In this study, we deposited amorphous Zn-doped tin sulfide (SnSx:Zn) thin films at 100°C using super-cycle ALD and performed post annealing at 400°C for controlling phase transition to SnS. The doping level was changed from [SnS:Zn] = 0% to 10% (every 2%). We developed Zn-doped SnS thin films using Tetrakis-dimethylamino Tin (TDMASn), Diethyl-zinc (DEZ) and H2S (99.99%) gas as the precursor and reactant. We performed 10 cycles of sulfur passivation before deposition to change the functional group of O-H to S-H on the surface for making more stable chemical energy state of sulfide. The effect of doping on the phase transition and crystal structure of SnS was analyzed through grazing-incidence X-ray diffraction (GI-XRD) and Raman. All the deposited films are polycrystalline SnS and the intensity of the XRD peaks are decreased for the higher Zn concentration. It is because reduction of

crystallinity due to the incorporation of more Zn impurity atoms into the SnS lattice. X-ray photoelectron spectroscopy (XPS) was utilized for chemical binding state. It was confirmed that Zn was well doped through an increase in the ZnS binding peak as the Zn concentration increased. To confirm the band structures and optical properties of a Zn-doped SnS, ultraviolet-visible (UV-vis.) spectroscopy, ultraviolet photoelectron spectroscopy (UPS) and photoluminescence (PL) were investigated. Energy band gap increases by zinc incorporation, exhibited 1.64 eV, 2.10 eV, 2.13 eV, 2.61 eV, 2.85 eV, 2.92 eV for as-dep, 2%, 4%, 6%, 8%, 10% doped samples. Increase of band gap was due to the value of ZnS direct band gap (3.6 eV) is larger than that of SnS. Thus, suitable Zn doping in the SnS thin films can change the optical band structures and other properties for various optical devices. Through this study, we research the effect of Zn-doped tin monosulfide thin films and a variety of optical, chemical, structural characteristics for various multifunctional devices.

Very High Gas Sensing Performance of SnS_2 Material to NO_2 at Room Temperature Miecio O. Melquiades[1,2], Ranilson A. da Silva[1] and Marcelo O. Orlandi[1]; [1]UNESP, Brazil; [2]IFAM, Brazil

Semiconductors based on tin-dichalcogenides have attracted attention in gas sensing application as sensors, as these materials are formed by chemically inert layers bonded by weak van der Waals interactions that promote a high surface-to-volume ratio. It is especially interesting that layers have (001) planes exposed, and this plane present electronic lone pairs, facilitating the adhesion of polar analytes on the material surface. The route of synthesis is a key point to obtain materials with optimal properties. In this context, mechanical grinding stands out for being an easy and low-cost route. Furthermore, this process produces samples with high density of defects, such as vacancies, grain boundaries and stacking faults, and these defects are important for gas detection due to the increased surface reactivity.
In the present work tin-dichalcogenides (SnS_2) was synthesized by high-energy mechanical milling using Sn (Alfa Aesar – 98,8%), Se (Alfa Aesar - 98,8%), and S (Alfa Aesar – 98,8%) precursors. The material phase was confirmed by X-ray diffraction analysis and the particles morphology was observed by scanning electron microscopy. For the gas sensing measurements, first a suspension of the tin-dichalcogenide powder was prepared. Then, devices were produced by drop casting the suspension onto alumina substrates coated with interdigitated platinum electrodes, followed by a heat treatment at 200 °C to remove the solvent and stabilize the material on the substrate.
The gas sensing response of SnS_2 material to NO_2, H_2 and CO analytes was obtained by monitoring the electrical resistance of devices in cycles of 20 min exposure to the analyte followed by 60 min of exposure in dry air. Very high NO_2 (2-100 ppm range) sensor response, from 10^2 to 10^6, was observed for temperatures between 25 °C and 300 °C, with devices presenting the highest response at room temperature (25 °C). In addition, devices presented high selectivity to NO_2 at room temperature. The lower detection limit was calculated as 6 ppb, which is much lower (one thousand times) than the Brazilian regulation for NO_2 exposition (6 ppm).

Efficient Polycrystalline N-I-P CdSeTe Thin-Film Solar Cells Enabled by Grain Boundary and Back Contact Interface P-Type Doping Sabin Neupane[1], Xiaomeng Duan[2], Dengbing Li[1], Yanfa Yan[1], Feng Yan[2] and Gang Xiong[3]; [1]The University of Toledo, United States; [2]The University of Alabama, United States; [3]First Solar Inc., United States

Current state-of-art CdSeTe thin-film solar cells rely on a p-n junction of which the bulk absorber is doped p-type with group-V elements such as As. However the activation of in-situ doped As requires careful engineering of absorber stoichiometry and could potentially induce front interface combination. Furthermore, there is a typical trade-off between high carrier (hole) density and long carrier lifetime. Herein, we report a n-i-p device structure as an alternative to traditional p-type CdTe solar cells. The polycrystalline CdSeTe grain interior is intrinsic, whereas the grain boundaries and back contact interface are p-type doped by ex-situ doping of group V elements such as As, Sb, or Bi. This ex-situ doping method allows to preserve front interface quality, while maintain the high carrier lifetime advantage of the intrinsic absorber. With this approach, we demonstrated n-i-p CdSeTe solar cells with efficiencies on par with our n-p junction-based CdSeTe solar cells doped with Cu or As. Our new approach presents a new strategy for further efficiency improvement of CdSeTe solar cells.

