]Università degli Studi di Modena e Reggio Emilia, Italy; [2]Istituto Italiano di Tecnologia, Italy

Electrolyte-gated transistors (EGTs) based on organic semiconductors and graphene derivates are emerging in the field of biosensing because they are ultrasensitive, label-free, can be fabricated on flexible substrates at low cost and interfaced with biological samples.[1,2] We show some examples to demonstrate the possibility to use this technology to develop biosensors for different healthcare applications, by just selecting the most effective device architecture and material.
All the presented devices share a common transistor architecture, consisting of two interdigitated electrodes, source and drain, covered with an active material, in contact with a gate electrode through an electrolyte. The biosensing event takes place at the gate/electrolyte interface, by functionalization of the gold gate with a biorecognition moiety, and it is amplified by the active material channel thanks to the high-capacitance electrical double-layers formed at the gate/electrolyte and electrolyte/channel interfaces.
We fabricated EGTs biosensors for ultrasensitive detection of biomarkers by using different materials in the channel, namely ambipolar Reduced-Graphene Oxide, organic p-type semiconductor TIPS-Pentacene and poly(3,4-ethylenedioxythiophene)polystyrene sulfonate (PEDOT:PSS) polymer mixture.
Thanks to tailored gate bio-functionalization, we realized a disposable rGO-EGT immunosensor for the detection of anti-Infliximab antibodies, which are produced by patients upon treatment with the immunotherapeutic drug Infliximab and can make the therapy ineffective. Furthermore, we developed an Electrolyte-Gated Organic Field-Effect Transistor (EGOFET) immunosensor for the detection of anti-Nivolumab antibodies, based on the organic semiconductor TIPS-pentacene, showing fM theoretical Limit of Detection (LOD).[3] We also successfully employed an organic electrochemical transistor (OECT) genosensor for the detection of oligonucleotides, thanks to a facile functionalization process based on polydopamine.[4] Finally, we demonstrated the possibility to use EGOFET for the specific detection of transcription factors, by using the consensus DNA sequence as biorecognition element.
We conclude that EGTs biosensors show promising performances for the future application at the Point-of-Care but also for fundamental studies on macromolecules interactions.

10:45 AM SB04.08.02

Enhancement of Bacteria Detection with an Extended-Gate Field-Effect Transistor (EGFET) by Dielectrophoretic Trapping of Bacteria Annalena Eckert[1], Lea Könemund[1], Tamina Kirklies[1], Svenja Herdan[1], Laurie Neumann[1], Felix Hirschberg[1], Rebekka Biedendieck[2], Hans-Hermann Johannes[1,3], Dieter Jahn[2] and Wolfgang Kowalsky[1,3]; [1]Technische Universität Braunschweig, Institut für Hochfrequenztechnik, Germany; [2]Institute of Microbiology and Braunschweig Integrated Centre of Systems Biology (BRICS), Germany; [3]Cluster of Excellence PhoenixD, Germany

Bacterial infections that do not respond to treatment are a leading cause of death worldwide and a major public health threat. For example, the O157:H7 strain of *Escherichia coli* (*E. coli*) is considered one of the most dangerous foodborne pathogens. It is crucial to detect pathogenic organisms at an early stage so that appropriate treatment and targeted use of antibiotics can be undertaken. Conventional detection techniques, such as enzyme-linked immunosorbent assay (ELISA) or polymerase chain reaction (PCR) are time-consuming, expensive, and require trained professionals. A method for rapid detection of bacteria that is inexpensive, provides a reliable result, and is easy to use is becoming increasingly important. The development of suitable electronic transducers that provide label-free, low-cost, rapid detection of bacteria is of great interest, as this approach could be extended to the development of handheld devices for point-of-care applications.

In previous work, a detection method based on an extended-gate field-effect transistor (EGFET) was developed for the detection of *E. coli* K12, a common well investigated apathogenic model strain. The sensing region of the EGFET was functionalized with modified porphyrins containing two different linkers: One linker connects the porphyrin to the electrode surface of the gate, and the other binds bacterial cells to the functional layer via a specific peptide chain. After applying a bacterial suspension onto the functional layer, the cells can thus bind to it. The negative charge on the surface of the cells changes the electrical potential at the electrode surface, which affects the electrical behavior of the EGFET. The presence of bound *E. coli* cells on the functionalized sensor surface has already been successfully detected[1].

The aim of this research is to concentrate bacteria specifically on the sensor surface of the EGFET by exerting a dielectrophoretic force on the cells in a combined system. The electrokinetic effect of dielectrophoresis (DEP) enables contactless manipulation of biological cells in fluids. DEP utilizes the geometry of electrodes to generate non-uniform high-frequency electric fields that exert an attractive or repulsive force on dielectric particles, inducing movement toward areas of maximum electric field gradient (positive-DEP) or minimum electric field gradient (negative-DEP). DEP is a flexible and versatile method for immobilizing, separating, and concentrating cells and has been successfully optimized for the fixation of bacteria on electrodes in previous work. It will be investigated to what extent the reliability and sensitivity of the sensor can be increased by dielectrophoretically trapping the bacteria on the transistor gate. Furthermore, it is possible to extend the functionality of the sensor with selectivity by combining it with DEP. DEP is capable of selectively separating biological particles by properties such as size, material, and shape, which allows selective detection of a bacterial species from a heterogeneous suspension.

All Printed Vertical Organic Electrochemical Transistor Mona Azimi[1], Chi-hyeong Kim[1], Harini Nagarajan[2] and Fabio Cicoira[1]; [1]Polytechnique Montreal, Canada; [2]Madras Institute of Technology, India

Recently printing techniques attracted significant attention for the fabrication of electronic devices especially organic electrochemical transistors (OECTs). Printing method is a low-cost additive process with fast prototyping and compatibility with different flexible or stretchable substrates. Poly(3,4-ethylenedioxythiophene) : polystyrene sulfonate (PEDOT:PSS) is a commonly used p-type material for OECTs due to its stability in aqueous media. Most of the reported OECTs to date have large channel lengths in tens of micrometers, which limits the transistor performance and transconductance. Downscaling the channel length is challenging by a common photolithography method. Here we used the printing technique to fabricate vertical configuration of OECTs where the channel length is defined by the thickness of printed active material (PEDOT:PSS), sandwiched between source and drain electrodes (silver electrodes). Printable semi-solid gel is used as an electrolyte for devices. We compared the planar configuration with vertical devices, and significantly higher transconductance is obtained for vertical configuration.

Electrical Control of Immune Cell Function Ann M. Rajnicek; University of Aberdeen, United Kingdom

Bioelectrical signalling drives behaviour of cells at scales from single bacteria to multicellular tissues. Improved understanding of bioelectrical phenomena, including their influence on immune cell function, will lead to improved electroconductive materials relevant to repair of epithelial and tissue damage. When an epithelium is wounded an endogenous, steady electric field (EF) of ~100 mV/mm is driven through the neighbouring tissues (cathode at the centre) and the success of wound closure relates to the presence and magnitude of this wound EF. In part this is because the EF steers migration of epithelial cells toward the wound site to close the gap. But Immune cells, including monocytes and macrophages, are also important contributors to successful wound healing. For many years the stimuli driving their function were principally attributed to chemical signalling factors present within the wound microenvironment, with no regard given to bioelectrical signals.
We therefore studied the responses of cultures of primary human monocytes and macrophages exposed to physiologically relevant EFs. Time lapse observation of monocytes, which are macrophage precursors, showed that an EF of 150 mV/mm applied for 2h steered migration toward the cathode and increased the speed of migration compared to controls (no EF). This suggests that these ‘first responders’ would be guided toward the wound centre (cathode) by an endogenous EF.
However, human macrophages responded differently. Macrophages migrated preferentially toward the anode (opposite to monocytes) and their speed of migration was increased compared to controls. Impressively, the macrophages were exquisitely sensitive to the EF stimulus, responding with migration toward the anode at EFs as small as 5 mV/mm, well below the threshold of endogenous wound EFs. This suggests that macrophages arriving, later than the monocytes, migrate to the wound edges (anode) to clear debris and microbes.
Directed migration of macrophages was associated with elongation of the cells parallel to the EF axis and reorganisation of the actin cytoskeleton toward the leading edge. Since a key role of macrophages is phagocytic uptake of microbes and apoptotic cells in the wound environment, we tested whether the EF also enhanced phagocytosis. Macrophages were exposed to an EF for 2h then carboxylate beads, *Candida albicans,* or apoptotic neutrophils were added to the cultures and left without any EF for a further 2h. Phagocytosis increased significantly in each case, demonstrating that the EF ‘priming’ improved phagocytotic efficiency.
Mechanistically, these EF-induced functional changes are accompanied by clustering of phagocytic receptors toward the anode, enhanced PI3K and ERK activation, and mobilization of intracellular calcium. EFs also modulated cytokine production selectively and can augment some effects of conventional polarizing stimuli on cytokine secretion.
Human T cells, which are present in wounded epithelia (skin or airway), also displayed directed migration toward the cathode and activation upon

stimulation with physiological EFs (50 or 150 mV/mm). We showed for the first time that EF stimulation downregulated T cell activation following stimulation with antigen-activated APCs or anti-CD3/CD28 antibodies, as demonstrated by decreased IL-2 secretion and proliferation. Mechanistically, STAT3 modulation by the EF was implicated in the functional changes.
There are increasing efforts to use electrical stimulation to aid wound healing. This is especially important for recalcitrant or chronic wounds prone to infection, such as diabetic foot ulcers. Our work can inform design of electrical wound dressing materials seeking to target immune function and infection.

11:25 AM SB04.08.05
Enhanced Electron Transfer in Biophotovoltaic Devices Based on Self-Assembled Photosystem I Protein Complexes Nahid Torabi[1,2], Xinkai Qiu[3], Sylvia Rousseva[1], Andreas Herrmann[4,1] and Ryan Chiechi[5,1]; [1]University Of Groningen, Netherlands; [2]Zernike Institute for Advanced Materials, Netherlands; [3]University of Cambridge, United Kingdom; [4]RWTH Aachen University, Germany; [5]North Carolina State University, United States

Biophotovoltaic (BPV) devices are a relatively new discipline in solar cells that utilize the components of natural photosynthetic proteins such as Photosystem I/II (PSI/II) from, for example, algae, plants, or cyanobacteria to effect photon-induced charge separation. The natural abundance and ease of isolation of these complexes, particularly PSI, make them ideal candidates for integration in biophotovoltaic devices. PSI converts photon energy into spatially separated electron/hole pairs. But does so with ~ 100% internal quantum efficiency by effectively building a precise, nano-scale junction into each protein complex. Our first work describes the fabrication of microfluidic devices with a focus on controlling the orientation of Photosystem I complexes, which directly affects the performance of biophotovoltaic devices by maximizing the efficiency of the extraction of electron/hole pairs from the complexes. The surface chemistry of the electrode on which the complexes assemble plays a critical role in their orientation. Recreating that self-assembly-driven precision and mimicking the replacement of degraded protein are two (of many) major challenges to the design of stable, high-efficiency devices. We addressed both of those problems with a simple device design that allows the circulation of fresh PSI through devices that use linkers to direct the equilibrium of a self-assembly process towards oriented, active complexes. The basic design of the BPV devices used to investigate the phenyl-C61-butyric acid (PCBA) and a peptide (IQAc, sequence: IQAGKTEHLAPDC which a cysteine residue was attached to the C-terminus) linkers is a co-fabricated microfluidic channel that defines an electrode comprising the liquid metal eutectic Ga-In (EGaIn), which is in contact with the electrolytic medium. The floor of the microfluidic channel, which is perpendicular to the EGaIn electrode, supports a nanostructured gold electrode fabricated by shadow evaporation. The performance of devices fabricated using a fullerene, PCBA, was superior to that of a peptide, IQAc, as determined via the short circuit current, open circuit photovoltage, and power output. The PCBA linkers self-assemble onto nanopatterned gold electrodes, simultaneously directing the orientation of PSI and facilitating the collection of photogenerated electrons which show that fulleroids are well-known acceptor materials in organic photovoltaic devices, and facilitate the extraction of electrons from Photosystem I complexes without sacrificing control over the orientation of the complexes, highlighting this combination of traditional organic semiconductors with bio-molecules as a viable approach to co-opting natural photosynthetic systems for use in solar cells.
Also, to achieve continuous, optimal charge-transfer flux through multiple layers stacked on top of each other in solid-state BPV cells and to maximize their efficiency, the PSI complexes need to be kept properly aligned with respect to the hole/electron injection and structurally intact. In other work, we achieved a record efficiency of 0.64% for solid-state biophotovoltaic devices by tailoring the transport layers to maximize the extraction of charges from a layer of photosystem I. Specifically, we inserted complexes of gold nanoparticles into reduced graphene oxide to adjust the level alignment without sacrificing carrier mobility. We paired that layer with a polytyrosine-polyaniline hole-extraction layer. Our results demonstrate that the functionality of photosystem I in the non-natural environment of solid-state biophotovoltaic cells can be improved through the modification of electrodes with efficient charge-extraction layers. The decoration of graphene electrodes with gold nanoparticles is a generalizable approach for enhancing charge transport across interfaces, particularly when adjusting the levels of the active layer is not feasible, as is the case for photosystem I and other biological molecules.

10:30 AM INTRODUCTORY REMARKS

11:00 AM SB05.01.02
Activity-Induced Polar Patterns of Filaments Gliding on a Sphere Chiao-Peng Hsu, Alfredo Sciortino, Yu Alice du la Trobe and Andreas Bausch; Technische Universität München, Germany

Active matter systems feature the ability to form collective patterns as observed in a plethora of living systems, from schools of fish to swimming bacteria down to cytoskeletal structures. While many of these systems move in a wide, three-dimensional environment, several biological systems are confined by a curved topology. The role played by a non-Euclidean geometry on the self-organization of active systems is not yet fully understood, and few experimental systems are available to study it. Gliding assays, in which cytoskeletal filaments are driven by molecular motors grafted to a substrate, are an ideal candidate to address the microscopic mechanisms that underlie pattern formation in active systems. Here, we introduce an experimental setup in which actin filaments glide on the inner surface of a spherical lipid vesicle, thus embedding them in a curved geometry. We show that filaments self-assemble into polar, elongated structures and that, when these match the size of the spherical geometry, both confinement and topological constraints become relevant for the emergent patterns, leading to the formation of polar vortices and jammed states. These results experimentally demonstrate that activity-induced complex patterns can be shaped by spherical confinement and topology.

11:15 AM SB05.01.03
Light-Modulated Dynamic Assembly and Mode Switching of Semiconductor Nanorod Swarms in an Electric Field Zexi Liang and Donglei (Emma) Fan; The University of Texas at Austin, United States

Collective behaviors are widely present in nature and artificial systems. The sizes of the constituting units range from nanometers to meters. Controllably tuning interactions among the constituting members in a swarm can result in complex assembling, structuring, and synchronous motion. Here, inspired by thermodynamic principles that govern phase transition in an equilibrium material system, we propose and explore a hypothesis for rationally creating various assembling modes in a non-equilibrium swarm made of semiconductor nanorods. Experimentally, we find the dense Si nanorods readily switch among three modes, *i.e.*, enhanced collective rotation, droplet-like clustering, and network formation by simply modulating visible light and applied electric field. Theoretical modeling considering light-controlled electrostatic interactions sheds light to the observation. This research presents a general approach for creating reconfigurable patterning and operation modes in a non-equilibrium swarm that points towards new opportunities for fundamental studies and applications.

11:30 AM *SB05.01.04
Optimally Transporting Active Drops Suraj Shankar; Harvard University, United States

Transportation, in its broadest sense, is an important task in many fields, including engineering, physics, biology, and economics, and a great deal is known about optimal and efficient strategies to move matter, energy, and information around. But can we craft similar optimal protocols to transport autonomously moving (active) matter, such as self-propelled drops or migrating cells? I will discuss how we solve this inverse problem by using optimal control theory in the context of transporting a drop of an active fluid with minimal viscous dissipation by dynamically varying spatial active stresses within the drop. I will highlight natural strategies and characteristic trade-offs that emerge from the optimal policies, suggesting general principles for optimal transportation in synthetic and biological active systems.

SESSION SB05.02: Topology and Packing
Session Chairs: Julia Dshemuchadse and Prashant Kumar
Monday Afternoon, November 28, 2022
Hynes, Level 1, Room 110

1:30 PM SB05.02.02
Inferring Topological Transitions in Pattern-Forming Processes with Self-Supervised Learning Marcin Abram[1], Keith Burghardt[1], Greg Ver Steeg[1] and Remi Dingreville[2]; [1]University of Southern California, United States; [2]Sandia National Laboratories, United States

The identification and classification of transitions in topological and microstructural regimes in pattern-forming processes is critical for understanding and fabricating microstructurally precise novel materials in many application domains. Unfortunately, relevant microstructure transitions may depend on process parameters in subtle and complex ways that are not captured by the classic theory of phase transition. While supervised machine learning methods may be useful for identifying transition regimes, they need labels which require prior knowledge of order parameters or relevant structures. Motivated by the universality principle for dynamical systems, we instead use a self-supervised approach to solve the inverse problem of predicting process parameters from observed microstructures using neural networks. This approach does not require labeled data about the target task of predicting microstructure transitions. We show that the difficulty of performing this prediction task is related to the goal of discovering microstructure regimes, because qualitative changes in microstructural patterns correspond to changes in uncertainty for our self-supervised prediction problem. We demonstrate the value of our approach by automatically discovering transitions in microstructural regimes in two distinct pattern-forming processes: the spinodal decomposition of a two-phase mixture and the formation of concentration modulations of binary alloys during physical vapor deposition of thin films. This approach opens a promising path forward for discovering and understanding unseen or hard-to-detect transition regimes, and ultimately for controlling complex pattern-forming processes. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525. SAND2022-3365 A

1:45 PM SB05.02.03
Templating and Nanostructuring of Hybrid Dendrimers, Knotty Polymers and Molecularly Imprinted Polymers (E-MIPS) Rigoberto C. Advincula[1,2,3]; [1]Case Western Reserve University, United States; [2]The University of Tennessee, Knoxville, United States; [3]Oak Ridge National Laboratory, United States

There is high interest in new polymer synthesis routes, topologies, mechanisms, and templating (molecular and colloidal) for various applications.

Mesoscale and hierarchically inspired assemblies have their origin in the microstructure and composition in soft matter. The choices for synthesis go from linear, grafted, and hyperbranched systems to hybrid organic-inorganic systems. However, there are many other topologies that are of high interest because of their relevance to cyclic and supramolecular polymerization routes that have yet to be demonstrated. Molecular templating is utilized for building "cavities" that facilitate high-resolution sensing and selectivity. This talk will focus on three concepts of targeted assembly and templating: 1) Dendimer topologies and hybrid nanoparticle electropolymerization, 2) Molecular imprinted polymer (MIP) using hybrid complexes, and 3) supramolecular polymer synthesis and assemblies in Knotty topologically inspired polymers. We also employ a number of macromolecular and surface characterization studies to define
successful synthesis strategies and assemblies The end goal are to demonstrate the topologies and patterns to produce higher throughput synthetic methods: unlocking the utility for real applications.

2:00 PM SB05.02.04
Multiscale Hierarchical Structures from a Nanocluster Mesophase Richard Robinson and Yuan Yao; Cornell University, United States

The spontaneous self-organization of nanoscale materials into complex macroscopic architectures has intrigued scientists for decades, because it offers insight into how complex structures can emerge from primitive building blocks. Hierarchical self-assembled systems offer structural advantages that are absent in isolated constituent units. Nature is replete with fascinating examples of hierarchical assembly, such as proteins or DNA, and natural photonic structures as seen in butterfly wings or fish. Although synthetic materials that afford the same level of accuracy and complexity as biomolecules are currently beyond reach, research into the self-organization of artificial units has increased dramatically. Organic molecules and copolymers are among the most commonly used elementary units to form large-area patterning. More recently, advances in nanomaterial synthesis have provided access to a versatile library of nanoparticle building blocks with tunable composition, morphology and atomic structure that give rise to physiochemical properties unattainable in naturally occurring materials.
In this study, highly aligned structures are obtained from an organic–inorganic mesophase composed of 1.5 nm monodisperse Cd37S18 magic-size cluster building blocks. Impressively, structural alignment spans over seven orders of magnitude in length scale: nanoscale magic-size clusters arrange into a hexagonal geometry organized inside micrometer-sized filaments; self-assembly of these filaments leads to fibers that then organize into uniform arrays of centimeter-scale bands with well-defined surface periodicity. Enhanced patterning can be achieved by controlling processing conditions, resulting in bullseye and ‘zigzag’ stacking patterns with periodicity in two directions. The multiscale arrangement of MSC building blocks in filaments and striped films presents intriguing analogies to hierarchical assemblies in biological systems as well as the pervasive hierarchical structural organization throughout the natural world. Additionally, our thin films show strong circular dichroism response and reversible, chemically induced isomerization which triggers more intriguing scientific questions on the properties. Overall, our work demonstrates the ability of semiconductor nanomaterials to assemble into complex macroscopic structures, which provides a potential platform to realize advanced function.

2:15 PM SB05.02.05
Emergent Elastic Fields Induced by Topological Phase Transitions in a Chiral Molecular Crystal Kyohei Takae[1] and Takeshi Kawasaki[2]; [1]University of Tokyo, Japan; [2]Nagoya University, Japan

Topological phase transitions into skyrmion and half-skyrmion phases are widely observed in condensed matter, such as chiral magnets and liquid crystals. They are utilized to design magnetoelectric, optical, and mechanoresponsive materials by controlling such topological phases. However, the role of the elastic field in nonuniform topological phases is elusive. To elucidate this problem, we construct a model describing chiral molecules and colloids in quasi-two-dimensional molecular crystals, which incorporates intermolecular chiral twisting and spheroidal steric interactions. We reveal that emergence of the elastic fields from the competition between steric anisotropy and intermolecular twisting is a key to control uniform, helical, and half-skyrmion structures. By utilizing the coupling between the spheroidal orientations and the elastic fields, these topological phases are switched by temperature, external electromagnetic fields, and anisotropic stresses, where a re-entrant phase transition between the helical and the half-skyrmion phases is discovered. Our results imply that controlling the emergent elastic fields is crucial for obtaining a fundamental physical principle for controlling topological phases using chiral molecular and colloidal crystals.

Investigating Atomic-Scale Mechanisms of Crystallization Using Machine Learning Rodrigo Freitas; Massachusetts Institute of Technology, United States

Solid-liquid interfaces have notoriously haphazard atomic environments. While essentially amorphous, the liquid has short-range order and heterogeneous dynamics. The crystal, albeit ordered, contains a variety of defects ranging from adatoms to dislocation-created spiral steps. All these elements are of paramount importance in the crystal growth process, which makes the crystallization kinetics challenging to describe concisely in a single framework. In this talk I will present data-driven approaches to systematically detect, encode, and classify atomic-scale mechanisms of crystallization. It will also be shown how this approach naturally leads to a predictive kinetic model of crystallization that takes into account the entire zoo of microstructural elements present at solid-liquid interfaces. The result is an approach that blends prevailing scientific methods with data-science tools to produce physically-consistent models and novel conceptual knowledge

4:00 PM *SB05.03.02
Metallization of Colloid Crystals Monica Olvera de la Cruz, Yange Lin and Dingwen Qian; Northwestern University, United States

Numerous colloidal crystals have been designed and devised following via functionalization of nanoparticles. Size-asymmetric nanoparticle crystals are often stabilized by ionic-type bonding, where the smaller in size and/or charge component sits at fixed points within the lattice of the large nanoparticles. Here, we study the transition from ionic to metallic bonding, by which the lattice of the smaller component melts, yet the crystal of the large particles is preserved, as in metallic bonding. We discuss the physical properties of the system, including charge transport under an external field. Under a high external field, we find a transient state where the small particles condense into clusters. The resulting patterns are stabilized modifying the physical interactions.

4:30 PM SB05.03.03
Establishing Design Rules through Coarse-Grained Simulations of Metal–Organic Framework Synthesis Reum Scott, Julia Dshemuchadse and Phillip Milner; Cornell University, United States

The capabilities of coarse-grained simulations are applied to the modelling of two-dimensional Metal–Organic Framework (MOF) synthesis. The isoreticular chemistry of crystalline MOFs allows for modular and scalable reagents in synthesis, and furthermore, the simple nature of the synthesis allows for translation to coarse-grained simulations. The HOOMD-blue toolkit is used to construct the MOFs building blocks (metal nodes and organic linkers) from isotropic beads, retaining the basic symmetries of the molecular components. Lennard–Jones and Weeks–Chandler–Andersen pair potentials are used to model attractive and repulsive particle interactions, respectively. We analyze the crystallinity of the self-assembled products and explore the role of modulators—molecules that compete with the organic linkers in binding to the metal nodes to moderate the crystallization reaction—to explore the self-assembly mechanisms in defect-engineered MOFs.

4:45 PM SB05.03.04
Demystifying Complex Crystal Growth by Classifying Order in Local Environments Maya Martirossyan[1], Matthew Spellings[2], Hillary Pan[1] and Julia Dshemuchadse[1]; [1]Cornell University, United States; [2]Vector Institute of Artificial Intelligence, Canada

Understanding how order emerges via crystallization is necessary for controlling the growth of meso- and nanoscale materials or targeting desired material properties. While crystal growth is well understood for simple, close-packed structures, theoretical descriptions break down when applied to structures of higher complexity, where identical particles can occupy different local coordination environments. Developing generalizable rules of how crystal growth proceeds for complex structures requires a sophisticated description of particle environments to understand their evolution throughout the self-assembly process. We use a high-dimensional order parameter that represents local environments with spherical harmonics and utilizes unsupervised machine learning to classify particle environments not only into solid, liquid, and gas, but also into different Wyckoff positions in the same crystal structure, outperforming nearest neighbor analysis approaches. Applying this order parameter to molecular dynamics simulations of self-assembled complex structures allows us to track the emergence of crystalline order from the melt and to observe how identical particles choose their distinct “roles” in a structure as the crystal grows.

8:30 AM *SB05.04.01
Advanced Electron Tomography for Colloidal Self-Assemblies Sara Bals, Ajinkya Anil Kadu, Daniel Arenas Esteban, Adrián Pedrazo Tardajos, Safiyye Kavak, Nathalie Claes, Thomas Altantzis and Da Wang; University of Antwerp, Belgium

The controlled organization of nanoparticles (NPs) into assemblies has gained increasing scientific interest. By modifying e.g. the size and shape of the individual NPs, the inter-particle distances or the chemical composition of the building blocks, assemblies with various shapes and functionalities have been obtained. Since the properties of these nanostructures are inseparably connected to their three-dimensional (3D) structure and shape, a thorough structural and morphological characterization is of great importance.

Transmission Electron Microscopy (TEM) is an ideal technique to investigate materials at the nanometer level or even at the atomic scale. The technique has therefore been widely used in the study of nano-assemblies. However, TEM images only correspond to a two-dimensional (2D) projection of a 3D object. Therefore, electron tomography, a technique that derives a 3D reconstruction from a tilt series of 2D projection images, has become a standard technique to characterize nano-assemblies in 3D. When assemblies of metallic nanoparticles are investigated, acquisition of electron tomography series is usually performed in High Angle Annular Dark-Field Scanning TEM (HAADF-STEM) mode. In this manner, diffraction contrast present in Bright-Field TEM (BF-TEM) images is minimized, and the projection requirement for tomography is fulfilled. For relatively small (consisting of 100 particles or less) or loose assemblies, in which the distance between the composing building blocks is rather large, conventional electron tomography techniques enable one to determine the morphology and the inner structure of the assemblies. Moreover, a manual segmentation allows one to determine, e.g. the 3D stacking of the nanoparticles in a quantitative manner. On the other hand, when the size and density (atomic number Z) of the investigated assembly increases, several challenges appear that hamper a reliable interpretation of the structure.

In this contribution, we will discuss how acquisition, reconstruction and segmentation during an electron tomography experiment can be optimised to enable a quantitative analysis of the structure under investigation [1-4]. Another challenge is related to the investigation of assemblies of nanoparticles under realistic conditions. We will therefore discuss how to combine a 3D characterization of nanoparticle assemblies with in situ and cryo TEM studies [5,6].

Packing Frustration and the Hidden Geometry of Bicontinuous Network Phases of Block Copolymers Michael S. Dimitriyev, Abhiram Reddy and Gregory Grason; University of Massachusetts Amherst, United States

Block copolymers can self-assemble into a variety of ordered nanostructures, including the triply-periodic, bicontinuous double-gyroid (DG), double-diamond (DD), and double-primitive (DP) network phases. These phases consist of complex, intercatenated, labyrinthine domains, yet are supramolecular soft crystals with long-range order. Despite a history of experimental observations, as well as theoretical and computational studies, the formation and stability of these phases remains poorly understood and reliant on the vague notion of packing frustration. Here, we paint a picture of packing frustration -- an interplay between the thermodynamics governing interface geometry and chain stretching that is required by packing constraints of the polymer melt -- by turning to the strong segregation theory of block copolymers. The thermodynamic costs of satisfying this packing constraint is closely connected to the geometry of the terminal boundaries of each domain, i.e. the set of points defining the extent of chain stretching from the intermaterial dividing surfaces. We show that these terminal boundaries are well-approximated by a suitable set of medial surfaces, and that such medial geometry is essential to the stability of the network phases, resolving a long-standing puzzle of the stability of network phases in the strong segregation theory. Furthermore, we uncover new heuristics for polymer architectures that promote stability of the DG phase and explore how the medial geometry of the DG phase makes it more optimal than the competitor DD and DP phases. Finally, we introduce a map of packing frustration "hot spots" in each phase and illustrate how targeted infill of these hot spots can stabilize the DD and DP phases over the DG phase.

9:30 AM SB05.04.03
Controlling the Assembly of Anisotropic Particles *via* the Geometry of a Confining Interface Rachael S. Skye[1], Erin Teich[2] and Julia Dshemuchadse[1]; [1]Cornell University, United States; [2]Wellesley College, United States

Understanding the controlling factors for structure formation in colloids is highly complex and currently the subject of intense scientific study. As we learn to synthesize a diverse array of individual particles, with varying shapes and sizes, we also aim to understand how to assemble those particles into useful structures. This study uses computational methods to examine the assembly of a class of tetrahedrally shaped particles, with assembly controlled *via* confinement inside of a spherical container. These particles exhibit a variety of assembled structures depending on their vertex truncation; however, their assembly behavior in confinement has not previously been explored. We show how small spherical containers force assembly into concentric shells, whose high curvature favors a vertex-to-vertex motif. In larger containers, the particles' behavior changes to conform to a locally flat wall. This effect favors a vertex-to-midpoint motif, causing shapes near the phase boundary to modify their assembled local structure in order to better pack against this lower-curvature wall. We show how the geometry of the confining wall interacts with particle shape anisotropy to change the resultant structure, and we propose using these walls as a medium for enhancing the crystallinity of colloidal crystals. Further, we show how wall geometry can cause texture, biasing the structure to orient along certain crystal axes relative to the wall, thus allowing for reproducible and controllable growth. Through understanding the interactions of confinement geometry and crystal structure, we demonstrate a method for understanding and controlling the assembly of anisotropic particles.

9:45 AM SB05.04.04
Reconfigurable and Mesostructured Liquid-Shelled Capsules Zhang Wu[1], Joerg G. Werner[2] and David A. Weitz[1]; [1]Harvard University, United States; [2]Boston University, United States

Mesostructured microcapsules with a core-shell structure are good candidates for housing, protecting, delivering, and capturing biocargo. Mesostructured soft-matter shells made from benign materials such as polymers confine the encapsulant within a compatible environment as well as control its mass transport and exchange with the external environment. Synchronous communication of the encapsulants with the changeable external environment requires smart response of the capsule shells for desired molecular exchange. Reversibly stimuli-triggered responsive capsules could regulate the molecular diffusion across the shell by altering its molecular affinity and permeability. However, large property changes upon stimuli and the reversibility of the trigger-response of such dynamic capsules remain a challenge due to limitation of promising soft materials and their fabrication as mesoscaled architectures. Here we introduce reconfigurable and mesostructured liquid-shelled capsules with reversible stimuli-triggered changes of the shell phase composition and structure. Liquids in contrast to polymers offer fast dynamics and in combination with colloidal assemblies and large solid-liquid interfaces can undergo reversible changes of key property metrics without material degradation or fatigue. To this end, we employ microfluidics to template colloidosome microcapsules by introducing surface-functionalized particles in the shell of water-oil-water double emulsions. Upon self-assembly and crosslinking of the colloidal particles, we achieve a porous nearly close-packed particle framework in the liquid double emulsion shell. For colloidosome capsules with reversible stimuli-triggered property change, double emulsions with shell liquids composed of a dual oil system with temperature-dependent miscibility are fabricated. Upon temperature change, the shell undergoes liquid-liquid phase separation, therefore causing the reconfiguration of the double emulsion shell to a two-phase shell, a path towards controlled wetting-dewetting transitions of the porous colloidal shell framework to enable, for example, active closing and opening of the capsules to molecular and particle diffusion.

Shape and Interaction Decoupling for Colloidal Preassembly Lucia Baldauf[1], Erin G. Teich[2], Peter Schall[3], Greg van Anders[4] and Laura Rossi[1]; [1]Delft University of Technology, Netherlands; [2]Wellesley College, United States; [3]University of Amsterdam, Netherlands; [4]Queen’s University, Canada

Creating materials with structure that is independently controllable at a range of scales requires breaking naturally occurring hierarchies. Breaking these hierarchies can be achieved via the decoupling of building block attributes from structure during assembly. Here, we demonstrate, through computer

simulations and experiments, that shape and interaction decoupling occur in colloidal cuboids suspended in evaporating emulsion droplets. The resulting colloidal clusters serve as "preassembled" mesoscale building blocks for larger-scale structures. We show that clusters of up to nine particles form mesoscale building blocks with geometries that are independent of the particles' degree of faceting and dipolar magnetic interactions. To highlight the potential of these superball clusters for hierarchical assembly, we demonstrate, using computer simulations, that clusters of six to nine particles can assemble into higher-order structures that differ from bulk self-assembly of individual particles. Our results suggest that preassembled building blocks present a viable route to hierarchical materials design.

10:45 AM SB05.05.02
Revealing the Emergence and Dynamics of Nanoparticle Moiré Patterns at the Nanoscale Chang Liu, Lehan Yao, John Crockett, Chang Qian and Qian Chen; University of Illinois at Urbana-Champaign, United States

Moiré patterns from misaligned periodic structures can bring merit to not only artistic designs but to material properties, a salient example being magic angle graphene where superconducting phase can be observed. Here, with liquid-phase transmission electron microscope (TEM), we construct nanoparticle superlattices and obtain for the first time Moiré patterns at the nanoscale in real time and real space, where we investigate laws of order emergence and evolution from a dispersion of nanosized entities. To be specific, layers of hexagonal lattices are assembled from individual gold nanoparticles. Distinct from 2D materials where the interlayer and intralayer interactions are with limited control, we control the nanoparticle shape to manipulate the interlayer and intralayer interactions, which leads to different Moiré patterns. We apply neural network-based machine learning to investigate the structures and single particle dynamics with high spatiotemporal resolution, which further helps to reveal the interplay between the Moiré pattern and the grain boundary evolution. Furthermore, calculations based on pairwise interaction potential show distinct local position adjustment in different Moiré patterns both in plane and out of plan, resulting in normal, reduced order and disordered Moiré patterns. This work provides better understandings on nanoscale interactions, which can serve as a guideline for bottom-up material design and helps to study related optical properties.

11:00 AM SB05.05.03
Chiral Self-Assembly of Cellulose Nanocrystals—The Role of Composite Morphology Thomas G. Parton, Richard M. Parker, Gea T. van de Kerkhof, Aurimas Narkevicius, Johannes S. Haataja, Bruno Frka-Petesic and Silvia Vignolini; Department of Chemistry, University of Cambridge, United Kingdom

Naturally-sourced cellulose nanocrystals (CNCs) are elongated nanoparticles that spontaneously form a left-handed cholesteric liquid crystal phase in aqueous suspension. This self-assembly process has been shown to be a promising way to create structurally colored films from sustainable materials (*Adv. Mater.* (2018) 30, 1704477), but the underlying mechanism by which chiral ordering emerges has remained unclear. Although the morphology of individual CNCs is believed to play an important role, most particles are not significantly twisted, and suspensions exhibit considerable polydispersity in both particle size and shape.

Here we will present an in-depth morphological analysis of sub-populations of individual CNCs, as imaged by transmission electron microscopy (TEM) and atomic force microscopy (AFM). We gradually tuned the size and shape of the CNCs using ultrasonication and correlated the morphology of individual particles with their ensemble behavior in suspension and in photonic films. This analysis revealed that CNC "bundles" (i.e. clusters of laterally-bound elementary crystallites) are essential for the formation of a cholesteric phase. These bundles act as chiral dopants, analogous to those used for molecular liquid crystals, and therefore explain how chirality is transferred across length-scales from the morphology of individual CNCs to the photonic nanostructure (*Nat. Commun.* (2022) 13, 2657).

11:15 AM SB05.05.04
Preparation of Pseudo-Single Grain Double Gyroid Thin Films for Advanced Optical Applications Jinwoo Oh, Mahesh Mahanthappa and Christopher Ellison; University of Minnesota Twin Cities, United States

Materials with three-dimensional network structures (*Nets*) on sub-micron length scales are of great interest for their optical properties. The vivid colors of insect wing scales and bird feathers arise from naturally occurring *Nets* with spatial periodicities ranging 400 – 700 nm, which interact with visible light as photonic crystals. On the other hand, *Nets* with sub-wavelength scale periodicities (< 400 nm) have potential applications as optical metamaterials with exciting properties such as negative refraction and strong circular dichroisms. While *Nets* may be fabricated by top-down methods such as two-photon lithography, such methods are limited by their achievable lengthscales and the challenges associated with fabrication throughput. Bottom-up self-assembly of block copolymers provides a possible alternative for addressing these limitations. For example, Vignolini *et al.* prepared a gold single gyroid nanomaterial using a template based on ABC triblock terpolymer self-assembly and demonstrated its strong, orientation-dependent dichroic responses. Although these results suggest the promise of bottom-up self-assembly as means of accessing *Nets*, a significant challenge facing these approaches is the lack of control over *Net* grain sizes and their orientations relative to a substrate that are important in their optical applications.
The self-assembly of block copolymers can be directed using chemical patterns or external fields, but few studies have applied these methods to block copolymers that form double gyroid (DG) *Nets*. Of these few examples, many rely on solvent annealing of block copolymer thin films sometimes in the presence of chemically or topographically patterned surfaces. In this study, we report a solvent-free, thermal processing method for producing pseudo-single grain DG thin films on silicon wafers bearing native oxide layers. Through top-down and cross-section scanning electron microscopy (SEM), we identify the well-defined orientation of the DG mesostructure with respect to the underlying substrate. These findings are corroborated using grazing-incidence small-angle X-ray scattering (GISAXS), and we use azimuthal angle-dependent GISAXS to investigate the degree of microstructural orientation. Thus, this thermal processing approach enables efficient unidirectional alignment of mesoscopic DG structures over large areas for future optical materials applications.