EQ04.11.08

Electromechanical Modulations in Transition Metal Dichalcogenides—Implications for Environmental Sensors Mauricio Bessa[1], Wellington Freitas[1], Natalia Neme[1], Luiz G.P Martins[2], Ana Barboza[3], Matheus Matos[3], Mario Mazzoni[1] and Bernardo R. Neves[1]; [1]University Federal-Minas Gerais, Brazil; [2]Massachusetts Institute of Technology, United States; [3]UFOP, Brazil

Transition metal dichalcogenides (TMDs) are key players in the two-dimensional materials nanoarena due to their exquisite optoelectronic properties under a standard environment (room temperature and atmospheric pressure). Nevertheless, they may also portray interesting physical properties under different environments. Here, we show two distinct and significant electromechanical modulations in TMD nanosheets which are tuned by the environmental conditions (applied pressure and adsorbents) [1]. Using scanning probe microscopy techniques, we modify the environmental conditions and observe steplike rises in the electrical response of all studied TMDs (MoS_2, WS_2, $MoSe_2$, and WSe_2 - monolayers (ML) and few layers (FL)). In a pressure-dependent experiment, we observe an initial electrical response modification at low pressure values (which requires previous exposure to an ambient atmosphere) that is followed by a second modification at higher pressure values (which occurs even without previous exposure to an ambient atmosphere). Experimentally, such electromechanical modulations are characterized by increasing plateaus in the charge injection efficiency, which normally are a signature for gap closure and/or conducting states availability. Our *ab initio* calculations indicate that the first transition is associated with pressure-induced hydrogenation of the chalcogen atom, which results in available conducting states. In the environment of our experiment, water, from the ubiquitous contamination layer atop the samples originated from any previous exposure to ambient atmosphere, is believed to be the current H source. The second modification, observed at high pressures, is associated with both layer−layer approximation (for FL flakes) and bond-angle modification (for both ML and FL flakes). These distinct processes, which are now concomitantly observed in a single experiment [1], evidence the unique environment-related electromechanical behavior of chalcogenide electronic materials.
Despite the physical insights unveiled by our results, it is their possible applicability that makes them stand out. Given the emerging use of chalcogenides at the core of a wide variety of nanoscale sensors, it is natural to foresee a significant impact of the observed electromechanical modulations on the design and operation of environment-related sensor devices, especially when a combination of pressure, temperature, and atmosphere is at play. Therefore, we believe the present work trails a few steps toward more comprehensive applications of the important class of chalcogenide electronic materials.

Alloy Broadening Effects in CdZnTeSe Alloy Studied with DFT, HR-XRD, and PL Jonathon Baker and Utpal Roy; Savannah River National

Laboratory, United States

Cadmium Zinc Telluride (CZT) is the leading room-temperature radiation detector material commercially available today. Despite much progress over the past 30 years, today's CZT crystals still suffer from performance-limiting material defects and a commensurate high cost of production. The emerging next-generation material $Cd_xZn_{1-x}Te_ySe_{1-y}$ (CZTS) overcomes some of these limitations for radiation detector applications. Here, we present theoretical results and experimental supporting data on how the addition of Se to CZT induces alloy broadening effects, causing an intrinsic degradation in crystal quality regardless of the presence or absence of large crystallographic defects. The impact of this on the use of crystal quality as a performance metric in this alloy space will be discussed.

EQ04.11.10
A Computational Re-Evaluation of Se as a Solar Absorber Alp E. Samli[1], Seán R. Kavanagh[1,2] and David O. Scanlon[1]; [1]University College London (UCL), United Kingdom; [2]Imperial College London, United Kingdom

Trigonal selenium (c-Se) was the first material to exhibit the photovoltaic (PV) effect and has recently experience a renaissance in research interest due to its desirable properties (suitable band gap, high earth abundance, low temperature processing and 'simple' chemistry) and potential implementation in silicon tandem cells.[1] Though cell efficiencies have improved much since 1883, c-Se lags behind leading technologies such as silicon and lead-halide perovskites.[2]

In this work[3], we use hybrid density functional theory (DFT) to investigate crystalline selenium's 5 known synthesisable polymorphs (trigonal, rhombohedral, β-monoclinic, γ-monoclinic, δ-monoclinic) and determine the ideal phase for solar cell operation. Trigonal Se has the lowest direct band gap (1.904 eV with spin-orbit coupling) and highest charge carrier mobilities, allowing it to reach the highest efficiencies. Analysis of the optical response shows that c-Se has a theoretical upper limit to its efficiency as a single-junction solar absorber of 23% at a thickness of 2 μm. We calculate the vacuum alignment of the electronic band edges, providing guidance for further optimisation of the absorber contact layers. In addition, we compute the formation energies and charge transition levels of all intrinsic point defects (vacancies and interstitials) at the hybrid DFT level, to characterise the defect chemistry and doping response in this material.