11:30 AM SB05.05.06
Hierarchical Self-Assembly of Bowtie Shaped Nanostructured Microparticles with Tunable Chiroptical Activity Prashant Kumar[1], Thi Vo[1], Minjeong Cha[1], Wenqian Xu[2], Anastasia Visheratina[1], Ji-Young Kim[1], Wonjin Choi[1], Sharon Glotzer[1] and Nicholas A. Kotov[1]; [1]University of Michigan–Ann Arbor, United States; [2]Argonne National Laboratory, United States

Mathematical descriptors of mirror asymmetry are continuous, but chirality in chemical disciplines is often viewed as a binary characteristic of molecules and there was no known chemical structure with widely variable chirality measures. Here we show that sub-microscale nanostructured particles can be self-assembled from anisotropic building blocks with widely variable geometry, chirality measures and optical asymmetry while retaining consistent bowtie shapes. The self-limited self-organization of anisotropic building blocks [1] makes possible high synthetic reproducibility and computational predictability of their geometries for different concentrations of reagents, ionic components, enantiomeric compositions, media polarity and other parameters. The positive and negative chiroptical peaks observed from UV to IR parts of the spectrum originate from absorptive and scattering phenomena with contribution from both dipolar and quadrupolar modes characteristic of nanostructured particles with submicron scale chirality.[2] The dependence of geometrical chirality measures and chiroptical characteristics enable the predictive synthesis of bowties with desirable polarization rotation. Controllable pitch, length, width, and thickness leads to tunable chiroptical activity across from UV to IR, which can be used to print chiroptical metasurfaces for

photonic markers for machine vision devices.

SESSION SB05.06: Data-Driven Materials Design
Session Chairs: Carl Goodrich and W. Benjamin Rogers
Tuesday Afternoon, November 29, 2022
Hynes, Level 1, Room 110

1:30 PM *SB05.06.01
Inverse Design for Learning in Soft Matter Systems Andrea Liu[1], Jason Rocks[2], Menachem Stern[1], Daniel Hexner[3], Douglas Durian[1], Eleni Katifori[1] and Sidney Nagel[4]; [1]Univ of Pennsylvania, United States; [2]Boston University, United States; [3]Technion–Israel Institute of Technology, Israel; [4]The University of Chicago, United States

Training an artificial neural network requires solving an inverse problem, so it is natural to apply concepts underlying machine learning to solve inverse design problems in soft matter systems. I will describe how global minimization of a loss function can be used to teach physical networks how to perform functions inspired by biology, such as the ability of proteins (e.g. hemoglobin) to change their conformations upon binding of an atom (oxygen) or molecule, or the ability of the brain's vascular network to send enhanced blood flow and oxygen to specific areas of the brain associated with a given task. Statistical physics teaches us that the ability to design ensembles of networks with the same function is crucial in order to understand the microscopic origins of collective phenomena. I will show how we apply persistent homology to such networks to learn how and what they learned. Finally, I will describe local learning methods that allow us to develop physical systems that can learn on their own, without requiring a processor or memory.

2:00 PM SB05.06.02
Targeted Discovery of Low-Coordinated Crystal Structures Using Highly Tunable Particle Interactions Hillary Pan and Julia Dshemuchadse; Cornell University, United States

Self-assembled soft-matter crystal structures have the potential to exhibit structural variety that vastly exceeds that of atomic-scale structures, mainly due to their highly tunable particle interactions. In simulation, particles interacting *via* simple, isotropic pair potentials have been shown to self-assemble into a wide range of crystal structures, yet how the shape of the interaction potential influences the resulting structure is still poorly understood. To search for new crystal structures, we have developed a new functional form for the interaction potential in which all energy wells and maxima can be tuned independently. Through targeted searches in a high-dimensional parameter space, we discover 20 new crystal structures, 14 of which are low-coordinated with average coordination environments ranging from 2 to 7 nearest neighbors. We will present specific characteristics of these structures, as well as general trends of the investigated systems. Our findings highlight the structural diversity of soft condensed matter that can potentially be used to design new soft materials with functional properties.

2:15 PM SB05.06.03
Towards the Data-Driven Design and Development of Materials Derived from Unstable Mixtures Matthew Jones and Nigel Clarke; University of Sheffield, United Kingdom

The field of polymer blending, which aims to combine the properties of polymers to create specialised materials, has the potential to play an important role in helping to tackle some of the major challenges that society faces in the 21st century. However, to realise this in a sustainable and time-effective manner, we must advance our knowledge of structure-property relationships and find ways to leverage these relationships in the design and development process of new materials. One obstacle to developing structure-property relationships is the challenge of characterising complex phase-separated microstructures using accessible experimental data. To overcome this, we recently proposed a method for succinctly describing such microstructures in terms of well-defined and quantifiable characteristics from scattering data using machine learning [1], namely Gaussian process regression. Our findings, which we obtained using numerical simulation data, suggest there is an opportunity for a more complete characterisation of experimental phase-separated microstructures using scattering data. Scattering is a powerful technique for monitoring phase separation in real-time. As such, the careful application of our method to future predictions of the scattering data could allow one to predict the future characteristics of the microstructure as it evolves. In the absence of a satisfactory nonlinear theory describing the time evolution of the scattering data during phase separation, we have demonstrated the ability of dynamic mode decomposition, a data-driven modelling method, to make accurate future predictions of numerical scattering data. We aim to combine these two works to develop a control system to manipulate phase separation to produce new materials with prescribed microstructures and, therefore, properties. We also aim to expand the scope of our work to systems other than polymer blends, for example, metallic alloys and ceramics.

Machine Learning Augmented Computational Reverse-Engineering Analysis for Scattering Experiments of Assembled Mixtures of Nanoparticles Christian Heil[1], Anvay A. Patil[2], Ali Dhinojwala[2] and Arthi Jayaraman[1]; [1]University of Delaware, United States; [2]The University of Akron, United States

In the field of materials science and engineering, structural characterization is a critical step needed to link the materials' structure to its macroscopic properties. Small angle scattering (SAS) is a useful technique to characterize structure at multiple length scales. The output of SAS experiments is the averaged scattering intensity at various wave vectors, $I(q)$ vs. q, whose interpretation often relies on fitting with analytical models. The selection of analytical models can be a limitation for analyzing the scattering profile if and when appropriate analytical models exist for the material's structure of interest. In this talk, we will present a computational method we have developed called Computational Reverse Engineering Analysis of Scattering Experiments (CREASE) and show its application for analysis of spherical nanoparticle mixtures' assembled structure. We test the strengths and limitations of CREASE by using a variety of *in silico* $I(q)$ obtained from simulations of binary nanoparticle assemblies and nanoparticle solutions with varying mixture composition/concentration, nanoparticle size distribution, and degree of mixing/aggregation. We will also highlight the machine learning (ML) model used in CREASE that links features of the nanoparticle solutions (e.g., concentration, nanoparticles' tendency to aggregate) to computed scattering

profile; this ML model is applicable to different nanoparticle sizes without the need for additional data to retrain the model to be specific to the size of interest. Finally, we show how the nanoparticle structure reconstructed from scattering using CREASE can serve as input to optical modeling and achieve a computed reflectance spectrum that matches ones from the experimental systems.

2:45 PM SB05.06.05
Mesostructure Formation and Phase Transition of Imidazolium-Based Ionic Liquid Systems for Training Deep Neural Network Algorithm
Kyungtae Kim, Jacob LaNasa, Darrick Williams and Benjamin Nebgen; Los Alamos National Laboratory, United States

Quantitative small-angle and wide-angle X-ray scattering data of ionic liquid/water mixture systems were obtained and analyzed as training data sets for developing deep neural network (DNN) based computation architecture that can predict non-equilibrium, dynamical phenomena such as chemical reactions, self-assembly, and ionization. Quantum mechanics (QM) describes the physical laws that govern such processes, but the computational effort required to solve the equations given by QM makes predictive simulations of realistic systems practically impossible. Specialized DNN-based architectures have recently proved to be an accurate, general, and computationally efficient alternative to QM calculations for obtaining interatomic forces. While these DNN models have application potential in a wide range of chemical and materials discovery areas, they lack the ability to describe non-equilibrium processes such as the long-range transfer of electron charge and finite electron temperature effects. The research of probing mesoscale structures of ionic liquid/water mixtures provides quantitative information on mesoscale structures as well as cation-anion interactions to the DNN machine learning algorithm and serves as critical learning set to develop an efficient and accurate computational algorithm that can predict materials properties from molecular structure.
Ionic liquids are known to form various hierarchical, mesoscale ordered structures when mixed with water, similar to the phase behavior of lyotropic liquid crystals. The hierarchical self-assembly of soft materials including the ionic liquid systems is a complex phenomenon often not easily predictable by computation. Thus, the system of ionic liquid/water mixtures is an excellent platform to produce large data set to train the DNN algorithm. In addition, the ionic liquids are easy to synthesize yet they exhibit diverse possible ordered structures, which further justifies the use of the system in this study. Model systems of ionic liquids, consisting of a cation having linear hydrocarbon tail and simple anions such as thiocyanate or nitrate, were mixed with varying amounts of water to form microphase-separated, mesoscale ordered structures and subsequently measured by X-ray scattering. The obtained data were quantitatively analyzed by crystallographic methods and radial distribution function calculations.

Programming Self-Limited Assembly of Helical Tubules Using DNA Origami W. Benjamin Rogers, Daichi Hayakawa and Thomas E. Videbaek; Brandeis University, United States

Inspired by Nature’s ability to make complex structures, self-assembly has emerged as a powerful technique for synthesizing nanoscale materials. While living systems are brimming with examples of functional nanomaterials that have one or more self-limited dimensions, such as virus capsids, cytoskeletal filaments, or complex molecular machines, most examples of synthetic self-assembly tend to produce periodic lattice structures with macroscopically uncontrolled dimensions. In this talk, I will explore the trade-offs between addressable assembly and self-closing assembly as routes to self-limitation using a specific class of self-limiting structure: helical tubules. We make triangular subunits using DNA origami that have specific, valence-limited interactions and designed binding angles, and study their assembly into tubules that have a self-limited width that is much larger than the size of an individual subunit. In the simplest case, the tubules are assembled from a single component by programming the dihedral angles between neighboring subunits. We show that the tubules can reach many micrometers in length and that their average width can be prescribed through the dihedral angles. However, we find that the same set of triangular subunits produces an ensemble of tubules with different widths and chirality---a fundamental limitation of using geometrical specificity alone to program self-limitation. The observed distribution is captured by a simple theoretical model that considers only the elastic bending energy of a curved sheet and the irreversibility of tubule closure. Finally, we demonstrate that the distributions of tubules can be further sculpted by increasing the number of subunit species, thereby increasing the assembly complexity. Rather than using a single type of triangular subunit, we use two species of triangles with distinct sets of specific interactions and show that even this simple binary mixture can eliminate half of the total number of off-target structures. Taken together, our findings highlight the complementary roles that programmed curvature and assembly complexity can play in self-limited assembly, which can be further generalized to the assembly of other complex, self-limited 3D geometries, such as helicoids, toroids, and crystalline frameworks.

4:00 PM *SB05.07.03
Assembling Biological Function Without Biology Carl Goodrich; Institute of Science and Technology Austria, Austria

Biology has discovered how to make exceedingly complex nano-machines — protein structures that consume energy to perform numerous functions, ranging from cargo transport to DNA replication. These machines are far more sophisticated than anything we can produce synthetically at this scale, limiting our ability to create new biological-like materials. Crucially, we lack a sufficient understanding of how such function can arise using simple synthetic building blocks. The past few decades have seen tremendous progress in synthesizing a variety of simple building blocks (e.g. DNA-coated colloids, de novo proteins, etc.) with controllable and specific interactions, and we are beginning to understand how to self-assemble complex structures out of them. However, biological nano-machines are more than just structure — they have kinetic and functional properties that cannot be inferred from their shape. I will show how differentiable programming enables us to design self-assembled nano-machines out of DNA-coated colloids. These machines have precisely controlled kinetics and can consume energy, drive themselves out of equilibrium without external input, and perform tasks. Finally, the simplicity of DNA-coated colloids as a model system enables us to learn general principles about functional self-assembly in non-biological settings.

4:30 PM SB05.07.04
Comprehensive View of Microscopic Interactions Between DNA-Coated Colloids for Colloidal Self-Assembly Fan Cui, Sophie Marbach, Jeana Zheng, Miranda Holmes-Cerfon and David Pine; New York University, United States

The self-assembly of colloidal particles into highly-ordered structures offers great promise for advanced optical materials. DNA has emerged as a most versatile tool to drive targeted structure formation due to its programmability, which enables specific attractive binding with controllable interaction strength and length scale. However, control of disorder, defects, melting, and crystal growth is hindered by the lack of a microscopic understanding of DNA-mediated colloidal interactions. Here we use total internal reflection microscopy to measure *in situ* the interaction potential between DNA-coated colloids with nanometer resolution and the macroscopic melting behavior. [1] The range and strength of the interaction are measured and linked to key material design parameters, including DNA sequence, polymer length, grafting density, and complementary fraction. We present a first-principles model that quantitatively reproduces our experimental data over a wide range of DNA ligand designs. Our theory identifies a subtle competition between DNA binding and steric repulsion and accurately predicts adhesion and melting at a molecular level. Combining experimental and theoretical results, our work provides a quantitative and predictive approach for guiding material design with DNA-nanotechnology and can be further extended to a diversity of colloidal and biological systems.

Novel Structures Found in Nanocrystal Self-Assemblies and the Thorough Characterization of the Superstructures and the Orientation of the Crystal Domains Yasutaka Nagaoka and Ou Chen; Brown University, United States

My poster presentation discusses novel structures found in nanocrystal self-assemblies and nanocrystal-based structured materials, as well as new synchrotron-based techniques to enable comprehensive structural characterization. The term "structural materials" refers to solid materials whose internal structures have been optimized to perform certain functions such as high mechanical properties, green and efficient catalysis, and optical properties for metamaterials and batteries. In the past few years, there has been a great deal of research dedicated to exploring further structures at the atomic and mesoscales of materials, and thanks to the efforts of scientists to enable large scale synthesis of nanocrystals with a variety of shapes, methods of processing, and the introduction of novel characterization techniques, the use of nanocrystals has gained a great deal of interest because of the expectation that nanostructured materials can address these functionality.
My poster presentation shows structures both at the atomic level and at the mesoscale, including amorphous, quasicrystals, and crystals, along with the characterization methods. We present a series of our works related to novel nanocrystal synthesis, self-assembly of superlattices, and a new method of creating bulk materials (high-pressure nanocrystal coining), which produces a variety of materials that could not otherwise be obtained. States like amorphous and quasicrystals, for instance, aren't often the most thermodynamically stable states, so they're not commonly observed in conventional structured materials. We demonstrated that Pd metal nanocrystals with appropriate surface states can contain ~98% amorphous states within their atomic arrangements, which could not be achieved by conventional methods. By compacting these nanocrystals into a solid, we have created the first amorphous pure metal possessing a centimeter-scale size. Another example is silver nanocrystals that form superstructures very sensitively based on the nanocrystals' morphologies. The polymorph of nanocrystal superlattices we present here contains structures that differ from predicted structures by simulation, proving nanocrystal self-assemblies as a very powerful methodology for creating novel structured materials. Furthermore, we present our characterization strategy to assess the structures thoroughly with respect to both the position of nanocrystals and the orientation of crystal domains. Combining rotational XRD measurements with TEM measurements, we constructed 3D structures in the superstructures and in the orientation of the crystal domains.

SB05.08.02
Simulating Pressure-Driven Solid–Solid Phase Transformations Across Crystal Structure Types Hongjin Du, Hillary Pan and Julia Dshemuchadse; Cornell University, United States

Pressure-induced phase transformations have been widely observed in many crystalline materials. Molecular dynamics simulations, in particular, have been used to understand high-pressure phase transitions—a typical example being the graphite-to-diamond transition. Here, we investigate the influence of pressure on the behavior of 16 known crystal structure types that have been shown to self-assemble in molecular dynamics simulations using isotropic, pairwise interaction potentials. We reproduce several experimentally-observed solid–solid phase transitions, and we discover two new crystal structures by running simulations under increasing pressure. A variety of other transformation behaviors as a function of pressure are also observed and analyzed to investigate the connection between different high-pressure behaviors and structural parameters such as coordination number, symmetry, and complexity. The results reveal that many simulated structures tend to approach an average coordination number of 12 at high pressure. Our work expands current knowledge of the relationship between structure and pressure, and it helps pave the way for the exploration of new materials.

SB05.08.03
Up-Conversion of Coherent Light Emission Inside of Polar Nematic Liquid Crystalline Media Daichi Okada, Hiroya Nishikawa and Fumito Araoka; RIKEN Center for Emergent Matter Science, Japan

Polar nematic liquid crystals (PNLCs) are kind of new types of fluid materials co-possessing fluidity and ferroelectricity. Since its discovery in 2017, it has attracted a lot of attention to the potential for novel applications such as flexible optical/optoelectrical devices. One of the most fascinating physical properties of PNLCs is efficient generation of optical second harmonics, which is ~100 times larger than quartz. Additionally, due to its fluidity, we can dope FNLCs with other functional molecules, enabling modification of their physical properties.
By taking such advantages of PNLCs, we herein demonstrate a flexible up-conversion system of coherent light emission. By doping fluorescent molecule into PNLCs and placing that into an optical cavity consisting of two dielectric mirrors with a distance around ~5μm, PNLCs layer can equip two functions for laser oscillation and second harmonic generation (SHG), simultaneously. We investigate their spontaneous SHG conversion process of lasing emission inside the optical cavity. Upon excitation of the doped fluorescent molecules by a pulsed laser light, clear and sharp emission peak with nonlinearity is confirmed beyond a certain excitation threshold. Under the lasing regime, additional emission peaks at the half wavelengths of lasing peaks are also detected, meaning intra-cavity wavelength conversion through the SHG process. The SHG intensity correlates the lasing emission intensity upon the excitation power change. Perhaps with the aid of the increase of the intracavity electric field at the resonance mode, the SHG efficiency of the intracavity conversion process is slightly higher than that of outside cavity without the laser oscillation process. Such a brand-new type of flexible up-conversion

device must be promising for future optical/optoelectric devices.

SB05.08.04
Predictive Design of Orientational Order in Confined Active Nematic Materials Hiroki Miyazako, Kohei Tsuchiyama and Takaaki Nara; University of Tokyo, Japan

Elongated biological materials can be modeled as nematic liquid crystals which can actively move by energy consumption, known as “active nematics [1].” Recent studies have shown that such active nematic behaviors are observed in many biological systems, such as cytoskeleton-motor protein compounds and cell monolayers. In active nematic materials, the orientational order and the active behaviors are affected by topological defects, at which the orientation angle cannot be defined. Therefore, many studies have demonstrated spatial control of defect positions and movement by topographic guides or confinement to achieve the reproducible generation of targeted orientational patterns or defect movement. However, the geometrical effects of the guides or confinement have not been fully understood. For precise control of the orientational order, it is necessary to establish calculation methods to predict defect positions in various geometries.

To this end, this study aims to establish a calculation method for predicting and designing defect positions of confined active nematic materials. In our previous study [2], we derived an explicit formula of orientational angles and Frank elastic energy of nematic materials confined in a two-dimensional space. The formula was expressed by complex potentials defined on a unit disk and a conformal mapping from the unit disk to a simply-connected domain. Thus, the derived formula can be applied to any simply-connected domain, which is an advantage of the derived formula. However, our previous study cannot predict stochastic fluctuations of defect positions caused by random movement of the active nematic materials.

To quantify the stochasticity of the defect positions, we propose a numerical method to calculate equilibrium distributions of defects. By using the explicit formula of the Frank elastic energy described as a function of defect positions, the equilibrium distributions can be efficiently calculated based on Markov chain Monte Carlo methods. The computed distributions quantify spatial localization and stochastic fluctuations of defect positions in a confined space. Since the geometry of the confinement is expressed as a complex function in our approach, we can easily evaluate geometric effects on the spatial localization of the defects. Therefore, we can predict an optimal geometry for suppressing stochastic fluctuations of defects by tuning the parameters of the geometry.

The proposed method was experimentally verified by culturing mouse myoblast (C2C12) cells, which were used as a model of active nematic materials. The C2C12 cells were cultured on PDMS microgrooves whose geometries were parametrically expressed as $f(z)=z+ az^3$. The cell alignment and the defects were observed by phase-contrast microscopy. The distributions of the defects were localized as the geometry became asymmetric, which were consistent with our proposed calculation method. The fluctuations of the defect positions were also evaluated from the experimental data by maximum likelihood methods. The evaluation suggested the spatial localization of the defects was mainly due to the geometric effects rather than the randomness of the cell migration and alignment. The proposed method will be applied to the high-reproducible and dependable fabrication of nematic orientational order in active nematic materials.

Development of a Mesoscale Framework to Model Degradation of Polyolefins Under Temperature Gradients Vaibhav A. Palkar and Olga Kuksenok; Clemson University, United States

A major focus in the area of recycling plastics has been towards chemically selecting and producing monomers for low ceiling temperature polymers. However, controlled depolymerization of abundantly used polyolefins remains a major challenge. Microwave irradiation can be used to cause such depolymerization by introducing microwave absorbing nano sheets in the bulk of the polymer. Under microwave irradiation, local temperature gradients are introduced in the bulk of the polymer in the vicinity of the nano sheets. In this work, we develop a framework for modeling the thermal degradation of polyolefins under the action of such local temperature gradients. We use the mesoscale energy conserving dissipative particle dynamics (eDPD) approach along with the modified segmental repulsive potential (mSRP) to model linear polymer melts under a thermal gradient. We model bond breaking via a stochastic approach that simulates first order degradation reaction kinetics with a local temperature dependent reaction rate constant. We first simulate the depolymerization under constant temperature conditions and track evolution of dispersity, average molecular weights, and molecular weight distribution in the system. The time evolution of these properties follows previously known analytical trends. Under the action of a temperature gradient, faster depolymerization near the high temperature region results in formation of shorter polymer fragments with higher diffusivity compared to the longer chains in the low temperature region. We analyze the time scale of diffusion of various fragments after the temperature gradient is removed. The framework we propose in this work can be used to model controlled depolymerization of polyolefins under the action of pulsed microwave irradiation.

SB05.08.06
Fabrication of Hierarchically Converging Polymer Nanofibers via Liquid Crystal-Templated Chemical Vapor Polymerization and Their Growth Mechanisms John Kim[1], Sangchul Roh[2], Soumyamouli Pal[2], Nicholas L. Abbott[2] and Joerg Lahann[1]; [1]University of Michigan, United States; [2]Cornell University, United States

Hierarchical structures found in biological systems play essential roles (e.g., strong adhesion of gecko lizard, nutrition absorption of tree roots, and effective mass transport between neurons). Many attempts to artificially replicate these hierarchical structures were made by inducing stochastic turbulent flow to form dendritic polymer particles, chemically treating the aramid or cellulose fibers. Although these top-down hierarchies were successfully demonstrated, bottom-up hierarchy of end-attached nanofibers arrays have not yet been presented. Nanofibers with bottom-up hierarchy and long-range order of alignment can inspire us to mimick the properties of hairy structures of villi, lotus leaf, and gecko feet. Unlike the inorganic materials, it is challenging to fabricate structured polymer materials due to the instrinsic amorphous properties of polymer chains. Recently, chemical vapor polymerization (CVP) templated by liquid crystalline (LC) film overcame these challenges and allowed for engineering the polymer nanofibers arrays with controlled diameter, length, and 3-dimensional morphologies. However, nanofibers obtained from LC-templated CVP lacked of hierarchy and their growth mechaisms were not fully understood. Here, we report the method to synthesize bottom-up hierarchical nanofiber arrays by lowering the polymerization temperature and unveil the growth mechanism of the nanofibers. First, we demonstrate that the order of hierarchy can be controlled by varying the synthesis temperature. Second, we control the CVP time to observe intermediate growth phases and elucidate the growth mechanisms. Finally, we qualitatively test the adhesiveness of nanofibers to the substrates by attaching PDMS tape to the fibers and observing where fracture is occurring when taking off the tape.

SB05.08.07

Clathrate-Water Interface Control by 2D Janus Amphiphilic Peptide Nanosheets for Ice Recrystallization Inhibition Ilhyung Choi, Nayeong Jeon and Eunji Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

: Ice-binding proteins (IBPs) in natural, which are known as the important components for preventing organisms from freezing damage, have been of significant interest for freezing point depression. Their ice recrystallization inhibition (IRI) capability has been investigated mainly at local atomic interactions between binding planes of ice crystals and ice-binding moieties. However, IBPs have a specific structure at the macroscale and the flat region on the protein surface binds to ice. We emulated the structural binding of IBPs to ice through the peptide assembly nanostructure. Amphiphilic peptides can be a versatile building block for the fabrication of hierarchical nanostructures based on a couple of non-covalent interactions of amino acids. We designed amphiphilic peptides with aromatic ring, alkyl chain, and negative charge to adjust mutual interaction between peptides. These peptides formed a β-sheet structure to further assemble a two-dimensional (2D) nanosheet with one side hydrophilic and the other side hydrophobic. The ice-binding moieties, coupled to one end of the peptide sequence, were located on the surface of the 2D nanosheet binding with water molecules on the ice crystal surface. The hydrophobic alkyl chains on the other side shielded ice crystal from water molecules which have the potential of becoming ice, thereby inducing IRI. This Janus 2D nanostructure served like a patch which is applied to the surface of the ice crystals, forming a depletion layer of water molecule between the ice crystals. Furthermore, we demonstrated that IRI ability is better when peptides with ice-binding moieties are formed into 2D morphology than into one-dimensional (1D) morphology via subtle modulation of peptide sequence because 2D morphology has a large contact area which can form bonds with water molecules.

Ice-Water Microcurvature Controllable MOF Cryopreservative with Lattice Matching of Hydrogen Bond Interactions Nayeong Jeon[1], In-ho Jeong[2], Eunyeong Cho[3], Jiyeon Lee[1], Ilhyung Choi[1], Eun Hee Han[4], Hee Jung Lee[3], Peter Chang-Whan Lee[2] and Eunji Lee[1]; [1]Gwangju Institute of Science and Technology, Korea (the Republic of); [2]University of Ulsan, Korea (the Republic of); [3]Korea Institute of Materials Science, Korea (the Republic of); [4]Korea Basic Science Institute, Korea (the Republic of)

The potential application of ice-binding proteins (IBPs) produced by some plants, insects, and fishes to survive in subzero environments has been of great interest as material candidates for the cryopreservation of drugs, cells, tissues, and foods. IBP adsorption to the ice surface can depress the water-freezing point and avoid ice-crystal growth, which is closely related to the presence of binding moieties complementary to the ice crystal plane. Inspired by the distinctive properties of IBPs, cryoprotectants adsorb to the ice, and hinder the growth, thus prohibiting the freeze damage to cells or tissue. Meanwhile, metal-organic framework (MOF) nanoparticles (NPs) can be a promising nanoscaffold that adopts the natural characteristics of IBPs, including the regular configuration and location of functional moieties affecting ice nucleation and growth at the molecular scale. Herein, MOF NPs with good biocompatibility were used as a cryoprotectant that is well dispersed and colloidal-stable in an aqueous solution. The interaction between the MOF NPs and the ice crystal planes was facilitated, by matching the distribution of hydroxyl groups that could be hydrogen bond donors or acceptors on the MOF NP crystal plane, and the spacing of hydroxyl groups on different ice crystal planes. The limited ice growth between MOF-801 NPs pinning on the ice surface increased the local curvature of ice, reducing the radius of these convex growth regions and making them thermodynamically unstable. The MOF-801 NP was size-controlled, that small NPs were absorbed on the ice surface, and the concave growth zone of the ice narrowed, consequently increasing the curvature of the ice surface, and further enhancing the ice recrystallization inhibition (IRI) effect. The peptides acting as ice-binding moieties in natural IBPs, were incorporated into the surface of the MOF-801 NPs, further increasing the number of anchored clathrate water molecules and strengthening the IRI effects. The cryopreservation efficacy of these MOF NPs was measured on the nucleated cell line, and the MOF NPs having a high IRI effect due to the small size and introduction of peptides showed a good post-thaw cell recovery rate that can be a potential cryoprotectant. This research provided the favorable applicability of our developed MOF NPs in practical cellular cryopreservation and further, organ transplantation, cord blood storage, and vaccines/drugs.

SB05.08.10
Experimentally Informed Structure Optimization of Amorphous TiO_2 Films Grown by Atomic Layer Deposition Jun Meng[1], Mehrdad Abbasi[2], Yutao Dong[1], Corey Carlos[1], Xudong Wang[1], Jinwoo Hwang[2] and Dane Morgan[1]; [1]University of Wisconsin-Madison, United States; [2]The Ohio State University, United States

Amorphous TiO_2 (a-TiO_2) has been widely studied in recent years since it was reported as an effective coating material for protecting photoanodes from corrosion in Photoelectrochemical (PEC) systems, which is an innovative approach for hydrogen production through solar water-splitting. The stability and longevity of a-TiO_2 is strongly affected by its synthesis method, thickness, structural heterogeneity, etc., which implies that understanding of the structure-property relationship of a-TiO_2 is crucial for improving the performance though targeted materials design.
This study characterized the structural and electronic properties of Atomic Layer Deposition (ALD) grown a-TiO_2 thin films (~17nm) on Si. Fluctuation spectra V(k) and angular correlation functions were determined with 4-dimensional scanning transmission electron microscopy (4D-STEM). The structural properties measured in this study and pair correlation function G(r) from previous literatures were combined with an interatomic potential and used together to determine a realistic atomic model of a-TiO_2. This atomic model was found with the StructOpt code using a genetic algorithm that simultaneously minimizes energy and maximizes match to experimental short- and medium-range order, represented by G(r) and V(k), respectively. Compared with melt-quenched models, the StructOpt a-TiO_2 model presents an improved agreements with the medium-range ordering as represented by V(k) and the k-space location of the dominant 2-fold angular correlations, although some minor higher order angular correlations are seen in the StructOpt structure that are not observed in the experiments. The electronic structure of the StructOpt a-TiO_2 model is studied by ab initio calculation and compared to experimental results on band gaps of crystalline and amorphous phases. This work provides a realistic a-TiO_2 structure model for further investigation of structure-property relationships and materials design and an updated StructOpt optimization package which optimizes against combined experimental and theoretical constraints to determine complex structures.

SB05.08.11
Effect of Plate Inclination on the Liquid Transfer between Nonparallel Plates Hyeokgyun Moon[1], Jinkee Lee[1,2] and Gyoujin Cho[2]; [1]Sungkyunkwan university, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

With increasing demand for printed electronics, roll-to-roll printing has been garnering attention from researchers due to its a cost-effectiveness and good scalability for mass production. In recent years, many researchers have focused on fabricating printed electronics that require high resolution using roll-to-roll printing. Few examples of such electronical devices include thin film transistors, sensors, and electronic circuits. For successful roll-to-roll printing, liquid transfer from pattern roll to target surface is of utmost importance, and the volume of liquid transferred divided by the total volume can be defined as transfer ratio. The desired liquid transfer can be achieved by precisely controlling the parameters that affect it such as physical properties of the liquid, volume, and surface wettability. Studies so far involving roll-to-roll printing have mainly focused on understanding the liquid transfer between two parallel plates by varying the parameters mentioned above. However, the actual roll-to-roll printing uses rolls instead of two parallel plates. In other words, the geometry is different for the two cases which results in change in the dynamics of the liquid transfer and hence the results of existing studies can no longer be applied. Therefore, in this study we replicate geometry closer to actual roll-to-roll printing system by using two nonparallel plates and we control their angle to study its effect on the transfer ratio of liquid between them. Additionally, we also vary the liquid viscosity, plate velocity and wettability to

understand the synergistic effect on the transfer ratio.
For our study, the mechanism of liquid transfer and diverse factors affecting the transfer ratio are investigated via both experiment and numerical simulation. The experiments are performed by varying parameters that affect liquid transfer (viscosity, plate velocity, plate wettability and plate angle) using the in-house asymmetric plate extensional rheometer. The process of liquid transfer is recorded using a high-speed camera and transfer dynamics is analyzed using MATLAB. The numerical simulation, based on the phase-field model and dynamic contact angle, facilitates reproducing the complex contact line motion such as slip and pinning which can help us understand and compare with experimental results. Based on the results, regardless of plate inclination, we could divide the transfer ratio into three regimes: quasi-static regime, transition regime and dynamic regime which showed dependence on the plate velocity[1]. Overall, the transfer ratio on the inclined plate increases in comparison to the parallel plate, and this phenomenon is further enhanced in the dynamic regime. Additionally, the liquid viscosity and surface wettability were also observed to significantly affect the transfer ratio. Hence, in this study we intend on developing an engineering framework that can be used for controlling the liquid transfer and further be applied to optimize the roll-to-roll printing conditions.

Conducting Polymers as Dual Charge Conductors for Electrochemical Systems Gao Liu; Lawrence Berkeley National Lab, United States

Electrically conductive polymers are a class of polymers, which can conduct electricity. Conductive polymers have found niche applications such as anti-statics. The electrochemical energy storage devices, especially lithium-ion rechargeable batteries, has grown significantly in the past two decades. Recently multifunctional conductive polymers have been designed as dual ion and electron transport materials, and synthesized through a thermal process. These class of dual charge conducting polymers play a significant role as electrode binders for Silicon (Si) and Tin (Sn) alloy based anode electrode. Si is an attractive candidate for lithium-ion batteries because it delivers 10 times greater theoretical (~4200 mAh/g) specific capacity than that of a traditional graphite anode (~370 mAh/g). However, the widespread application of silicon materials has remained a significant challenge because of the large volume change during lithium insertion and extraction processes, disrupting both the Si electrode surface and electrode mechanical integrity. This large volume change causes electrode failure, leading to loss of the electrical contact and drastic capacity fading. Nanosizing the Si and Sn based anode materials provides better performance, but poses significant challenges to manufacturing of the electrode, including particle aggregation, and difficulties in maintaining constant electrical contacts to the nanoparticles, and excessive surface area. Conductive polymer binders can play multiple functions for Si electrode, including improved adhesion and connectivity, lithium ion compensation, better ion and electric conductivity as well as surface and interface modification. Organic and polymer chemistry has provided almost infinity possibilities to modify the polymeric binders to include the desired functionalities. This presentation will discuss the specific molecular design principles and synthetic steps to realize the structures and functionalities of the binders, how these binders interact with different alloy materials, and the electrochemical performances of the electrodes based on these binders.

SB05.08.13
Large-Area 2D Colloidal Microchannel Formation Under Non-Equilibrium Condition Ryan Dumont, Deepika Kakarla, Ashish Aphale and Bo Li; Kennesaw State University, United States

To face formidable challenges of future electronics with complex functionality and architecture, not only new materials but also new fabrication method need to be developed. However, topographical micropatterns (such as microchannels) are conventionally fabricated by complicated lithographic method, which are usually expensive and time-consuming, and not suitable for high throughput manufacture. Therefore, a low-cost, large-scale method for topographical template preparation needs to be developed. Recently, cracks formed in drying colloidal film have been demonstrated as ideal materials for microscale manufacturing. In this work, we first studied the key parameters that affect the dimensions of colloidal microchannel, such as channel-to-channel distance, channel width, and theoretical model is proposed to provide insights on colloidal microchannel formation. Then, the criteria for 2D microchannel formation (i.e., microchannel formed in both x and y direction) are investigated. The dimensions of 2D microchannel will be tuned by varying non-equilibrium condition, such as convective flux, temperature and evaporation rate. This work will provide a general strategy for generating of 2D microchannels, thereby offering a low-cost, large-area and lithography-free method for fabrication of patterns for printed electronics.

SB05.08.14
Pore-Size Dependent Adsorption Mechanism of Ammonia into MIL-101(Cr) Metal-Organic Framework Byeongryun Jeon and Jae Hyun Park; Gyeongsang National University, Korea (the Republic of)

Metal-organic frameworks (MOFs), nanoporous materials composed of metal nodes and organic ligands, are remarkably paid attention to as adsorption and storage medium for gases. A controllable pore-size nature of MOF enables species-specific adsorption for a particular purpose. However, the adsorption mechanism is not well understood yet. Among diverse gases, we focus on ammonia because it is popular for energy systems due to its nature of large vapor pressure and enthalpy of evaporation. The large vapor pressure can promote heat and mass transfer rate, and the large enthalpy of evaporation enables the reduction of the adsorption bed size.
Considering all the above, in this study, by employing extensive grand-canonical Monte Carlo (GCMC) simulations, we probe the adsorption mechanism of NH3 into MIL-101(Cr) MOF depending on the pore sizes. The pore size is modulated by increasing the number of benzene rings in the ligand. Three different ligands with one (original), two, and three benzene rings are considered while the metal node remains unchanged. As a result, the original MOF without modification has 6.8 Å, 26.1 Å, and 33.6 Å -sized pores, the MOF with two benzene rings has 9.7 Å, 39.4 Å, and 49.9 Å -sized pores, and the MOF with three benzene ring has 12.7 Å, 52.5 Å, and 66.1 Å -sized pores. For each structure, the isotherm is calculated by varying the pressure from 1 to 9 bar. Interestingly, the results show that the original MOF with the shortest ligand absorbs the ammonia most rather than the other MOFs with the longer ligands except for the high pressure of 9 bar. When the pressure is sufficiently high, the MOFs with two ligands adsorbs NH3 most. Also, we observe that at a certain pressure, the NH3 isotherm suddenly increases as the pore surface is closed (filled by gas completely) and the interior of the pore starts to be filled. At low pressure, the interaction between gas and MOF node governs the adsorption. However, at high pressure, the gas-gas interaction becomes dominant since all the nodes in a pore are occupied by the gas molecules already.
The potential energy analyses confirm the observations by GCMC simulations. Until the surface of the pore is fully occupied, the vicinity of the surface has the lowest energy sites. However, when the surface is closed by gas molecules and the pore interior starts to be filled, the NH3-attractive sites are found in the middle of the pores. When an NH3 molecule is adsorbed on the node, it creates additional favorable sites nearby for other NH3 molecules. Therefore, the small pores have a NH3 structure inside that is dominated by the shape of pore while the large pores permit regular NH3 structure inside because the NH3's in the middle are adsorbed mostly on the site created by the other NH3 molecules.

This work was supported by Korea Institute of Energy Technology Evaluation and Planning (KETEP), which is funded by the Korean government (MOTIE) (No. 20212050100010, Chemisorption heat pump system using electrochemical compressor).

***In Situ* Investigation of Low-Friction Tribofilm Formation in Transmission Fluids** Matthew Flynn-Hepford[1], Arya Ahmadi[1], Holland Hysmith[1], Zixuan Li[2], Kerry Cogen[2] and Olga Ovchinnikova[3]; [1]University of Tennessee- Knoxville, United States; [2]Infineum, United States; [3]Oak Ridge National Laboratory, United States

On average, one third of the energy consumed by passenger cars is used to overcome friction in the system. About 15% of this total energy loss is converted to heat by friction in the transmission. In order to understand the mechanism of low-friction tribofilm formation in transmission fluids, Multimodal Atomic Force Microscopy (MM-AFM) was used to generate tribofilms and monitor their development on steel surfaces. This technique allows in situ nanoscale imaging of the tribofilm, combining Friction Force Microscopy (FFM) to monitor friction changes, with Nanoscale infrared spectroscopy (nano-IR) to monitor chemical changes on the surface. Several friction modifiers combined with phosphorus-based antiwear chemistry were analyzed as a function of contact pressure. Using MM-AFM to track frictional and chemical behaviors during tribofilm formation provides unique insight into the evolution of low-friction films while helping advance toward the goal of developing more efficient drivetrains.

SB05.08.16
Compositional Changes at Epoxy-resin/Inorganic Interfaces Revealed by 1-nm Resolution Electron Spectroscopy Tomohiro Miyata[1,2,3], Yohei Sato[1], Kaname Yoshida[4], Hsin-Hui Huang[4], Teruyasu Mizoguchi[5], Katsumi Hagita[6], Masashi Mizukami[1] and Hiroshi Jinnai[1]; [1]Tohoku University, Japan; [2]University of Maryland, United States; [3]National Institute of Standards and Technology, United States; [4]Japan Fine Ceramics Center, Japan; [5]University of Tokyo, Japan; [6]National Defence Academy, Japan

Epoxy resins are widely used in adhesives and fiber-reinforced plastics owing to their excellent adhesive and workable properties. The adhesive strength between the epoxy resin and inorganic surfaces directly affects the mechanical strength of composite materials. Therefore, understanding the origin of the adhesive properties has been anticipated. However, molecular-scale investigations on epoxy-resin/inorganic interfaces have little been performed due to the difficulty in measuring such “buried” interfaces. This study prepared the adhesive interfaces between an epoxy resin and two types of silicon substrates with different surface chemical states. Moreover, the compositional distributions in the vicinity of the epoxy-resin/silicon interfaces were analyzed with a 1-nm resolution using scanning transmission electron microscopy (STEM) and electron energy-loss spectroscopy (EELS).