EQ04.11.11
Influence of S and Cd Atom on Photoluminescence in Tin Sulfide Films Ayaka Kanai[1], Keina Kusatsu[2] and Mutsumi Sugiyama[2]; [1]Nagaoka University of Technology, Japan; [2]Tokyo University of Science, Japan

There has been a great deal of interest in research on low-cost and non-toxic semiconductors from both technological and theoretical viewpoints. In particular, tin sulfide (SnS) exhibits appropriate properties as an absorber layer in thin film solar cells, with p-type electrical conductivity, a high absorption coefficient ($\geq 10^4$ cm^{-1}), and a bandgap of approximately 1.3 eV. Therefore, it has the potential to be used as an environmentally friendly solar cell material. Recently, a relatively high efficiency exceeding 4% in n-CdS/p-SnS structured solar cells was reported. However, the efficiency of SnS film solar cells remains low for various reasons, including the poorly understood carrier/defect properties of SnS. In highly efficient n-CdS/p-Cu(In,Ga)Se_2 (CIGS) solar cells, the surface of the CIGS layer becomes n-type after chemical bath deposition (CBD) of the CdS layer because of the presence of donors such as Cd on the Cu sites (Cd_{Cu}). This contributes to the relatively high efficiency of CIGS solar cells. However, the fundamental defects in the CdS/SnS interface have not yet been revealed. Therefore, understanding the carrier originating from defects in the CdS/SnS interface is critical for improving device performance. In this study, the effects of Cd and S impurity-related defects in SnS films in the CdS layer were investigated using photoluminescence (PL) measurements.
A 1μm-thick SnS film was deposited via RF sputtering on Mo-deposited soda-lime glass substrates. The PL spectra of the three CdS/SnS samples subjected to different treatments were investigated to separate the Cd and S impurity-related defects from those in the CdS layer. First, to obtain normal CdS/SnS, a 60 nm-thick CdS buffer layer was deposited on the SnS layer through CBD using an aqueous solution of $CdSO_4$–NH_3–CH_4N_2S. Second, to examine the S-related defects in the SnS film, the SnS thin film was sulfurized in a sulfur vapor and N_2 atmosphere before depositing the CdS layer. Finally, to examine the Cd-related defects in the SnS film, Cd partial electrolyte (Cd-PE) treatment was carried out on the SnS film, using the same process as for CBD-CdS but without CH_4N_2S before depositing the CdS layer. PL measurements were carried out for all CdS/SnS using the 532.0 nm line of an Nd:YAG laser as the excitation source. Phase-sensitive detection was carried out from 1200 to 1700 nm using a liquid N_2-cooled Ge photodetector. All experiments were performed using a cryostat at 26 K.

EQ04.11.12
Influence of Ge Inclusion on Surface Morphologies of $Cu_2(Sn_{1-x}Ge_x)S_3$ Films Grown by Sulfurization of Cu/Sn-S Precursors Ayaka Kanai[1], Mutsumi Sugiyama[2] and Kunihiko Tanaka[1]; [1]Nagaoka University of Technology, Japan; [2]Tokyo University of Science, Japan

Recently, next-generation renewable energy devices, such as sensors, solar cells, and water splitting using solar cells, have attracted worldwide attention. Furthermore, there has been a great deal of interest in research on environmentally friendly and low-cost photo-absorber materials from both theoretical and technological viewpoints. For this reason, p-type copper sulfide-based ternary compounds, such as Cu_2SnS_3(CTS), Cu_2GeS_3, and Cu_2SbS_3, which have high absorption coefficients of ~10^4 cm^{-1}, are expected to be used as absorption materials in the future. In particular, the pseudo-ternary alloy $Cu_2(Sn_{1-x}Ge_x)S_3$ (CTGS) has recently attracted interest because the bandgap energy can be continuously controlled from 0.9 to 1.6 eV by changing the Ge/(Ge+Sn) ratio, *x*. In addition, compositional grading in the depth direction of the absorber layer in the CTGS film by changing the bandgap can substantially improve the performance, approaching the quality of $Cu(In_{1-x}Ga_x)Se_2$ (CIGS) solar cells. However, the reported energy efficiency of solar cells using CTGS is still low at approximately 6%. One reason that the surface morphology of CTGS cannot be controlled is the high vapor pressure of germanium sulfide (GeS_x). In addition, the surface roughness of the CTGS thin films increases with increasing *x*. The increase in the surface roughness of the p-n junction directly affects the electrical properties of the device, resulting in decreased device performance. In this study, to reveal the change in the surface morphology of CTS films by the inclusion of Ge, the effect of sulfurization temperature on the root-mean-square (RMS) roughness of CTGS films was investigated using a laser microscope. To examine the growth mechanism of the CTGS films, cross-sectional secondary ion mass spectrometry (SIMS) measurements were carried out to investigate the distribution of the atomic compositions of the CTGS films.
A Cu/SnS_2 precursor was deposited via RF sputtering on Mo-deposited soda-lime glass substrates. The Ge ratio was controlled by varying the sputtering time of the Ge layer. The CTGS thin films were then sulfurized using sulfur vapor. To investigate the sulfurization mechanism of the Ge-containing Cu/Sn-S precursor, the ramping rate (10°C min^{-1}), high-temperature holding time (5 min), and Ge layer thickness were kept constant. The crystal structures and compounds of the CTS and CTGS films were determined using X-ray diffraction with Cu Kα radiation. The RMS roughness of the films was evaluated

using laser microscopy. Depth profiles of the CTGS films were obtained using SIMS. SIMS measurements were carried out using O^{2+} as the primary ion, with acceleration.

EQ04.11.13
Investigations into n-CdTe/p-ZnTe Solar Cells Luke Thomas, Theodore D. Hobson, Laurie J. Phillips and Ken Durose; University of Liverpool, United Kingdom

In this work we use an n-type CdTe absorber layer as opposed to the conventional p-type CdTe layer. The motivation behind this stems from the possibility of high stable n-type doping in the absorber layer which offers high *Voc* and Ohmic contacting in photovoltaic devices, both of which currently hinder p-type CdTe devices. We explore n-type doping via post-growth and in-situ routes using indium as a dopant with CSS-grown CdTe films and report on the feasibility of doping. We also study the feasibility of ZnTe:Cu as a p-type partner layer in devices.

We have successfully doped CdTe n-type using both post-growth and in-situ methods. Post-growth doping methods trialled include in-diffusion of evaporated indium metal and the annealing of films that had been sprayed with $InCl_3$, in either aqueous or methanolic solutions. Annealing was conducted either in air or under flowing nitrogen. Indium incorporation into the films was confirmed by quantitative SIMS measurements with concentrations up to 10^{19} cm^{-3}. Conductivity type was confirmed as n-type by determination of the Fermi level position from photoemission measurements (XPS).

In-situ n-type doping was achieved by growing CdTe films via CSS from pre-doped melt-synthesized CdTe:In source material. Chemical incorporation of the indium was quantified with ICP-OES and the bulk CdTe:In was verified as n-type with 10^{17} cm^{-3}. Thin film doping densities from SIMS were in the range of 10^{16}-10^{19} cm^{-3} depending on growth conditions, these films were verified as n-type by photoemission (HAXPES) determination of the Fermi level position.

ZnTe layers were deposited via rf-sputtering and were characterized with surface profilometry, optical spectroscopy, and resistivity and Hall Effect measurements. Copper doping was implemented by evaporating a thin layer of Cu onto the ZnTe surface followed by annealing in an inert atmosphere. With optimized Cu content and annealing temperatures, we fabricated p-type ZnTe layers with sheet resistances below 1000 Ω/sq. Similar processing resulted in carrier concentrations in the range of 10^{16}-10^{21} cm^{-3} by varying the copper content. Optical spectroscopy measurements showed that Cu-doping did not affect the optical transmission or the band gap of the ZnTe layer.

Devices were then fabricated with the following structure; TEC15/n-CdTe/p-ZnTe/Au. This structure was used in both superstrate and substrate configurations with either thin CdTe absorber layers or thin Au contacts respectively. Devices in the substrate configuration yielded efficiencies up to 1.5% whereas those in the superstrate configuration yielded efficiencies up to 3.5%. Capacitance-voltage measurements confirmed carrier concentrations of around 10^{14} cm^{-3} in the substrate geometry with 3 µm CdTe whereas superstrate devices with 800 nm CdTe showed carrier concentrations as high as 10^{16} cm^{-3}.

Work in progress includes investigating CuI as either a hole-transport layer in conjunction with ZnTe or as an individual p-type partner layer to n-CdTe. In addition to this, Au contacts will be replaced with an appropriate transparent contact (such as ITO) for the substrate devices.

EQ04.11.14
Perovskite-Antimony Selenide Tandem Solar Cell Harigovind Gokul Menon, Vijayaraghavan Sankaranarayanan Nair, Al Amin, Xiaomeng Duan, Wenjun Xiang and Feng Yan; University of Alabama, United States

Tandem solar cell represents a promising solar cell technology to overcome the Shockley–Queasier limit in the single-junction solar cell. However, it is a challenge to make an affordable and highly efficient tandem device. Particularly, it is in high demand to use the earth-abundant materials for both the wide bandgap and narrow bandgap sub-cells, respectively. In this work, we reported new tandem solar cells using earth-abundant wide-bandgap perovskite (1.7 eV) and narrow bandgap antimony selenide (Sb_2Se_3, 1.2 eV). A device-level simulation using SCAPS has been performed to predict the device performance. A prototype tandem cell with device architecture Perovskite/Sb_2Se_3 has been fabricated to validate the simulation. The experimental results show promising device performance and pave the way to further improve device performance by engineering the device architecture and interfaces.