Diglycidyl ether of bisphenol A (DGEBA) (Mitsubishi Chemical Co., Ltd., Japan) and *para*-diaminodicyclohexylmethane (PACM) (Tokyo Chemical Industry Co., Ltd., Japan) were used as the epoxy-resin prepolymer and curing agent. They were mixed so that the molar ratio of the epoxy groups to the active hydrogens of the amino groups becomes 1:1. (111) substrates of a silicon single crystal were prepared. The organic residue on the surface was removed with piranha solution. Subsequently, hydrogen (H)-terminated surfaces were prepared with 1.5 wt% hydrofluoric acid for 30 min. Some H-terminated surfaces were processed by water vapor plasma to be terminated with hydroxyl (OH) groups. The mixture of DGEBA and PACM was pasted on these silicon substrates and then cured at 100 °C for 90 min. Thin cross-sectional samples of the epoxy resin/silicon interfaces were fabricated using a Cryo Ion Slicer (JEOL Ltd., Japan). These samples were analyzed by annular dark-field STEM (ADF-STEM) and STEM-EELS using a transmission electron microscope JEM-ARM200F (JEOL Ltd., Japan).

ADF-STEM observation revealed that oxidized silicon layers with thicknesses of ~2 nm at both adhesive interfaces between the epoxy resin and H- or OH-terminated silicon substrates exist. In addition, C-K adsorption edge spectra, originating from the epoxy resin, were measured by EELS at 1 nm intervals in the vicinity of the adhesive interfaces. Because DGEBA contains aromatic rings in the molecular structure, a characteristic peak (π^* peak) appears in the C-K edge. However, PACM does not show the π^* peak in the C-K edge because it has no π bond in the molecular structure. The measured C-K edge spectra clarified that epoxy resin molecules infiltrated into the oxidized layers at the interfaces. Moreover, the π^* peak became smaller only at the interface of the OH-terminated silicon, suggesting that the compositional ratio of PACM to DGEBA became more significant at the interface of the OH-terminated silicon rather than that of the H-terminated silicon. Our study revealed that the compositional ratio of epoxy resins, which results in adhesive properties, changes in the vicinity of the epoxy-resin/inorganic interfaces under the influence of the surface chemical conditions of inorganic materials.

Charge-Transport Solution-State Seeding and Growth of Conjugated Polymers into Well-Defined Nanowire Yoon Junyeon, Junho Hwang and Eunji Lee; Gwangju Institue of Science and Technology, Korea (the Republic of)

Controlling the nanoscale morphology of the conjugated polymers (CPs) has been approaching an amount of interest due to its possibility of adjusting charge transfer property. In particular, one-dimensional nanostructures are ideal for charge transfer as they have effective carrier transport properties along the anisotropic stacking directions. Along this line, the pre-assembly of conjugated nanowires (NWs) in the solution state has drawn great interest as a potential replacement for the post-annealing process, securing roll-to-roll manufacturing with a large-area production and a significant cost decrease. The whisker method and the mixed solvent method are frequently utilized as typical solution processing techniques to provide additional driving forces for CPs assembly. Herein, in order to accomplish NW growth and doping without a physical driving force simultaneously, we have focused on charge transfer at the CPs and dopant contact, which can cause seeds-triggering growth of the CPs, rather than the doping procedure, which is often used to tune the electrical property of the CPs to induce the enhancement of the conductivity. Specifically, we will talk about the charge-transport driven CPs-crystal seeding and growth into NWs by adding dopant. Interestingly, it is clearly confirmed through in-situ liquid-cell TEM that controlling the concentration of the dopant or the molecular weight of the CP may have a strong effect on the formation of the NWs in the solution-state. This study might provide an innovative manufacturing strategy for mass production of high-efficiency doped organic semiconductor NWs for optoelectronic devices through solution-processing.

SB05.08.21
Biophysical Characteristics of amyloid-β Protein Aggregates Using a Molecular Structure-Specific Label-Free THz Spectroscopy for Alzheimer’s Disease Chaejeong Heo[1,2], Taewoo Ha[1] and Young Hee Lee[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Institute for Quantum Biophysics, Korea (the Republic of)

Alzheimer's pathology is correlated with structural conformation change of aggregated amyloid beta (Aβ) proteins. We identify the progressive aggregation stages of the Aβ protein growth in a buffer solution using by the near-field THz spectroscopy and the newly defined biophysical marker based on real-time THz optical conductance. Here, we clearly detected and analyzed the Aβ aggregation growth through solution-based label-free THz conductance measurement by precisely controlling the thickness of the protein sample in a buffer solution. Frequency-dependent conductance for Aβ aggregates was obtained by measuring the differential transmittance of the time-domain spectroscopy in the THz range with a molar concentration of monomer, oligomer, and fibrillar forms. The monotonic decrease in the conductance at low frequency was dominated by a simple Drude component in the monomer with concentration and nonlinear conductance behaviors in the oligomer and fibril. By extracting the structural localization parameter, a dimensionless constant,

with the modified Drude–Smith model, we defined this to the biophysical value ($0 < DQ < 1$) as a structure-specific metric for a various Aβ aggregates at a low concentration of 0.1 μmol/L; $DQ = 1.0 \pm 0.002$ (fibril by full localization, mainly by Smith component), $DQ = 0.64 \pm 0.013$ (oligomer by intermixed localization), and $DQ = 0.0 \pm 0.000$ (monomer by Drude component). Furthermore, we can label-free monitor Aβ growth dynamics to identify various morphological phase transitions and steps during macro scale fibrils from monomers under physiological conditions. This suggests the new biophysical characteristics with intrinsic property of Aβ proteins for Alzheimer's disease.

SB05.08.22
Bulk Self-Assembly of Hybrid GO-clay Nanosheets Paulo H. Michels Brito[1], Barbara Pacakova[1], Martin Bygdas[1], Andrew N. Akanno[1], Veslemeløy Osmundsen[1], Josef Breu[2] and Jon Otto Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]University of Bayreuth, Germany

Bulk self-assembly provides an efficient technique for large-scale production of materials which is often limited using the interfacial or deposition methods. One promising system in this context could be provided by functionalization of insulating nanosheets for the production of conductive/insulative heterostructures, for instance use in electronic devices. One such material is clay which completely delaminates in water to form insulating nanosheets, exhibiting one of the largest electron bandgaps known so far in 2D layers (1).

Here we present the self-assembly of graphene oxide (GO-) and synthetic fluorohectorite clay heterostructures in a bulk mixture of the two individual components in the presence of polyethyleneimine-ethyleneoxide (PEI-EO). The synthetic clay mineral used here is superior to other clays in terms of charge distribution, homogeneity, and crystalline perfection (2). This clay mineral delaminates in water to form nematic structures with cations present in the interlayer regions. Double layer clay nanosheets can be readily obtained via ordered stratification by partial interlayer cation exchange using ammonium cations (NH_4^+), providing bilayers with a net negative charge, and which can be double side coated with the polymer (2, 3). The GO is incorporated onto the clay surface via the polymer adhesion layer to form the complex GO-clay heterostructures. These 2D nanosheets have been investigated using SPM and XRD to determine their composition, mechanical and adhesion properties.

The results indicate that the synthesized GO-clay nanosheets presents interesting properties for possible applications in electronics and semiconductive devices. We are currently extending this work and attempting the cleavage of the double layer GO-clay nanosheets into single GO-clay layers to produce micrometer sized GO-clay Janus platelets.

Multiscale Structure and Properties Measurement of Soft Matter Using a Single Platform—Tribo-Rheology Chungman Kim[1,2], Jaewon Shim[1], Sangmin An[3], David A. Weitz[2], Manhee Lee[4,2] and Wonho Jhe[1,2]; [1]Seoul National University, Korea (the Republic of); [2]Harvard University, United States; [3]Jeonbuk National University, Korea (the Republic of); [4]Chungbuk National University, Korea (the Republic of)

Soft matter exhibits viscoelasticity, which is generally associated with the rheological structure of materials. To comprehensively understand the rheological structure and properties, it is, therefore, necessary to probe materials at the multiscale; materials should be measured with probes from bulk- to nano-scales, to fully reveal the internal structures of materials. However, conventional rheometers mostly limit the rheological measurements to the bulk scale. Here, we demonstrate multiscale measurement of structure and properties for polymer solutions, e.g., silicone oils, using a single platform: quartz tuning fork-based tribo-rheometer. This unique platform with different-sized probes allows to measure bulk rheological properties, molecularly ordered structures of polymers, and the tribo-rheological characteristics at solid interfaces. Our results offer a unified understanding of structures and properties relation for soft matter.

SB05.08.24
Phase Separation and Liquid Crystallinity in Mixtures of Rigid and Flexible Biopolymers Kimberly L. Weirich[1], Steven Huntley[1], Sam Rubin[1], Rui Zhang[2] and Juan de Pablo[3]; [1]Clemson University, United States; [2]The Hong Kong University of Science and Technology, Hong Kong; [3]University of Chicago, United States

Structured soft materials have internal order that give rise to unusual mechanical properties and emergent organization of inclusions and defects. Here we present a composite structured liquid formed from biopolymers of distinct rigidities. Biopolymer filaments, such as actin and microtubules, behave as rigid rods when much shorter than their persistence length. These short, rigid filaments are known to crowd into a thin fluid layer that can form a nematic liquid crystal, where filaments have orientational order but not positional order. Here we investigate the phase space in a mixture of short, rigid, nematic forming filaments with more flexible biopolymers, which are much longer than their persistence length. Using fluorescence microscopy, we investigate the domain and defect formation as the phase separated polymer mixture evolves. Using a continuum model of lyotropic liquid crystal, we extract material properties of the liquid crystal. Our results suggest a novel structured soft composite, which potentially informs physical mechanisms of controlling material properties in structured fluids and templating functional polymeric materials.

Pressure Processing of Nanocrystals and Nanocrystal Assemblies Ou Chen and Yasutaka Nagaoka; Brown University, United States

Pressure processing emerges as a fast and clean mechanical method to fabricate and transform novel nanomaterials without involvement of chemical reactions and post-purification processes. Recent studies have revealed that the pressure-treatment of nanomaterials is able, not only to induce structure transformation at the atomic level, but also to regulate translational alignment at nano-, meso- and even macro-scales. Exciting nanomaterials with unique structures and properties have been generated through a stress-driven "permanent-sintering" process. In this talk, I will discuss several of our recent studies about pressure processing of different types of nanocrystals and their ordered and non-ordered assemblies, including halide perovskite nanocrystals, metal nanoparticles, and quantum dot-metal heterostructure nanocrystals. In particular, I will focus on our new discovery of a novel method to produce tailored grain-boundary conditions with nanoscale precision from colloidal metal nanocrystals by a pressure-sintering process. The resulting bulk grain-boundary materials (which we call ''nanocrystal coins'') possess a metal-like appearance, high conductivity and exceptional strength while inheriting the original domain features of the nanocrystal building blocks. Our studies may spur the development of new materials (through pressure-treatments) with functionalities crucially depends on the domain configuration at nanometer scale, such as superhard materials, thermoelectric generators, and functional electrodes.

The Onset of Glassy Dynamics in Two Dimensions as a Kosterlitz-Thouless Transition Muhammad R. Hasyim[1], Dimitrios Fraggedakis[1] and Kranthi K. Mandadapu[1,2]; [1]The University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The dynamics of glass formers exhibit dramatic slowdown below an onset temperature that delineates the high-temperature and supercooled regimes. For two-dimensional (2D) glass formers, we propose that the onset temperature can be described by a Kosterlitz-Thouless transition, driven by the elastic excitations underlying the relaxation mechanism for glassy dynamics. Analogous to dislocation-mediated melting in 2D crystals, the excitations exist as a bound dipole-dipole (or quadrupole) state in the supercooled regime and as free dipoles above the onset temperature. The Kosterlitz-Thouless scenario explains the emergent elastic behavior of 2D supercooled liquids at intermediate timescales, and thus the Mermin-Wagner fluctuations observed in experiments and simulations of 2D glass formers. The present work reveals the nature of 2D glass formers, where quasi-long-range order emerges in an analogous manner to 2D crystals at intermediate time scales, and is relevant to understanding colloidal films and other soft condensed matter systems under extreme confinement.

9:15 AM SB05.09.03
Depletion-Mediated Crystal Nucleation and Growth of Attractive Colloids Sanghyuk Park[1], Hyerim Hwang[2] and Shin-Hyun Kim[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Ewha Womans University, Korea (the Republic of)

Colloids are exquisite mimics of atoms or molecules in condensed matter. Since the particles are thermalized by the solvent, they form the same phases of atomic or molecular systems such as crystals, glasses, alloys, and liquids. Each particle mimics the behavior of an individual atom and their collective behavior mimics that of a condensed phase. Due to experimentally accessible time and length scales, they serve as an excellent model system to investigate a variety of phase behaviors that have not been accessible to experiment on the atomic level. Intensive studies have been done using hard-sphere or soft-sphere colloids to elucidate mechanisms underlying crystallization, melting, solid-solid transitions, and glass deformation, which provided new fundamental insights into the phenomena; structure, dynamics, and their time-dependent evolution are directly measured to find out key parameters that govern the processes. Progress in the synthesis of model colloids with controllable surface chemistry allows an alteration in the simplest interaction potentials, which, however, is still far behind from mimicking real atoms and molecules. In general, pair potentials of atoms and molecules are described using the Lennard-Jones potential, which represents one particular type of Mie potential. Therefore, it remains of great importance to design realistic colloidal systems with Mie potential that can more closely depict the phase behavior of atoms and molecules.
We employ the depletion interaction in aqueous suspensions of spherical colloids to formulate total pair potential to be comparable with that of atoms and molecules. Depletion force has been applied to modulate interparticle interactions in colloidal systems. Depletants in the suspension are excluded from the surfaces of colloids, which causes outward osmotic flow from the depletant-depleted interstitial region among colloids, exerting attractive force. This attractive interaction has been used to assemble colloidal particles into condensed phases. We suspend polystyrene particles with negative surface charges in water containing sodium chloride and depletant of poly(acrylamide-*co*-acrylic acid) (*p*(Am-*co*-AAc)) with a hydrodynamic radius of r_h = 32.5 nm. In the presence of the depletant, depletion attraction contributes to total pair potential in the range of separation smaller than the diameter of the depletant. Superposition of the depletion attraction with electrostatic repulsion and van der Waals attraction renders the particles to strongly repel in very short-range, gently attract in middle, and not interact in long-range, similarly with Mie potential.
With the pair potential, fluids, crystals, and glasses are respectively represented depending on the depth and slope of the pair potential. For example, the phase boundary between the fluids and crystals is roughly defined by the depth of the potential well, whereas that between the crystals and glasses is represented by the rate of colloidal assembly. For the crystalline phases, the nucleation rate is dictated by the depth and the growth is limited by slow colloidal diffusion. During growth, Ostwald ripening causes large crystallites to get larger while small ones shrink and disappear, in particular for large Laplace pressure gradient. The final morphology of crystals is either dendritic or polygonal, which is selected by whether or not the concentration gradient is maintained during the growth. The shape of the dendrites is determined by the crystal orientation, to be either six-fold or elongated X-shaped. These crystal growth behaviors are highly relevant to atomic and molecular systems. As the growth is dictated by the nucleation rate, the depth of potential energy well is the most important determinant that governs the overall pathway of nucleation and crystal growth.

Amorphous Calcium Phosphate (ACP) as a Precursor for Mineralization in Bone Tissue Yongjae In, Urasawadee Amornkitbamrung and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

Bone mineralization refers to the crystallization of amorphous calcium phosphate in the extracellular matrix of all vertebrates. Human bones are composed of organic/inorganic mixture, and about 60% of inorganic components are hydroxyapatite (HAp), which is one of calcium phosphate. It is known that the crystallization of HAp does not follow classical nucleation theory. It has been found that the mineralization of HAp is achieved through a transient amorphous calcium phosphate (ACP) step both in vitro and in vivo. However, the proposed mechanisms of ACP transformation to HAP remained elusive for example, a dissolution-reprecipitation, the reconstruction of Posner's clusters, and a surface-mediated transformation. Therefore, the study of ACP-mediated HAP nucleation pathways and mechanisms is required and has profound implications for biomineralization. Synthetic ACPs were discovered by Betts and Posner's X-ray experiments in the 1970s to have a Ca:P molar ratio of ~1.5, a spherical feature, and a chemical structure of $Ca_9(PO_4)_6$. In human bone, it has been reported that Ca and P ions, which are constituents of HAp, are initiated from the mitochondria of osteoblast and are released in the form of ACP through the matrix vesicles (MV). After that, ACP crystallizes inside the collagen fibers to be crystalline hydroxyapatite platelets. So far, there are sufficient studies related to the properties of synthesized ACPs, but the analysis of crystallization of ACPs released from the cells into HAp is insufficient. In this study, the characteristics of ACPs secreted from cells and synthesized ACPs were analyzed, and collagen fibrils were mineralized using both ACPs. The Ca/P atomic ratio and chemical composition of ACPs were analyzed by Inductively Coupled Plasma and Transmission Electron Microscopy (TEM), and the phase of ACP was analyzed by powder X-ray diffraction. In the case of synthesized ACPs, spherical nucleation was observed in a solution containing Ca and P, and the Ca/P ratio in the process of becoming a ribbon was analyzed. The Ca/P ratio in the initial spherical state was about 0.9, but it increased with time. ACPs released by cells were obtained by ultrafiltration of matrix vesicles from osteoblasts and analyzed mainly by TEM. We

dispersed cell exosomes on a TEM grid by using ultrafiltration and finding the dark contrast due to the electron scattering by inorganic substances, Ca and P, in bright-field imaging, we also analyzed the mineral contents. Based on the study on the characteristics of ACP, mineralization in the collagen matrix was carried out to conduct a study on the synthesis of bone formation from the actual release of ACPs from osteoblasts to the mineralization of collagen. Therefore, the results presented in this study may better understand the mechanism of HAp mineralization in collagen fibrils and the actual bone formation process and ultimately help in the successful material design of tissue engineering.

9:45 AM SB05.09.05
Effects of Electrostatic Repulsion and Steric Exclusion on Single-Stranded DNA Attaching to the ZnS Surface of Quantum Dots Xingfei Wei and Rigoberto Hernandez; Johns Hopkins University, United States

DNA linked quantum dot (QD) assemblies have been applied in biological drug delivery, programmable materials, and photonics. The mechanism of a DNA chain attaching to the QD surface is very important to developing new DNA-QD nanostructures. In this work, we combine all-atom molecular dynamics simulations and experiments to reveal the mechanism of a single-stranded DNA (ssDNA) attaching to the ZnS surface of CdSe-ZnS (core-shell) QDs. We verified the ssDNA model chain conformation through agreement with experimental and theoretical conformations in the literature. We report the ssDNA chain conformation on a flat ZnS surface and on differently sized ZnS QD surfaces. They depend on the combined effects of electrostatic repulsion and steric exclusion from 3-mercaptopropionic acid (MPA) and O-(2-mercaptoethyl)-O'-methyl-hexa (ethylene glycol) (mPEG) capping on ZnS QDs. Both simulations and Förster Resonance Energy Transfer (FRET) experiments indicate that ssDNA tail is closer to the QD surface when the QD size is larger. In addition, we find through both simulations and Transmission Electron Microscopy (TEM) experiments that the maximum valence numbers are 1, 2 and 3 on QDs of 6, 9 and 14 nm in diameter, respectively. We emphasize the critical role of the electrostatic repulsion on the conformation and the number of attached ssDNA on the QD surface.

Soft Material Assembly Assisted with Polymer Pen Nanolithography Jacob LaNasa and Kyungtae Kim; Los Alamos National Laboratory, United States

The intrinsic thermodynamics of polymeric and molecular materials can drive assembly into advantageous structures on the nanometer length scale. Specifically, block copolymers with two or more chemically distinct and covalently linked blocks that are enthalpically immiscible have the propensity to phase separate. These phase-separated regions can conform to many interesting structures that have been useful in areas including lithography, optics, and membrane design. Likewise, molecular aggregates are structures that readily assemble to a similar macromolecular length scale and can have unique interactions with visible light. In these assemblies, the long-range order is limited by uncontrolled nucleation and growth. Well-defined long-range order in these materials can strengthen photonic coherence and can make them intriguing candidates for visible-light integrated circuits. With state-of-the art competencies at the Center for Integrated Nanotechnologies at Los Alamos National Laboratory, the structural assembly of soft materials can be assisted with polymer pen nanolithography. The polymer pen lithography technique is a novel approach to precise, high throughput application of soft materials onto a surface. In the case of polymeric assembly, strategic placement of defects can be used to predetermine nucleation sites and limit grain growth, effectively assisting the assembly process. In the case of molecular aggregates, printing of aggregate assemblies on the length scale of visible light can reduce the quantum incoherence of randomly assembled and multilayer grains. Here, a substrate can be pre-treated with a quasicrystalline-patterned poly(dimethylsiloxane) (PDMS) photoresist that is then photopolymerized to yield a durable and chemically selective defect architecture intended to influence the self-assembly of a poly(dimethylsiloxane)-*block*-poly(lactic acid) block copolymer. The structural and characteristics of the resulting assemblies are quantified using X-ray scattering and microscopy techniques.

10:45 AM SB05.10.02
Phase Separating Inks for the Additive Manufacturing of Porous Polymer Composites in Battery Applications Andrew L. Fassler[1,2], Ryan R. Kohlmeyer[1,2,3], Gregory Horrocks[1], Luke A. Baldwin[1], Abigail Juhl[1] and Michael F. Durstock[1]; [1]Air Force Research Laboratory, United States; [2]UES, Inc, United States; [3]Xerion, United States

The additive manufacturing of batteries offers great potential for the future of power integration in electronics, freeing up design space and enabling new device capabilities. This is especially true for thin film and flexible devices where current packaging (ex. coin cells, cylindrical cells, and pouches) prevents intimate incorporation of the battery into the device and must be designed around to maintain a device's flexibility. The ability to fabricate a cell directly onto the device itself can remove this restriction, as the shape and structure of the cell can be tailored to the device, fitting into unique form factors or even being designed to enable deformation. To achieve this, additive manufacturing approaches must be developed to deposit high performance battery component materials and to combine these materials to create high functioning galvanic cells.

One of the great challenges in the additive manufacturing of batteries is developing process compatible materials with the suitable composition and microstructure to enable appropriate performance, particularly porosity and pore structure. Electrodes must be porous to allow for electrolyte penetration and ion conductivity, highly loaded with active material to maximize energy density, and electrically conductive to transport energy to and from the active material. Likewise, separator membranes must be porous for electrolyte penetration and ion conductivity, but these features must be small enough and mechanically robust enough to prevent shorting and dendrite growth. In addition, the processing requirements for these materials must be straight forward to make techniques like 3D printing and coating possible.

We have developed an evaporation induced phase separation technique that utilizes a mixed solvent system to fabricate polymer materials and polymer-particle composites with controlled porous microstructures. The polymer is dissolved in a solvent solution composed of a good and poor solvent for the polymer, chosen such that the good solvent evaporates preferentially to the poor solvent. This leads to an instability in the ink upon drying, thereby causing phase separation into polymer poor and polymer rich phases and creating porosity upon solidification. We have used this process to develop a PVDF and Al_2O_3 composite that functions as a separator membrane for lithium ion batteries and can be deposited by multiple printing and casting techniques.

Additionally, we have demonstrated the ability to control the microstructures that form in these polymer-particle composites through the selection of particle size and loading, including creating both foam-like and granular morphologies. When combined with similar composite electrode materials, such as graphite or $LiFePO_4$ for lithium ion batteries, printed full cells can be achieved. Here, we explore approaches to how we can create fully printed batteries from these materials, as well as how to fabricate them on complex and non-planar substrates to enhance energy storage integration. Furthermore, we examine the challenges faced in controlling microstructure in multi-material and multi-layer additive manufacturing, particularly at the interfaces between different materials and how this can impact performance.

11:00 AM SB05.10.03
Large-Area Emerging Patterns by Thermally Engineered Template-Guided Self-Assembly Sung Bum Kang[1], Guanglong Huang[2], Gaurav Singhal[1], Dajie Xie[1], Daniel Hwai-En Hsieh[1], Youngmun Lee[1], Ashish A. Kulkarni[3], Alexander J. Littlefield[1], John W. Smith[1], Qian Chen[1], Sanjiv Sinha[1], Katsuyo Thornton[2] and Paul Braun[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Michigan, United States; [3]Brookhaven National Laboratory, United States

Template-directed self-assembly is a promising way of manipulating microstructure, enabling emergent functional properties including photonic, phononic, and mechanical. Moreover, the template can evolute microstructures that are distinct from initial starting structures, yielding ordered emerging patterns. However, instabilities at the interfaces between materials and templates hinder the formation of uniformly ordered emerging patterns in a long-range order, limiting practical applications. Here, we design low-thermal fluctuated templates which reduce instability of eutectic self-assembly materials at the interface, leading to a large area (~ 0.01 mm2), ordered checkerboard array of emerging patterns. The FDTD simulation suggests that the low thermal conductivity of the template can minimize temperature fluctuation, giving rise to uniformly ordered emerging patterns. In the serial sectioning of directionally self-assembled AgCl-KCl within the template, we note that microstructures are strongly influenced by the thermal conductivity of the template, and particularly large instability of microstructure at the interface between the template and material results in short-range order. The low thermal conductive template fabricated by porosification constrains thermal fluctuation caused by rapid thermal transport and produces a large-area emerging pattern. We also find that by using selective etching of self-assembled materials or templates, a variety of mesostructures are observed and can control optical properties, which reveal the promising potential for photonic and microscale-based applications.

11:15 AM SB05.10.04
Fabrication of Waterborne Polyurethane (WPU) Porous Layers Through Binary Particle Stabilized Pickering Foam Templating Zhenghao Shi and To Ngai; The Chinese University of Hong Kong, Hong Kong

As important raw materials utilized in fire-proof, sound insulation, thermal insulation, gas sorption, etc., the traditional solvent phase inversion methods to produce porous materials have resulted in air/water pollution and residual VOCs in the products, which have been restricted by many countries. Waterborne polymer products possess the superiority of being eco-friendly during manufacturing but are limited by foam stability. Pickering foam is an air-water mixture whose interface is stabilized by the particles without interfacial activity. Excess particle desorption energy from the air-water interface over surfactants ensures superior stability and potential templating porous material production. The classic view of Pickering foam requires specific particle wettability, explained through the maximum capillary pressure concept, which hinders its application in industry.

We have reported a new strategy to prepare ultra-stable aqueous foams from PVA-Silica binary component system1. A series of Pickering aqueous foams were therefore achieved as the hydrophilic polymer and hydrophobic colloidal particles stabilized the Janus bilayer air-water interface in one step without massive particle wettability modification. The resulting Pickering foam afforded convincing stability over one month and templated the porous materials monolith. The work opened a new door for binary component Pickering foam and waterborne composite porous materials preparation.

In our recent work, the stabilization mechanism and kinetics of binary colloidal particles stabilized Pickering foam are under investigation. We are seeking for the potential to get the typical Pickering foam applied as a low-cost and eco-friendly scheme for porous materials industrial production. The Pickering aqueous foam systems, including hydrophilic-hydrophobic and hydrophilic-hydrophilic colloidal particles systems, are derived from waterborne polyurethane (WPU), hydrophobic silica particles (SP), and cellulose nanofibrils (NF) with typical wettability, surface charge, size distribution have been achieved.

Key Words: Porous material, Pickering foam, WPU, Silica particles, Cellulose nanofibrils

Understanding and Controlling Tunable Organic-Inorganic Nanoparticle Self-Assembly Xin Qi; Dartmouth College, United States

Inspired by naturally occurring hierarchical materials, numerous beautiful and functional mesoscale architectures have been constructed in labs using solid-state nanoscale building blocks and bio- or biomimetic molecules via self-assembly. Their structures and assembly dynamics are tightly regulated by the system's convoluted energetics and entropic information, which may even respond to a minuscule change. For example, we recently reported a pH-regulated self-assembly of silica nanoparticles facilitated by an engineered bifunctional silica-binding protein sfGFP::Car9-Car9. The assembly and disassembly can be reversibly and cyclically modulated by alternating the solution pH between 7.5 and 8.5. In another study, we observed that an increment of the peptoid (i.e., the ligand) length by two monomers at a time would change the arrangement of a CdS quantum dot superlattice from close packing to square, further to monoclinic. However, the complexity of the nanoscale colloidal system often makes it difficult to probe the underlying physics via experimental means. Alternatively, we can construct suitable multi-scale theoretical toolkits by carefully selecting and combining theories and simulation algorithms from different levels (i.e., from ab initio to coarse-grained models) to connect the scales and gain physical insights into the assembly mechanisms. In this talk, I will elaborate on how we used multi-scale theoretical frameworks to reveal the key driving forces of self-assembly in these two cases. The knowledge we gained on the distinctive roles of organic ligands has further inspired new design principles in future studies.

A Model Collective System Made of Spinning Micro-Disks—From Fundamentals to Microrobot Swarms Gaurav Gardi and Metin Sitti; Max Planck Institute for Intelligent Systems, Germany

Self-organization in colloidal systems has led to various fundamental studies on non-equilibrium systems and development of microrobot swarms. However, typical colloidal systems are limited in their behaviors and each system can only facilitate a few specialized studies. Therefore, developing a single model system that can controllably transition among diverse behaviors, would be very useful for various fundamental studies and for the development of microrobot swarms. We develop a collective system that utilizes the mutual interactions among its constituents, and its behaviors can be controlled via global stimuli. Our system consists magnetic micro-disks that interact via various physical interactions (magnetic dipole-dipole, hydrodynamic and capillary interactions) and the relative dominance of these interactions can be tuned by an external oscillating magnetic field. In this talk, we present various studies enabled by our system. First, we demonstrate that our system can form rotating collectives with varying degree of orientation order that can be controlled by a single control parameter: the rotation speed of the external magnetic field. These behaviors enable a fundamental study on development of a general-purpose order-parameter based on the information content of the self-assembled patterns. Next, we show that the mutual interactions among the micro-disks can be tuned to form various collective modes ranging from isotropic (rotating and static collectives) to anisotropic (chains) behaviors, and a gas-like behavior consisting self-propelling pairs. The mutual interactions are tuned by changing the profile of a 2D oscillating magnetic field, demonstrating that the external driving field and the mutual interactions can conjunctively generate transitions among behaviors and enable various controllable robotic functions. Last, we study the effect of heterogeneity in our system and demonstrate that our system can transition on-demand from a driven (following an external field) to an active (self-propelled) behavior or a mixture of both. Through these studies, we hope to convey that our system can act as a versatile model system facilitating fundamental studies that link driven and active behaviors, and also provide a step towards developing versatile and controllable microrobot collectives.

Self-Assembled and Nanostructured Triblock Terpolymer Organogels for Infusion Templating Yuanzhi Li and Joerg G. Werner; Boston University, United States

Extended nanostructured materials are abundant in natural systems such as butterfly wings and beetle shells with high interior periodic order that produces splendid optical appearances and multifunctional mechanical and interfacial properties. Inspired by the versatility, durability, and functionality of natural materials, material scientists are seeking synthetic analogues of functional materials in bulk phase with highly ordered three-dimensional nanostructure for various applications in optics, catalysis, water purification, and energy storage. Herein, we introduce a versatile and scalable concept towards the fabrication of bulk nanostructured functional materials. We take advantage of the self-assembly of synthetic triblock terpolymers with chemically distinct blocks that self-assemble into ordered continuous nanostructures as bulk materials. Each of the three blocks serves a distinct purpose: One block within the self-assembled bulk material can be selectively crosslinked with tunable crosslink density which enables the formation of organo-gels with controllable swelling degrees in various kinds of organic solvents with retention of the periodicity of the ordered nanostructures. Another functional block is chemically tunable towards attracting and depositing reagents and nano-sized functional building blocks, while a chemically inert third block acts as a freely swollen gel phase that enables mass transport throughout the bulk structure. The size and symmetry of the nano-scaled features are tunable through the block fraction, the molecular weight of the polymer, crosslink density, and solvent quality. The monolithic triblock terpolymer organo-gels can serve as a versatile soft-template for the creation of various functional materials attribute to the unique physical and chemical properties of the triblock terpolymer. Specifically, the varied affinity of the building blocks to solvents and reagents, as well as the tunability of the functional groups facilitate the mass transfer and selective chemical reactions in infusion-deposition templating, respectively.

2:15 PM SB05.11.03
Using a Membrane to Impose Curvature and Alter the Morphologies of Growing Crystal Hao Wan[1], Geunwoong Jeon[2], Weiyue Xin[2], Gregory Grason[1] and Maria Santore[1]; [1]University of Massachusetts, Amherst, United States; [2]University of Massachusetts Amherst, United States

Current understanding of two-dimensional crystal growth focuses on the interactions between flat substrates and flat growing crystals. By contrast, the understanding of the growth of curved crystals, especially those of non-zero Gaussian curvature of which limited examples exist, considers the stresses imposed by a curved template on a growing two-dimensional crystal, where molecular or colloidal units add to the growing crystal edges from above. In the current study, we demonstrate that when crystals grow within curved vesicle membranes, forces from the membrane and its bending, acting at the edges of the growing crystal, along with the impact of internal pressure, produce morphologies and scaling that run counter to expectations based on systems without the pulling of a growing crystal at its edges. In vesicle membranes, processing conditions, such as cooling rate and transport considerations cause variations in tension history, producing different interplays between bending energies and line tensions. The overall result, demonstrated in quantitative experiments and supported by modeling, is that flat compact solid domains grow reproducibly in small vesicles. However, despite more gradual curvature but higher membrane tension on larger vesicles, flower shaped domains are found and their shapes exhibit increasing complexity with increased vesicles size, tension and, ultimately, bending energy.

Computational and Experimental Study Linking Polysulfamide Chain Design to the Hydrogen Bonding Induced Chain Aggregation Zijie Wu[1], Jiun Wei Wu[2], Quentin Michaudel[2] and Arthi Jayaraman[1,1]; [1]University of Delaware, United States; [2]Texas A&M University, United States

Poly-N, N'-disubstituted sulfamides [Kulow et al. *Chem. Sci.*, 2020, **11**, 7807-7812], a new class of polymers structurally analogous to polyureas, are gaining attention in organocatalysis and medicinal chemistry. It is essential to have a fundamental understanding of poly-N, N'-disubstituted sulfamides to facilitate their wider commercial applications as replacements of polyureas. In this talk, we present a collaborative computational and experimental study of polysulfamide chains and their assembly driven by hydrogen bonding interactions between the sulfamide groups. We first share our newly developed coarse-grained (CG) model of polysulfamide that captures the directionality of inter-chain hydrogen bonds between sulfamide groups and allows us to study self-assembly of polysulfamide chains in molecular dynamics (MD) simulations. These simulations link the contour length, bulkiness, and flexibility of the N, N'-substituents on either side of the sulfamide groups to the morphology (e.g., positional and orientational order) of the polysulfamide assembly. We validate our CG model and simulation approaches by showing that the MD simulation results agree with the trend in assembly crystallinity for various aliphatic and aromatic N, N'-substituent chemistries measured by X-ray diffraction (XRD) and infrared (IR) in experiments. We then use the validated computational approach to explore new substituent chemistries and study the effects of substituent length and bulkiness on morphology of polysulfamide self-assembly, with the predictions tested against additional experimental syntheses and characterizations.

3:45 PM SB05.11.05
Calcium Ions Enable Intrinsically Disordered Phosphopeptides to Form Self-Oriented Filaments Jiaqi Guo[1], Fengbin Wang[2], Chen Liu[3], Yimeng Huang[1], Weiyi Tan[1], Hongjian He[1], Meihui Yi[1], Xixiang Zhang[3], Edward H. Egelman[2] and Bing Xu[1]; [1]Brandeis University, United States; [2]University of Virginia, United States; [3]King Abdullah University of Science and Technology, Saudi Arabia

Biomimetic bone regeneration remains a major challenge because of limited understanding of protein-controlled biomineralization to form oriented architecture at molecular level. During the study of an intrinsically disordered peptide (IDP) containing phosphoserine and pyrene, we unexpectedly found that calcium ions transform the IDP from nanoparticles to self-oriented filaments via hierarchical self-assembly. HAADF confirms the interaction between strontium and phosphate in the filaments. Cryo-EM structure reveals that the hydrophobic pyrene forms the structured core and the IDP constitutes the flexible periphery of the helical nanofibers. These results indicate that calcium ions interact with flexible periphery of the nanoparticles to form fibrils and enhance interfibrillar interactions to form oriented filaments. To further understand the roles of the IDP for forming filaments, we synthesized analogs with controlled phosphorylation site, hydrophobic interactions, sequences, chirality, and mode of pairing to evaluate the significance in forming oriented filaments. The results confirm that noncovalent pairing, phosphoserine, and a proline residue prior to phosphoserine in the IDP are critical for the formation of the oriented filaments. Combining cryo-EM structural elucidation and molecular engineering, this work illustrates a useful model system based on strong hydrophobic interactions and IDPs for understanding and mimicking the initiation of phosphoprotein-controlled biomineralization.

4:00 PM SB05.11.06
Synthesis of Self-Supporting Porous Au Sponges Using Polymer Gel Templates Seohyeon Jang, Jihyeon Kang, Seyoung Choi, Ohhyun Kwon, Hojong Eom, Junhyeop Shin, Jongkwon Park and Inho Nam; Chung-Ang University, Korea (the Republic of)

Porous metal structures can be applicable in wide range of fields including electrochemical or acid-base catalyst, heat dissipation, and bio filtration. Porous template mediated metal structures have higher surface area (1 m^2g^{-1}) than pure metal structures. Though the template method has been advanced rapidly using starch gel, dextran, pumice, and alumina, sacrificial template method has been seldom investigated. Here, sponge-like porous Au structures were synthesized using agarose gel, $HAuCl_4$, and $NaBH_4$ as sacrificial soft template, Au precursor, and reductant with simple heating method. First, agarose gel has a 3D cross-linked pore structure, which is easy to control the porosity, shape, and scale. This implies that the use of agarose as a soft sacrificial template enables synthesis of pure Au sponges with purposed porosity and shape. To synthesize the porous Au structure, agarose gel was formed by mixing agarose with water at elevated temperature around 95 °C. The Au precursor was penetrated into the agarose gel by a capillary force at room temperature for 18 h in a sealed container. The metal ions were easily soaked into the 3D pores of agarose gel, as it has hydrophilic characteristics, which supply high loading amount of metal. The metal ions in agarose gel was reduced by $NaBH_4$. The agarose is composed of many aldehyde groups, which promotes the reduction of metal ions ad nucleation of metal clusters. Because of the reduction of Au ions in the pores of agarose, the agarose was getting darkened. The resulting Au-filled agarose gel was dried at room temperature and calcined for 5h at various temperatures to remove the agarose template and to form 3D Au structure. To understand the decomposition behavior during calcination step, thermal gravimetric analysis (TGA) was conducted. The weight loss observed from 200°C to 550°C by the decomposition of agarose template and the weight loss was around 80.5 wt %, which implies that the approximately 19.5 wt % of pure Au was formed in agarose gel. To investigate the structural change depending on the temperature, the Au-agarose bi-continuous structure was calcined at various temperatures of 200, 300, 500, 70, and 800 °C for 5 h. The porous Au showed continuous interconnected open-pore structure maintaining the intrinsic porous nature of the agarose matrix under 500 °C. In addition, the EDS showed that the synthesized Au had negligible impurities. However, the Au nanoparticles were aggregated showing dough-like structure without pore at the temperatures greater than 500 °C. The chemical states of the Au structure calcined at 200 °C are identical to that of pure Au crystal, demonstrating peak of Au (0) $4f_{7/2}$ and Au (0) $4f_{5/2}$ at 83.5 eV and 87.2 eV. The crystal structure of the Au sponge was also examined by XRD and Rietveld refinements. The measured lattice distance was 4.0705 Å, which is similar value to that of bulk Au (4.07 Å) calculated by DFT calculations. The chemical features at the interface between Au and carbon from agarose were investigated using TEM-EELS analysis. The EELS spectra of agarose template are identical to that of amorphous carbon with two peaks at 285 eV, and 290 eV, corresponding to the transition energy to the π^* and σ^* molecular orbitals of sp^2 bonds. Near the Au-carbon interface, slight peak shift of amorphous C signal was observed, indicating negligible interaction or bonding between Au and agarose template. In the Au region, the EELS spectra demonstrated strong localized electron energies. Based on the above results, the agarose template takes an excellent roll as a sacrificial template providing porous structure without interaction with Au nanoparticles and retaining the porous structures of Au sponges. In summary, the agarose is highly attractive material for the production of macroporous pure metal sponges with simple heating method. Furthermore, agarose gel is nature abundant, bio-degradable, and mechanically strong compared with other natural polymers.