EQ04.11.15
Wide Bandgap Metal Oxide Buffer Layers on the Eco-Friendly Selenium Thin-Film Solar Cells Cheng-Ying Chen[1], I-Jui Hsieh[2], Thi-Thong Ho[3], Pochun Chen[2], Kuei-Hsien Chen[3] and Li-Chyong Chen[4]; [1]Department of Optoelectronics and Materials Technology, National Taiwan Ocean University, Taiwan; [2]Institute of Materials Science and Engineering, National Taipei University of Technology, Taiwan; [3]Institute of Atomic and Molecular Sciences, Academia Sinica, Taiwan; [4]National Taiwan University, Taiwan

The element selenium (Se) was used in the first solid-state solar cell in 1883 and has a high absorption coefficient and mobility, making it a p-type absorber for wide energy gap (~1.8~2.0 eV) thin film solar cells. In addition, direct bandgap, earth-abundance, simple composition, non-toxicity, low melting point and environmental stability make Se inexpensive and developable for solar cells. However, in the n-type buffer layer perspective, so far, has not been found a suitable buffer layer for modulating conduction band offset (CBO) between n-type buffer layers and p-type Se absorbers.
In this work, we utilized atomic layer deposition (ALD), depositing ZnSnO as buffer layers for p-type Se absorbers. The benefit for using ALD growth ZnSnO can be summarized the as following points: (1) ZnSnO is wide band gap material (~3.2eV); (2) Controllable of Zn and Sn ratio, which can intentionally modulate the CBO become spike type (i.e., 0<CBO<0.5 eV); (3) ALD can effectively growth larger scale of thin-film and precisely control the thickness. Finally, the result presented the $Zn_{1-x}Sn_xO$ (x=7%) under the optimization of ZnO and SnO ratio, the power conversion efficiency can be achieved at about 2.68%.

EQ04.11.16
Realizing High Responsivity Sb_2Se_3-Based NIR Photodetector by Employing Selenization Process and Controlling Crystallinity Su K. Kim, Hee-Kyoung You, Kwang Ro Yun, Jong-Ho Kim and Tae-Yeon Seong; Korea University, Korea (the Republic of)

Chalcogenide semiconductors (alloys with chalcogen elements) are well known for their stability under heat, moisture, and light exposure. Among these semiconductors, antimony selenide (Sb_2Se_3) is of increasing interest as a suitable light absorber material suitable for solar cells and photodetectors in the visible to near-infrared wavelength range. In particular, photodetectors are of increasing interest because of their applications in optical communications, sensors, and broadband imaging technologies for military systems. Sb_2Se_3 has a narrow band gap, (varying from 1.6 to 1.2 eV by controlling annealing temperature), low toxicity, and high absorption coefficient. However, there is a challenge to be addressed for various applications due to the intrinsically low electrical conductivity of Sb_2Se_3. Additionally, Se loss occurs during thin film deposition, which negatively affects the characteristics of film and device performance. Thus, to solve the problem, many studies have been conducted to deposit Sb_2Se_3 films with additional Se by annealing with Se powder

and H_2Se gas environment, and Se co-sputtering process. Researches on Sb_2Se_3 films and associated devices have been mainly carried out to improve the performance of solar cells, and studies related to Sb_2Se_3-based photodetectors have not been conducted so far.
In this study, we first report on the fabrication of selenized Sb_2Se_3 film-based photodetectors through a facile co-sputtering process. Sb_2Se_3 films were deposited by a sputtering method and were then crystallized by employing an annealing process. To compensate for the loss of Se atoms during deposition, a process of co-sputtering Se and Sb_2Se_3 targets was adopted. The performance of photodetectors fabricated with selenized and unselenized Sb_2Se_3 films was examined. All samples were annealed at temperatures of 150 - 300 °C for 30 min. The XRD results showed that selenized-Sb_2Se_3 films exhibited better crystallinity. The selenized-Sb_2Se_3films were crystallized at 150 °C, whilst unselenized Sb_2Se_3 films were crystallized at 200 °C. For the unselenized Sb_2Se_3 films, the photocurrent increased with the temperature, whereas the selenized-Sb_2Se_3 films showed maximum current at 250 °C. The 250 °C-annealed selenized-Sb_2Se_3 photodetectors exhibited the responsivity of 1130 mA/W at the light intensity of 200 μW/cm^2 and the detectivity of 4.62 x 10^{11} Jones. The rise/fall time of the 250 °C-annealed selenized-Sb_2Se_3 detectors was 4.54 ms/8.50 ms at 200 μW/cm^2, and sensitivity and external quantum efficiency were 94.2 and 155%, respectively. The fast response time indicates the formation of high crystal-quality films. The bandgap of the selenized-Sb_2Se_3 film was 1.65 and 1.23 eV before and after annealing at 250 °C, respectively. Based on XPS, STEM and AFM results, the improved behaviours of selenized photodetectors will be explained in terms of the formation of donor-like defects, dense crystallinity, and surface characteristics. These results show that the selenization of Sb_2Se_3 films could be a promising process for the fabrication of high-performance NIR photodetectors.