4:15 PM SB05.11.07
Liquid Crystal Mesophase in Supercooled Liquid Gallium and Eutectic Gallium Indium Muhammad Yunusa[1], Alex Adaka[2], Amirreza Aghakhani[1], Hamed Shahsavan[1], Yubing Guo[1], Yunus Alapan[1], Antal Jákli[2] and Metin Sitti[1]; [1]Max Planck Institute for Intelligent Systems, Germany; [2]Kent State University, United States

The unusual structure and property of supercooled liquid metals have baffled scientists for decades. Unravelling the origin of the structural ordering in supercooled liquid gallium (Ga) has been a great scientific quest due to the recent emerging applications of liquid metals in soft electronics and sustainable energy. Hitherto, the liquid crystal (LC) properties of liquid gallium and eutectic gallium-indium have remained elusive. Here, reflective polarized optical microscopy on liquid Ga sandwiched between two glasses treated with rubbed polymers reveals the onset of an anisotropic reflection at 120 °C that increases on cooling and persists down to room temperature or below. The polymer rubbing usually aligns the director of thermotropic liquid crystals (LCs) parallel to the rubbing direction. On the other hand, when liquid Ga is sandwiched between substrates that align conventional LC molecules normal to the surface, the reflection is isotropic, but mechanical shear force induces anisotropic reflection that relaxes in seconds. The anisotropic response of the cell under the influence of mechanical force results in realignment of the aligned structure. Such alignment effects and shear-induced realignment are typical to conventional thermotropic LCs and indicate a LC structure behavior of liquid Ga.
Albeit, powder X-ray diffraction (PXRD) measurement conducted on the liquid gallium shows a downward shift of sharp peaks during heating above 70 °C in a glass capillary, the diffraction pattern cannot be indexed for any known gallium oxide or gallium hydroxide phase structure. Thus, the diffraction result could be attributed to a fluidic smectic behavior of the Ga clusters or plate-like structures in the supercooled liquid with layer arrangement. The characterization of the lamellar structure via atomic force microscopy was employed to measure the layer thickness of the nanometer-thick transparent films. We have exfoliated transparent lamellar films of tens of nanometer by the use of PDMS and clean glass surfaces at RT. The liquid-phase exfoliated transparent lamellar layers are obtained with thickness up to 120 nm, and parallel to the PDMS surface. Specifically, Ga textures obtained by atomic force and scanning electron microscopy reveal the existence of a lamellar structure corresponding to a smectic LC phase, where the nanometer-thin lamellar structure is transparent under transmission polarized optical microscopy. Counterintuitively, the molecular behavior of LC-Ga enabled electro–optics switching, where an anisotropically reflecting state was induced via the application of 1.8 V μm^{-1} (DC) electric field at RT in between two ITO-coated glasses separated by 10 µm. Moreover, the homeotropic ITO cell was prepared by a polyimide (PI) polymer coating in which the electro–optical switching was realized by applying a square wave-alternating field (AC) of 1.9 V μm^{-1} at 0.5 and 1 Hz across the cell.
Such spatial molecular arrangements may be attributed to dimer or plate-like molecular entities in the supercooled liquid Ga. The LC structure observation of electrically conductive liquid Ga can provide new opportunities in materials science, energy and LC applications.

Microrororollers Make Motifs—Emergent Structure in a Driven Colloidal Suspension Michelle Driscoll; Northwestern University, United States

Does a rotating bead always spin in place? Not if that bead is small and near a surface: in this case, rotating leads to translational motion, as well as fast flows around the bead, even quite far away. These flows cause strong hydrodynamic coupling to nearby microrollers (rotating beads), which leads to a rich variety of collective effects. This system is experimentally realized by using magnetically actuated colloidal particles, and we find that these collective effects manifest as a wide array of emergent structure from shocks, to fingering patterns, to stable, hydrodynamically-bound clusters. We study these emergent structures using a variety of computational and experimental techniques, including Stokesian dynamics simulations and a coupled magnetic-optical imaging system. We find that in all cases, the scale of the emergent structures is set by a single geometric parameter: the height of the microroller above the surface. Recently, we have begun to study the interaction of microrollers with a structured environment, for example a forest of fixed obstacles or a sea of passive particles. In the case of fixed obstacles, we find a strong hydrodynamic trapping effect occurs in our experimental system, and we have used our simulation methods to characterize this trapping in detail. When the obstacles are free to move, we observe that the microrollers restructure the landscape around them, at length scales many times the size the roller.

Studies of Surface Wetting Phenomena Using Colloidal Crystals and Glasses Yilong Han; Hong Kong University of Science and Technology, Hong Kong

Colloids are outstanding model systems for the studies of phase transitions and related phenomena because Brownian motions of micrometer sized particles can be tracked by optical microscopy. Colloids with tunable attractions open the way to study solids' free surfaces. Here we experimentally observed three surface wetting phenomena at the single-particle level for the first time: premelting of crystal and glass, and pre-solid-solid transition. The latter two phenomena are proposed by us.
1. Crystal surface typically premelts into a thin liquid layer slightly before reaching the melting point. We find that the thickness of the premelted surface liquid diverges as a power law (i.e. complete premelting) for monolayer colloidal crystals, whearas saturates to a constant (i.e. blocked premelting) for bilayer and trilayer crystals [1]. Such behaviors are verified by simulation [2].
2. We propose that a crystal's surface can develop a thin layer of polymorphic crystal when the two crystals can form a coherent interface near their crystal-crystal transition point. We coin the word 'pre-solid-solid transition' because it is analogous to premelting or prefreezing with the same wetting mechanism: the total energy of the newly formed two interfaces is lower than the surface energy of the original solid. Although its mechanism is simple and should certainly hold, it is a blind spot in material science and can be viewed as the third type surface wetting precursor of phase transition. This phenomenon is confirmed by colloid experiments and simulations. The thickness of the surface crystal increases with the temperature as a power law, similar to premelting. It can also occur in nonequilibrium processes such as melting, crystallization and polycrystal annealing. We suggest several atomic and molecular crystals which may exhibit such phenomenon. Moreover, pre-solid-solid transition and premelting and can coexist under thermal equilibrium when two triple points are close [3].
3. Glass melting has been poorly explored experimentally at the single-particle level. We assemble monolayer and multilayer colloidal glasses by vapor deposition such that they are sufficiently stable to melt from the surface. Structural and dynamic parameters reach their bulk values at different depths, which define a surface liquid layer and an intermediate glassy layer. The thicknesses of both layers increase in power laws upon approaching the glass transition point by slow heating, similar to crystal premelting. This circumvents the ambiguity in distinguishing supercooled liquid and glass. Such power-law behavior has been reported in polymer glass melting, but was not called as premelting. Moreover, melting is studied by rapidly changing temperature across the glass melting temperature, and the melting front behaviors are similar to crystal melting [4].

Confinement-Induced Mechanical Phase Separation in Shear Thickening Suspensions Qin Xu and Haitao Hu; Hong Kong University of Science and Technology, Hong Kong

We experimentally investigated the rheology of confined granular suspensions during shear-thickening transitions. When the shear dimensions are reduced to tens of particle diameters, the dense suspensions show unexpected flow behaviors across multiple length scales in response to the physical confinements. On macroscopic scales, the stress-controlled shear rheology was highly dependent on the measuring time for each applied shear stress, and S-shaped flow curves were observed at steady states. At microscopic levels, by using boundary stress microscopy (BSM), we observed sustained local stress oscillations with a time interval of approximately twice the global rotation period of the shear plate. The temporal fluctuations were also associated with a dynamically evolved phase separation, which indicated the migrations of high-stress regions involving locally jammed suspensions. We further show that the non-monotonic flow curves and local stress oscillations will simultaneously reduce as the system size increases. The study shows how boundary confinements can induce sustained mechanical phase separation in dense suspensions, and therefore controls their global rheological properties.

Function Follows Form—Semiconductor-Free Electronics from Morphology Controlled Metal Assemblies Khalil ur Rehman[1,2,1], Yu-Ting Chiu[3], Lu-Hsi Wang[3], Radha Raman[4,1,1], Yueh-Yuan Li[2], Fang-Fei Chou[3], Ya-Ping Hsieh[1,1] and Mario Hofmann[2]; [1]Academia Sinica, Taiwan; [2]National Taiwan University, Taiwan; [3]Taipei First Girls' High School, Taiwan; [4]National Central University, Taiwan

Current electronics are inextricably linked to the carrier transport properties of
semiconducting materials. Novel requirements from wearable and ubiquitous computing applications, however, have highlighted the limitations of such materials in terms of scalable production, robustness, and achievable performance. We here demonstrate that complex electronic functionality can be achieved without the use of semiconductors. By controlling the connectivity 20 between metallic particles, emergent structures can be realized that exhibit directed carrier transport – a hallmark of semiconductor devices. Experimental realization of this prediction was
achieved in concentration gradients of percolative metal assemblies, where spatial changes in the number of neighbors produces distinct differences in conduction properties for carriers traveling with or against the direction of increasing concentration. This directed percolation process was 25 observed in both aqueous particle dispersions and solid-state particle/polymer composites and yielded electronic devices with performances comparable to conventional semiconductor diodes. Connectivity-controlled assemblies provide attractive alternatives to semiconductors due to their robustness, high carrier mobility and tunability of fundamental device properties. The underlying ratchet-like rectification process unexpectedly imparts metallic assemblies with sensitive light 30 detection abilities and opto-mechanical multifunctionality. Our advances not only open up a route
towards the ultra-large-scale production of future electronics but shed light at a century-old question about the foundation of electronic functionality.

Colour with a Twist Silvia Vignolini; University of Cambridge, United Kingdom

The most brilliant colours in nature are obtained by structuring transparent materials on the scale of the wavelength of visible light. By designing the dimensions of such nanostructures, it is possible to achieve extremely intense colourations over the entire visible spectrum without using pigments or colorants. Colour obtained through structure, namely structural colour, is widespread in the animal and plant kingdom. Such natural photonic nanostructures are generally synthesised in ambient conditions using a limited range of biopolymers. Given these limitations, an amazing range of optical structures exists: from very ordered photonic structures, to partially disordered, to completely random ones.
In this seminar, I will introduce some striking examples of natural photonic structures and share some insight on their development. Then I will review our recent advances to fabricate bio-mimetic photonic structures using the same material as nature. Developing biomimetic structures with cellulose enables us to fabricate novel photonic materials using low-cost polymers in ambient conditions. Importantly, it also allows us to understand the biological processes at work during the growth of these structures in plants.

Ultrafast Crystallization of Ordered Mesoporous Metal Oxides and Carbon Structures in Seconds Leyan Wang and Kwan Wee Tan; Nanyang Technological University, Singapore

Ordered crystalline mesoporous metal oxides and carbon materials face risks of mesostructral collapse as a result of untamed atomic migration during crystallization at high temperatures and long hours. We introduce a facile approach combining block-copolymer-directed self-assembly with electric Joule heating (SNAP method) to realize ultrafast crystallization of various ordered nanocomposite systems, including Al_2O_3-carbon, Al_2O_3/MgO-carbon, TiO_2-carbon, Fe_2O_3-carbon and carbon structures. Removing the carbon matrix yields fully inorganic ordered Al_2O_3 and TiO_2 structures. SNAP-derived ordered oxide and oxide-carbon structures samples exhibit high CO_2 capture and efficient Li-ion battery performances than their furnace-treated counterparts. The SNAP method enables high energy efficiency and time savings and generalizability to other functional materials combinations that would appeal to a wide range of applications such as catalysis, sensing and clean energy generation.

New Series of Electron Donor Conjugated Polymers Towards Improving the Performance and Stability of Organic Solar Cells Christos Chochos[1,2]; [1]Advent Technologies Inc, Greece; [2]Institute of Chemical Biology/National Hellenic Research Foundation, Greece

It will be demonstrated the development of a series of conjugated polymers based on the donor-acceptor (D-A) approach consisting of benzodithiophene and quinoxaline derivatives as the electron rich and deficient building block that when employed as electron donor components at organic solar cells exhibit high performance and stability, simultaneously. Moreover, it will be shown how the highest occupied molecular orbital (HOMO) can be precisely control by only an atom change at the side substituents. This allowed for a detailed analysis when matching the energy levels of polymer donors and small molecule acceptors. Therefore, we were able to investigate organic solar cells with highest occupied molecular orbital energy level offsets (ΔE_{HOMO}) between 0 - 300 meV. It will be shown that exciton quenching at negligible ΔE_{HOMO} takes place on timescales approaching the intrinsic exciton lifetimes, drastically limiting external quantum efficiency. This finding it is quantitatively described via the Boltzmann steady-state equilibrium between charge transfer states and excitons and further reveal a long exciton lifetime as a decisive design criterion for maintaining efficient charge generation at negligible ΔE_{HOMO}. Moreover, the Boltzmann equilibrium quantitatively describes the major reduction in non-radiative voltage losses at very small ΔE_{HOMO}.

Development of Deuterated Non-Fullerene Acceptors for Use in Selective Tracking of Morphological Changes in Organic Photovoltaic Active Layer Blends Matthew W. Bidwell[1], Zhengxing Peng[2], Andrej Classen[3], Thomas Heumueller[3], Christoph J. Brabec[3], Harald Ade[2] and Iain McCulloch[4,1,5]; [1]Imperial College London, United Kingdom; [2]North Carolina State University, United States; [3]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [4]University of Oxford, United Kingdom; [5]King Abdullah University of Science and Technology, Saudi Arabia

Organic semiconducting polymers and small molecules have shown a remarkable ability to act as photoactive components in organic photovoltaic (OPV) devices over the past decade, with widespread efficiencies of 18-19% for binary OPV systems which have rapidly approached the fabled 20% efficiency threshold needed for OPV technology commercialisation. Overall, there has been a paradigm shift in OPV device performance from 8% in 2012 to over 20% PCE in 2022.[1] This step-change has been propelled by the development of novel electron-accepting (n-type) materials, moving away from fullerene-based acceptors ($PC_{60}BM$/$PC_{70}BM$) to emerging third-generation OPV materials, known as non-fullerene acceptors (NFAs). These NFAs are typically composed of rigid electron-rich fused aromatic ladder-type cores with electron-deficient end groups such as ITIC and IDTBR, most notably with the recent emergence of a new family of high-performance Y6 NFA materials. However, the monumental increase in device efficiency has not been in lock-step with donor polymer:NFA solar cell device stability, which often show poor tolerance to oxygen, UV-light, thermal stimuli, and water which lead to photo-oxidative and chemical degradation, alongside thermodynamic instabilities in the photoactive blend, which remains a critical bottleneck towards real-world commercialisation of OPV technologies.[2]

This work presents a series of NFAs with deuterated side chains (d-NFAs), based on O-IDTBR and EH-IDTBR hydrogenated acceptors (h-NFAs), which share the same physical and optoelectronic properties as their hydrogenated counterparts and allow them to act as ideal proxies for accurately representing the h-NFAs within the chosen polymer:NFA blend morphologies. Understanding the morphological and chemical stability of donor polymer:NFA OPV blend systems is critical to optimising the delicate balance between the donor and acceptor blend mixing in devices, which is crucial for both long-term operational stability and high performance. With this in mind, the d-NFAs were selectively blended with the donor polymers Poly(3-hexylthiophene) (P3HT) and PffBT4T-2OD (PCE11) in OPV devices which were then sealed in degradation chambers under N_2 and placed under environmental stress, either via light soaking under AM 1.5 G or heating at 80 °C in the dark for 100-1300 hrs with continuous tracking of the device's J-V performance. This was done in order to decouple chemical and morphological changes in the active layer blend due to photo-degradation and thermal morphological demixing processes, which were then selectively investigated by ToF-SIMS (Time-of-Flight Secondary Ion Mass Spectrometry) and photoluminescence measurements.

Both sets of P3HT:d-IDTBR and PCE11:d-IDTBR active layer systems demonstrated excellent long-term thermal stability in the dark, with no significant losses in PCE, which was further corroborated through vertical and lateral ToF-SIMS measurements which showed no discernable phase separation of the d-NFAs from the donor polymers. Similarly for the light-aged devices, there were no notable losses in PCE which was further confirmed by ToF-SIMS measurements. The results suggest that overall P3HT:d-IDTBR and PCE11:d-IDTBR active layer blend systems are chemically and morphologically stable and that using deuterated NFAs is an effective methodology for probing blend morphologies of systems with polymers and NFAs that possess very similar chemical structures and heteroatoms. Future work would involve utilising d-NFAs as third components in ternary OPV blends with d-Y6 and similarly

tracking the morphological evolution of this component in active layer blends as a function of thermal and light aging conditions.

Homoconjugated Non-Fullerene Acceptor Compounds with Very High Molar Extinction Coefficients Stefan Warrington and Iain A. Wright; Loughborough University, United Kingdom

Development of novel molecular and macromolecular materials for optoelectronic devices is an exciting field constantly evolving and motivated by an increasing understanding of the physical processes involved in how light and matter interact. The optoelectronic properties of organic semiconductor materials underpin their utility. This can be tuned and optimized using structural motifs and molecular design.

The development of new materials for organic solar cells (OSCs) has continued to expand rapidly in recent years driven by the emergence of non-fullerene acceptors as highly efficient components of these devices. Multi fused aromatic systems lead the way in high power conversion efficiency devices, most notably the non-fullerene acceptor Y6.[1] These materials design motifs such as fused electron deficient cores with strongly electron accepting arms facilitate high extinction coefficients and efficient charge transport lending valuable design rules for developing new high-performance materials.

Homoconjugation across electron poor iptycene cores has been shown to induce an intramolecular charge transfer (ICT) state through a delocalized LUMO increasing the probability of transitions to and from this ICT state.[2] This has been demonstrated to lead to super-summative enhancements in molar extinction coefficients and oscillator strength compared to non-homoconjugated chromophores and revealed a new approach to circumventing the energy gap law in low band gap delayed fluorescent emitters.[3]

Here we present a new generation of homoconjugated ICT molecules designed for use as non-fullerene acceptors in OSC devices.

10.6% Organic Solar Cells Fabricated from Nanoparticle Dispersions Enabled by Electrical Doping Felix Manger, Philipp Marlow, Karen Fischer, Jonas Armleder, Christian Sprau and Alexander Colsmann; Karlsruhe Institute of Technology, Germany

Solution processing from nanoparticle dispersions allows the use of eco-friendly processing agents for the deposition of organic semiconductor thin-films for photovoltaic and other optoelectronic applications. Omitting surfactants to stabilize the dispersions is essential to not jeopardize the solar cell performance. So far, solar cells could only be fabricated from surfactant-free P3HT dispersions which show some intrinsic self-stabilization. In this work, the self-stabilization of P3HT nanoparticle dispersions is demystified, and electrostatic effects are identified as the origin of self-stabilization. By application of this gained knowledge, novel surfactant-free nanoparticle dispersions from other, high-performance organic semiconductors are synthesized by nanoprecipitation. Electrical doping warrants the electrostatic stabilization of the dispersions. For the first time, the corresponding solar cells achieved power conversion efficiencies of up to 10.6%, demonstrating the general feasibility of this alternate, all-eco-friendly processing route.

SESSION SB06.02: Device Physics and Engineering
Session Chairs: Thuc-Quyen Nguyen and Safa Shoaee

1:30 PM *SB06.02.01
Understanding Materials from the Device's Point of View and Vice Versa Sapir Bittons, Dan Liraz, Gil Sheleg and Nir Tessler; Technion-Israel Institute of Technology, Israel

Often one studies the chemical physics of materials with the goal to improve or understand their performance in a device, be it a solar cell or a field effect transistor. However, when we operate and measure the device performance, the device implements a very specific filter on the chemical or physical processes. The device structure and its operation conditions would decide on the relative importance of processes, and not less importantly on how the microscopic properties are being averaged to produce the device's output. I will demonstrate the above philosophy through examples like:
1) The standard FET operates with the current being a drift current. I will present a device structure where the current is determined by diffusion. Interestingly, the source operates as a pressure hose.
2) The exciton binding energy that organic bulk-heterojunction device "sees" is very different to what one would measure through careful (possibly irrelevant) measurements.
3) Mobility imbalance in solar cells was an important topic 20 years ago. It is time to move on.
4) Perovskite devices have rich electrochemistry. Trying to incorporate it into a device model tends to raise more questions than answers. Should we worry about it?

2:00 PM SB06.02.02
Device Physics of Dilute-Donor Narrow Band Gap Organic Solar Cells with Highly Transparent Active Layers Nora Schopp[1], Gulnur Akhtanova[2], Thuc-Quyen Nguyen[1] and Viktor Brus[2]; [1]University of California Santa Barbara, United States; [2]Nazarbayev University, Kazakhstan

Organic Photovoltaics (OPVs) offer sustainable, solution-processable, and cost-effective energy harvesting solutions. While opaque devices underwent enormous progress in the past decade, it remains a challenge to meet the high transparency requirements for integrated semitransparent OPVs for windows, skylights, or greenhouses, and only a few examples with average visible transmittance (AVT) over 60% exist. Moreover, a systematic understanding of the photoelectronic processes in visibly transparent devices is still absent. In this work, we investigate the generation-recombination dynamics in three semitransparent blend systems with varied donor concentrations to understand their performance limitations. [1]
Specifically, we study charge generation, multi-mechanism recombination, and extraction in three OPV systems that are based on an ultra-narrow non-fullerene acceptor COTIC-4F and a polymer donor that absorbs in the visible range PCE10. The systematic reduction of the donor content from 40% to 30% and 20% leads to highly transparent active layers with blend AVTs of 64%, 70%, and 77%, respectively. Opaque devices in the optimized highly-reproducible device configuration comprising these transparent active layers lead to PCEs of 7.0%, 6.5%, and 4.1%. The investigation of these structures yields quantitative insights into changes in the charge generation profile, non-geminate recombination losses via the bimolecular, bulk and interface trap-assisted mechanisms, and extraction dynamics upon dilution of the donor. Lastly, we give an outlook for employing the highly transparent active layers in semitransparent OPV devices.

Hole Transport-Limited Electrochemical Doping in Conjugated Polymers Scott T. Keene[1], Joonatan Laulainen[1], Raj Pandya[1,2], Maximilian Moser[3], Christoph Schnedermann[1], Paul Midgley[1], Iain McCulloch[3], Akshay Rao[1] and George G. Malliaras[1]; [1]University of Cambridge, United Kingdom; [2]École Normale Supérieure, France; [3]University of Oxford, United Kingdom

Organic mixed ionic electronic conductors (OMIECs) have recently risen as a promising material choice for bioelectronic devices due to their low impedance, soft mechanical properties, and ability to transduce ionic signals to electronic currents. These materials properties have enabled the development of high-performance devices for electrophysiological recordings, chemical sensing, cell monitoring, energy storage, and neuromorphic devices. The unique behaviour of OMIECs arises from ion intercalation through the bulk of the material which can modify the oxidation state, and therefore charge carrier concentration, of the conjugated polymer backbone. However, the current understanding of the dynamics of mixed charge transport remains limited.

The lack of mechanistic understanding of mixed transport hinders rational design of OMIECs, where assumptions must be made to assess their performance. For instance, in most semiconducting electrodes, mixed transport is assumed to be limited by ion motion due to their large effective mass compared to electrons/holes. Here, we show that this basic assumption does not hold for conjugated polymer electrodes. Using *operando* optical microscopy to differentiate between ionic and electronic transport, we reveal that, at low hole densities, electrochemical doping is limited by filling of low energy, low mobility hole sites. We show that the transition from hole- to ion-limited doping is determined by the degree of heterogeneous disorder in the polymer microstructure. Further doping leads to four orders of magnitude increase in hole mobility, resulting in an inversion from hole to ion-limited doping. This transition between hole and ion transport-limited doping results in much slower switching than expected for electrochemical devices employing otherwise high-performing materials. The results help inform the ideal microstructural features to optimize performance of electrochemical devices across their full range of operation.

2:30 PM SB06.02.04
Dual-Mode Organic Electrochemical Transistors Based on Self-Doped Conjugated Polyelectrolytes for Reconfigurable Electronics Tung Nguyen-Dang[1], Sangmin Chae[1], Jirat Chatsirisupachai[2,1], Vinich Promarak[2], Hiba Wakidi[1], Yon Visell[1] and Thuc-Quyen Nguyen[1]; [1]University of California, Santa Barbara, United States; [2]Vidyasirimedhi Institute of Science and Technology, Thailand

Dual mode transistors, the type of transistors that work in both depletion mode and enhancement mode, were reported more than 50 years ago using inorganic semiconductors (with silicon in 1963 and with III-V semiconductors in 1966). Thus far however, this type of devices has not been shown in organic electronics. In this talk, we report the dual mode organic transistors based on organic electrochemical transistors (OECTs) using self-doped conjugated polyelectrolytes as the active material. Via spectroelectrochemistry, we revealed a unique dual ionic transport property of these materials: they can be both doped and dedoped upon the interaction with anions and cations in an electrolyte. This property enables dual-mode functionality in OECTs, whose mode switching is accomplished by simply altering the polarity of the applied gate and drain voltages. Furthermore, we developed a device physics model which accurately describes the behavior of these transistors. We also demonstrated the utilization of dual-mode organic transistors in reconfigurable electronics by fabricating logic gates that could be switched between AND and NOR, and OR and NAND on the fly. Being simple, power efficient, and compatible with high throughput microfabrication techniques, dual mode OECTs are a promising candidate for the next generation of efficient computing systems and adaptive electronics.

2:45 PM BREAK

3:15 PM *SB06.03.01
Static Disorder, Dynamic Disorder, Wavefunction Delocalisation—Using Optical Spectroscopy to Assess Their Influence on Charge Transfer States in Organic Solar Cell Materials Julian Kahle[1], Alexander Rudnick[1], Rishabh Saxena[1], R. Ammenhäuser[2], U. Scherf[2], Sergey Bagnich[1], Heinz Bässler[3], S. Athanasopoulos[4] and Anna Köhler[1,3,3]; [1]University of Bayreuth, Germany; [2]Universität Wuppertal, Germany; [3]Universität Bayreuth, Germany; [4]Universidad Carlos III de Madrid, Spain

Charge transfers (CT) states play a key role in organic solar cells (OSC). In this presentation, I shall demonstrate how we can use time-dependent photoluminescence measurements to identify the contributions of static and dynamic disorder in charge transfer states and their spectra. Notably, from the temperature and time dependent linewidths of absorption, fluorescence, and CT emission, we infer the static and dynamic contributions to the total disorder. We discuss the role of spectral diffusion in this process. The impact of intermolecular interactions and excited state delocalisation will also be addressed.

3:45 PM SB06.03.02
Static and Dynamic Disorder in Thermal Vacuum Evaporated Organic Solar Cells Anna Jungbluth[1], Pascal Kaienburg[1], Andreas E. Lauritzen[1], Ming Zhu[1], Irfan Habib[1], Francis Otieno[2] and Moritz Riede[1]; [1]University of Oxford, United Kingdom; [2]University of the Witwatersrand, Johannesburg, South Africa

Organic solar cells (OSCs) have attracted interest over the last decades for their ease of processing and potential to generate inexpensive electricity for a growing population [1]. However, the commercial success of OSCs has long been hindered by their low power conversion efficiencies (PCEs). The main reasons for low PCEs are radiative and non-radiative energy losses of 100s meV that usually occur via charge transfer (CT) states at the interface between donor (D) and acceptor (A) molecules.
The origin of the CT state linewidth, and its influence on device performance, is still heavily debated [4]. Usually, broad spectral tails and large Stokes shifts between absorption and emission spectra are indicative of energetic disorder that negatively impacts charge transport, recombination, and the open-circuit voltage [4]. This energetic disorder can be classified into dynamic (temperature-dependent) and static (temperature-independent) contributions. While some work found negligible static disorder in OSCs [4], [6], other work observed the opposite and reported static disorder contributions of 50-150 meV [7], [8], [9].

In this work, we revisit the debate on dominant contributions to energetic disorder for small molecule OSCs. Using vacuum deposition techniques, we fabricate solar cells based on blends of C60 and donors like TAPC, α-Sexithiophene, DCV5T, CuPc, and Rubrene that show representative and comprehensive electronic and microstructural properties. By fabricating devices with 5 mol.% and 50 mol.% donor content, we study the impact of energetic disorder in dilute donor and intermixed D:A blends. We quantify electronic disorder by fitting temperature-dependent external quantum efficiency (EQE) spectra via semi-classical Marcus Levich Jortner theory.
We find that static disorder presents a dominant contribution to the CT state linewidth across our materials systems. In addition, by coupling our device data to grazing incidence wide-angle X-ray scattering (GIWAXS) measurements, we find larger energetic disorder for aggregating than for amorphous donors. Finally, we highlight the need for reducing energetic disorder to achieve lower voltage losses in both fullerene- and well-performing non-fullerene-based blends.

Engineering an Injecting Layer for Light-Emitting Field Effect Transistors Lauren Miller and Mujeeb Chaudhry; Durham University, United Kingdom

Light-emitting field effect transistors (LEFETs) integrate transistor logic with the light emission of an organic light-emitting diode (OLED). Their dual functionality has the potential to simplify circuitry in several high-end applications, such as next generation displays. LEFETs incorporate a wide range of materials as the charge transporting and light-emitting layers within its complex device architecture. These include small molecules, polymers, single crystals, oxides and perovskites. However, LEFETs reported to-date suffer from poor external quantum efficiencies (EQEs), as balanced charge transport and injection into the light-emitting layer are difficult to realise.

Herein, we report an effective method for improving charge injection into hybrid LEFETs, comprising a n-type metal oxide layer for electron transport and a conjugated polymer for light emission. LEFETs exhibit charge carrier mobilities in the range of 10 $cm^2V^{-1}s^{-1}$, on/off ratios above 10^5 and low threshold voltages. Furthermore, a maximum EQE of 2 % was achieved at a brightness of 2500 cdm^{-2}. These devices show a significant improvement in key performance parameters and are a significant step towards the development of highly efficient LEFET technology.

Functional Patterning of Graphene via an All-Supramolecular Strategy Quentin Fernez[1], Shiva Moradmand[2], Céline Fiorini-Debuisschert[3], Fabrice Charra[3], Imad Arfaoui[2] and Lydia Sosa Vargas[1]; [1]Sorbonne Université -CNRS, France; [2]Sorbonne Université-CNRS, France; [3]Université Paris-Saclay, CEA-CNRS, France

Surface-confined, supramolecular self-assembly has been the focus of extensive research in the past decade[1]. A number of strategies have been developed and reported for surface patterning leading to novel applications in molecular electronics, photonics and nano-mechanical devices.[2] Despite

this, we are still at the early stages of exploiting them in viable, practical technologies since we are limited by their inability to form reproducible, ordered, integrated systems [3]. More specifically, in the case of graphene, we also have to overcome the strong charge transfer that occurs when electronically-active molecules are adsorbed on its surface.
To address this problem, we have developed a series of molecular dyads that can form ordered assemblies on graphene-like substrates and also bear an emissive component located out-of-the plane of the substrate. These dyads are held together via non-covalent interactions, which enable us to easily mix & match the components, resulting in a highly tunable system.
This relatively simple design allows us to control the orientation and distance of an emissive component above a graphene-like substrate through different supramolecular interactions and opens up an accessible route to electronically de-couple an optically-active molecule from graphene.[4]

Nanoscale Electrical Characterization of Organic and Hybrid Materials for Energy Applications Philippe E. Leclere, Van Dang Tran and Sy H. Pham; University of Mons, Belgium

The recent development of alternative sources of energy to fossil ones will play a crucial role in global electricity generation and should be one of the global strategies to reduce CO_2 emissions and stop climate change. To develop efficient and competitive modern electronics from semiconducting (organic, inorganic, or hybrid) materials for energy conversion and storage (flexible) devices, it is essential to understand the relationships between molecular architecture, supramolecular organization, microscopic morphologies, and optoelectronic properties in detail.
By using AFM-derived techniques (such as Conducting AFM, Kelvin Probe Force Microscopy – KPFM, and Scanning Microwave Impedance Microscopy - sMIM), electrical properties can be measured at the local scale (together with the morphological and mechanical characterization of the samples) helping the optimization of the device performances. For instance, for photovoltaic organic devices, we can spatially resolve by KPFM the surface photo-voltage in high-efficiency nanoscale phase segregated photovoltaic blends of conjugated polymers. We show on poly(thiophene)-based organic and hybrid systems how the lateral resolution in KPFM and in the photo(conducting) AFM can allow direct visualization of the carrier generation at the donor-acceptor interfaces and their transport through the percolation pathways in the nanometer range.
In fine, to fabricate flexible devices, we considered the high performances of flexible Transparent Conductive Electrodes (TCEs) based on silver nanowires (AgNWs) percolation networks. With optimized experimental conditions for the deposition, the AgNWs-based electrodes show low sheet resistance of 10 Ohm/sq combined to a high optical transmittance of 92.6% at $\lambda = 550$ nm. This leads to a valuable figure of merit as compared to other TCE's and the electrodes were successfully used for flexible organic and perovskite-based solar cells and light-emitting diodes.

5:00 PM *SB06.03.06
Probing Light-Matter Interactions in Hybrid Perovskites Marina S. Leite; University of California, Davis, United States

Metal halide hybrid organic-inorganic perovskites display near-optimal optical properties for optoelectronic devices, including photovoltaics and light-emitting diodes. Yet, this class of material has not been commercialized due to often-seen degradation. Overall, establishing the correlation between structure and optoelectronic performance is essential and requires the implementation of in situ characterization techniques that can assess material-light interactions. At the nanoscale, we realize atomic force microscopy (AFM) methods that enable us to resolve how grains and their boundaries are affected by photo-induced processes, such as ion migration. Through Kelvin-probe force microscopy we quantify spatial variations in photo-voltage. In the realm of material stability, we use high-throughput and automated optical measurements, such as steady-state photoluminescence (PL) and PL lifetime to monitor the effects of environmental stressors in hybrid perovskites. Here, we submit the material to distinct values of temperature and relative humidity and monitor, *in situ*, their optical response. We implement machine learning neural networks to forecast material behavior. The vast hyper-parameter space of hybrid perovskites' chemical composition is benefiting tremendously from artificial intelligence methods. To illustrate how one can gain understanding about the physical behavior of perovskites, we will showcase baseline models that apply machine learning, encompassing how to predict device power output as a function of temperature and how to find hidden correlations between property (electrical conductance) and dark-field optical images of material morphology.

SESSION SB06.04: Poster Session I
Session Chairs: Philippe Leclere and Caterina Soldano

SB06.04.01
Chemical Synthesis of All-Peptide-Based Rotaxanes from Proline-Containing Cyclic Peptides. Taichi Kurita[1], Masahiro Higashi[1], Joan Gimenez-Dejoz[2], Seiya Fujita[1], Hirofumi Sato[1], Hirotaka Uji[1] and Keiji Numata[1,2]; [1]Kyoto University, Japan; [2]RIKEN CSRS, Japan

Mechanically interlocked molecules have a unique dynamic nature while permanently maintaining a spatial association between the components. This characteristic has been exploited to synthesize slide-ring materials [1] and molecular machines [2] with excellent properties that cannot be achieved with covalently bonded molecules. In the field of synthetic polymers, various mechanically interlocked molecules have been synthesized and applied in a wide range of fields. On the other hand, in the field of peptides and proteins, the synthesis of mechanically interlocked peptides is still difficult, although the construction of assemblies and host-guest chemistry, such as cation recognition, using cyclic peptides have been widely investigated [3,4]. Kimura et al. and Thomson et al. reported the synthesis of rotaxane using cyclic peptides [5,6]. However, all of them used synthetic polymers as the axis molecules, and there are no examples of chemical synthesis of all-peptide-based rotaxanes. This is because peptides do not have a strong mutual recognition motif. Recently, Leigh et al. reported that nucleophilic acyl substitution reactions between primary amines and electrophiles in the presence of crown ethers led to the synthesis of rotaxanes via axle-forming reactions inside the ring [7]. The characteristic feature of this method is that the crown ether forms a hydrogen

bond with the primary amine to enhance nucleophilicity, and the crown ether stabilizes the positive charge developing in the reaction intermediate on the axle-formation reaction, enabling the synthesis of rotaxane even with relatively weak interactions.
In this study, we designed and synthesized cyclo[PGPGPGPGPC(StBu)], having an alternating sequence of proline and glycine, which is a cation recognition motif [4]. This cyclic peptide was mixed with a primary amine and a nucleophile. Electrospray ionization mass spectrum of the mixture showed a peak corresponding to rotaxane, suggesting that rotaxane was formed. The yield was calculated to be 0.19% by high-performance liquid chromatography. To estimate the reaction mechanism, ^{1}H NMR titration experiment was performed. The binding constant of cyclo[PGPGPGPC(StBu)] for primary amines was calculated to be 27 ± 2 M^{-1}, which is not significantly different from the binding constant of 24-crown 8-ether for primary amines (32 ± 2 M^{-1}) [4]. This result suggests that the primary amine binds to the cyclic peptide via hydrogen bond in the initial state of the reaction. Although the nucleophilic acyl substitution reaction inside the cyclic peptide is considered sterically unfavorable, the rotaxane is presumably synthesized by two factors: hydrogen bonding to the cyclic peptide would enhance the nucleophilicity of the amine, and the cyclic peptide stabilizes the positive charge developing in the tetrahedral intermediate. In the current presentation, we will also present the influence of ring members and the solution structure of the cyclic peptide on the rotaxane-forming reaction.

SB06.04.02
Donor-Acceptor Type Molecules for High Performance Green-Light-Selective Organic Photodiodes Younhee Lim[1], Sungyoung Yun[1], Daiki Minami[2], Taejin Choi[1], Hyeong-Ju Kim[1], Jisoo Shin[1], Chul-Joon Heo[1], Kyung-Bae Park[1] and Byoungki Choi[1]; [1]Samsung Advanced Institute of Technology, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of)

The specific properties of organic semiconductors, such as the color tenability, mechanical flexibility, and low-cost process-ability, have attracted interest for future optoelectronic device applications. In particular, the dipolar donor (D)–acceptor (A) approach is a representative and powerful strategy to design the wavelength-selective organic absorbers, as the optical and electrical properties of the D–A type materials can be tuned using an appropriate combination of D and A moieties. Herein we report dipolar donor (D)-π-acceptor (A) molecules for application to green-light-selective organic photodiodes (OPDs). Novel p-type molecules combined with two types of fused heterocyclic donors and an electron-accepting unit has been synthesized and characterized. The molecules exhibit cyanine-like properties that are characterized by intense and sharp absorption. This molecular design leads to improved absorption properties, thermal stability, and higher photoelectric conversion compared to those of a molecular design based on a non-fused ring. A maximum external quantum efficiency of 66% (λ_{max} = 550 nm) and high specific detectivity (D*) of 8 × 10^{13} cm $Hz^{1/2}$/W are achieved in an OPD consisting of a bulk heterojunction blend of the p-type molecule and fullerene (C_{60}). Finally, the green-light-detection capability of the green-selective OPD is demonstrated by the optical simulation of a stacked-type organic-on-Si hybrid full-color photodetector comprising the green-light-selective OPD and a bottom Si photodiode with only blue and red color filters.

SB06.04.03
Development of High-Performance Near-Infrared Organic Phototransistors Using Diazapentalene-Containing Ultralow-Band-Gap Copolymers Doyoung Lee[1], Seoyoung Kim[2], Jungho Lee[2], Yongjoon Cho[2], So-Huei Kang[2], Wonbin Choi[1], Joonhak Oh[1] and Changduk Yang[2]; [1]Seoul National University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of)

Absorbing near-infrared (NIR) range (760-1100nm) low-band-gap π-conjugated polymers are an interesting family of semiconductor materials and have opened up possibilities of being used in various functional optoelectronic applications, such as organic field-effect transistors (OFETs), organic photodetectors (OPTs), and electrochromic devices. Incorporating a quinoid structure into the polymer backbone is one of the powerful strategies for reducing the band gap, which has been verified by theoretical and experimental studies of the well-known poly(isothianaphthene) and poly-(thieno[3,4-b]pyrazine), which exhibit band gaps of less than 1.0 eV. However, such quinoid-type polymers typically have a very small band gap and poor stability toward oxidation, which renders them difficult to be employed in the aforementioned devices. Alternatively, utilizing donor-acceptor (D-A) interactions is recently widely employed in low-band-gap polymers, owing to its unique possibility of tuning the energy levels almost independently as well as their band gaps. But because of the limited availability of synthetic strategies and strong acceptor units, constructing new types of low-band-gap donor−acceptor-type copolymers for use in multiple functional applications remains a big challenge.
Herein, we report the synthesis, characterization, and optoelectronic applications of a novel class of ultralow-band-gap copolymers (PDAP−Fu, PDAP−Th, and PDAP−Se) on the basis of the unique, interesting, yet rarely researched bicyclic 2,5-diazapentalene (DAP) strong acceptor in conjugation with chalcogenophene donors (furan (Fu), thiophene (Th), or selenophene (Se)). All of the copolymers exhibit broad NIR absorption and optical band gaps as low as ∼1.0 eV. The effects of the actual chalcogen atoms on the geometry, optical properties, energy levels, and film organization are carefully determined for OFET and OPT applications. Regarding the OFET studies, all of the copolymers show unipolar transport behavior in bottom-gate and top-contact OFETs, and PDAP−Se exhibits the highest hole mobility of 4.76 × 10^{-1} cm^2 V^{-1} s^{-1} , with grazing-incidence X-ray diffraction (GIXD) data demonstrating a three-dimensional (3D) charge-conduction channel through the edge-on and face-on mixed large crystallites. Besides, investigations of the OPTs indicate that a high photoresponse is achieved for all of the copolymers at a wavelength of 1060 nm in the NIR spectral region combined with an excellent external quantum efficiency (η) and photodetectivity (D*). This is particularly true for PDAP−Se (η =6.56 × 104% and D* = 1.80 × 1012 Jones). It demonstrates that NIR light facilitates the photocurrent generation in DAP-based OPTs with good photochemical stability as shown by Fourier-transform infrared (FT-IR) and UV-vis-NIR spectra of the copolymer thin films before and after irradiation with 1060nm light for 24h. Thus, such ultralow-band-gap copolymers are promising candidates for use in integrated circuits and optoelectronic devices, ultimately realizing the potential benefits of the DAP-accepting unit as a conjugated backbone.

SB06.04.04
Paper-Based Wearable Ammonia Gas Sensor Using Iron(III)-Added PEDOT:PSS Hajime Fujita[1], Meiting Hao[2], Shinji Takeoka[2], Yuji Miyahara[3], Tatsuro Goda[4] and Toshinori Fujie[1]; [1]Tokyo Institute of Technology, Japan; [2]Waseda University, Japan; [3]Tokyo Medical and Dental University, Japan; [4]Toyo University, Japan

Paper electronics hold great potential that could replace conventional plastic electronics. Paper electronics are disposable and cost-effective, two distinct advantages for developing broadly accessible devices. However, the approach for functionalizing paper with electronic materials has not been sufficiently characterized from a chemical point of view. As a result, most paper-based electronic devices have an inferior electrical performance compared with plastic-based devices, which largely constrains their practical use. The design and fabrication of electronic materials on paper needs refinement to make

paper electronics a valid, practical option. Here, we report a high-performance, paper-based, wearable ammonia sensor comprising composite poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) and iron(III) compounds. We combined different printing and coating methods to develop the ammonia-sensitive, composite substance PEDOT:PSS:Fe^{3+} on paper. Our sensor achieves 10-times smaller size than the conventional sensor on Kapton film and high tolerance for humidity without impairing practical sensor response. We demonstrate the utility of our device toward wearable ammonia-sensing in a facial mask and a nasal filter; wireless battery-free monitoring of food spoilage; and wireless battery-free monitoring of the ammonia level in a paper diaper. All the comprising materials—cellulose paper, PEDOT:PSS, and iron(III) compounds—are abundant and eco-friendly, a further benefit for applications in which biological tissues or disposable wearable products are eventually discarded with the sensor attached. Our approach may open the door to advanced healthcare based on ubiquitous wearable sensing.

SB06.04.05

Organic Devices for Solar Energy Conversion and Storage Fengling Zhang[1], Nannan Yao[1], Leiqiang Qin[1] and Yanfeng Liu[1,2]; [1]Linköping University, Sweden; [2]NingboTech University, China

Flexible organic solar cells (OSCs) made on plastic substrates with traditional printing techniques can be semitransparent and have broader applications than their inorganic counterparts. After the power conversion efficiencies (PCEs) of bulkheterojunction (BHJ) OSCs reached 19 % with non-fullerene acceptors (NFAs), a major challenge to further increase PCEs to >20% is how to reduce charge recombination in the BHJs. In the past 20 years, we have been working on optimizing processing of fullerene/non-fullerene OSCs and studying device physics to deepen understand on the mechanism of devices for enhancing the power conversion efficiency.
In my presentation, I will introduce our recent progress on organic devices for solar energy conversion and storage.

1. Monitor morphology formation of BHJ
To understand the BHJ morphology formation during solution processing, we studied three BHJ systems with the same donor PBDB-T and three different acceptors ($PC_{71}BM$; IT-M and N2200) via monitoring the morphology evolution during blade coating with a versatile in situ spectroscopy by recording photoluminescence (PL) and laser scattering (LS) signal, which indicated that the component with higher molecular weight dominates the blend film formation and the final morphology. (Liu et al., *Small Methods*, 2021, 2100585, https://doi.org/10.1002/smtd.202100585)

2. Dilute donor NFA OSCs
The morphology and Donor/Acceptor ratio are crucial for PCEs of OSCs. In our recent work, we surprisingly found that the PCE is tolerant to PM6 contents ranging from 10 to 60 wt % in the OSCs based on PM6:Y6. Most surprisingly, a PCE over 10% was achieved in OSCs with only 10 wt% donor. The findings indicate low dependence of composition on charge generation, transport and extraction in NFA OSCs. (Yao et al., *J. Phys. Chem. Lett.* 2021, 12, 5039, https://doi.org/10.1021/acsaem.1c03017) It's worth to note that even with large domains, the blends with low donor contents can still yield J_{sc} approaching 20 mA cm^{-2}. As the emerging NFAs have been demonstrated with long exciton diffusion length (Firdaus, Y. et al. *Nat. Commun.* 2020,11, 5220), therefore, the charge generation process is more tolerant to the domain size. The findings are significant in the context of enabling large processing window, which is essential in a later scale-up stage, since it means lower sensitivity to compositional variations.

3. The Sunlight varies with time, season, and location on the earth. To extend the application of organic solar cells, storing electricity converted from the sunlight is necessary. Super-capacitors are components, which can store electricity. We developed hybrid super-capacitors based on MXene and polymers as well as integrating organic solar cells with super-capacitors (Photo-supercapacitors (PSCs)). Flexible semitransparent photovoltaic supercapacitors based on water-processed MXene electrodes were realized. The photovoltaic and storage performance of the PSC has potential applications as portable power units to charge low power consumption electronics/IoT. (L. Qin et al, J. Mater. Chem. A, 2020, 8, 5467, https://doi.org/10.1039/d0ta00687d)

SB06.04.06

Characterization of Organic Semiconducting Photoelectrodes for Electrically Floating Phototransduction Inside Biological Tissues Luca Bondi[1], Maria Rosa Antognazza[2], Edgar Gutierrez Fernandez[3,4], Beatrice Fraboni[1], Jaime Martín[3,4], Camilla Marzuoli[2,5], David Mecerreyes[3,4], Gabriele Tullii[2] and Tobias Cramer[1]; [1]University of Bologna, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]University of the Basque Country, Spain; [4]POLYMAT, Spain; [5]Politecnico di Milano, Italy

Photoactive organic semiconductors are envisioned as a novel class of materials able to transduce light into stimulating signals inside biological cells or tissue [1]. These materials stand out due to their high optical absorbance coefficients, mechanical flexibility, ability to operate in a wet environment, and potential biocompatibility, enabling ultrathin and minimally invasive form factors not accessible with traditional inorganic materials. The chemical and physical nature of the interface between the semiconductor and the electrolyte gives rise to different, competing electrochemical phenomena. We addressed the problem considering polymeric as well as molecular organic materials in the form of both single-layer and p/n junction thin-films [2]. These are material systems that have been recently demonstrated to achieve the photomodulation of cardiac regeneration processes [3] or retinal neurons response [4]. The aim of our research is to unveil the fundamental processes that govern these photoactive devices and to develop both explicative and predictive models, which are necessary for the development of freestanding photoelectrodes, requiring no wiring or external bias, and which are stable in physiological conditions.
To decouple the intrinsic photovoltage generated by the material itself from the one generated at the semiconductor electrolyte interface, we compare photovoltage transients and spectra as observed both in presence and in absence of electrolyte. In addition, we compare photocurrent and photovoltage transients in presence and absence of oxygen to explore the processes leading to oxygen reduction reactions and ROS species generation in such interfaces. Quantitative determination of hydrogen peroxide generation with HRP-TMB assay permits to further determine the electrochemical conversion efficiencies for different materials. By combining the findings with electrochemical impedance spectroscopy, we develop simple equivalent circuit models to explain the observed photovoltage and its build-up dynamics in OSC floating photocathodes in contact with electrolyte. Circuital modeling also allows to relate macroscopic as well as morphological features to physical properties, and to explore how utilization and ageing reflect on the device operativity performances. Applying different bias voltages, we explore the photoelectrical behavior of the system, determining how faradaic and capacitive contributions follow the variation. By modelling such dynamics, we obtain a quantitative description of the photovoltage transients and charging behaviour of floating photoelectrodes.

SB06.04.07

A Chemically Doped Phenylene Vinylene Polymer with High Electron Conductivity Marc-Antoine Stoeckel[1], Han-Yan Wu[1], Chi-Yuan Yang[1], Yang

Lu[2], Ziang Wu[3], Han Y. Woo[3], Jian Pei[2], Magnus Berggren[1] and Simone Fabiano[1]; [1]Linköping University, Sweden; [2]Peking University, China; [3]Korea University, Korea (the Republic of)

High-performing organic materials are required for efficient opto-, bioelectronic and thermoelectric applications. Among these materials, (semi-)conducting polymers are particularly appealing for these technologies, as they benefit from unique optoelectronic properties, low-cost production and their solution processability make them fully compatible with large-scale deposition methods. The most common way to reach high electrical conductivities with this class of materials is to dope the polymers through the addition of a heterogeneous doping entities to the system.
With the goal to produce highly-performing materials, huge efforts have been provided by the scientific community, notably through molecular design adjustments of these active materials. A current strategy towards this end is the planification and the rigidification of the polymer backbone, leading to a higher degree of order through a favorable molecular packing while decreasing the energetic disorder. This is the case, for example, for poly(p-phenylene vinylene) derivatives that benefit from both carbon-carbon double bonds between polymer units and intramolecular hydrogen bonds.
Another way of enhancing the performances of (semi)conducting polymers is to increase the microscopic order and then the crystallinity of the polymeric assembly by adjusting the processing of deposition. One way to do so is to use Langmuir-Schaefer (LS) technique that relies on the assembly of the polymer chains at the air/water interface when compressed between two moving barriers. The assembled film composed by a monolayer of polymers with a low degree of defect is then transferred onto a substrate integrating electrodes to make a fully functional device.
Here we report on LS films that are highly ordered and oriented at the monolayer limit. This describes a microscopic structure that is optimized for the transport of charges with strong anisotropic properties of electron conduction. Through a systematic analysis including scanning probe microscopy, optical spectroscopy, GIWAXS, and electrical measurements, we characterized the system in terms of structure, packing, energetics, and thermoelectric properties. We further optimized the electrical performances of the film when doping it with different molecular entities through secondary doping mechanisms, reaching n-type conductivities up to 4 S cm^{-1}, and a power factor of 1.5 µW m^{-1} K^{-2}. Finally, we integrated this system as active material in organic electrochemical transistors (OECT) to study the penetration of ions within this structured thin-film to optimize the transconductance of these devices.

SB06.04.09
Exploring Ultrafast Symmetry-Breaking Photoinduced Charge Separation in Optoelectronic Materials George C. Fish[1], Frank Nüesch[1,2] and Jacques-E. Moser[1]; [1]École Polytechnique Fédérale de Lausanne, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

In organic photovoltaics (OPVs), it is widely accepted that the open circuit voltage (V_{OC}) is predominantly determined by the energy level offset between the donor and acceptor material. A consequence of this is that increasing the driving force for charge separation negatively impacts upon the V_{OC}.

Recently, symmetry breaking photoinduced charge separation (SB-CS) has become an attractive topic in the field as it would allow for charges to be separated in systems with no energetic offset between the donor and acceptor material, thus increasing the V_{OC} and device efficiency.[1]

Here, we use ultrafast transient absorption spectroscopy to probe photoinduced charge generation in cyanine and squaraine dyes, both classes of materials with a storied history in the OPV field. The high extinction coefficients of cyanine dyes have led to them being used extensively alongside fullerene acceptors in planar heterojunction devices, as well as being used as model systems to study the dissociation of charge transfer states.[2,3]

In this work, we build upon results that demonstrated the possibility of pristine pentamethine cyanine (Cy5) thin films to undergo intrinsic charge generation.[4] We demonstrate that SB-CS takes place in pristine Cy5 thin films and proceeds with a quantum yield of 86%, providing the first direct proof of high-efficiency intrinsic photoinduced charge generation in organic salt semiconductors. The driving force for the SB-CS process was determined to be, in part, due to local electric fields arising from the anions being located outside of H-aggregated cationic chromophore stacks. Furthermore, the counterion of the cyanine dye was varied in order to establish that the degree of aggregation plays a vital role in determining the efficiency of the charge separation process.[5]

Comparatively, our ultrafast studies on dicyanomethylene substituted squaraine dyes, which are promising materials for short wave infrared photodetectors[6], revealed that an intrinsic SB-CS process does not occur. An absence of counterions resulted in there being no local electric fields to provide the driving force for the charge separation to take place.

Shape Morphing Technology Based on a Plastic-Elastomer Framework for 3D Electronics Dukkyu Park, Jung Il Yoo and Heungcho Ko; Gwang-ju Institute of Science and Technology, Korea (the Republic of)

Three-dimensional electronics provide a strong advantage in the omnidirectional capability in sensing, displaying, communicating, and others. When direct device fabrication on 3D structures is extremely difficult, three-dimensional transformation technology based on a supporting substrate that mounts the planar membrane-type electronics becomes an excellent indirect method. When plastics are used for an additional substrate, the materials guarantee overall mechanical stability but allow only a small strain range. On the other hand, elastomers allow a large amount of strain but seem to be very soft mechanically. This study demonstrates a means of developing a plastic-elastomeric framework to achieve three-dimensional (3D) electronics with non-zero Gaussian curvature without losing mechanical stability. When using two controversial materials, it is important to guarantee the interfacial adhesion between the two materials and the possibility of controlling the shape transformation. To address the first issue, we used a self-assembled monolayer assembly that chemically bonds the two materials to guarantee strong interfacial adhesion. Regarding the second issue, we used shear-printed plastic lines to provide a driving force for automatic 3D transformation during thermal relaxation above the glass transition temperature and the elastomeric films to provide a basis for mounting the membrane electronics and allow a large amount of strain for complex 3D shapes. In a detailed study, we examined the shape morphing based on geometrical and mechanical parameters such as annealing temperature, annealing time, and other control parameters, including shear rate, line pitch, and relative thickness of plastic/elastomeric structure. In particular, we have successfully developed unusual 3D shapes such as cone, dome, and saddle shapes, among shapes predicted through mechanical finite element method simulation. To validate the feasibility of this strategy in 3D electronics, semiconductor-processed electrodes and indium-gallium-zinc-oxide transistor arrays were mounted on a plastic-elastomeric framework to

demonstrate a 3D-shaped membrane electronics device.

SB06.04.13
Microgravity as a Tool for a Molecular Understanding of the Active Layer Formation in Organic Solar Cells Leif K. Ericsson, Ishita Jalan, Jan van Stam and Ellen Moons; Karlstad University, Sweden

Solution–processed organic photovoltaic (OPV) devices have gained serious attention during the last decade.[1] The active layer of an OPV solar cell consists of a thin solid film of an electron donor blended with an electron acceptor. One important factor for the performance is the nanostructured morphology of the active layer. It is known that molecular interactions govern the morphology formation process, whether it is a polymer–polymer system or a polymer-small molecule system.[2] Understanding the factors determining this structure formation on a molecular level enables not only morphology control, but also the prediction of suitable and more environmentally friendly solvents for a greener processing of OPV.
One way to enable a detailed study of the initial stage of the phase separation and hence the influence of molecular interactions, is to slow down the phase-separation process. Minimizing the influence from gravity on the film formation is known to slow down this process during the film formation.[3,4]
In this work we have prepared active layers under microgravity conditions at parabolic flights.[5] For this purpose, we have designed a custom–built experiment setup for dip–coating from volatile solutions under microgravity conditions, meeting the security measures for parabolic flights.[6] The resulting thin blend films are characterized using AFM and AFM-IR, the latter combining the high resolution of AFM with the chemical fingerprint of infrared spectroscopy. It is shown that the morphology is similar to films prepared at 1g conditions, but with differences that can be related to the absence of a gravitational field during the drying of the applied liquid coating. Film thickness as well as the size of structures due to phase–separation are shown to depend on the level of gravity during the drying of the films.
In parabolic flights, the microgravity phase lasts for 20–25 seconds, which is too short to ensure complete evaporation of the solvents. To guarantee complete evaporation under microgravity conditions, sounding rocket experiments with 6 minutes of microgravity will be performed in the autumn 2023. The construction of the equipment for sounding rocket flights is ongoing and the design concept will be described.

Deformable Polymer Semiconductor Thin-Film Crosslinked with Flexible Azide Photo-Crosslinker Sein Chung and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Stretchable transistors that use intrinsically deformable semiconducting conjugated polymers (CPs) as active layers are emerging as the next-generation key of electronics technology. To impart high deformability to a semiconducting polymer, a photo-initiated crosslinking approach has been reported with nitrene chemistry of azide-incorporated molecular additive. In this study, we elaborately investigated the complicated effects of azide photo-crosslinker's molecular length on various physicochemical characteristics and resultant deformability of photo-crosslinked conjugated polymer films.
For a systematic comparison, we newly synthesize a series of nitrene-induced photo-crosslinkers (*n*-NIPSs) with different numeric ethylene glycol units (*n* = 1, 4, 8, and 13) that bridge two tetrafluoro-aryl azide end groups. A benchmark near-amorphous conjugated polymer, IDTBT, is co-processed with *n*-NIPSs and crosslinked by brief exposure to UV light with 254 nm. We found that the length of ethylene glycol unit in *n*-NIPSs affects the deformability of crosslinked IDTBT films, and the improvement is achieved not with semi-crystalline conjugated polymers such as DPPDTT or RR-P3HT but only with near-amorphous polymers such as IDTBT or RA-P3HT. Based on the systematic studies, we suggest that crosslinking density in an amorphous regime is significant in the improvement of thin-film deformability. We believe that these results will provide valuable insight into establishing a design principle of azide-based photo-crosslinkers for deformable polymer semiconductors with conjugation.

SB06.04.16
Organic Semiconductors with DNA Induced Chirality and Optoelectrical Functionalities Moon Jong Han[1], Hee Seong Yun[2], Yongjoon Cho[3], Minkyu Kim[1], Changduk Yang[3], Vladimir Tsukruk[1] and Dong Ki Yoon[2]; [1]Gerogia Institute of Technology, United States; [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Ulsan National Institute of Science and Technology, Korea (the Republic of)

We fabricate highly organized patterned thin films of DNA-templated perylene diimides (PDIs), which can realize the bio-organic field-effect transistor (BOFET) that has chiroptical and electrical functionalities. Shear-oriented PDI/DNA complex films show how periodic molecular orientation and charge transport are related, resulting in drastically different electro-optical properties at each condition, in which DNA is used as the chirality-inducing scaffold and charge-injection layer. BOFET shows a well-ordered supramolecular structure with high electron mobility, photoresponsivity, and photosensitivity, reaching 3.97 $cm^2\ V^{-1}\ s^{-1}$, 1.18 $A\ W^{-1}$, and 7.76×10^3, respectively. Interestingly, the resultant BOFET enables the definitive response to the handedness of circularly polarized light. We believe our work can be a cornerstone for the natural chirality of DNA and the electron conductivity of organic semiconducting molecules to be mutually used in the unique chiro-electro-optical functions.

SB06.04.18
Electrochemical Fabrication and Characterization of Organic Electrochemical Transistors (OECTs) Using poly(3,4-ethylenedioxythiophene (PEDOT) Junghyun Lee, Shrirang S. Chhatre, Peter Sitarik, Yuhang Wu, Quintin Baugh and David C. Martin; University of Delaware, United States

Organic electrochemical transistors (OECTs) with conductive polymers (CPs) as the active materials are one of the devices getting particular attention for bioelectronics due to their special properties such as low operating voltage and mixed ionic-electronic conductivity. Among various CPs, commercially available poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) dispersions in the aqueous solutions have been widely used because they have high conductivity and biocompatibility. However, it has been difficult to modify the chemistry of PEDOT:PSS to control and functionalize device characteristics because of its high chemical stability. In this work, EDOT was electrochemically polymerized as the active material of OECTs with commonly used counterions of lithium perchlorate ($LiClO_4$), sodium *p*-toluene sulfonate (*p*TS), and poly(sodium 4-styrene sulfonate) (PSS). Commercially available gold interdigitated electrodes were used as the substrate and PEDOT served as the active channel material by filling the gaps between interdigitated electrodes during the electrochemical polymerization process. The electrochemically polymerized PEDOT films with large sized counterions (PSS), showed smooth and regular surfaces, while PEDOT films with relatively small sized counterions ($LiClO_4$ and *p*TS) showed much rougher and bumpy surfaces. PEDOT films with either *p*TS or PSS showed much better surface coverage ability for filling gaps between interdigitated electrodes rather

than with $LiClO_4$. OECTs were successfully fabricated with PEDOT and various counterions by the electrochemical polymerization process. The maximum transconductance, g_m, of a PEDOT OECT was 46 mS with the highest on-current level (> 10 mA) using *p*TS as the counterion. These results provide a relatively simple and efficient way to fabricate high performance OECTs with various monomers, counterions, and additives as active materials in order to modify and control the device characteristics for various applications.

SB06.04.19
Template Induced Highly Ordered Aggregates of Merocyanines for the Tuning of Optical Properties Anna J. Kny[1], Max Reimer[2], Noah Al-Shamery[1], Ritu Tomar[1], Thomas Bredow[1], Selina Olthof[2] and Moritz Sokolowski[1]; [1]University of Bonn, Germany; [2]University of Cologne, Germany

Merocyanines are widely investigated molecules with large dipole moments, adjustable optical bandgaps, and high absorption coefficients. They are of interest for the use in optoelectronic devices, in particular, for the application in organic solar cells [1]. By controlling the molecular packing, either via template mediated film growth on crystalline surfaces or by modification of the molecular structure such as a variation of the peripheral substituents, the optical properties can be tuned by the formation of J- or H-aggregates [2].

Here, we present a study on the adsorption and molecular ordering of the prototype merocyanine 2-[5-(5-dibutylamino-thiophen-2-yl-methylene)-4-*tert*-butyl-5*H*-thiazol-2-ylidene]-malononitrile (HB238) and its derivatives on single crystalline Ag(100) and KCl(100) surfaces. Measurements were performed on ultrathin films (range of about one monolayer) by a variety of surface sensitive techniques such as high resolution low energy electron diffraction (SPA-LEED), scanning tunneling microscopy (STM), and photoelectron spectroscopy (XPS, UPS). The results are complemented by density-functional theory (DFT) calculations.
Remarkably, the thermodynamically preferred phase of HB238 on the Ag(100) surface at room temperature is a commensurate superstructure which is considerably different from known bulk structures [3]. We observe domains of several hundreds of Angstroms in diameter composed of homochiral aggregates of four molecules which are arranged in a nearly circular manner. Hence, properties of J-aggregates are expected for this phase. This structure is stabilized mainly by hydrogen bonds between donor and acceptor groups of neighboring molecules. Interestingly, the molecular packing between the above described homochiral aggregates can be affected by a change of the sterically demanding peripheral substituents. We will demonstrate this by comparing the structure formation of HB238 to that of derivatives on the Ag(100) surface.

Finally, the question arises if similar structures can be prepared on different template surfaces, for example those of insulating layers that are needed to investigate the resulting optical properties. To answer this question it is important to understand how the structure formation on the Ag(100) surface depends on the interfacial bonding. For this purpose, we discuss the role of the functional groups on the interfacial bonding and compare the structure formation of HB238 on Ag(100) to its structure formation on a thin insulating layer of KCl(100) epitaxially grown on Ag(100). On the basis of these results we discuss the interplay of intermolecular and interfacial bonds essential for the film formation and hence most important for the tuning of the optical properties.

MCs were kindly provided by the group of Prof. K. Meerholz (Cologne).

High Performance Organic Thermoelectrics Enabled by Controlling Counter-Ion-Induced Disorder in Highly Doped Conjugated Polymers Jimin Kim, Duckhyun Ju and Kilwon Cho; Pohang University of Science and Technology (POSTECH), Korea (the Republic of)

The degree of structural and energetic disorder in conjugated polymers governs how effectively the charge carriers are transported as it impinges on the molecular geometry or π-orbital overlap. Thus, how the counter-ion-induced disorder affects the charge transport in highly doped conjugated polymer systems should be investigated to achieve high thermoelectric (TE) performance. However, experimentally controlling the disorder caused by the Coulomb interaction between the polymer and the dopant is difficult due to the limitations of dopant engineering. Herein, we systematically control the counter-ion-induced disorder and investigate the effect of disorder on the TE transport properties in poly(3,4-ethylenedioxythiophene) (PEDOT) by using anion exchange method. Multi-cyano-functionalized counter-ions, which exhibit different Coulomb interaction with PEDOT, change the structural and energetic disorder in PEDOT. To quantify the counter-ion-induced disorder, the degree of disorder is evaluated in several microscopic aspects: molecular ordering, density of states (DOS), and polaron behaviors. The low extent of counter-ion-induced disorder increases the planarity of the PEDOT chains and simultaneously narrows the DOS of PEDOT. In addition, an analysis of the number of unpaired polarons derived from the Curie susceptibility shows how the charge carriers are localized by the counter-ion-induced disorder. Consequently, these changes result in the opposite behaviors of the electrical conductivity and the Seebeck coefficient depending on the extent of disorder and thereby produce a remarkable power factor of 630.6 $\mu W\ m^{-1}\ K^{-2}$ and figure-of-merit *ZT* of 0.21 with the lowest degree of disorder. This work would provide a comprehensive understanding of counter-ion-induced disorder effect on charge transport in terms of optimizing TE performance.

SB06.04.21
Large Area Flexible Radiation Dosimeters for Radiation Therapy Derek Dremann[1], James Ververs[2], Daniel Bourland[2], John Anthony[3], Karl Thorley[3] and Oana D. Jurchescu[1]; [1]Wake Forest University and Center for Functional Materials (CFM), United States; [2]Wake Forest School of Medicine, United States; [3]University of Kentucky Center for Applied Energy Research, United States

Cancer is one of the leading causes of death globally. Radiation therapy represents an important and popular treatment technique for many types of cancer. However, the effectiveness of radiation therapy is critically dependent on the accurate administration of the correct radiation dose to the target cancer cells. Another challenge is the risk presented by the radiation to surrounding healthy, non-cancerous cells. Therefore, knowing the exact radiation dosage a patient receives and the spatial distribution of that dosage is important for minimizing the damage to surrounding cells while ensuring enough radiation is delivered to treat the cancer. Well-established dosimetry techniques currently used in clinical settings are limited to single point-based measurements to determine the absolute radiation dose a patient receives, and accurately measuring the radiation dose over a large area remains a challenge.

Radiation detectors based on organic field-effect transistors (RAD-OFETs) offer a solution for flexible, conformal, large area, and high-resolution *in vivo* dosimetry at the skin surface. In this research, samples consisting of an array of 12 rows and 8 columns of organic field-effect transistors covering an active area of approx. 1.5 cm^2 were slot-die coated using 2,8-Difluoro-5,11-bis(triethylsilylethynyl)anthradithiophene (dif-TES ADT) or 5,11-bis(triethylgermylethynyl)anthradithiophene (dif-TEG ADT) blended with Poly(alpha-Methylstyrene) (PαMS) in a 1:1 W/W ratio providing a spatial resolution of 1.5 ± 0.02 mm^2. Samples of each blend received a 200 cGy dose of radiation with a source-to-surface distance of 100 cm using a 6 MV radiation source. Additionally, for one sample from each type we inserted a solid water bolus between the source and the RAD-OFETs. The bolus acts as a

tissue equivalent material shifting the peak radiation dose received closer to the surface of a patient. The shift in the threshold voltage before and after exposure to radiation was used to compare the variation in the radiation dose across the array of RAD-OFETS, while the sensitivity was observed to be constant across the devices, $S = 1.8 \pm 0.9 \times 10^{11}$ μC Gy^{-1} cm^{-3}, with no significant difference being observed between samples. 2D-mapping the spatial distribution of the threshold voltage shift revealed that the samples with bolus overtop experienced greater variations in the threshold voltage, with hotspots near the center beam placement. These observations indicate that the presence of the bolus slab alters the radiation profile, and, in turn, the dose received by the patient. Our results are important because they provide for the first time the much-needed tools that can generate the information on the variations in the radiation dose over a large area, relevant to cancer therapy in a clinical setting.

SB06.04.22
Optimization of Porous TiO2 Electron Transport Layer in Carbon-Based Perovskite Solar Cells Takaya Shioki, Ryuki Tsuji, Kouta Oishi and Seigo Ito; University of Hyogo, Japan

Carbon-based multi-porous-layered-electrode perovskite solar cells (MPLE-PSCs) are the most promising for the general PV market due to their simple fabrication process with full printing and extremely high durability. However, the low photoelectric conversion efficiency (PCE) of MPLE-PSCs (less than 20% PCE) has been cited as an issue for practical use. In this study, we focused on the porous TiO2 layer used as the electron transport layer in MPLE-PSCs and aimed to improve the device performance by optimizing the TiO2 particle size.

The MPLE-PSC devices were fabricated as follows. Materials were stacked on an FTO glass substrate: a compact TiO2 layer (as a blocking layer), a mesoporous TiO2 layer (as an electron transport layer), a mesoporous ZrO2 layer (as an insulating layer to prevent short circuit), and a mesoporous carbon layer (as a hole transport layer and back electrode) [1-2]. After that, a perovskite precursor solution was dropped on the electrode, and it was crystallized by annealing process.

In this study, six types of TiO2 particle sizes of 98, 52, 43, 26, 18, and 14 nm were used for the mesoporous electron transport layer, and the performance of these six types of MPLE-PSCs was evaluated. As a result, the MPLE-PSCs using 43-nm TiO2 showed the highest photoelectric conversion efficiency (PCE). In addition, it was confirmed that the short-circuit current density (Jsc) of the MPLE-PSCs changed for each TiO2 particle size. This is thought to be due to the influence of the light absorption rate of the device. In this presentation, we will report the results of detailed analysis in the conference.

100% Yield, 4-Inch Wafer-Scale Non-Volatile Optically-Guided Organic-Inorganic Heterostructure Memory Array with Simultaneous Detection and Storage of Text Image Seongjae Kim[1], Juhyung Seo[1], Taehyun Park[2] and Hocheon Yoo[1]; [1]Gachon University, Korea (the Republic of); [2]Chemical and Biological Engineering, Korea (the Republic of)

Photoreactive optically-guided memory allows photodetector and memory functions to be combined in a single device. Accordingly, the above-mentioned memory device reduces unnecessary signal delay by reducing the metal wiring between the photodetector and the memory device, and the detection and storage functions of two different devices can be available with one device, thereby reducing the overall system size [1-2]. Due to these advantages, an optically-guided memory is considered significantly promising as a potential thin-film transistor memory for next-generation applications, where image sensing and processing capabilities are simultaneously required. In this light, this talk presents an organic/inorganic heterogeneously stacked optically-guided memory. In the proposed memory devices, the number of electrons formed in the channel layer is modulated by the intensity of incident light, and thereby the excited electron/hole pairs change the degree of electron carriers trapped in the floating gate. Based on the proposed heterogeneous memory structure, this work also implements a 4-inch wafer-scale 12 × 12 memory transistor array consisting of 144 devices enabling image detection with 100% yield. This study also demonstrates a text image detection with non-volatile memory characteristics depending on the presence or absence of light irradiation during the programming operation.

Nanoimprint Formation of the Atomically Ultra-Smooth Surface of the PEDOT: PSS Conducting Polymer Thin Film for Flexible Optoelectronic Devices Yuto Maeda[1], Naho Kaneko[1], Tomoaki Oga[1], Satoru Kaneko[2,1], Akifumi Matsuda[1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

Conductive polymer materials such as PEDOT: PSS with features of light weight and large area have become increasingly important in flexible electronics of organic thin-film solar cells or other optoelectronic devices [1]. In the construction of electronic devices on these polymer thin film electrodes, surface flatness and atomic- and/or nano-level surface control of conductive polymer thin films are essential for formation of fine and highly integrated devices. So far, by using the ultra-smooth sapphire (α-Al2O3 single crystal) wafers with self-organized approx. 0.3-nm high atomic-step straight nanopatterns as nanoimprinting molds [2], we had reported on the fabrication of surface ultra-smooth substrates by transferring their nanoscale patterns onto the surfaces of oxide glasses and thermoplastic polymers [3-5]. On the other hand, as for nanopatterning of PEDOT: PSS having no thermo-plasticity, there were only a few reports on stripe surface patterning (10nm depth and 700nm period) onto the thin film for increase of the organic photovoltaic device efficiency [6]. In this study, for formation of the atomically smooth surface on the PEDOT: PSS thin film, we investigated transcription of 0.3nm-high atomic-step and atomically flat terrace pattern of the sapphire mold onto the spin-coated PEDOT: PSS thin film surface via thermal nanoimprinting. We also characterized electric properties as well as the thermal or UV-light durability of the nanoimprinted pattern on the sample surfaces.
A flexible transparent polyimide sheet (PI; t~20 μm, ECRIOS® VICT-Bnp, Mitsui Chemicals Co., Japan) was used as a polymer substrate for thin film deposition. PEDOT: PSS thin films were prepared by spin-coating PEDOT: PSS aqueous dispersion and drying at 170°C for 60 min. Thermal nanoimprinting was then performed at 200-270°C and 15 MPa for 40 min in vacuum on the PEDOT: PSS thin film surface using the sapphire mold with an atomic step and terrace width of about 600 nm. As a result, it was confirmed that an atomic step and terrace pattern corresponding to the sapphire mold could be transferred accurately onto the PEDOT: PSS thin film on the polyimide sheet in case of nanoimprinting at 260ºC. The successful transfer was achieved under conditions near the glass transition temperature (about 265°C) of the polyimide substrate, suggesting that the nanopattern transfer onto the

PEDOT: PSS thin film might be related to softening phenomena of the substrate.

SB06.04.26
Effects of Post-treatment on the Transport Properties of Te/PEDOT:PSS and Ag_2Te/PEDOT:PSS Hybrid Thermoelectric Thin Films Rodrigo Rubio[1,2], Roberto Félix[1], Regan G. Wilks[1], Marcus Baer[1,3,4] and Katherine A. Mazzio[1,2]; [1]Helmholtz-Zentrum Berlin fur Materialien und Energie GmbH, Germany; [2]Humboldt-Universität zu Berlin, Germany; [3]Friedrich-Alexander-Universität Erlangen-Nürnberg, Germany; [4]Helmholtz-Institute Erlangen-Nurnberg for Renewable Energy, Germany

Hybrid organic/inorganic materials composed of tellurium (Te) nanowires (NWs) embedded into poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) have been prominently studied after it was reported that their transport properties could be tuned by varying the length of the NWs and modulating the amount of PEDOT:PSS incorporated into the system.[1] Nevertheless, the influence of each constituent on the observed transport properties was not fully understood. Recently, based on molecular dynamics simulations and density functional theory calculations, it was proposed that the templating effect of PEDOT over the Te NWs surface is responsible for the enhanced transport properties of Te/PEDOT:PSS hybrids, and it was later experimentally demonstrated that the electronic transport occurs predominantly through the organic portion of the hybrid.[2,3] However, no direct experimental evidence of the existence of the templating effect was given.

It is well known that the electrical conductivity of conducting polymers (CPs) can be considerably enhanced when subjected to post-treatment processes, such as primary (i.e. charge transfer or acid-base processes) or secondary (morphological rearrangement that only impacts mobility and not oxidation level) doping. The transport properties strongly depend on the creation of polaron/bipolaron clusters dispersed through the polymer matrix, so their concentration and mobility are dependent on the oxidation level and the degree of crystalline domains.

In this work, we investigate the effects of tetrakis(dimethylamino)ethylene, sulfuric acid, and ethylene glycol post-treatments on the thermoelectric performance of p-type Te/PEDOT:PSS and n-type Ag_2Te/PEDOT:PSS hybrid materials. By analyzing the materials with X-ray diffraction, Raman spectroscopy, hard X-ray photoelectron spectroscopy, and Hall measurements, we find that variations of the thermoelectric performance are related to modifications in the morphological and chemical structure of PEDOT:PSS that is reflected in changes to the charge carrier density and mobility. Additionally, we present experimental evidence that strongly supports the templating effect causing the planar alignment of the first few layers of PEDOT over the NWs surface.

Organic Optoelectronic Devices Processed from Green Solvents Zhifang Du[1], Hoang Luong[1], Sina Sabury[2], Austin Jones[2], Manjunatha Reddy[3], John Reynolds[2] and Thuc-Quyen Nguyen[1]; [1]University of California, Santa Barbara, United States; [2]Georgia Institute of Technology, United States; [3]University of Lille, CNRS, Centrale Lille Institut, Univ. Artois, UMR 8181, France

Organic semiconductors (OSCs) comprise small molecules or polymers are attractive candidates for the fabrication of a range of technologies including large area and flexible plastic solar cells, photodetectors, organic thin film field-effect transistors (OFETs), and organic light-emitting diodes (OLEDs) for displays and lighting applications. New opportunities that integrate soft semiconductors are also emerging, including thermoelectric devices, bioelectronic monitoring devices, and hybrid soft/hard electronic materials. To accelerate the mass fabrication of OSCs, green solvent processing is crucial to reducing the environmentally hazardous effects of halogenated solvents. However, there are only a limited number of studies that focus on the improvement of device performance using green-solvent processing, and the connection between the green-solvent processing, morphology, and performance is still poorly understood. In this talk, I will discuss the design, synthesis, and performance of organic semiconductors processed from green solvents such as xylene and 2-methyltetrahydrofuran (2-MeTHF). 2-MeTHF is a biomass-derived (furfural or levulinic acid) and environmentally friendly solvent that is widely used in organic synthesis, which can be produced from low-cost and renewable agriculture feedstock. A combination of characterization methods were employed to gain insight into the film morphology and solar cell and photodetector performance.