EQ04.11.17
Above Ambient Pressure Synthesis of Antimony Chalcohalide Semiconductors Ivan Cano Prades[1], S Boussegui[1], Kunal J. Tiwari[2,1], Sergio Giraldo[1], Alejandro Navarro Güell[1], Zacharie Jehl Li Kao[1], Marcel Placidi[1], Joaquim Puigdollers[1] and Edgardo Saucedo[1]; [1]Universitat Politècnica de Catalunya, Spain; [2]Catalonia Institute of Energy Research, Spain

Antimony chalcogenides Sb_2X_3 (X=Se,S,Te) and its alloys have become a topic of active research through the past decade due to their interesting electrical and optical properties stemming from an intriguing quasi-1D crystal structure. Observation of anisotropic charge transport properties coupled with ease of synthesis at relatively lower temperature are important characteristic observed for this class of semiconductor compounds which have been studied both in bulk and thin film form. Amongst the various possible chemical compositions, Sb_2Se_3 has garnered particular attention from the PV community due its ideal 1.3 eV band gap and high absorption coefficient a > 10^{5-6} cm^{-1} in the visible region, positioning it as a promising absorber layer for thin film photovoltaic applications. State of the art Sb_2Se_3 based thin film solar cell devices have reached a record efficiency = 12% [1] and to the growing community is aiming for much higher values in the short term. Beyond the various strategies being implemented to improve performance, there is also a need to further expand the range of application beyond stand-alone PV by tuning the band gap of the parent Sb_2Se_3 material. The inclusion of halogen elements such as iodine and bromine has been proposed as an interesting strategy to widen the band gap of Sb_2Se_3 making it optically suitable for application in building integrated PV as well as top cell in tandem solar cells [2].
We present here a novel method for the fabrication of antimony chalcohalide thin films and report on recently obtained results on SbSe(I/Br) absorber synthesis. The process relies on the high pressure (> 1 atm) reactive thermal annealing under Se atmosphere and SbI_3 and $SbBr_3$ precursors at low temperature (≤ 450 degree celsius) for the preparation of SbSeI and SbSeBr semiconductor thin films. A series of optimizations for different experimental conditions such as temperature, pressure, duration etc. were performed leading to the formation of highly *c-axis* oriented chalcohalide semiconductor on Mo coated glass substrates with a unique micro columnar grain morphology. Detailed structural and compositional studies were performed on the as prepared absorber layers in order to study their physical characteristics as well as propose plausible conversion pathway starting from Sb_2Se_3 to SbSeI and SbSeBr. First proof of concept solar cell devices was completed in the substrate configuration of Mo/SbSe(I/Br)/CdS/i-ZnO/ITO and their photovoltaic properties as well as spectral response were investigated. Best performing devices with SbSeI (E_g = 1.6 eV) and SbSeBr (E_g = 2 eV) exhibited V_{oc} = 633 mV and 600 mV respectively, demonstrating the potential of these materials as wide bandgap absorbers. We postulate that the main limitation of the current devices comes from a poor carrier extraction due to the use of a CdS buffer layer with a cliff-like p-n interface and poor coverage due to micro-columnar morphology presenting shunt paths. The replacement of the n-partner layer by a material with a more suited band structure, or the use of electron selective contacts will be discussed as ways to markedly improve performance.

Fabrication of a Flexible CMOS Image Sensor Integrating Crystalline Selenium Photoconversion Film and Thinned FDSOI Circuit Shigeyuki Imura and Masahide Goto; NHK Science & Technology Research Laboratories, Japan

In a smart society based on the surrounding sensing and monitoring infrastructure, high-performance flexible sensing devices that adapt to various shapes and object movements are necessary. Although flexible sensors using organic and inorganic thin-film transistors have previously been developed to automatically collect and visualize large information around us, a further performance and reliability enhancement of the devices for practical use is required. Here, we demonstrate the flexible silicon (Si)-based complementary metal-oxide semiconductor (CMOS) image sensors with high performance and flexibility by transferring the ultra-thinned CMOS circuits and photoconversion films onto flexible substrates. Combining CMOS circuits on a fully depleted silicon on insulator (FDSOI) substrates [1], which allows very thin device layers, and a crystalline selenium (c-Se) photoconversion film with its outstanding light absorption properties [2] achieves high-performance and excellent flexibility. In this presentation, we discussed substrate thinning and transfer technology, as well as the deposition process of c-Se-based photoconversion film, confirming the mechanical flexibility and operation of thinned CMOS circuits.

The CMOS circuit is formed on the FDSOI wafer with a handle layer, device except for handle layer, and CMOS active layer with thicknesses of 725 μm, 6 μm, and 50 nm, respectively. After dicing into chips and bonding to the temporary fixing substrates, we first ground the handle layer to a thickness of 30 μm mechanically and then removed it using xenon fluoride etching, where the Si is selectively etched and the reaction stopped at the surface of the buried oxide layer. Next, we bonded the device to a 50-μm-thick flexible polyethylene terephthalate (PET) substrate with an adhesive film and removed the temporary fixing substrate after the ultraviolet irradiation. Finally, the photoconversion film, which comprises a 20-nm-thick wide-bandgap n-type gallium

oxide layer, 300-nm-thick p-type c-Se absorption layer, and 30-nm-thick indium tin oxide transparent electrode is directly provided on the CMOS circuit. A c-Se was fabricated by annealing amorphous Se at 200 degrees, whereas tellurium was used as a nucleation layer to prevent Se film from peeling. Consequently, we successfully produced a 6-µm-thick FDSOI device with a 350-nm-thick c-Se-based photoconversion film on a flexible PET substrate.