9:00 AM SB06.05.02
The Morphological Stability of "Burn-Up" Non-Fullerene-Acceptor Organic Solar Cells Rachel Kilbride[1], Matthew Bidwell[2], Emma Spooner[1], Robert Dalgliesh[3], Philipp Gutfreund[4], James Tellam[3], Nicola Gasparini[2], Iain McCulloch[5], David Lidzey[1], Richard Jones[6] and Andrew Parnell[1]; [1]University of Sheffield, United Kingdom; [2]Imperial College London, United Kingdom; [3]ISIS Pulsed Neutron and Muon Source, United Kingdom; [4]Institut Laue-Langevin, United Kingdom; [5]University of Oxford, United Kingdom; [6]The University of Manchester, United Kingdom

Over the past decade, the development of small molecule non-fullerene acceptors (NFAs) as the photoactive components in organic photovoltaic (OPV) devices has pushed efficiencies close to the fabled 20%[1,2], an efficiency threshold considered essential for commercially viable OPV technologies. Unfortunately, increases in OPV device efficiency have not been in step with increased long-term operational stability and devices typically demonstrate an initial '*burn-in*' period of rapid performance loss. The origin of this performance loss remains poorly understood and mitigation strategies are yet to be developed. In this work, the stability of a well-studied polymer : fullerene system (PTB7-Th : $PC_{71}BM$) is compared with a series of polymer: NFA systems based on PTB7-Th and the IDTBR family of NFAs. Polymer : IDTBR systems demonstrate superior stability, characterised by an unusual fill-

factor-driven efficiency enhancement or '*burn-up*' improvement period within 24h of fabrication. The morphological origins of this phenomenon are explored across a broad range of length scales (Å – nm - µm) using grazing incidence wide angle scattering (GIWAXS), small angle neutron scattering (SANS) and neutron reflectivity. Neutron scattering measurements of polymer : NFA blend films are made possible by the synthesis of deuterium-labelled NFA analogues (d-NFAs), providing unparalleled sensitivity and insight into the morphological stability and phase separation of the bulk-heterojunction photoactive blend. It is found that subtle changes in the degree of phase separation and NFA crystallinity during device ageing under inert conditions are closely linked to changes in PV efficiency. The findings described here provide a more thorough understanding of the morphological stability of the bulk heterojunction blend, essential for improving the operational lifetime and commercial viability of OPV technologies.

Synthesis and Structure-Function Relationships in Fused Aromatics for Electronic and Photonic Applications John Anthony; University of Kentucky, United States

In thin film devices, the preciese nature of the interaction between chromophores is critical to the performance of any device. In acenes, we long ago developed a method to induce crystalline order that yields excellent performance in applications requiring efficient charge transport, such as organic transistors. Much more recently, we have begun to address the impact of dynamic disorder - disruptive phonon modes - to improve both the performance and reproducibility of our materials in organic transistors. Here, I will discuss three approaches we have explored to alter disruptive phonon modes through systematic structural variations, and will describe the approach and impact of each of these structural changes. The production of these structurally modified mateirals also required the development of new synthetic methods for the preparation of fused aromatic compoounds, which will also be presented.

Green Emissive Blends in the Limit of *Field-Effect* Transport in Organic Light-Emitting Transistors Caterina Soldano, Ornella Laouadi and Katherine Gallegos-Rosas; Aalto University, Finland

Organic light-emitting transistors are photonic devices combining the function of an electrical switch with the capability of generating light under appropriate bias conditions. Achieving high-performance light-emitting transistors requires high mobility organic semiconductors, optimized device structures and highly efficient emissive layers.
Here, we studied the opto-electronic response of TCTA:$Ir(ppy)_3$ blends with varying doping concentration in the limit of field-effect within a transistor configuration. Increasing the dye concentration within the blend leads to a quenching of the photoluminescence signal; however, when implemented in the vertical stack in the transistor, we observed an approximate 5-fold improvement in the light output for a 10% $Ir(ppy)_3$ doping blend. We analyzed our results in terms of balanced charge transport in the emissive layer, which, in the limit of *field-effect* transport, leads to an improved exciton formation and decay process.
While the efficiency of our devices is yet to achieve state-of-the-art diode counterpart, this work demonstrates that engineering the emissive layer is a promising approach to enhance the light emission in field-effect devices. This opens the way for a broader exploitation of organic light-emitting transistors as alternative photonic devices in fields ranging from display technology to flexible and wearable electronics.

The Interplay Between CT and Singlet Exciton Emission and Its Impact on Organic Solar Cells Safa Shoaee; University of Potsdam, United States

Organic solar cells (OSCs) have rapidly advanced, reaching state-of-the-art efficiencies of above 19 % for single-junction solar cells [1]. Yet, these cells suffer from non-radiative recombination, which limits their FF and VOC. It is generally believed that free charge carrier recombination in OSCs proceeds primarily via reformation and decay of charge transfer (CT) states, involving radiative and non-radiative pathways. The latter typically dominates the decay rate and is, therefore, responsible for the VOC loss. The situation becomes more complex when the energy of the CT state, ECT, approaches the energy of the lowest singlet exciton, the local exciton of the component dominating the optical gap. In this case, reformation of the singlet exciton from the CT state becomes more likely, documented e.g. by an increased singlet exciton emission intensity in electroluminescence (EL) [2]. As singlet excitons are generally more emissive than CT states, this causes a significant reduction of the non-radiative voltage loss. It has, therefore, been proposed that OSCs benefit from a strongly-emitting singlet exciton [3]. In contrast, we have recently shown for the prototypical PM6:Y6 blend, that predominant emission from the S_1 state does not automatically mean that free charge recombination proceeds through this state [4]. Understanding the interplay between these two states and how they determine the voltage losses in relation to ΔE(S1-CT) is therefore of great interest.
We combine PM6 with three different acceptors which have similarly low offsets while leaving the S1 energy of the polymer unaffected. We show that the emission of the blends becomes dominated by the S1 of the acceptor in all cases, but that the CT state properties determine the non-radiative processes and the VOC in all devices. Importantly, the high oscillator strength of the singlet exciton reduces the non-radiative voltage loss not because it is more emissive, but because its higher absorption as compared to the CT state lowers the radiative VOC limit. We suggest that it's only for very low CT state oscillator strengths and a fairly high radiative efficiency of the CT state that the VOC benefits from the radiative properties of the singlet excitons.

11:00 AM SB06.06.02
Direct Exciton Harvesting from a Bound Triplet Pair Guiying He[1], Kaia R. Parenti[2], Luis M. Campos[2] and Matthew Sfeir[1]; [1]Advanced Science Research Center, City University of New York, United States; [2]Columbia University, United States

Singlet fission is commonly defined as the generation of two triplet excitons from a single absorbed photon, which has received considerable attention because of its potential to overcome the Shockley-Queisser limit on the power conversion efficiency (PCE) of solar cells. However, ambiguities within this definition arise due to the complexity of the various double triplet states that exist in SF chromophores and corresponding interconversion processes. To

clarify this process, singlet fission is frequently depicted as sequential two-step conversion in which a singlet exciton decays into a bound triplet pair biexciton state which dissociates into two “free” triplet excitons. However, this model discounts the potential for direct harvesting from the coupled biexciton state. Using intramolecular SF dimers, we demonstrate that individual triplet excitons can be extracted directly from a bound triplet pair state prior to dissociation. These compounds have well-defined electronic interactions that allowing for detailed studies of multiexciton state and its dynamics. We show that due to the requirement for geminate triplet-triplet annihilation in these compounds, unique spectral and kinetic signatures can be used to quantify triplet pair harvesting yields. We achieve an internal quantum efficiency for triplet exciton transfer from the triplet pair of greater than 50%, limited only by the solubility of the compounds. The harvesting process is not dependent on the net multiplicity of the triplet pair state, suggesting that an explicit dissociation step is not a requirement for using triplet pairs to do chemical or electrical work.

11:15 AM SB06.06.03
Large Magnetic Field Sensitivity in a High Spin Ground-State Donor-Acceptor Conjugated Polymer Hamas U. Tahir[1], Naresh Eedugurala[2], Sheng-Ning Hsu[1], Daniel Adams[2], Jason D. Azoulay[2], Brett M. Savoie[1] and Bryan W. Boudouris[1]; [1]Purdue University, United States; [2]The University of Southern Mississippi, United States

Open-shell macromolecules are an emerging class of materials that have the potential to be implemented in multiple applications (e.g., energy storage devices and electronic systems). The presence of unpaired electrons endows these materials with unique properties that are difficult to achieve with conventional organic semiconductors, such as extremely long spin relaxation times. In addition to exhibiting weak spin-orbit coupling and hyperfine interactions, these polymers are paramagnetic due to their unpaired spins. This added functionality, which is not available in well-studied closed-shell organic semiconductors, make these materials suitable for spintronics applications. It is because radicals retain their magnetic moment in solid state electronic devices, thus enabling facile coupling with an external magnetic field. However, the utilization of open-shell macromolecules that could favor spin polarization and spin conservation during transport have been less studied. Here, we evaluate the magnetic behavior of poly(4-(4-(3,5-didodecylbenzylidene)-4H-cyclopenta[2,1-b:3,4-b’]dithiophen-2-yl)-6,7-dimethyl-[1,2,5]-thiadiazolo[3,4-g]quinoxaline), a high spin donor acceptor conjugated diradical polymer that has a low bandgap and triplet ground state. We confirmed the high spin behavior with a series of temperature-dependent electron paramagnetic resonance and superconducting quantum interference device (SQUID) experiments. We also observe that, for $T < 180$ K, this polymer exhibits giant negative magnetoresistance (i.e., –95% at $T = 10$ K), which is largest negative magnetoresistance observed for organic molecules up to date. As the temperature increases, the thermal population of triplet state decreases and hence magnetoresistance decreases as well. Moreover, for $T >$ 180 K, the magnetoresistance becomes positive, and relatively large positive magnetoresistance (+ 13%) is observed at room temperature. These tunable magnetoresistance results suggest the indispensable correlation between diradical character and large magnetoresistance due to spin-spin interactions. Our results indicate that donor-acceptor conjugated diradical polymers with thermally accessible triplet state have potential for spintronic applications.

11:30 AM SB06.06.04
Efficient Single-Layer Inverted Organic Light-Emitting Diodes Based on TADF Emitters Xiao Tan, Paul Blom and Gert-Jan Wetzelaer; Max Planck Institute for Polymer Research, Germany

Recently, a yellow organic light-emitting diode (OLED) based on a single layer of a neat thermally activated delayed fluorescence (TADF) emitter sandwiched between two ohmic contacts has been demonstrated to achieve similar efficiency and longer lifetime compared to more complex multilayer architectures.[1] For blue emitters, however, the required energy gap of ~3 eV, will often lead to trap-limited charge transport for either electrons or holes[2], leading to severe charge imbalance in an OLED. Since for most organic blue emitters the electron affinity is lower than 3.6 eV, electron transport is frequently impaired. As a result, in a single-layer OLED, the emission zone will be situated close to the metallic cathode, leading to severe light-outcoupling losses. Here, this issue is solved by the design of inverted single-layer OLEDs. Despite the severely imbalanced transport of the used emitters, high external quantum efficiencies up to 19% are achieved even for blue TADF emitters. The high efficiencies are the result of the emission zone being shifted away from the metallic top electrode, due to a combination of using an inverted device structure and taking advantage of the superior hole transport through the emitters. This new device strategy bypasses the severe limitations of imbalanced and trap-limited transport inherent to blue emitters, which leads to improved performance in blue OLEDs.

1:30 PM *SB06.07.01
Characterizing the Microstructure in Donor-Acceptor Blends and Linking It to Device Properties Alberto Salleo; Stanford University, United States

Donor-acceptor blends for organic photovoltaics have intricate microstructures with several characteristic lengthscales that all affect different aspects of the active layer performance, whether it’s charge transport, charge splitting efficiency or photovoltage. I will describe how the microstructure of the high-performance PM6:Y6 blend changes with composition using semi-quantitative x-ray diffraction and high-sensitivity EQE measurements. I will show that transport and photovoltage are maximized at different compositions leading to a fundamental trade-off.
Spatially resolving the microstructure at the donor-acceptor interface can also lead to interesting insights. In this respect I will show a quantitative TEM study of a polymer-polymer blend to show that donor and acceptor exhibit a preferential relative orientation, suggesting a form of soft epitaxy. The effect of additives will also be examined quantitatively and linked to photovoltaic performance.

2:00 PM SB06.07.02
From Amorphous to Polycrystalline Rubrene—Charge Transport in Organic Semiconductors Paralleled with Silicon Julie Euvrard[1,1], Oki Gunawan[2], Antoine Kahn[1] and Barry P. Rand[1,1]; [1]Princeton University, United States; [2]IBM T. J. Watson Research Center, United States

While progress has been made in the design of new organic semiconductors (OSCs) with improved transport properties (i.e., high mobilities), our understanding of the mechanisms involved is still limited and hinders further development, due in large part to the inherent difficulty when comparing OSCs with different molecular structure and morphologies. For silicon, enhanced understanding finally came once comparisons could be made with

variations in morphology from single crystals to fully amorphous films. In this work, we achieve a similar feat in one single organic molecular system. In particular, rubrene is employed as the OSC as it spans transport mechanisms from thermally activated hopping in its amorphous form to band-like transport in highly ordered crystals. Various transport characterizations including variable temperature conductivity, advanced Hall effect and magnetoresistance measurements are performed on rubrene films with varying levels of order (polycrystalline vs amorphous), crystal phase (orthorhombic vs triclinic) and morphologies (platelet-like vs spherulitic grains). We find that conductivity can be tuned over four orders of magnitude when changing the level of order in the film from fully amorphous to polycrystalline with a few high-quality grains. Our results show that transport in polycrystalline orthorhombic films is limited by grain boundaries, as observed in polycrystalline silicon. The use of advanced Hall measurement, for the first time performed on OSC thin films without the use of "gating" (gate voltage applied through addition of a dielectric and gate electrode), provides access to the intrinsic properties of the semiconductor. Despite the very high resistivity of amorphous and triclinic rubrene, we are able to probe a Hall signal, pointing to the existence of a marginal density of delocalized carriers. Overall, our Hall and magnetoresistance measurements suggest a gradual transition from predominantly hopping transport to predominantly band-like transport as order is increased and crystal phase optimized.
In summary, through this work we provide a comprehensive understanding of the interplay between order, molecular packing, morphology and charge transport in OSCs, akin to research on silicon decades ago. Our results point toward the application of a unified transport model with varying contributions of delocalized and localized carriers. More importantly, our study highlights that order alone is insufficient whereas intermolecular coupling is paramount for optimal transport, providing guidelines for the design of new molecules.

2:15 PM SB06.07.03
Supramolecular Self-Assembly as a Tool to Preserve Electronic Purity in Perylenediimide Chromophores Sascha Feldmann; Harvard University, United States

Organic chromophores are promising for the next generation of molecular electronic devices owing to their inherently flexible mechanic properties and the fact that the desired optoelectronic properties can be tailored through chemical design. Perylenediimide (PDI) is such acandidate for molecular electronics but, like most, also shows strong excited-state quenching upon aggregation or upon chemical functionalization for better processing, hindering its use in future device applications. Here, we employ supramolecular self-assembly as a precise tool for preventing these undesired and performance-limiting effects. We form a supramolecular pseudo-cube based on functionalized PDI molecules and demonstrate that the rigidity provided by the cage framework allows us to retain the electronic purity of its individual PDI subcomponents that is typically lost upon aggregation, while also suppressing vibronic losses observed in the free ligand. This rigidity extends even to the solid state upon thin film formation. We demonstrate a rare case of benign inter-chromophore interactions in a cage and confirm delayed and enhanced fluorescence, mediated through both an excited multimer and a triplet reservoir. Supramolecular coordinationthus provides an attractive route for controlling multi-chromophore interactions to fully enable device integration.

3:00 PM *SB06.08.01
Ambipolar Blend-Based Organic Electrochemical Transistors and Inverters Gitti L. Frey; Technion--Israel Institute of Technology, Israel

Bioelectronic circuits translate biological to electric signals using organic electrochemical transistors (OECTs) based on organic mixed ionic-electronic conductors (OMIEC) in CMOS-like circuit architectures. Ambipolar OECTs, i.e. devices that can act as both p-type and n-type, can therefore reduce the complexity of circuit fabrication and increase device density. Ambipolarity in bioelectronics has another major advantage, the simultaneous detection of both cations and anions in one device, which further expands the prospects for diagnosis and sensing. Ambipolar OMIECs however, are scarce, limited by intricate material design and complex synthesis. We recently demonstrated that blending p-type and n-type OMIEC materials offers a simple and tunable approach for the fabrication of ambipolar OECTs and corresponding circuits. Building on the processing-morphology-performance relationships in organic solar cells, we implemented blends of polymers and small molecules where the morphology of the active layers can be controlled by materials selection blend composition and processing conditions. We will present two families of blends: n-type polymer and p-type small molecules, or p-type polymer and n-type small molecules, confirming the generality and versatility of the approach. We will also discuss how the molecular design of the materials, with respect to energy level alignment and solubility, affect device performance. Finally, we will show that the ambipolar OECTs can be used as building blocks for CMOS-like circuits, more specifically, inverters made of two identical ambipolar OECTs. These inverters show high current and voltage amplification factors and excellent stability over multiple alternating polarity cycles with ON/OFF ratios exceeding 10^3 on both polarities and high gain. This work presents a simple and versatile new paradigm for the fabrication of ambipolar OMIECs and corresponding circuits with little constraints on materials design and synthesis and numerous possibilities for tunability and optimization towards higher performing bioelectronic applications.

3:30 PM SB06.08.02
Toward Stable p-type Organic Electrochemical Transistors Silan Zhang[1], Penghui Ding[1], Mikhail Vagin[1], Marc-Antoine Stoeckel[1], Tero-Petri Ruoko[2], Xianjie Liu[1], Mats Fahlman[1], Magnus Berggren[1], Renee Kroon[1] and Simone Fabiano[1]; [1]Linkoping University, Sweden; [2]Tampere University, Finland

Organic electrochemical transistors (OECTs) have shown great promise in various applications ranging from digital logic circuits to biosensors and neuromorphic devices. Achieving high operational stability is paramount to enabling their broad commercial implementation into products. However, undesired electrochemical side reactions, such as the oxygen reduction reaction (ORR), affect the stability of both p-type and n-type OECTs. While several strategies have been proposed to mitigate ORR in OECTs, a deeper understanding of the relationship between ORR and material degradation is required to drive the design and synthesis of new high-performance materials. Here, we will elucidate the impact of ORR on the stability and degradation mechanisms of thiophene-based OECTs. We will also present a strategy to suppress ORR, thus boosting the OECT stability dramatically without sacrificing device performance.

3:45 PM SB06.08.03
Uniaxial Alignment of Polymer Chains—A Versatile Strategy to Achieve Faster Switching and Higher Performing Organic Electrochemical Transistors Olivier Bardagot[1], Pablo Durand[2], Shubhradip Guchait[3], Gonzague Rebetez[1], Martin Brinkmann[3], Nicolas Leclerc[2] and Natalie Banerji[1]; [1]University of Bern, Switzerland; [2]ICPEES-CNRS, France; [3]ICS-CNRS, France

Organic electrochemical transistors (OECTs) are the cornerstone of emerging bioelectronic devices such as artificial synapses[1] and electrophysiological signal amplifiers[2]. To boost their development, two key parameters must be improved: (i) the signal amplification (to maximize device sensitivity), and (ii) the OECT response time (to detect sub-ms scale signals).

In parallel to polar side-chain engineering that proved to be an efficient strategy to improve concomitantly OECT response time and electronic performance[3], we herein present a complementary strategy relying on uniaxial alignment of polymer chains between the source and the drain of the transistor. Using high temperature mechanical rubbing, Durand *et al.* demonstrated metal-like conductivity up to 50 000 S cm^{-1} along the alignment direction for a chemically doped films of poly(2-(4,4'-bis(7-butoxyheptyl)-[2,2'-bithiophen]-5-yl)thieno[3,2-b]thiophene) (PBTTT-^{8}O), a PBTTT polymer with a polar single ether side chain.[4] In this presentation, we extend the potential of aligned PBTTT-^{8}O to aqueous OECT-based applications.

First, the signal amplification was estimated through the product [μC*] of electronic charge carrier mobility (μ) and volumetric capacitance (C*), extracted for transistors of varying channel volumes. The isotropic, non-aligned, PBTTT-^{8}O-based OECTs demonstrated state-of-the-art values over 600 F cm^{-1} V^{-1} s^{-1} confirming the potential of single ether side chains.[5] Interestingly, uniaxial alignment of PBTTT-^{8}O led to a thirtyfold enhancement up to 20 000 F cm^{-1} V^{-1} s^{-1}, opening doors to unprecedented device sensitivity. Such increase is attributed to higher inter/intramolecular interactions in the probed direction resulting from the polymer chain alignment. Using chronoamperometry to evaluate C*, a hole mobility of over 30 cm^2 V^{-1} s^{-1} was found.

Second, the response times of aligned and non-aligned PBTTT-^{8}O-based OECTs were quantified by combining spectroelectrochemistry and multivariate curve resolution (MCR) analysis. We found that neutral species in aligned OECTs (i) dope about twice faster and (ii) dedope more than four times faster than non-aligned OECTs. These significant improvements are tentatively ascribed to faster ion injection/expulsion due to higher surface-to-volume ratio[6] and faster charge injection/extraction due to higher hole mobility.

To summarize, we demonstrate not only that single ether side chains is an efficient molecular engineering strategy, but more importantly that uniaxial alignment of polymer chains between the source and the drain of OECTs is an effective strategy to concomitantly boost signal amplification and device response time. In particular, high temperature mechanical rubbing is a versatile and easily implementable method compatible with roll-to-roll processing. This work promises a bright future for highly structured OECT channels for fast and high performance bioelectronic devices.

4:00 PM SB06.08.04
Separating the Double Layer from the Faradaic Processes at Conducting Polymer/Electrolyte Interfaces Using Electrochemical and Color Impedance Spectroscopies Zhiting Chen and Erin L. Ratcliff; University of Arizona, United States

The hybrid electrical-ionic transport properties of π-conjugated polymers offer a number of promising energy conversion and storage and biosensing applications for soft material semiconductors. Current studies focus predominantly on either electronic transport or ionic transport characteristics and structure-property relationships. As the electronic and ionic transports are highly coupled in electrochemical devices, it is a challenge to differentiate a redox process of the conjugated backbone (Faradaic) from the complementary intercalation of supporting electrolyte (non-Faradaic) at polymer/electrolyte interfaces with both energy and frequency resolution.
Spectroelectrochemical approaches offer enhanced sensitivity to particular reactions of interest; in particular, polaronic motion can be monitored at various time scales upon doping using the electrochromic properties of π-conjugated systems. Herein we use color impedance spectroscopy (CIS) to resolve the dynamic responses of a prototypical system, poly(3-hexylthiophene), thus separating out contributions from non-polaronic processes – specifically ion intercalation and solvation effects – from Faradaic processes.
Using CIS, we observe that higher doping potentials show a greater motion of polarons above the DC-bias baseline concentration, while all potentials considered demonstrates a critical frequency at which polaronic motion is frozen. This critical frequency offers a unique figure of merit, measured independent of complicated electrochemical impedance spectroscopy (EIS) analysis, by which to compare across polymer/electrolyte interfaces, including the role of charge-supporting electrolyte, solvent, and alternative Faradaic processes (ex. electrocatalysis).

SB06.09.01
Elimination of Charge-Carrier Trapping by Molecular Design Oskar Sachnik, Jasper Michels, Gert-Jan Wetzelaer and Paul Blom; Max Planck Institute for Polymer Research, Germany

Most organic semiconductors suffer from an unbalanced charge transport, which is caused by trapping of holes and/or electrons by contaminants, such as water or oxygen. Devices that benefit from a balanced charge transport, such as organic light emitting diodes, organic solar cells and organic ambipolar transistors, ideally make use of organic semiconductors that possess energy levels within an energetic trap-free window with a width of 2.5 eV, for which charge trapping is near absent. However, for blue-emitting OLEDs, which require materials with a band gap larger than this window, removing or disabling charge traps poses a significant challenge. In this work, we demonstrate a strategy to design organic semiconductors, of which the HOMO and LUMO orbitals are spatially separated on different parts of the molecule. By modification of the chemical structure the molecular stacking can be tuned in a way

that the LUMO orbitals are protected from impurities that cause electron trapping, increasing the electron current by orders of magnitude. This illustrates a path towards large band gap organic semiconductors with balanced charge transport.

SB06.09.02
N-Type Small-Molecule Semiconductors for Bioelectronic Applications Simiao Yu[1], Christina J. Kousseff[1], William Neal[1], Han-Yan Wu[2], Simone Fabiano[2] and Christian Nielsen[1]; [1]Queen Mary University of London, United Kingdom; [2]Linköping University, Sweden

Organic electrochemical transistors (OECTs) have drawn tremendous attention in research communities all over the world due to their biocompatibility and synthetic tunability. In the last few years, molecular design has been playing an essential role in developing organic semiconductors for OECT devices. Previous research was mainly concentrated on the design of p-type materials for OECTs. Ever since a novel polymer comprising the naphthalene diimide (NDI) monomer was successfully designed and synthesized in 2016, considerable efforts have been devoted to developing novel n-type channel materials. The quick development of this field during the past few years can be attributed to the synthetic methods, various materials design strategies and device engineering protocols. With the emergence of novel molecules, detailed structure-property relationships of channel materials and reasons for their excellent performance should be explored further.
The work I will present is about a series of n-type small-molecule semiconductors based on naphthalene diimide (NDI) and perylene diimide (PDI) building blocks. When functionalized with different ion-transporting groups at the imide nitrogen positions, such as different length linear and cyclic ethylene glycol motifs, mixed ionic-electronic conduction properties were observed for thin films in aqueous environment. The solubility and aggregation behavior of these organic mixed conductors can be modified without changing the optical and electrochemical properties of the π-systems. Besides, PDI functionalized with an ion-selective ethylene glycol moiety exhibited good ion doping of the thin film with markedly different behavior in sodium chloride and potassium chloride solution, which paves the way for ion-selective mixed conductors as promising materials in organic electrochemical transistors and biosensors.

SB06.09.03
Understanding Interfacial Recombination Processes in Narrow-Band-Gap Organic Solar Cells Nora Schopp[1], Hoang Luong[1], Benjamin Luginbuhl[1], Patchareepond Panoy[2,1], Vinich Promarak[2], Viktor Brus[3] and Thuc-Quyen Nguyen[1]; [1]UC Santa Barbara, United States; [2]Vistec, Thailand; [3]Nazarbayev University, Kazakhstan

Recombination losses in organic photovoltaics (OPVs) remain a performance-limiting factor, including bulk trap-assisted recombination and interfacial recombination at the electrode:active layer interface. In this talk, we demonstrate the role of the front electrode:active layer interface in a narrow-band-gap system, **PCE10**:**COTIC-4F**, a promising candidate for semitransparent organic photovoltaics. Charge generation, recombination, and extraction are addressed, with a focus on interfacial recombination via surface traps by a comparison of four device structures with electrodes based on ZnO, ZnO/PFN-Br, PEDOT:PSS, and a self-doped conjugated polyelectrolyte (CPE-K). The amount of interfacial recombination is affected significantly by the electrode choice, while similar levels of bulk recombination are maintained. For the studied blend, we identify ZnO as a suitable choice, pairing low surface recombination rates with beneficial charge carrier generation, favorable energy level alignment, and efficient extraction. In contrast, PEDOT:PSS-based devices suffer from interfacial recombination, which can be suppressed when CPE-K is used instead.

SB06.09.04
Impact of Molecular Weight on Mixed Conduction—The Unexpected Role of Electrolyte Choice Dilara Meli[1], Joshua Tropp[1], Ruiheng Wu[1], Bryan D. Paulsen[1], Christopher J. Takacs[2] and Jonathan Rivnay[1,1]; [1]Northwestern University, United States; [2]SLAC National Accelerator Laboratory, United States

Organic mixed ionic electronic conductors (OMIECs) have shown promise in applications such as sensing of biological signals, organic inverters, and neuromorphics. OMIECs are particularly desirable due to their synthetic tunability, though this requires thorough understanding of structure-property relations in these materials. One such tunable parameter is the polymer molecular weight (Mn). While the effect of molecular weight on conjugated polymers for organic thin film transistor (OTFT) applications has been well studied, its effect on mixed conduction remains largely unknown. Shedding light on this relationship is important, not just to optimize performance of known polymer systems, but to improve understanding of mixed charge transport in OMIECs.

To elucidate the effect of molecular weight on mixed transport, a series of glycolated thiophene based polymers were synthesized via Kumada catalyst transfer polymerization to obtain polymers with molecular weights ranging from 13.9 to 32.5 kg/mol. This range had previously been found to contain the entanglement threshold of P3HT molecular weights in OTFTs. Organic electrochemical transistors (OECTs), a common test bed for OMIECs, were tested in both aqueous NaCl and KTFSI electrolytes, which are the most ubiquitous salts in aqueous metal halide electrolytes as well as ionic liquids and battery electrolytes, respectively. To help explain origins of observed differences in electronic performance, we performed operando grazing-incidence wide angle x-ray scattering (GIWAXS) and electrochemical quartz crystal microbalance (EQCM) experiments.

OECT measurements in NaCl show little differences in mobility (μ), volumetric capacitance (C*), nor their product (μC*) across the range of molecular weights. However, when tested in KTFSI, we observed a significant increase in μC* due to an increase in μ between 18.2 and 22.4 kg/mol, which persisted across all higher Mn. GIWAXS data on both systems show similar passive swelling in both electrolytes as assessed from shifting of the lamellar peak after electrolyte exposure. Upon doping via application of a gate bias, polymers in KTFSI show a lamellar contraction in real space, whereas polymers in NaCl show an expansion, regardless of Mn. This suggests that in order to compensate for the positive electronic charges in the polymer, polymers in KTFSI expel K^+ ions and polymers in NaCl take up additional Cl^- ions. The relative shift in d-spacing is much smaller for the KTFSI than the NaCl, however, indicating that the polymer microstructure is much more stable against perturbations in KTFSI. This could, in part, be due to the affinity of the TFSI for the polymer, which could stabilize the microstructure.

In this work, we discovered a mobility threshold around 20 kg/mol when OECTs were operated in KTFSI, which is absent in devices operated in NaCl. Leveraging operando characterization techniques, we found that this absence could be explained by a more unstable microstructure of the material in NaCl, as observed via larger modulation of the lamellar spacing during doping and dedoping. In conclusion, percolation thresholds in OMIECs may only be accessible in suitable electrolytes, which can help guide materials choices given target applications.

SB06.09.05
Flexible Covalent Organic Framework Films Sandwiched with Ferroelectric Polymers for Electrostatic Energy Storage He Li, Chongqing Yang and Yi Liu; Lawrence Berkeley National Laboratory, United States

With the rapid development of science and technology, ever-increasing demand has been directed towards high-performing energy storage devices. Among the various electrical energy storage devices, dielectric film capacitors store charges electrostatically and thus have the fastest discharging rate compared to

batteries and supercapacitors. In addition, polymer-based electrostatic film capacitors exhibit intrinsic merits such as greater processability, flexibility, lightweight and voltage tolerance capability with respect to inorganic dielectric ceramics. Because film capacitors account for more than 25% of the volume and weight of electric power systems, the enhancement in energy density of film capacitors will help to reduce the volume, weight, and cost of electrified systems such as electrical vehicles and aircrafts. While the industrial benchmark capacitor film represented by biaxially oriented polypropylene (BOPP) exhibits high dielectric breakdown strength and charge-discharge efficiency, the energy density has been largely limited by its low dielectric constant (~2.25 at 1 kHz, 25 ºC), which is smaller than 5 J/cm^3 at its breakdown strength limit. It is therefore imperative to develop polymer dielectric materials with concurrent high dielectric constant and breakdown strength to achieve high energy densities.

Herein, we demonstrate an approach to high energy density devices by incorporating a layer of covalent organic framework (COF) within two layers of ferroelectric poly(vinylidene fluoride-*ter*-trifluoroethylene-*ter*-chlorofluoroethylene) P(VDF-TrFE-CFE) polymer. The imine-based COF films were synthesized using 2,5-dimethoxyterephthalaldehyde and 1,3,5-tri-(4-aminophenyl)benzene precursors at room temperature. The sandwich-structured ferroelectric polymer/COF films are prepared through a facile layer-by-layer solution casting method, which possess the largest *k* values (>35 at 1 kHz, 25 ºC) amongst known polymer dielectrics. In addition, the combination of crystalline COF layer and soft ferroelectric polymer layers incurs excellent mechanical flexibility while retaining high mechanical strength (Young's modulus) of the COF film. More importantly, due to their all-organic nature, COFs exhibit desirable compatibility with polymers, circumventing issues caused by defects at the organic-inorganic interface in traditional dielectric polymer composites. The corresponding sandwich-structured film capacitors display high breakdown strength (>600 MV/m), and high discharged energy density of ~25 J/cm^3, which is 5 times higher than the state-of-the-art BOPP film capacitor and 3 times higher than the pure P(VDF-TrFE-CFE) polymer. Furthermore, successive charging/discharging cyclic tests validate that the developed dielectric film capacitors show excellent operational stability under high-electric-field electrification conditions.

A Conjoint Theoretical and Experimental Approach for Structure-Relationship Comparison Between ITIC and Y Family Acceptors—From Molecules to Devices Antoine Rillaerts, Florian Regnier, Jerome N. Cornil and Pascal Viville; UMons, Belgium

Since NFA molecules have made it possible to achieve nearly 20% yield, a lot of studies has been made on fine tuning to rise the record. In this work we have focused on structure-relationship properties of two important families of compound: ITIC, Y5 and their respective derivatives. The main goal is to give a better understanding behind this recent breakthrough in OPV. The theoretical part which consists of quantum-chemical calculations of electronic, optical and packing properties to have a closer look of structural changings on the electronic level energies, optical absorption coverage and modifications on the charge transport capabilities, considering the acceptor only. Calculations were made considering different solvent. The halogenation of both acceptors shows an electronic level energy lowering without impacting the optical absorption which make it possible to tune easily the V_{OC}. Regarding the crystal structures of each compound, halogenation change the way molecule are packed together and can modify charge carrier transport. About the experimental part, we carried out optical absorption, morphological and electrical properties analysis for each acceptor and blends with PM7 polymer donor. Absorption spectra gives us information about optical coverage and molecule behaviour transition between low-density system in solution and high-density system in films. The red shift that results from solution to film transition is more important for the Y molecules than ITIC series. In terms of morphology, AFM analysis demonstrated different solubility behaviours in function of the solvent used to spin-coat films and the structural changes like halogenation and side-chains length. Charge carrier mobility was analysed using impedance spectroscopy on MIS devices to probe vertical transport. Particularity of this acceptor generation is to accumulate both charge carrier and tend to be ambipolar. At the end, devices were built to make a correlation between all these characteristics and photovoltaic parameters.

SB06.09.07
Influence of Inter-Tube Junctions on the Charge Transport and the Thermoelectric Properties of Conjugate Polymer/Carbon Nanotube Composites Seong Hyeon Kim and Kilwon Cho; Pohang University of Science and Technology, Korea (the Republic of)

Conjugated polymer (CP)/carbon nanotube (CNT) composites have a variety of advantages as next-generation thermoelectric materials such as lightweight, flexibility, and biocompatibility. Thermoelectric performance of CP/CNT composites has been substantially enhanced compared with that of the individual components over decades. However, the origin and strategy for the performance improvement remains vague, without clear explanations at the molecular level. By complementarily using experimental methods with molecular dynamics simulations, we reveal the function of the CPs' structure to the thermoelectric properties at inter-tube junctions between adjacent CNTs. Indacenodithiophene-*co*-benzothiadiazole (IDTBT), which has a highly planar backbone chain and does not aggregate at inter-tube junctions, can facilitate intramolecular charge transport along backbone chains between adjacent CNTs than poly[2,5-bis(3-tetradecylthiophene-2-yl)thieno[3,2-*b*]thiophene] (PBTTT). The continuous distribution of IDTBT backbone chains spread out radially from CNTs enables both holes and phonons to be transported effectively at inter-tube junctions, which significantly increases electrical conductivity but also increases thermal conductivity somewhat. Nevertheless, IDTBT/CNT composites yield the highest thermoelectric power factor among CP/CNT composites not subjected to the chemical doping. The structure-performance relationships revealed in this study may contribute CP/CNT composites to be developed into commercially available thermoelectric materials.

SB06.09.08
Designs of Flexible Transparent Electrodes with Antireflection Coatings for High Performance Flexible Perovskite Solar Cells Eunmi Cho[1,2], Jin-Seong Park[2] and Sang-Jin Lee[1]; [1]Korea Research Institute of Chemical Technology (KRICT), Korea (the Republic of); [2]Hanyang University, Korea (the Republic of)

Flexible perovskite solar cells (F-PSCs) are of great interest because of their flexibility, light weight, portability, and compatibility with various form factors including curved surface, and low fabrication cost. Despite of enormous potential in applications, F-PSCs still suffer from low power conversion efficiency (PCE) compared to rigid PSCs largely because of the reduced photocurrent driven by low transmittance of their flexible substrate and transparent electrode. In this regard, we propose a newly developed plasma-polymerized-fluorocarbon (PPFC) thin film as an antireflection (AR) coating material for enhancing the efficiency of F-PSCs. The PPFC is a thin film with an amorphous structure produced by sputtering a composite target made by mixing PTFE and carbon nanotubes. The PPFC thin films have excellent AR effect due to low refractive index (~1.38), good adhesion to the substrate, uniformity of nanometer-level thickness and water repellency. When PPFC AR coating are deposited on the flexible polyethylene terephthalate (PET) substrates, the average difference in the transmittance of PPFC/PET increases by 3.23%, and the average difference in reflection decreases by 3.23%. After coating the PET/ITO with 100 nm PPFC film, the average difference in the reflectance decreases by 2.22%, and the average difference in transmittance increases by 1.40% in the visible region, resulting in maximum light transmittance due to the AR effect. The PPFC thin film is employed to improve the efficiency of F-PSCs, thereby increasing light absorption in the perovskite layer, and finally enhances the photocurrent in the F-PSCs. The enhanced photocurrent in the F-PSCs with the PPFC thin film is also verified by measuring the external quantum efficiency (EQE) spectra of F-PSCs without and with the PPFC thin film. All the F-PSCs with the PPFC thin film shows increased EQE in the entire visible range. The optimized F-PSCs with the 100 nm PPFC thin film greatly improves the PCE of F-PSCs from 18.6% to 20.4%. In addition, PPFC thin film have a hydrophobic surface and very flexible, its properties is enhanced the device stability against under harsh environmental conditions. These PPFC thin films are expected to be useful not only for F-PSCs but also for flexible

electronic devices in general, considering their excellent broadband light enhancement properties, self-cleaning surface, environmental stability and flexibility.