We compared the characteristics of the drain current-gate voltage of the transferred CMOS circuit with that of the bulk (before transferred) ones, where the gate length is 2 µm. The measurement results reported no significant changes in the characteristics of the devices before and after the transfer, thereby indicating that the thinning and transfer process does not adversely affect the circuit operation. Furthermore, the flexural rigidity (*D*) of an object is expressed by the following equation [3]:

$D=E\times t^3 / 12(1-v^2)$

where *E*, *t,* and *v* are the Young's modulus, thickness, and Poisson's ratio, respectively. FDSOI, which is mostly composed of silicon dioxide, has a smaller Young's modulus and Poisson's ratio than Si. Additionally, the thickness of the device, which comprises the photoconversion film and the FDSOI circuit, can be made extremely thin, thereby allowing the device flexibility. Also, the fabricated device can be wrapped around a cylindrical glass rod with a curvature of 6 mm without cracking, confirming its mechanical flexibility.

Conclusively, we developed a fabrication process for a flexible CMOS image sensor that integrates a c-Se-based photoconversion film and a thinned FDSOI circuit. Since this technology enables the flexibility of various Si devices, it can open up new fields of application in image sensors and several high-performance flexible Si devices.

PRESENTED ON-DEMAND ONLY: Fabrication and Characteristics of Co_xS_y Thin Films for Gas-Sensing Applications Myeong Gyu Kim and Yun-Hyuk Choi; Daegu Catholic University, Korea (the Republic of)

Transition-metal oxides have been widely studied for detecting toxic and dangerous gases as a semiconductor-type gas sensor. However, those metal oxide-based semiconductor materials usually suffer from high operating temperatures, high noise, and poor selectivity. For this reason, transition-metal sulfides (MoS_2, WS_2, etc.) begin to stand out in gas sensors. Despite numerous investigations on the material selection, cobalt sulfides have rarely been studied for the gas sensor application. In this work, gas sensing properties of cobalt sulfide thin films were investigated. Co_xS_y thin films were synthesized by a two-step process using the thermal metal-organic deposition of Co_3O_4 and subsequent sulfidation using a horizontal tube furnace. We have optimized processing temperature and time for the preparation of the Co_xS_y thin films. The gas sensing properties have been investigated with varying gas type and concentration at various operating temperatures. Finally, the gas sensing and structural characteristics of cobalt sulfide thin films were evaluated and demonstrated in terms of processing-structure-property. In addition, the oxidation behaviors on the surface of sensors during the sensor measurements have been examined.

Solar Cells of Antimony Sulfide-Selenide Absorber Thin Films with ZnS-CdS Window Layers Fabiola De Bray Sanchez, M.T. Santhamma Nair and P. Karunakaran Nair; Universidad Nacional Autonoma de Mexico, Mexico

Antimony chalcogenides, Sb_2S_3 and Sb_2Se_3, and their solid solutions $Sb_2S_xSe_{3-x}$ with band gaps in the 1.88 – 1.1 eV interval are prospective absorber materials for thin film solar cells. In the present work, we used thermal evaporation of commercial Sb_2S_3 and Sb_2Se_3 compounds to obtain the thin films of $Sb_2S_xSe_{3-x}$ with optical band gaps of 1.29 – 1.6 eV, depending on the value of x, and optical absorption coefficients of > 10^5 cm^{-1} in the visible region. The films show photoconductivity of 10^{-6} - 10^{-5} Ω^{-1} cm^{-1}. Heterojunction solar cells of these thin films as absorbers were developed with CdS, ZnO, or ZnS/CdS bilayer as buffer/window on SnO_2:F-coated glass substrates. With colloidal graphite paste of 0.2 – 1 cm^2 area as the back contacts, the solar cell of glass/FTO/ZnS-CdS/Sb_2SxSe_{3-x}/C-Ag structure showed an open circuit voltage of 0.435 V, a short circuit current density of 32.9 mA cm^{-2}, and a conversion efficiency of 7.34 % with Fill Factor, 0.52. We present the details of preparation of the different component films, their properties, and the latest results on the performance of these solar cells.

Tailoring the Optical and Electrical Properties of $MoTe_2$ via Electrochemical Intercalation of Lithium Ions Alyssa Shiyu Xu, Shunran Li, Mengjing Wang, Joshua Pondick, Peijun Guo and Judy Cha; Yale University, United States