SB06.09.09
Correlating Charge Transport with Intrinsic Energetic Disorder, Paracrystallinity and Carrier-Dopant Distance in Doped Conjugated Polymers Michael Lu-Díaz[1], Muhamed Duhandzic[2], Zlatan Aksamija[2] and Dhandapani Venkataraman[1]; [1]University of Massachusetts Amherst, United States; [2]The University of Utah, United States

High-performing organic electronics rely on organic materials with efficient charge transport. Recent advances in understanding the effects of dopants in polymers pushed the field towards a deeper understanding of dopant-induced energetic disorder. Yet, the interaction between intrinsic energetic disorder, caused by polymer morphology, and extrinsic energetic disorder, caused by Coulomb interactions with dopant ions, has not been fully established. Here we investigate the role of repeat unit connectivity and long-range order of thiophene-based polymers on dopant-induced energetic disorder. The charge transport properties were obtained by measuring Seebeck coefficient and electrical conductivity using a vapor doping-de-doping procedure. The thin film structures were studied using UV-Vis spectroscopy, X-ray scattering, and atomic force microscopy. A phonon-assisted hopping model was used to simulate charge transport and fit to experimental data. This experimental-computational study shows that polymers with shorter polaron-counterion distances lead to increased extrinsic dopant-induced disorder due to additional Coulomb interactions. Our work shows a need for an integrated molecular design that requires both low intrinsic disorder and extrinsic dopant-induced energetic disorder for efficient charge transport.

SB06.09.10
Flexible Smart Labels for Mobile Authentication Using Photonic Physical Unclonable Functions Lilia Dias[1], Tiago Silvério[2], Lianshe Fu[1], Paulo Andre[2] and Maria Rute Ferreira Andre[1]; [1]CICECO, Portugal; [2]Instituto de Telecomunicacoes, Portugal

The Internet of Things (IoT) is a network of connected objects, interacting in real-time, without human supervision. However, the large-scale dissemination and the development of digital ecosystems requires mobile applications with fast and reliable methods to generate secure cryptographic keys, such as Physical Unclonable Functions (PUFs). In this work, functional operating photonic PUFs based on flexible tokens were produced at low-cost, energy-efficient, and scalable methods, using an organic-inorganic hybrid doped with lanthanide ions (Ln^{3+}=Eu^{3+}), displaying unique challenge-response pairs for two-factor authentication. Under laser irradiation, a speckle pattern is attained, and under UV light-emitting diodes, it displays a random luminescent intensity-based pattern, ensuring the two-factor authentication precision and recall values around 100%. Moreover, the two-factor authentication possibility enables this system to be used as a conventional PUF encryption proving a new paradigm of cryptographic key generation by featuring perceptual hash key extraction with images taken from a smartphone which can provide easy and fast remote authentication.

Effect of pH-Controlled Dye Solution on Improving the Performance and Stability in Organic Solar Cells Nara Han and Dong-Yu Kim; Gwangju Institute of Science and Technology, Korea (the Republic of)

In bulk-heterojunction of organic solar cells (OSCs), the morphology of photoactive layer can be controlled through various chemical and physical treatment methods including alcohol treatment, anti-solvent method, and layer-by-layer deposition technique. In particular, it is meaningful that the appropriate film morphology for better charge generation, transport, and extraction is achieved by a simple and accessible process. Our group recently reported ‘water treatment’ with a small amount of water introduced in the preparation process of the active solution to give a physical impact that induces vortex agitation. In this work, we study the effect of pH-controlled dye solution on enhancing the device performance and stability in OSCs. We employed structure-changeable dye molecules within a variety of pH ranges (1-13) as an additive in the process. This strategy makes it possible to obtain more clear phase separation in the thin films treated under high pH conditions. More crucially, by applying this treatment under the basic condition with NaOH as a pH controller, the chemical reaction between the active solvent and additive was generated, thus resulting in enhanced short circuit current densities and fill factors. As a result, an improved efficiency (13.98%) of the device treated with pH-controlled dye solution was achieved compared with the efficiency (13.35%) of PM6:Y6 cells. All these results demonstrated that the treatment using pH-controlled dye solutions is a feasible and promising strategy to construct efficient and eco-friendly OSCs.

SB06.09.12
Highly Flexible Polymer Solar Cells Made with Uniform Silver Nanowire Patterned Electrodes on Robust PEN Substrate Su Hong Park, Na Yeon Kwon, Hyeondoo Je, Jin Young Park, Min Ju Cho and Dong Hoon Choi; Korea University, Korea (the Republic of)

The polymer solar cells (PSCs) have been extensively researched in recent years, and have the advantage that they can be applied to flexible devices. Although the brittle indium-tin-oxide (ITO) electrode was employed for flat=panel device, flexible transparent conductive electrodes should apply for the flexible and stretchable next-generation device, exhibiting low sheet resistance, high optical transmittance, low surface roughness, and increased flexibility. Various flexible transparent conductive electrodes, such as conducting polymers, graphene, metal nanowires, and hybrid types, have been proposed to replace ITO, and many studies have been conducted to demonstrate the excellent properties of electrodes using the above materials.
Generally, AgNWs were dispersed with the solvent of isopropanol, it is hard to spread uniformly on the hydrophobic plastic substrate because of the surface tension and its wettability To overcome this problem, a few groups have attempted to confer hydrophilicity to the substrate by using PVA and PEDOT: PSS. However, the aqueous solution of the above polymers disadvantageously forms a non-uniform thin film; thus, the AgNW layer applied to the upper layer tends to be non-uniform. Therefore, it is necessary to study new coating materials that can change the surface properties of PET and PEN. However, all these methods only improve the adhesion between the AgNWs network and the substrate and are not ideal in terms of the overall uniform patterning process owing to the unsolved issue of random AgNWs distribution.
In this study, we successfully fabricate a patterned AgNW-based electrode on a flexible PEN substrate after the UV irradiation/washing of an overcoat layer composed of PEDOT: PSS and a UV sensitizer. To increase the wettability between the PEN substrate and the AgNWs, a stable, optically transparent, hydrophilic poly(2-hydroxyethyl methacrylate) (PHEMA) film is coated as an underlayer for the AgNWs. Furthermore, the conductivity and transmittance of the AgNW layer are optimized by varying the concentration of the AgNW solution. The patterned AgNW electrode achieves a low sheet resistance (Rsh) of 22.6 Ω/square and high transmittance of 92.35% at 550 nm. A polymer solar cell (PSC) was fabricated to evaluate the characteristics of the device employing the flexible electrodes. This PSC not only showed a high power conversion efficiency of 11.20%, similar to that of ITO-based devices, but also excellent mechanical stability, which is difficult to achieve in ITO-based flexible devices

SB06.09.13
Crosslinkable Conjugated Polymers for Improvement in the Stability of Flexible Polymer Solar Cells Na Yeon Kwon, Su Hong Park, Hong Diem

Chau, Sung Hoon Jung, Min Ji Kang, Min Ju Cho and Dong Hoon Choi; Korea University, Korea (the Republic of)

The polymer solar cells (PSCs) have been extensively researched in recent years, and have the advantage that they can be applied to flexible devices. Although PSCs with bulk-heterojunction (BHJ) systems are composed of an active layer with binary blends of polymer donors and polymer acceptors and display high performance, the device stability is still challengeable. Even in well-mixed polymer blend films, long-term high-temperature conditions can induce phase separation in the films. Therefore, the shelf-life and operational stability of the PSCs in ambient and high-temperature environments should be carefully considered for the practical application of all-PSCs. Among the several strategies reported for improving the high-temperature stability of all-PSCs, the crosslinking reaction has emerged as an effective method for improving the stability and functions of the polymer films. On the other hand, single-component polymers via conjugated donor-acceptor block copolymers (CDABPs) have been proposed for use in many strategies to overcome the drawback of BHJ. These polymers can suppress phase separation and exhibit inert internal morphologies compared to the polymer blends; however, their thermal stability remains an issue to be addressed.
In this study, we demonstrated a novel crosslinkable polymer system: extrinsic single component system(PBDBT-BV_{20} and N2200-TV_{10}) and intrinsic single component system(P(OXBTT-co-NDI2T)). First, random terpolymers were successfully synthesized by introducing thiophene-based monomers bearing vinyl functional groups in the side-chain. The physical properties of the blend films of PBDBT-BV_{20} and N2200-TV_{10} before and after thermal crosslinking were extensively investigated and compared to those of the homogeneous individual polymer films. In addition, the PSCs with the crosslinked blend film exhibited an excellent shelf-life of over 1200 h and a thermally stable power conversion efficiency(PCE). Furthermore, the crosslinked blend film exhibited excellent mechanical stability under bending stress in flexible PSCs using plastic substrates. After all, we synthesized a new CDABP (P(OXBTT-*co*-NDI2T)) bearing crosslinking groups to minimize phase separation and secure thermal stability of the internal morphology. The P(OXBTT-*co*-NDI2T) film exhibited a relatively high PCE and excellent thermal stability compared to the all-PSC device based on the P(OXBTT):P(NDI2T) blend film. The results of these studies indicate the promising potential of PSCs with crosslinkable conjugated polymers for future PSCs that require a long shelf-life, thermal and mechanical stability, and high performance.

SB06.09.16
Counterion Influence on Thermoelectric Properties of Electrochemically Doped Regioregular and Regiorandom poly(3-hexylthiophene) Kyle N. Baustert[1], Augustine Yusuf[1], Joel Bombile[1], Ahmed Ayyash[1], Ashkan Abtahi[2], Chad Risko[1] and Kenneth R. Graham[1]; [1]University of Kentucky, United States; [2]Purdue, United States

Doping of π-conjugated polymers is critical for tuning their properties and making them operable in many organic electronic devices including organic light emitting diodes, organic thermoelectrics, and organic electrochemical transistors. In both chemical doping and electrochemical doping an ionized dopant or counterion is required to balance the newly acquired charge on the doped π-conjugated polymer. The characteristics of this dopant or counterion, such as size, shape, and relative polarity, can significantly impact the optical, electronic, and thermoelectric properties of the resulting material. Here, we investigate how the counterion structure impacts the electrochemical doping ability, oxidation potential, ionization energy, and polaron absorbance of regioregular (rr) and regiorandom (rra) P3HT. We also probe how electrochemical doping with these different counterions leads to changes in conductivity and Seebeck coefficients influencing thermoelectric performance. The most prominent change in the polymer oxidation potential is observed for rr-P3HT with the large tetrakis[3,5-bis(trifluoromethyl)phenyl]borate anion. We propose that this large anion is excluded from the tightly packed crystalline regions and thus the oxidation potential is closer to that of the mostly amorphous rra-P3HT. The anions also result in significant differences in polaron absorbance and ionization energies as well as notable changes in peak broadening in epr spectra with increased doping. These results emphasize the important role that the counterion has in influencing the optical and electronic properties of doped π-conjugated polymers.

SB06.09.17
Large-Scale Anisotropy of Charge Transport in Molecular Ultrathin Film-Based OFETs Fabricated with Laser-Assisted Zone Crystallization Method Krzysztof Janus and Adam Kiersnowski; Wroclaw University of Science and Technology, Poland

Control of the crystallinity, crystal perfection, sizes and orientation of crystal domains in organic semiconductors (OSc) is essential for developing efficient electronic devices based on organic thin films. One of the key issues to be addressed is a control over anisotropy and size of crystal domains in the active layer of a device, as they both affect the overall device performance. The crystal anisotropy can cause locally directional charge carrier transport and, consequently, may lead to an inhomogeneous operation of devices, especially in an array. A broad distribution of size or a mismatch between ordered domains size and a device scale may as well cause issues with homogeneous operation devices in arrays. That is why formation of ordered, oriented domains is of importance. Growth of these domains is related to kinetic conditions and direction of the mass transport during solidification (crystallization) of the film. This is the reason why crystal structure and morphology of the OSc films are fabrication method-sensitive. Moreover, scalability of a fabrication method is a key in successful transferring laboratory results up to the industry scale.
In this contribution we therefore demonstrate a potential of laser-assisted zone crystallization (LAZEC) method in freely scalable fabrication of ultrathin films of organic semiconductors. The working principle of the LAZEC consists in scanning the surface with a laser beam in order to induce thermal gradients of surface free energy and ink viscosity. The gradients cause a flow-induced motion of the ink on the surface whereas a controlled evaporation of the solvent, as the laser is moving, causes solidification of non-volatile ink components on the surface to form a film. The gradients can be precisely controlled by adjusting the laser parameters (power, scanning speed) depending on the substrate and ink properties. The substrate temperature additionally controls the crystal growth temperature and hence further control over formation of crystal domains in the film.
In this contribution we demonstrate potential of the LAZEC by showcasing processing of small-molecular or polymer inks. The inks were chloroform, toluene or dichlorobenzene solutions of poly(hexylthiophene-co-thiophene (P3HTT) or TIPS-pentacene (TP). We used TP and P3HTT to fabricate films with 20 nm thickness using different coating parameters. Morphology of the films was studied with optical and atomic-force microscopy. The crystal anisotropy was studied with synchrotron wide-angle X-ray diffraction (WAXD). In order to probe the charge carrier transport anisotropy and homogeneity we coated the films on arrays of top-gate, bottom-contact field effect transistors (OFETs). The film coating axis was oriented at variable angle with respect to source-drain electrode axis (i.e. the transistor channel axis). The WAXD studies revealed that the LAZEC coating can produce the films with crystal domains almost uniaxially oriented along the coating direction. Fine tuning of laser parameters and scanning speed enabled formation of films where the crystal domains revealed only just +/- 10 deg. deviation from the director (coating) axis over the whole sample. The size of crystal domains was controlled with the laser speed and power. In line with morphological findings, OFET testing revealed several-fold difference between charge carrier mobility measured along and transverse to the coating direction. The morphology control in the LAZEC process enabled efficient, freely scalable fabrication of high-performance ultrathin films. For instance, the maximum p-type charge carrier field mobility recorded for 20-nm TP reached almost 0.1 cm^2(Vs)^-1 whereas the maximum reported charge carrier mobility for bulk TP was a few cm^2(Vs)^-1. Qualitatively similar observations were made for P3HTT films.
The work was supported by National Science Centre Poland (NCN) through the grants UMO-2017/25/B/ST5/02869 and UMO-2016/22/E/ST5/00472

Photonic Processing of Printable Optoelectronic Device Materials for Flexible Hybrid Electronics (FHE) Applications Charles Trudeau[1], Bilge Altay[2], Patrick Beaupre[1], Arjun Wadhwa[3], Sylvain G. Cloutier[3] and Martin Bolduc[4]; [1]INO - Institut National d'Optique, Canada; [2]Rochester Institute of

Technology, United States; [3]École de Technologie Supérieure, Canada; [4]Université du Québec à Trois-Rivières, Canada

In this work, we present our recent progress on rapid photonic processing in the fabrication of printable and flexible hybrid electronic (FHE) devices and circuits. The pulsed photonic irradiation utilizes microseconds to milliseconds processing time onto thin flexible polymer or paper-based substrates, which suffer from low glass-transition temperatures. These new processing technologies show great promise in maintaining the integrity of the substrates without structural degradation due to shrinkage, charring or decomposition.

We will present flash-lamp [1-2] and laser [3] sintering experiments that show optimized sheet resistance values for silver and copper inks printed onto PET and SBS paper obtained at very high speed and spatial precision in comparison with conventional oven annealing. In addition, the results will show how these techniques can provide a greater control over the optoelectronic material properties in the fabrication of perovskite-based devices [4].

Solid-Solvent Hybrid Additive for the Simultaneous Control of the Macro- and Micro-Morphology in Non-Fullerene-Based Organic Solar Cells
Daehwan Lee and Taiho Park; Pohang University of Science and Technology, Korea (the Republic of)

Most organic solar cells based on a bulk-heterojunction active layer are fabricated with the assistance of high boiling point solvent additives to optimize the phase separation of the donor and acceptor. The macroscopic phase separation can be controlled by this solvent additive. However, the control of the microscopic morphology (e.g., π-π stacking, orientation) of the inside phase is still dependent on the interaction and self-assembly characteristics of each donor and acceptor. In this work, we introduce a solid-solvent hybrid additive on PM6:Y6 solar cells to optimize both the macroscopic phase separation and the microscopic morphology at the same time. For the solvent additive, the well-known 1-CN solvent additive was used. For the solid additive, newly synthesized 3D star-shaped solid additives (Star-A and Star-F), which were delicately designed to achieve adequate electrical properties, electrostatic potential, and geometrical structure, were used to further optimize the microscopic morphology. Grazing-incidence small-angle X-ray scattering (GISAXS) and grazing-incidence wide-angle X-ray scattering (GIWAXS) measurements showed that the star additives not only induce the dense and enhanced microscopic intermolecular π-π stacking within the phase, but also further optimize the phase separation. By adding only 1% star-series solid additives, a significantly enhanced efficiency was achieved from PM6:Y6 solar cells.

SB06.09.21
Covalently Tethered, Semiconductor-Insulator-Conductor Polymer Networks for High-Reliability Foldable Transistors Seokran Choi, Hyukmin Kweon, Ukjin Jeong, Borina Ha, Jiyeon Ha and Do Hwan Kim; Hanyang University, Korea (the Republic of)

Polymer-based foldable electronics have gained significant attention as next-generation devices in the field of display and sensor technologies because of the flexible nature of polymers. Generally, the devices possess a heterogeneously multi-layered structure, indicating that mechanical stress derived from repeated folding and unfolding conditions can propagate both bulk and interfacial regimes of each component layer. This can cause not only cohesive failure of the bulk but also interfacial delamination between the layers. Therefore, to demonstrate foldable devices with high resistance to repetitive folding-unfolding stress, it is essential to secure excellent mechanical stability at both failure points. However, most approaches only focused on either enhancing deformability of component layers or improving interface stability by utilizing physical or chemical crosslinking between layers, resulting in insufficient mechanical stability against continuous folding stress. This strongly indicates that a practical strategy to simultaneously prevent cohesive and interfacial failures is sought after for the realization of high-performance foldable electronics against severe mechanical stress.
Herein, we present a novel molecular design approach of deformable and covalently attachable interpenetrating polymer networks (DcA-IPNs) in which a ladder-like polysiloxane network is physically entangled with polymer matrix (conductor, semiconductor, and insulator). The interpenetrated polysiloxane network can induce short-range aggregation of polymer and restrain fragmentation of deformed chains so that mechanical energy dissipation in the bulk regime of layers can be efficiently proceeding. Moreover, DcA-IPNs possess unreacted silanol (Si-OH) groups at their surface regimes, which is capable of the formation of covalent bonds between adjacent layers for enhanced interfacial adhesion property. Based on this, we fabricated DcA-IPNs-based foldable transistors showing high operational stability against repeated folding-unfolding stresses without degradation of their electrical performance. We believe our novel approach will provide new insights into foldable electronics.

SB06.09.22
Thickness Tuned Ultra-Strong Light-Matter Coupling and Self-Grouping of Exciton-Ensemble in Single Crystals of Metal-Organic Framework
Dileep Kottilil and Wei Ji; National University of Singapore, Singapore

Exciton-polaritons are coupled particles resulting from a strong interaction between electron-hole pairs (excitons) inside material and photonic modes of a microcavity. The unique features of these particles can be engineered for new technological applications such as inversionless lasers, all-optical logic gates and others. Recently researchers have been exploring ultra-strong coupling (USC) which is a new light-matter interaction regime that exceeds both weak and strong coupling schemes. Here, we introduce a solid-state organic polariton light source, for the first time, based on pristine and single-crystalline microplates of a dye-coordinated Metal-Organic Framework (MOF) operating under the USC regime. From optical measurements, we extract a record-high Rabi splitting value of 1.15 eV, which is 51% of the molecular transition energy. Further, the percentage of virtual photons in the polariton ground state is determined to be 1.79 %, indicating MOF as a promising platform for vacuum emission. A miniaturized form of such light sources has a wide variety of applications in science, technology and medicine. More importantly, we propose a novel physical mechanism for the first time, named 'self-grouping of exciton-ensemble', to explain the anomalous thickness dependence of multimode Rabi splitting. All the experimental results can only be explained using the correction factor introduced by this new mechanism.
An ultra-low threshold and a high degree of emission polarization have been achieved by stimulated polariton scattering occurred in single-crystallites of as-synthesized MOF microplates. With combined experiments and theoretical modelling, we found that the exciton-polaritons are formed at room temperature because of the strong coupling between Fabry-Perot cavity modes inherently formed by two parallel surfaces of a microplate and Frenkel excitons provided by the 2D layers of the dye linkers in the MOF. Such a cost-effective exciton-polariton cavity is realized at room temperature, without the support of any external mirrors made by metal coatings, or distributed Bragg reflectors (DBRs). Our findings confirm that MOFs, which can be synthesized readily from easily available materials under relatively mild conditions, are the potential candidates to unveil the previously unexplored fundamental physics and advanced applications of the USC regime without needing any complicated material fabrication procedures.

Towards a Comprehensive Theory of Organic Electrochemical Materials and Interfaces Loren G. Kaake; Simon Fraser University, Canada

The relationship between electrochemistry and organic electronic materials is over forty years old. Despite this long history, and the widespread use of electrochemical methods to characterize the electronic structure of pi-conjugated materials, the field has failed to reach consensus on many important questions. It is generally agreed that upon the application of potential, ions move into the bulk of an organic electronic material, doping p-type materials with holes by the inclusion of anions. However, this is not always the case, as demonstrated in the field of organic electrolyte gated field effect transistors. It has long been known that the same material combination can exhibit a transition from one mode of operation at a threshold voltage[3] What determines the stability of the electrified interface between an ion conducting medium and a polymer semiconductor? This behavior can be described as a special case of mixing thermodynamics using a voltage dependent enthalpy of solvation. In the case where the free energy of mixing is negative, ions and their counterbalancing charge carriers move into the film. Because the film bulk is charge neutral, this process can be understood, to a first approximation, as diffusion according to Fick's law. More recently, the expression for Fickian diffusion in a thin film can be used to describe both in-operando infrared measurements, as well as the scan rate dependence of traditional cyclic voltammetry experiments. It is important to point out that the expression of Fick's law is a slowly converging series of exponential functions, presenting a dangerous dead-end for those fitting ion transport in terms of empirical models based on RC circuits and other ad-hoc exponential corrections. With respect the structure-property relationship that governs the ion diffusion constant, the enthalpy of mixing presents a key inroad. The Vogel-Tammann-Fulcher equation, popular for aliphatic ion conductors, can be extended to describe the voltage dependence of the diffusion constant, as well as the seemingly paradoxical result that larger ions can sometimes move more quickly in organic semiconductors. This expression is also useful to understand the stability of organic solar cells. Ade and co-workers showed that the stability of organic solar cells can be understood in terms of molecular diffusion, the rate of which was influenced by solubility interactions. Importantly, the VTF equation contains a term related to the volume of mixing, providing a key parameter from which to understand the relationship between polymer crystallinity and ion diffusivity. The utility of the solvation enthalpy will also be demonstrated in understanding polymer swelling during electrochemical doping. However, it must be pointed out that a simple one-component diffusion model, even one which including enthalpy considerations is insufficient to describe the entire diversity of organic electrochemical materials. However, a two-component model which allows for the interconversion between species of different diffusivities is considerably more flexible. The ability of this model to describe charge trapping, and apparent non-Fickian diffusion will be described, with the aim of providing a description of ion transport phenomena in organic electronic that provides much-needed context for the detailed morphological understanding that has, and continues, to emerge.

Designs for Upconversion and Photomultiplication in Organic Shortwave Infrared Detectors Tse Nga Ng; University of California, San Diego, United States

Upconversion imagers that combine photosensing and display in a compact structure are attractive since they avoid the costly and complex process of pixilation. This talk will present the designs of polymeric upconversion imagers that combine photo-sensing and display in a compact structure, to enable visualization to 1300 nm (*Adv. Func. Mater.* 2021, **31**, 210056). This shortwave infrared spectral region is particularly powerful for a variety of applications including environmental monitoring and medical diagnosis, enabling greater penetration depth and improved resolution in comparison to visible light.

The organic photodetectors are further improved by incorporating a new heterojunction interlayer to trigger trap-assisted photomultiplication. Previous approaches to induce photomultiplication in organic diodes have increased the photosignal but lacked control over reducing background noise. This work presents a new interlayer design based on a heterojunction bilayer that concurrently enables photomultiplication and suppresses the dark current in organic shortwave infrared detectors to improve the overall detectivity (*Mater. Horiz*. 2022, accepted). The heterojunction bilayer is consisted of a hole-transporting material copper thiocyanate and an electron-transporting material tin oxide. This combination serves to suppress the dark current and enhance the photoresponse, leading to an external quantum efficiency up to 560% and a detectivity of 3.5 x 10^9 Jones. The upconversion efficiency of the imager is doubled with 1.7 fold improvement in contrast compared to the imager without the heterojunction interlayer. The new interlayer design is generalizable to work with different organic semiconductors, making it attractive and easy to integrate with emerging organic infrared systems.

9:15 AM SB06.10.02
Synthesis and Characterization of Novel Chiroptical Low Bandgap π-Conjugated Polymers for Circularly Polarized Near-Infrared-Sensing Organic Thin-Film Phototransistors Hyemi Han, Jongtae Ahn, Do Kyung Hwang and Jung Ah Lim; Korea Institute of Science and Technology, Korea (the Republic of)

Chiral optoelectronics manipulating the circularly polarized (CP) light has received extensive attention over the past decades due to its promising opportunities in next-generation optoelectronics such as quantum computation, optical spintronics, encryption, and 3D displays. For achieving technological advances in such fields, various chiral organic semiconducting materials, that differentially absorb CP light according to the polarization direction, have been developed, but the chiroptoelectronic devices using them have not been rarely explored, which is still at a very early stage. Particularly, chiral semiconducting materials with optical activity in near-infrared (NIR, 700~1700 nm) spectral region have become increasingly important because it can fully extend their applicability including long-distance optical communication. Recently, in order to develop chiral material applicable to the chiroptical organic optoelectronic devices operating in NIR region, we synthesized novel chiral low bandgap π-conjugated polymers through four-step chemical reaction procedure, in which the chirality is induced by incorporating enantiopure (*R*)- or (*S*)-side chain substituents into donor-acceptor type polymer backbone showing excellent charge transport and NIR absorption properties. In spin-coated thin films, intrinsically chiral sidechain polymers brought about distinct circular dichroism in the NIR region at the local/molecular level, which was amplified by long-range structural chirality of polymer chains depending on the film thickness increment to 200 nm. We pursued to understand the origin of such chiroptical phenomenon of chiral sidechain polymer thin films by using a combination of molecular/spectroscopic analysis and peculiar morphological stacking features of supramolecular self-assembles of chiral polymers. Based on this, we applied the chiral π-conjugated polymer thin films to circularly polarized NIR-sensing photoactive channel layer in organic thin-film phototransistors for direct detection of CP light and efficient amplification of photosignals, and optimized their thickness for a

high CP NIR-sensing efficiency. As a result, by distinguishing the left or right handedness of incident CP NIR lights with wavelength of 830 and 920 nm, they achieved excellent photoresponsivity of 31.6 and 26.1 A/W for each wavelength, along with a high photocurrent dissymmetry (g-factors > 1) as well as a fast optical response time (<100 ms) at film thickness below 100 nm. This presentation provides new approaches for the design of chiroptical organic semiconducting materials and devices that can pave the way to high-performance chiral optoelectronic applications.

9:30 AM SB06.10.03
Acceptor-Substituted Squaraine Dyes for Organic Optical Upconversion Devices Michael Bauer[1], Wei-Hsu Hu[1], Frank Nüesch[1,2] and Roland Hany[1]; [1]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]École Polytechnique Fédérale de Lausanne, Switzerland

Near infrared optical sensing and imaging are essential to an increasing number of next-generation photodetector applications in communications, process control or medical imaging. Recently, 1,3-squaraine dyes have been established as near-infrared absorbing or emitting dyes for these type of applications. However, most squaraine dyes show peak absorptions well below 1000 nm, a threshold wavelength below which organic photodetectors can hardly compete with the current inorganic silicon-based photodetector technology. Here, we show an approach to shift the peak absorption wavelength of squaraine dyes above 1000 nm through substitution on the central squaric acid core. The acceptor strength of this central moiety is enhanced by incorporation of dicyano- and rhodanine electron accepting groups. In addition, the central squaraine core is flanked by two benz[*cd*]indoles to generate a pronounced donor-acceptor-donor π-system. The feasibility of these core-substituted squaraine dyes for NIR detection above 1000 nm is demonstrated by integration in all-organic upconverter devices. These devices consist of an organic NIR sensitive photodetector and an organic light-emitting diode, connected in series. Organic upconverters convert NIR photons to visible photons and allow for pixel-free direct NIR imaging. Our NIR squaraine-based upconverters show a response well below the band gap edge of silicon and provide a low-cost opportunity for novel consumer and low-end imaging applications far into the shortwave infrared range.

Bulk Heterojunction for Improved Solid-State Upconversion with Non-Fullerene Acceptors Emma Belliveau, Manchen Hu and Daniel Congreve; Stanford University, United States

Solid-state upconversion, a process whereby two lower energy photons are converted to one higher energy photon, is promising for a variety of applications, including photovoltaics, bioimaging, and night vision. For upconversion to be useful in these and other applications, a high external quantum efficiency (EQE) is required to generate sufficient quantities of upconverted light. Typical solid-state upconversion systems, based on intersystem crossing (ISC) in a sensitizer and subsequent triplet-triplet annihilation (TTA) in an annihilator, use dilute mixtures or very thin films of sensitizer, which results in minimal absorption of the low energy light to be upconverted, and hence low EQEs. Recent work from Izawa and Hiramoto [1] uses non-fullerene acceptors (NFAs) as sensitizers, which are paired with a donor-annihilator in a bilayer structure to generate triplets at an interface without the need for ISC or triplet diffusion in the sensitizer - significant loss mechanisms in solid-state upconversion systems. With this method, they achieve record near infrared (NIR)-to-visible EQEs of up to 2.3%. Our work builds upon this concept, inspired by organic photovoltaic (OPV) architectures, to create a bulk heterojunction (BHJ) upconversion film where the sensitizer and annihilator are combined in one solution-processed layer. This results in superior EQEs than their bilayer counterparts, due to the increased surface area between the two materials resulting in improved triplet generation. The benefits and applicability of this optimized BHJ upconversion system are then demonstrated with a NIR-to-visible imaging system.

Controlling and Tracking Dopant Distributions and Morphologies in Molecularly-Doped n-Type Conjugated Polymers via Pendant Group Modification Ryan Chiechi[1,2] and Lambert Jan Anton Koster[2]; [1]North Carolina State University, United States; [2]University of Groningen, Netherlands

The structural diversity of n-type conjugated polymers is somewhat lacking compared to their p-type equivalents, which have benefited considerably from nearly three decades of research in polymer-fullerene photovoltaic cells. However, n-type materials are finding applications in their doped form, which presents different synthetic design challenges than the aforementioned p-type semiconductor paradigm. In this contribution I will present some of our recent work on the versatile naphthalenediimide-bithiophene (PNDI2) framework and its performance as a thermoelectric material.
Charged dopants will phase-separate from conjugated polymers with non-polar pendant groups, hence the now-common use of polar (typically ether-containing) pendant groups. Using the PNDI2 backbone doped with n-DMBI, we investigated three different pendant groups: 1) branched alkyl (non-polar); glycol ether (polar); and alkyl-glycol-ether (non-polar and polar). We varied the regiochemistry of these chains such that the naphthalenediimide and bithiophene units had (mis)matching pairs of the various combinations of polar, non-polar and mixed pendant groups.
Counter-intuitively, the PNDI2 derivative with all polar pendant groups did not give the best performance. Rather, two polymers stood out. The highest doping efficiency (40 fold compared to the benchmark) correlated to both the regiochemistry and identity of the groups, while the highest power factor (5 fold compared to the benchmark) correlated to pendant groups with alkyl spacers between the backbone and the glycol ether functionality.
We ascribe these observations to the ability of the pendant groups to direct the charged dopant molecules, which is supported by spatially resolved absorbance spectroscopy. A central problem with doped, n-type polymers is that the polarons tend to localize more easily than in their p-type counterparts. This localization is exacerbated by coulomb interactions with the ionized dopant. Thus, pendant groups that place a polar phase far from the backbone and, importantly, farther from the acceptor units than the donor units in the backbone achieve morphologies that mitigate phase separation while achieving high

charge-carrier mobilities by avoiding the localization of carriers via nearby dopants. The use of spatially resolved absorbance spectroscopy allowed us to correlate topographical features from AFM to the intensity of absorption bands associated with doped polymer, linking morphological and electronic features to figures of merit.

Double Doping of a Low-Ionization-Energy Polythiophene with a Molybdenum Dithiolene Complex Emmy N. Järsvall[1], Till Biskup[2], Yadong Zhang[3], Renee Kroon[1,4], Stephen Barlow[3,5], Seth R. Marder[3,5] and Christian Müller[1]; [1]Chalmers University of Technology, Sweden; [2]University of Saarland, Germany; [3]Georgia Institute of Technology, United States; [4]Linköping University, Sweden; [5]University of Colorado Boulder, United States

Doping of organic semiconductors is crucial for tuning the charge-carrier density of conjugated polymers. The exchange of more than one electron between a monomeric dopant and an organic semiconductor allows the polaron density to be increased relative to the number of counterions that are introduced into the host matrix. Here, a molybdenum dithiolene complex with a high electron affinity of 5.5 eV is shown to accept two electrons from a polythiophene that has a low ionization energy of 4.7 eV. Double p-doping is consistent with the ability of the monoanion salt of the molybdenum dithiolene complex to dope the polymer. The transfer of two electrons to the neutral dopant was also confirmed by electron paramagnetic resonance spectroscopy since the monoanion, but not the dianion, of the molybdenum dithiolene complex features an unpaired electron. Double doping allowed an ionization efficiency of 200% to be reached, which facilitates the design of strongly doped semiconductors while lessening any counterion-induced disruption of the nanostructure.

SESSION SB06.12: Modeling, Optoelectronic Properties in Organic Semiconductors

Atomistic-Level Considerations of the Multitude of Factors to Engineer Crystalline Organic Semiconductors Chad Risko; University of Kentucky, United States

Organic semiconductors derived from π-conjugated molecules are of broad interest across a range of electronic and optical technologies. How molecular design and processing merge to result in semiconducting materials with optimal performance remains a mixture of art and science. Here we will discuss atomistic-scale simulations that explore how molecular chemistry and topology and processing conditions can provide insights into the development of crystalline organic semiconductors. We will also discuss data-driven approaches to explore molecular and materials properties of relevance for organic semiconductors.

2:00 PM SB06.12.02
Unraveling the Absorption Spectra and Relaxation Energy of NF-SMAs Using Multiparameter Franck Condon Models—A Structure-Function Study Somayeh Kashani[1,1], Zhen Wang[1,1], Chad Risko[2,2] and Harald Ade[1,1]; [1]North Carolina State University, United States; [2]University of Kentucky, United States

Understanding correlations among the molecular structure, conformational diversity, and relaxation energy of a nonfullerene small molecule acceptor (NF-SMA) used in organic solar cells (OSCs) and their functional, optoelectronic properties is important to rationally design new materials with controlled properties. Although, correlations among molecular structure, optical and electronic gaps, and electron affinity of NF-SMAs have been studied extensively, an analysis of absorption spectra that classifies the NF-SMAs based on their electronic and vibrational finestructure is still missing. Here, we study the absorption spectra of 10 high-performing NF-SMAs in dilute solutions at room temperature, the most common tool utilized to uncover structure-spectra relations. Utilizing multiparameter Franck Condon (FC) analysis and quantum-chemical calculations, we show that the absorption spectra of NF-SMAs can be categorized into three types based on the molecular structures-spectra correlation: 1) The absorption spectrum of a linear ITIC-like molecular structure can be described by a single vibrational progression with one electronic transition and one effective vibrational mode. 2) The absorption spectra of curved, Y6-like structures can be described using a multiparameter FC model with two electronic transitions and two effective vibrational modes. Our results show that Y6 exhibits a highest conformation uniformity and the smallest intra-molecular relaxation energy, characteristics that may contribute to the Y6 success in state-of-the-art OSCs. 3) In contrast, structures like EH-IDTBR with π-bridges between the core and end groups have broader absorption spectra. The result of FC analysis and quantum-chemical calculations confirm the coexistence of different conformations and larger intra-molecular relaxation energies for these systems when compared to the other NF-SMAs in this study. These results provide insights for the design of new NF-SMAs, in particular a need for a simultaneously small number of molecular conformations and energetic disorder, and small relaxation energies, critical parameters that if controlled should improve the efficiency of organic photovoltaics or organic devices in general. The results clearly demonstrate that DFT calculations are able to provide excellent relative relaxation energies that can be utilized to assess molecules prior to synthesis.

2:15 PM SB06.12.03
A Quantum Mechanics/Molecular Mechanics Simulation Approach to Access the Charge Photo-Generation Properties in Organic Photovoltaic Materials Leandro R. Franco[1], Cleber Marchiori[1], Ellen Moons[1] and Moyses Araujo[1,2]; [1]Karlstad University, Sweden; [2]Uppsala University, Sweden

The development of new organic photovoltaic materials based on non-fullerene acceptors (NFAs) has led to a significant increase in the power conversion efficiency of organic photovoltaics (OPV) in the last years[1]. However, the fundamental understanding of the charge photogeneration mechanism at the molecular level is still lacking, a scientific challenge whose solution could be the watershed in the discovery of novel OPV materials. To contribute to this end, we are developing a multi-scale method that combines Quantum Mechanics (QM) calculations and Molecular Dynamics (MD) simulations within the scope of a sequential-QM/MD approach [2] to assess the charge photo-generation properties in organic photovoltaic materials. Despite being a well-established method to study small molecules in solution, it has not yet been developed to investigate polymer (and small organic molecule) films cast from solution. Our methodology starts with the simulation of film formation through solvent molecules evaporation using classical molecular dynamics simulations. Then additional MD simulations are carried out on the obtained film to generate uncorrelated configurations to be used on the properties' calculations. The latter is assessed through an electronic embedding scheme where a pre-defined molecular region, of the generated configuration, is treated at the QM level, incorporating explicit effects of the environment. For the QM calculations, density functional theory (DFT) and time-dependent DFT have

been employed. The quality of the force field parameters adopted in the MD simulations have been carefully analyzed. A set of representative NFAs small molecules and polymers have been studied, e.g. Y5, Y6, and PF5-Y5 polymer. Given the flexibility of the computational approach, we have been able to study these systems both in solution (chlorobenzene) and film. First, we have analyzed the structure of the films with focus, for instance, on the tendency to stabilize pi-pi stacking conformations. Then, the dynamics and molecular environment effects on the electronic transitions have been quantified with an improved description of the optical absorption. Finally, through the calculation of the fundamental and optical gaps the exciton binding energies have been estimated. Here, we have considered both the singlet and triplet excitons. The comparisons with experimental results confirm the suitability of the developed s-QM/MD approach, highlighting the importance of properly describing the dynamics and molecular environment effects in the modeling of the electronic properties of OPV materials.

Impact of Phonons on Charge and Heat Transport in Organic Semiconductors Nemo McIntosh[1], Alexandre Vercouter[1], Marco Bardini[1], Samuele Giannini[1], Claudio Melis[2], David Beljonne[1] and Jerome N. Cornil[1]; [1]University of Mons, Belgium; [2]University of Cagliari, Italy

Charge transport in molecular crystals is reduced by the dynamic disorder induced by thermal fluctuations. This implies that the key parameters controlling charge transport at the molecular level (in particular the electronic couplings also referred to as transfer integrals) strongly fluctuate over time under the influence of intermolecular vibrations (phonons). Such thermal effects can be grasped from molecular dynamics simulations by extracting snapshots along the trajectory and by tracking the time evolution of relevant parameters. Nevertheless, such simulations do not tell us about the nature of the phonons contributing the most to the fluctuations of the transfer integrals, which would be of prime interest to design new strategies to freeze such detrimental degrees of freedom. In this context, I will first describe in this talk our recent efforts in this direction aiming at assessing the individual role of phonons as well as the possible impact of phonon dispersion. Interestingly, the same phonons are involved in heat transport so that their impact on the thermal conductivity can be also inferred. This is of high relevance to the field of organic thermoelectrics requiring strategies to minimize the thermal conductivity. The second part of the talk will describe some recent simulations of heat transport in molecular crystals, pointing to strong anharmonic effects for some structures leading to strongly localized phonons.

4:00 PM SB06.13.02
Bipolaron Formation Mechanism in Doped Conjugated Polymers Joel H. Bombile and Chad Risko; University of Kentucky, United States

Chemical doping is a powerful strategy for tuning the electronic properties of organic semiconducting materials based on π-conjugated polymers (CP), enhancing the performance of several organic electronic devices such as thin film transistors, light emitting diodes, photovoltaics, and thermoelectric generators. Large dopant concentrations are often necessary to achieve large electrical conductivities. As the dopant concentration increases, the natures of the charge carriers in doped CP's can change from polarons, singly charged quasi-particles with a spin, to bipolarons, which are doubly charged quasi-particles without a spin. Bipolaron formation can lead to improved electrical conductivity. Understanding the mechanism of their formation could provide an avenue to further optimize charge-carrier transport in doped CP's. We use first-principles calculations based on density functional theory (DFT) and time-dependent Density Functional theory (TD-DFT) with an optimally tuned hybrid functional to examine bipolaron formation in CP's. We perform calculations on charged oligomers in spin configurations corresponding to a bipolaron (singlet) or two polarons (triplet), with and without dopant counterions. We find that the effective attraction between two polarons by sharing the same distortion of nuclei or polarizable medium is not strong enough to overcome their repulsive coulomb interaction. However, when the polarons are forced to be sufficiently close to one another, as is the case in highly doped CP chains, the short-range attractive exchange coulomb interaction, working in synergy with the shared distortion of the surrounding medium, can make bipolarons more stable than polarons.

Screen Printed CO_2 Sensors Enabled by Functionalized Carbon Nanotubes Tianyi Liu, Rebekah Baggett, Zun (Cathy) Chen, Christopher Landorf, Vijaua Kayastha, Daniel Padilla, Marriana Nelson, Louis McCarthy and Jiadeng Zhu; Brewer Science, United States

The demand for CO_2 detection steadily increases mainly due to the greenhouse effect caused by CO_2 emission. Herein, we have demonstrated a low-cost and effective CO_2 sensor based on composite materials of polyethyleneimine (PEI) along with functionalized carbon nanotubes (f-CNTs). In this design, CNTs, which were modified for a better adhesion and a more evenly distribution, served as an adsorbent and a conductive component. PEI, which have reactive amine groups, served as the responsive materials for the sensor. The sensors were finally fabricated by screen printing using the f-CNTs/PEI composite ink with a proper viscosity, which showed excellent sensitivity and good stability. Effects of environmental chamber temperatures, humidity, and material topologies on the performance have been further explored. Besides material design, devices for sensor setup and a testing system have been demonstrated in this study.

SB06.14.02
First-Principles Study of Cyanine Analogues for Photon Upconversion Natalia P. Neme, Remco W. Havenith and Thomas la Cour Jansen; University of Groningen, Netherlands

Solar energy is the most promising renewable energy source, and therefore, solar cell power conversion efficiency (PCE) is a primary concern. The theoretical maximum conversion efficiency for solar cells is known as the Shockley-Queisser limit, and to go beyond it is crucial to improve the PCE. One approach to surpass this limit is by upconversion performed by a lanthanide-based inorganic-organic system. The strategy consists of attaching an antenna to a nanoparticle doped with lanthanides [1]. The antenna absorbs near infrared light, and subsequently the energy is transfer to the nanoparticle that ultimately will perform the upconversion.

The aim of this study is to investigate the photophysical properties of a cyanine dye analogue to be used as antenna, by performing first-principles calculations based on Density Functional Theory (DFT) and Time Dependent-DFT. Our goal is to investigate dyes that absorb in Near Infrared and cyanine ones are versatile compounds that by modifying their end groups and chain's length we influence their photophysical properties. The vinylene shift is experimentally known for these molecules, and it consists of a bathochromic shift of approximately 100 nm of the 0-0 vibronic transition when a vinyl group is added to the polymethine chain [2,3]. Our study showed that the saturated moiety of the ring in the methine bridge can interact with the conjugated pi-system. We showed here the origin of this interaction and how it can be used to fine tune the absorption energy of this class of dyes.

SB06.14.03
Polarized Light Microscopy as a Rapid, Non-Destructive Evaluation Method for Qualitative Evaluation of Morphology in Organic Semiconductor Thin-Films Christopher E. Petoukhoff[1] and Deirdre M. O'Carroll[2,2]; [1]King Abdullah University of Science & Technology (KAUST), Saudi Arabia; [2]Rutgers, The State University of New Jersey, United States

While preparation of thin-films of organic semiconductors *via* solution-based processing techniques is relatively straight-forward, understanding the morphology of these thin-films at different length scales, from micro- to nano-, which is critical in designing high-efficiency devices, can be fairly complex. High-efficiency organic photovoltaics (OPVs) are fabricated from blending two or more organic semiconductor components. This mixing process must be fine-tuned based on the ratio of different components, solvents utilized, and morphology-controlling additives, to obtain uniform thin-films at micro- and nano-scales. To characterize the uniformity, researchers must often turn to time-consuming or destructive techniques, such as atomic force microscopy (AFM) or scanning electron microscopy (SEM), which are not amenable to high-throughput, automated device fabrication facilities.

Polarized light microscopy (PLM) is a relatively unexplored technique for the characterization of organic semiconductor thin-films. PLM uses a set of orthogonal polarizers in the excitation and collection paths. As such, most of the incident light is filtered out from the image, and only the local optical birefringence is imaged, providing enhanced contrast compared to standard bright-field light microscopy. Organic semiconductors tend to have high degrees of anisotropy based on their molecular orientations and local degrees of crystallinity. Thus, PLM is a powerful imaging technique to qualitatively evaluate the morphology of organic semiconducting thin-films. Because it is a form of light microscopy, it is non-destructive, has a wide-field of view, and has potential to be employed in automated device fabrication facilities.

In this work, we employ PLM to evaluate the quality of thin-films of the stable conjugated polymer, PCDTBT. PCDTBT thin-films are an example of polymer thin-films that are challenging to prepare due to the neat polymer's poor solubility in typical organic solvents, its high viscosity, and its ease of aggregation. We optimized PCDTBT thin-films by varying the solvent, molecular weight, heating times and temperatures, and filtering conditions. Using PLM, we rapidly evaluated the quality of PCDTBT thin-films with various preparation conditions to find optimal conditions for uniform thin-films with low degrees of aggregation. Based on these optimal conditions, we fabricated PCDTBT hole-only devices in a metal-insulator-metal Schottky photodiode geometry for thick (200 nm) and thin (80 nm) PCDTBT layers. We extracted the Schottky barrier height and hole mobility of PCDTBT from current-voltage measurements and drift-diffusion simulations, respectively.

We will discuss the potential of PLM to interpret the nanoscale morphology and crystallinity of several other common organic donor-acceptor blends.

SB06.14.04
Controlling Anisotropic Properties Through Manipulation of Chiral Small Molecule Orientation Jessica Wade[1], Francesco Salerno[1], Rachel Kilbride[2], Dong Kuk Kim[1], Julia Schmidt[1], Joel Smith[3], Luc LeBlanc[4], Emma Wolpert[1], Adebayo Adeleke[4], Erin Johnson[4], Jenny Nelson[1], Tadashi Mori[5], Kim E. Jelfs[1], Sandrine Heutz[1] and Matthew Fuchter[1]; [1]Imperial College London, United Kingdom; [2]University of Sheffield, United Kingdom; [3]University of Oxford, United Kingdom; [4]Dalhousie University, Canada; [5]Osaka University, Japan

Chiral π-conjugated molecules offer new functionality to thin film technologies and represent a highly exciting and rapidly expanding area of scientific research. Due to the anisotropic functional properties of such materials such as the absorption and emission of circularly polarised light or the transport of spin-polarised electrons, the functionality, performance, and efficiency of chiral devices is critically dependent on the orientation of chiral molecules in thin films. Despite this, broadly applicable, simple methods to control molecular orientation of chiral materials in the bulk are yet to be developed. Here a novel approach is presented to control the orientation of a chiral small molecule (2,2'-dicyano[6]helicene, **CN6H**) in thin films: the use of organic (3,4,9,10-perylenetetracarboxylic dianhydride, PTCDA) and inorganic (copper(I) iodide, CuI) templating layers. All **CN6H** and templating layers were grown via organic molecular beam deposition (OMBD), ensuring good film quality and reproducibility. Using grazing incidence wide angle X-ray scattering (GIWAXS) measurements, it is shown that using 3,4,9,10-PTCDA templating layers, **CN6H** molecules adopt a '*face-on*' orientation and self-assemble into upright supramolecular columns oriented with their helical axis perpendicular to the substrate. Alternatively, copper(I) iodide (CuI) templating induces the formation of supramolecular columns in an '*edge-on*' orientation with their helical axis lying parallel to the substrate. Structural templating is further verified by 2D GIWAXS simulations of the **CN6H** crystal structure in face-on and edge-on orientations, demonstrating excellent agreement with experimental results. Through such control of orientation, it is shown that low- and high-energy chiroptical responses can be independently 'turned on' or 'turned off' as a function of molecular orientation. As such, the templating methodologies described here provide a simple way to engineer orientational control, and by association, anisotropic functional properties of chiral molecular systems for a range of emerging technologies.

SB06.14.06
Chiropical Conjugated Polymer/Chiral Small Molecule Hybrid Thin-Films Based on Chirality Transfer Phenomenon Jung Ah Lim; Korea Institute of Science and Technology, Korea (the Republic of)

Chiral optoelectronics based on circularly polarized light (CP light) has recently garnered significant interest in various fields, including biosensing, 3D displays, cryptography, and quantum optics. CP light, continuously rotating at a steady-state along the propagation axis, enables structural chirality and quantum spin directions to be used as the main information vector. One forefront for the realization of chiral optoelectronic systems is the development of semiconducting materials with strong chiroptical activity and excellent electrical properties. π-Conjugated molecules (i.e. organic semiconductor) are one of the most promising chiroptical semiconductor materials because their optical rotation properties can be modulated by intentional designing of structural asymmetry. Considering that the performance of chiroptical electronic devices is determined by the photophysical, electrical, and morphological properties of the conjugated molecules, a new strategy for obtaining organic semiconductor thin-films with not only strong chiroptical activity but also good charge transport properties that can be directly applicable to the optoelectronic devices, is needed. In this presentation, we will suggest an effective way to obtain chiroptically active semiconductor thin films by blending of achiral conjugated polymer with excellent charge transport properties and versatile small molecules with strong chiroptical activity. We found that controlled phase separation and crystallization of these hybrid films resulted in a unique heterojunction bilayer structure that consisted of small chiral molecules at the top and a conjugated polymer-dominant mixed layer at the bottom. A photodiode based on this chirocentric hybrid film has demonstrated the ability to detect left- and right-handed circular polarization. In addition, a fundamental understanding on the crystalline structure of the hybrid film and the effect of intermolecular interactions on the chiroptical properties of the hybrid film will be discussed.

SB06.14.07

Silicone-Integrated Hole Transport Networks for High-Performance and High-Resolution OLED Microdisplay Borina Ha[1], Hyukmin Kweon[1], Seonkwon Kim[2], Ukjin Jeong[1], Seunghan Lee[3], Moon Sung Kang[3], Jeong Ho Cho[2] and Do Hwan Kim[1]; [1]Hanyang University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Sogang University, Korea (the Republic of)

Organic light-emitting diodes (OLEDs) have attracted great attention due to their unprecedented color purity, thin form factor, superior response time, and expanded color gamut. OLEDs are one of a major display technology exerting strong influence from comercialized display to microdisplay for virtual, augmented, mutual, and extended reality (VR/AR/MR/XR) devices. As the applicable scope of OLEDs has been expanded, high pixel densities over 1,000 pixels per inch (PPI) are strongly sought after. However, reduction of inter-pixel distance can induce pixel crosstalk which is resulting in deterioration of color gamut area and color purity, even though emission layers are completely separated. This is derived from parasitic currents flowing through common hole transport layers (HTLs) between adjacent pixels, indicating that for prevention of the crosstalk phenomenon, the HTLs must be pixelated with micro-scales in conjunction with emission layers. Practically, photolithographic patterning is the best candidate to effortlessly achieve precise micropatterns of the HTLs; however, it is not adaptable to organic hole transport materials because of their low chemical and physical endurance.
Herein, for realization of fine pixelated HTLs, we demonstrate silicone-integrated hole transport network (SI-HTN) in which silicone binder are homogeneously crosslinked with small molecule hole transport materials. Due to the embedded silicone moieties, the SI-HTN exhibited exceptional physico-chemical robustness, so that reactive ion etching (RIE)-coupled photolithography pattering can be utilized for realization of high-resolution pattern. On the basis of this, ultra-fine patterns of the SI-HTN (down to 1 um) was demonstrated based on the photolithography process. Furthermore, the SI-HTN showed improved hole injection capability compared to the neat HTL, thus, solution-processed high efficient OLEDs can be achieved. This indicates that the SI-HTN can simultaneously obtain not only high-resolution patterns, but also enhanced light-emitting performance of the OLEDs. We believe that our approach will provide guidance for next-generation of high-resolution OLEDs.

SB06.14.11

Using Density Functional Theory and Fukui Function to Analyze the Reaction Site of Hemoglobin to CO, O2 and NO Wei Chen[1], Chi Hua Yu[1], Xiao Ru Wang[1] and Francisco Martin-Martinez[2]; [1]National Cheng Kung University, Taiwan; [2]Swansea University, United Kingdom

Carbon monoxide poisoning is the most common cause of death from gas poisoning worldwide. About 6,600 people suffer long-term cognitive sequelae from carbon monoxide poisoning each year, with a total cost of about $925 million. Carbon monoxide poisoning has always been a very important problem, but there are many environmental limitations in existing treatment methods, and the effect of treatment often causes sequelae. When a large amount of carbon monoxide enters the human system, it will quickly combine with hemoglobin to form carbon monoxide hemoglobin (COHb). The affinity of carbon monoxide to hemoglobin (Hb) is 200 to 200 times that of oxygen to carbon monoxide hemoglobin. Heme dissociates about 3,600 times faster than oxyhemoglobin, so heme transports oxygen poorly, leading to carbon monoxide poisoning. In biology, the dissociation and binding of CO, O^2, and NO to hemoglobin are very important. In this study, we performed density functional theory (DFT) and computed the Fukui function to analyze the reaction site of heme with CO, O2, and NO. By comparing the calculations results for heme and different oxygen-containing molecules such as CO, O^2, and NO, we found the specific reaction sites of ferrous ions and carbon atoms in carbon monoxide molecules. This finding can help us to understand the binding mechanism of COHb. We can further extend the research to design an antidote that can break the carbon monoxide-heme bond quickly. The antidote for carbon monoxide poisoning can achieve the fastest therapeutic effect. Our work can be applied to develop an effective antidote and bring great benefits to the treatment of carbon monoxide poisoning.

SB06.14.12

Fabrication of Bulk Heterojunction Donor Polymer—Non-Fullerene Acceptor Nanoparticles for Use in Photocatalytic H_2 Evolution from Water Matthew W. Bidwell[1], Jan Kosco[2], Hyojung Cha[1], Calvyn Howells[2], Michael Sachs[1], James R. Durrant[1] and Iain McCulloch[3,1,2]; [1]Imperial College London, United Kingdom; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]University of Oxford, United Kingdom

As the global energy demand increases, finding cheap and sustainable sources of energy is increasingly important, with an urgent need to develop new materials and technologies capable of providing clean and fossil-fuel free energy on a Terrawatt scale worldwide. The use of fossil fuels has led to unprecedented levels of atmospheric CO_2, causing devastating anthropogenic climate change and has driven the search for alternative sources of energy. The past decade has witnessed a renaissance in photovoltaic (sunlight to electrical conversion) technologies with remarkable increases in performance and stability, establishing solar energy as a viable source of renewable energy worldwide.

A major obstacle to utilising the full potential of solar energy is the challenge of storing it for future use. Solar intensity and availability are intermittent and often mismatch with high consumer electricity demand, which regularly peaks after sunset. One way to address this issue is to store sunlight in the form of chemical bonds, known as “solar fuels”. The simplest solar fuel is H_2 which can be generated from the electrochemical splitting of water, using H_2 evolution photocatalysts (HEPs). This H_2 can then be further stored and used by consumers on-demand with the advantage of water being the only combustion by-product, free of any CO_2 emissions. Currently, most HEPs consist of single component inorganic semiconductors which are well established and have been used prominently in the field of photocatalysis. However, these materials also suffer inherent drawbacks. These include limited visible light absorption, high materials cost, and limited chemical tuneability, which severely hinder H_2 production efficiency. In contrast, organic semiconductors such as conjugated donor polymers and non-fullerene acceptors (NFAs) have been explored as alternatives to these inorganic systems and have the advantages of strong optical absorption properties, facile synthetic modification, low cost, and easily tuneable optoelectronic properties.

Amongst the numerous strategies for photoelectrochemical energy conversion of sunlight to solar fuels, the use of a one-pot particulate-based photocatalytic system, in which semiconductor photocatalysts are dispersed directly into water, is regarded as a cheap and economical approach toward industrial-scale solar hydrogen production. This is in part due to the intrinsic simplicity of the methodology, which forgoes the use of any electrical circuitry or device fabrication, requires a low initial investment of capital, and has the potential for sustainable scaling of the technology with the possibility of H_2 being directly collected from large batch flow photoreactors irritated by the Sun.

With this in mind, the donor polymer PCE10 and NFA EH-IDTBR were investigated as HEPs in blended two-component nanoparticle systems with ascorbic acid as the sacrificial electron donor.[1] Through the synthesis and implementation of novel conjugated surfactants, as well as fine-tuning of NP fabrication conditions, it was possible to control the internal structure of the HEPs and transform them from a prototypical core-shell structure into a highly intermixed bulk heterojunction two-component system. Through this enhancement in internal morphology, improved nanoparticle surface charge extraction was realised, which led to stable HEPs for over 35 hrs. This change in morphology was elucidated through the use of cryogenic transmission electron microscopy and small-angle neutron scattering of deuterated EH-IDTBR and led to a ten-fold increase in H_2 efficiency and to an unprecedentedly high H_2 evolution rate of over 60 mmol h^{-1} g^{-1}, with EQEs exceeding 5.6% across 660 - 700 nm in the visible spectrum, which is one the highest for organic HEPs reported to date.

SB06.14.13
Design Redox-active Semiconducting Polymers with High Stretchability and Mixed Ionic/Electronic Conductivity for Stretchable Organic Electrochemical Transistors Yahao Dai, Shilei Dai and Sihong Wang; University of Chicago, United States

Organic electrochemical transistor (OECT) is an emerging device platform for next-generation human-integrated bioelectronics owing to its high amplification and sensitivity to biological signals, and non-volatile signal retention for memory and computing applications. However, owing to the lack of stretchable redox-active semiconducting polymers, skin-like softness and stretchability have not yet been realized in high-performance OECTs for achieving seamless tissue-electronics interfaces. Here, through the molecular engineering approach, we report two stretchable redox-active semiconductors for OECT devices, namely poly(2-(3,3′-bis(2-(2-(2-methoxyethoxy)ethoxy)ethoxy)-[2,2′-bithiophen]-5)yl thiophene) (p(g2T-T)) and poly-[3,3′-bis(2-(2-(2-methoxyethoxy)ethoxy)ethoxy)-2,2′-bithiophene] (p(gT2)), which give exceptional stretchability over 200% strain and 100 stretching cycles, together with the OECT performance on par with the state of the art. Validated by the systematic structural characterization, sufficient chain alignment during stretching for stress dissipation is determined as the key enabler of high stretchability. By controlling the symmetricity and chain length of polymer semiconductors, the key structural features for enabling the combination of high stretchability and high OECT performance are determined as non-linear backbone architecture, moderate side-chain density, and sufficiently high molecular weight. Using those highly stretchable polymer semiconductors, we fabricated an intrinsically stretchable OECT with the high normalized transconductance (~223 S cm^{-1}) and biaxial stretchability up to 100% strain, which has been further demonstrated as an ideal device platform for building stretchable electrocardiogram sensors and neuromorphic transistors.

SB06.14.14
Pyrrolic Small Molecule Chromophores for Applications in Electrochromic Materials Tiffany Q. Chen and Timothy Swager; Massachusetts Institute of Technology, United States

Electrochromic materials (EC) provide functional solutions for a variety of applications, including smart windows and optical display technologies. The use of organic materials provides advantages over inorganic materials in electrochromic devices. The ability to readily tune structure in organic materials through synthetic methods affords precision in controlling redox, optoelectronic, mechanical, and processing properties. As superior light-absorbing materials to inorganic materials, organic materials enable high optical contrast, allowing for the use of thinner films. In addition, the solution-processability of organic materials and their relatively low cost allow the use of coating methods to form functional, reproducible thin films that can be layered on a substrate.

Although organic electroactive polymers are promising candidates in this realm, these materials have distinct drawbacks, including inherent structural disorder resulting in spectral diffusion, limited modularity in structure and bandgaps, depletion of absorption at long wavelengths, and diminished performance with material deformation. In contrast, electrochromic small molecules with highly delocalized structures such as fused ring systems are promising chromophores that have received less attention in this field. Recent research in using small molecules has been motivated by their well-defined and rationally tunable structures, enhanced stability toward oxidative degradation, and batch-to-batch reproducibility. We report the development of a new class of symmetric small molecule chromophores based on pyrrolic scaffolds to address these current limitations in the field of electrochromic materials.

Program Acknowledgment: This research was supported by an appointment to the Intelligence Community Postdoctoral Research Fellowship Program at Massachusetts Institute of Technology administered by Oak Ridge Institute for Science and Education (ORISE) through an interagency agreement between the U.S. Department of Energy and the Office of the Director of National Intelligence (ODNI).

SB06.14.15
Accelerated Photodegradation Study of Multi-Component Organic Photovoltaic Materials with Robotic Micro-Experimentation Jacob Mauthe, Mihirsinh Chauhan, Ambika Pathak, Tonghui Wang, Samuel Shepard, Xingao Zhang, Benjamin Hines, Felix Castellano, Harald Ade and Aram Amassian; North Carolina State University, United States

With the advent of non-fullerene acceptors (NFA), the efficiency of organic photovoltaics (OPVs) has broken previous records and currently stands at a certified power conversion efficiency (PCE) of 19% [1]. Multi-component OPV blends have been increasingly used to improve the performance and stability of devices [2]. However, there is a lack of understanding of the fundamental mechanisms behind improvements in performance and even less so how these blends stabilize devices. Investigating photodegradation of a vast library of materials and their multi-component combinations is a demanding problem that currently requires considerable effort in terms of time and resources. We take the view that workflow automation combined with micro-experimentation and data-driven and machine learning-guided sample selection allowing for (semi-)autonomous workflows can significantly accelerate photodegradation investigations as well as multiparameter optimization. In this work, we describe a robotic platform, the RoboMapper, which formulates and prints miniature OPV active layer areas on transparent substrates and enables rapid evaluation of photodegradation in inert atmosphere under 4 to 40 suns. Printing on a scale $1/10^{th}$ to $1/20^{th}$ of the size of traditional samples consumes a fraction of materials, whereas robotic micro-UV-Vis characterization enables high throughput evaluation of photobleaching of all materials printed on chip. Using the RoboMapper, we conducted photodegradation campaigns on neat donor and acceptor materials[AA1] , PM6, PTQ10, Y6, IT-4F, and $PC_{71}BM$, their binary, and multi-component blends. The performed photodegradation analysis of the vast library of materials showed that all acceptors and donors have different degradation behavior in neat films and blends as compared with different donor-acceptor combinations. Additionally, the data allows us to select the right donor-acceptor combinations for optimal

photostability in binary and ternary systems. Our study shows that approaches like the RoboMapper can be powerful for collection of big data equivalent to years of work in just a few weeks or months. The ability to prepare multiple samples simultaneously from a small amount of stock materials also considerably reduces the waste generated for the same quantity and quality of data.

SB06.14.16
Controlling Interlayers in Organic Semiconductor Devices towards Photo-Stimulated Bio Interfaces Maxim Shkunov, Leslie Askew and Aimee R. Sweeney; University of Surrey, United Kingdom

Photosensitive organic semiconductor materials designed as active layers in bioelectronic devices provide an effective mean to stimulate cells using optical excitation. Such devices are entirely self-powered, fully compatible with operation in bio-electrolyte environment, and can stimulate a variety of cells from peripheral neurons to retinal neurons. The nature of the excitation mechanism is expected to be mostly due to induced photo-voltage changes as well as photocurrent at the cell membrane. Device efficiency is hugely dependant on the interfaces, including organic semiconductor/electrolyte, semiconductor/electrode, and any heterojunction interfaces present in the device structure. Here, we present a study involving charge blocking/charge transport interlayers that are used to control both the polarity at the active interface, and the optoelectronic transduction process between the active layer and the electrolyte, be it Faradaic or capacitive. Donor-acceptor small molecules as well as conjugated polymers with various bandgaps are used to i) provide selective colour response of the devices to resemble the photoresponse of human cones and rods in the retina, and ii) target human tissue transparency window in the red part of spectrum towards peripheral nerves excitation. The results demonstrate that the addition of interlayers can control the charge species at the working electrode and substantially enhance photocurrent magnitude, whereas bulk-heterojunction interfaces provide further increase in both photovoltage and photocurrent.
We further discuss the suitability of organic semiconductors for potential medical applications as retinal bio-engineered prosthesis for the restoration of human vision, and peripheral nerves opto-stimulation, as well devices fabrication strategies via pixelation using ink-jet printing approaches on flexible substrates.

SB06.14.17
Accurate Threshold Voltage and Field-Effect Mobility Estimation for Thin-Film Transistors with Gate Voltage-Dependent Mobility in Linear Region Yuchen Zhou, Xiao Wang and Ananth Dodabalapur; University of Texas at Austin, United States

Carrier mobility is an essential figure of merit for transistors used in various electronic applications. High mobilities are generally desired for thin-film transistors (TFTs) with amorphous metal oxide and organic/polymer semiconducting channel materials, as it enables faster operating speeds for various applications including displays, RFID tags, and integrated circuits. Saturation mobility in TFTs will be inaccurate due to the dependence on carrier concentration in the gradual channel approximation. However, the reported linear mobility calculations are often inaccurate. This results in an overestimation of mobility under the gradual channel approximation, which is a direct consequence of the mobility being gate voltage-dependent instead of any artifact in the measurements.
The gradual channel approximation assumes a constant mobility independent of carrier density, which is often not the case for TFTs. Here we propose a calculation procedure that differs from the conventional field effect mobility calculation by explicitly considering the gate voltage-dependence of the mobility. The resulting equation consists of three terms: the transconductance term on the left-hand side, the differential mobility term with respect to gate voltage, and the modified field effect mobility on the right-hand side. The inclusion of the second term or the differential mobility term often results in calculated mobility values larger by a factor of between one and two.
Accurate threshold voltage values must also be considered for an improved mobility extraction. Previous literature demonstrated threshold voltage extraction using the linear extrapolation method on the drain current as a function of gate voltage, which often leads to a gate bias-dependent threshold voltage. The onset voltage V_{on} where the conduction starts increasing has been proposed to be used for mobility calculation. Another proposed method of calculating threshold voltage suggests that the voltage at which the gate voltage-dependence transitions into a power law dependence in the drain current can be used as the threshold voltage for TFTs. This definition considers that the exponential increase in drain current corresponds to the diffusion-limited subthreshold region but not the drift-limited subthreshold region. Corrected field effect mobility calculated using the conventional threshold voltage, corrected threshold voltage, and the onset voltage will be compared.
Amorphous indium-gallium-zinc-oxide (a-IGZO) TFTs and organic TFTs are used to illustrate the corrected field effect mobility and threshold voltage calculation process. In one sample TFT, the conventional field effect mobility calculation yields a value of 2 cm^2/V-sec while the corrected field effect mobility is approximately 1.2 cm^2/V-sec, resulting in at least an overestimation of ~ 67%.
This mobility calculation process can be applied to transistors with any semiconducting materials with non-constant mobilities in the linear region. It is a robust tool when it comes to accurately characterizing the device performance of thin-film transistors in the linear region.

Ultrafast Photochemistry of Melanin and Organic-Inorganic Melanin-Based Heterostructures Using Modern Ultrafast Pump-probe Microscopy and Spectroscopy Max DeMarco, Farnoush Nourigheimasi, Mathew Ballard, Lillian Getter and Elham Ghadiri; Wake Forest University, United States

Using melanin as organic biopolymer for optoelectronic or bioelectronic is intriguing. Melanin family are organic ubiquitous pigments found in human skin, hair, eyes, and the brain and almost in every higher-level organism in different forms. The functionality of melanin as a natural pigment is defined (although not fully understood) by its physical and chemical properties, such as its featureless broad UV-NIR optical absorption, antioxidant properties, temperature-dependent photoconductivity, and free radical scavenging behavior, chemical signatures that can support reversible cation binding. Many physical properties (such as dark current and photoconductivity) are dramatically affected by hydration and doping. Little has been understood so far about the nature of conductivity in melanin.
In this work, we integrate state of the art pump-probe transient absorption microscopy (PP-TAM) and pump-probe transient absorption spectroscopy (pp-TAS) to localize and investigate photochemical processes in melanin and melanin-based organic-inorganic and organic-organic heterostructures. The technique uniquely enables to visualize the photoexcited processes in few hundred nanometer spatial resolution and femtosecond time-resolution. Through chemical synthesis, we have prepared melanin nanoparticles with controlled sizes (70 nm, 100 nm, and 250 nm) and chemical structures of dopamelanin and eumelanin. The active thin-film layer of melanin nanoparticles are prepared using inkjet printing and spin coating. To achieve multifunctional melanin-based nanostructures, we synthesized and fabricated donor-acceptor bilayers of melanin nanoparticles. The photochemical characteristics of the donor-acceptor melanin-based constructs are studied by photocatalytic degradation of methylene blue dye under selective UV-NIR and Vis-NIR irradiation condition. The melanin-TiO_2 nanostructured films and Melanin-PEDOT:SS films exhibit enhanced photocatalytic characteristics compared to pristine melanin upon both UV-NIR and Vis-NIR irradiation condition. The enhanced photocatalytic characteristics of the melanin-based heterostructures motivate to investigate the fundamental processes involved using ultrafast spectroscopy and microscopy. Using ultrafast broadband

measurements, we identified the spectral characteristics of excited state, and excited state relaxation dynamic in pristine melanin and melanin heterostructures. The ultrafast photochemical studies are remarkable in the sense that they shed light on the unknown photophysical characteristics of melanin, rationalize the enhanced photocatalytic activities, and identify melanin based heterostructures as a viable photochemical material for broad applications.

SB06.14.19
Self-Assembled Microbead Lasers Using Organic and Organic/Inorganic Hybrid Gain Materials for Multiplexed Bio-Imaging Kwon-Hyeon Kim[1,2] and Seok-Hyun A. Yun[1,2]; [1]Harvard Medical School, United States; [2]Massachusetts General Hospital, United States

Fluorescent microbeads are widely used for applications in life sciences and medical diagnosis. The spectral contrast and sharpness of photoluminescence are critical in the utilities of microbeads for bio-imaging and multiplexing. Recently, there has been growing interest in using microbead lasers capable of generating ~100 times narrower emission linewidth than conventional fluorescence. Stimulated emission of microbead enhances spectral brightness and multiplexing capability. Here, we demonstrate novel types of microbeads that exhibit compact size and sub-nanometer linewidth using two types of gain material: Colloidal quantum dots and aggregation-induced emission (AIE) dyes. Self-assembled microbeads are fabricated by microfluidic chip using the oil-in-water emulsion method. Their high optical gain and refractive index allow lasing with a size less than 2 μm in the air. The feasibility of intracellular tagging and multi-color imaging in vivo is demonstrated. Multicolor imaging with proposed microbeads shows greatly enhanced spectral density and color-multiplexing capability compared to conventional fluorescence imaging.

SB06.14.20
All-Solution-Processed and Intrinsically Flexible Multicolor Perovskite Light-Emitting Diodes and Photodetectors on Textile and Paper Substrates Junyi Zhao; Washington University in St. Louis, United States

Solution-processable optoelectronic devices hold great potential for emerging low-cost and scalable fabrications of flexible electronics. Textiles and papers, made of percolation yarn- and fiber- networks that are commonly used in our daily life, are becoming novel platforms for next-generation wearable and health-monitoring electronics. In this work, we report a versatile and ultra-fast mask-free fabrication strategy that enables printing, even direct-handwriting, of all-solution-processed optoelectronic devices onto papers, textiles (cotton, polyester, and nylon), and other unconventional substrates including metal foil, plastic film, rubber, vinyl glove, and even 3-dimensional surfaces such as glass vial and spheres. Compared with existing microfabrication and printing processes, handwriting allows high-performance optoelectronics to be fabricated by untrained individuals in a time-efficient (a batch of devices could be made within a few minutes) and cost-effective manner. The handwriting technique is especially meaningful for early-stage demonstration or large-area applications with less stringent requirements on resolution such as E-Textiles, E-Packaging, and E-Papers. More specifically, we have formulated universal electronic inks that could either be used in printing/coating machines or loaded into ballpoint pens for direct handwriting on target substrates. These electronic inks include poly(3,4-ethylenedioxythiophene) polystyrene sulfonate (PEDOT:PSS) and poly(ethylene oxide) (PEO) composite ink for transparent anodes, halide perovskite ($MAPbX_3$) and polystyrene (PS)/ poly(methyl methacrylate (PMMA) composite ink for the photoactive layer, polyethylenimine (PEI) ink for the electron transporting layer, and silver nanowires ink for semi-transparent cathodes. The PEO component blended in the PEDOT:PSS conducting ink not only helped planarize the rough percolating yarn/fiber substrates, but also improved the conductivity and conformability of conducting film, thus leading to improved device performance and stability. High-performance multicolor light-emitting diodes (LEDs) with emissions covering the entire visible spectrum and photodetectors (PDs) in both a vertical photodiode configuration and a lateral photoconductor configuration were obtained on paper substrate: LEDs exhibited a brightness up to 15,225 cd m^{-2}, a turn-on voltage of 2.4V, and current efficiency over 6.65%; PDs showed an on-off ratio over 10^4 with a response time of less than 15 ms. Owing to the intrinsic flexibility and stability of each functional layer, the hand-drawn LEDs could be bent to a 1 mm extreme curvature radius for over 5000 cycles without decay in performance. Overall, such low-cost and eco-friendly textile/paper-based LEDs and PDs via printing and handwriting could pave a way for the integration of optoelectronic devices with lightweight and human-machine interactive applications.

SB06.14.21
Transition Metal-Based NIR Material with Heteroleptic Structure for Bio-Medical Application Yongjin Park[1], Gyeong S. Lee[2], Hye R. Choi[3], Chang H. Huh[3], Yun H. Kim[2] and Kyung C. Choi[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Gyeongsang National University, Korea (the Republic of); [3]Seoul National University Bundang Hospital, Korea (the Republic of)

Among the near-infrared (NIR) ranges, the area between 700 nm and 1000 nm, called the optical tissue window, is widely used in the bio-medical field because it has less scatter with skin cells and can penetrate deep into the skin to promote cell metabolism. However, it is very challenging to develop a low-gap organic material that emits light in the NIR region due to the increased proportion of non-radiative decay rate by the energy gap law. In order to overcome this hurdle, various types of development methods are being studied such as the use of thermally activated delayed fluoresce (TADF) and transition metal-based phosphorescent materials.

In this study, a novel Ir(III) complex was synthesized and designed using a thienothiophene moiety. This material is composed of a fused thiophene structure, and thus is exceedingly rigid and has an extended construction length, thereby reducing the energy gap. In addition, since it has a high electron density structure, the covalent bond between the ligand and iridium can be strengthened to provide stability to the device. Moreover, dipole moments are more likely to be horizontally oriented in heteroleptic structures than in homogeneous structures, thus boosting the performance of the device. Notably, it has a lower non-radiative decay rate than other reported Ir(III)-based NIR emitters. The radiative lifetime is 660 ns, allowing for efficient luminescence with a narrow energy gap. To demonstrate the properties of this novel material, a NIR OLED was fabricated with an emission peak of 700 nm. This optoelectronic device has a very high radiant emittance and a stable operation lifetime with a Lambertian light distribution. It exhibits excellent electrical and optical properties compared to previously reported Ir(III)-based NIR OLEDs. Furthermore, significant proliferation results were verified compared to the control group in fibroblast cell experiments.

SB06.14.22
Coarsening-Induced Hierarchically Interconnected Porous Carbon Polyhedrons Derived from Metal-Organic Frameworks for Stretchable Ionogel-Based Supercapacitors Incheol Heo, Chanyoung Lee and Won Cheol Yoo; Hanyang University, Korea (the Republic of)

For ultrahigh-energy-density supercapacitors (SCs), hierarchically interconnected micro-/meso-/macroporous carbons (HICs) are desirable for both effective ion polarization and transport, especially when electrochemically stable but dynamically sluggish ionic liquids are employed as the electrolytes. In this presentation, we develop an effective strategy for preparing HICs with well- developed all-pore regimes for ultrahigh-energy-density SCs using electrochemically stable ionic liquid (IL) electrolytes. The HICs are synthesized *via* coarsening of the Cu nanoparticles (NPs) within carbon polyhedrons de- rived from the polymer-infiltrated metal-organic framework (MOF). During thermolysis process, the coarsening process of Cu NPs occurs, in which the locations vacated by the Cu NPs are left as large meso/macropores. HIC polyhedron presents an ultrahigh specific surface area (SSA, 3064 m^2 g^{-1}) and the HIC-based SCs exhibit an outstanding capacitance of 268.4 F g^{-1} with an ultrahigh energy density of 149 Wh kg^{-1}, which are comparable to the best values

reported to date, indicating that expedited ion-transport via hierarchically interconnected large meso/macropores affords maximum utilization of the micropores of the carbon electrodes. Furthermore, stretchable all-solid-state SCs operating at 120% strain with a very high areal capacitance of 33 mF cm^{-2} and an energy density of 0.041 mWh cm^{-2} are also demonstrated. These results provide a ubiquitous strategy for developing MOF-based hierarchically interconnected carbonaceous materials with ultrahigh SSA for high-performance SCs compatible with stretchable and wearable electronic devices.

Selective Plasticization and Three-Dimensional Transformation Based on Membrane-Type Electronics and Supportive Plastic Framework Jiun Cha[1,2], Gi-Gwan Kim[1,2], Seunghyun Kim[1,2] and Heungcho Ko[1,2]; [1]National Research Foundation of Korea, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)

Three-dimensional(3D) transformation of planar-type electronics has been widely studied in various devices such as solar cells, batteries, antennas, photodetectors, image sensors, and displays for superior electrical and mechanical properties to overcome the two-dimensional limitation. The shape transformation method seems promising when direct device fabrication on 3D structures is extremely difficult. Here, we demonstrate a straightforward electronics-level 3D transformation method by creating supportive substrates containing microfluidic channels that can insert a liquid plasticizer for hard-to-soft transition and allow bending under mild manners in the plasticized regions. In particular, spatially designed microfluidic channels allow the control of the plasticizer's flow direction and the confinement of a specific amount of plasticizer to diffuse around the channels. For example, small microfluidic channels allow the plasticizer's flow to adjacent channels without losing mechanical strength, whereas large size allows extreme bending up to a 180 ^{o} bending angle without electrical failure of the device layer. Using this method, an extreme case of bending metal electrodes and indium gallium zinc oxide (IGZO) thin-film transistors is possible without device failure. Finally, a truncated octahedral LED array is also developed to demonstrate the capability of this method for complex three-dimensional electronics.