Intercalation of lithium (Li) ions is one of the most effective methods to realize structural transformation and to tune the optical and electrical properties of two-dimensional transition metal dichalcogenides (2D TMDCs). Numerous studies have focused on the phase transition from semiconducting 2H phase to metallic 1T (or 1T') phase in MoS_2 and WS_2 induced by the intercalation of lithium ions. However, few reports explore the effects of lithium intercalation in other TMDCs, such as Mo- or W- ditellurides. In particular, novel electronic and energy devices can be realized using the lithium-intercalated $MoTe_2$ with its intriguing electrical, topological and catalytic properties.
Here, we report electrochemical lithium intercalation into 1T'- $MoTe_2$ flakes. The 1T' phase is stable down to 0.9 V of the applied electrochemical voltage using poly(ethylene glycol) methyl ether methacrylate (PEGMA)/ bisphenol A ethoxylate dimethacrylate (BEMA) solid polymer electrolyte and Li anode, and two new phases are observed at 0.7 V (phase I) and 0.4 V (phase II) of the applied electrochemical voltage. At 0.7 V, lightly intercalated phase I is evidenced by the disappearance of the A_g peak at ~77.7 cm^{-1} and appearance of a new peak at ~86.9 cm^{-1} in Raman spectroscopy as well as a 10% increase of electrical resistance in two-terminal measurements. For heavily Li-intercalated phase II at 0.4 V, we observe the emergence of additional new peaks at 16.8 cm^{-1}, 109.0 cm^{-1} and 132.8 cm^{-1} in Raman spectroscopy and the dramatic increase of electrical resistance for over 8 folds. *In situ* Hall effect measurements show that the carrier density falls from 10^{15} cm^{-2} of pristine 1T'-$MoTe_2$ to 10^{14} cm^{-2} (phase I) and 10^{12} cm^{-2} (phase II) despite the supposed electron doping from Li intercalation. Temperature-dependent resistivity measurements further show increasing resistivity with decreasing temperature for phase II, suggesting a gap opening in initially metallic 1T'-$MoTe_2$. Our results thus demonstrate electrochemical intercalation of lithium ions as a powerful tool to manipulate phase stability and electron density of 2D TMDCs, and report new phases in $MoTe_2$ induced by lithium intercalation.

8:50 AM EQ04.12.05
A Gapped Phase in Semimetallic T_d-WTe_2 Induced by Lithium Intercalation Mengjing Wang[1,2], Aakash Kumar[1], John Woods[1], Hao Dong[1], Joshua Pondick[1], Alyssa Shiyu Xu[1], Peijun Guo[1], Diana Qiu[1] and Judy Cha[1,2]; [1]Yale University, United States; [2]Cornell University, United States

Lithium intercalation in two-dimensional (2D) materials can introduce useful electronic and structural phase transitions, as enabled by its high electron doping power on the order of 10^{14} e/cm^2. For example, lithium intercalation can transform semiconducting 2H-MoS_2 into metallic 1T'-MoS_2. Despite the extensive studies of lithium intercalation in MoS_2 and WS_2, the effects of lithium intercalation in 2D transition metal tellurides and thickness effects on intercalation-induced phase transitions have rarely been explored. Herein, we report a reversible structural phase transition in WTe_2 from 2D Weyl semimetal T_d phase to semiconducting T_d' phase by electrochemical lithium intercalation.[1] We systematically investigated the phase transition dynamics as a function of electrochemical intercalation voltage and layer thickness using combined *in situ* Raman spectroscopy, *in situ* x-ray diffraction, and *in situ* electron transport characterization. Structurally, the new T_d' phase has an in-plane structure resembling the theoretically predicted 2x2 charge density wave (CDW) of monolayer WTe_2 with electron doping.[2,3] Electronically, the new T_d' phase has an increased longitudinal resistance and a reduction of carrier density both by two orders of magnitude, probed by *in situ* Hall measurements. The more resistive T_d' phase also exhibits an increasing resistance with decreasing temperature, suggesting that this T_d' phase is a semiconductor with a gap opening at the Fermi level. Our *ab initio* calculations further predict that this T_d' phase has an indirect band gap of 0.14 eV and a direct band gap of 0.66 eV, which supports our transport data. Our finding of a new gapped phase, potentially a CDW phase, in a two-dimensional (2D) semimetal demonstrates electrochemical intercalation as a powerful tuning knob for modulating electron density and phase stability in 2D materials. The greatly expanded electronic and structural phase diagram of 2D materials accessible using lithium intercalation will stimulate the research for novel quantum phases, such as topological superconductivity.

Structure-Property-Function Relationships of Novel Chalcogenides from Combinatorial Synthesis and High-Throughput Characterization
Thomas Unold; Helmholtz-Zentrum Berlin, Germany

Emerging chalcogenide materials such as BaZrS3 have raised considerable interest for their attractive optoelectronic properties, earth-abundance and high stability. However, many material properties such as carrier mobilities, carrier densities, defects and band positions are still relatively unclear. Reports of these properties in literature usually refer to few sample studies, with specific synthesis conditions. It would be useful to be construct more general structure-property-function (SPF) relations for which wider regions of the phase-diagram of these multinary materials are explored. We present such SPF relations for combinatorial BaZrS3 thin films that are synthesized by PLD and sulfurization with large gradients of the Ba/Zr content. We show that SPF relationships obtained by high-throughput XRF, XRD, Raman, UV-Vis, Photoluminescence, Conductivity, THz-Absorption enable important insights in the material properties and their potential application in optoelectronic devices.

Strategies for Synthesis of Large-Area Epitaxial Transition Metal Dichalcogenides
Tanushree Choudhury[1,2], Mikhail Chubarov[2], Haoyue Zhu[2], Nicholas Trainor[2], Thomas McKnight[2], Shruti Subramanian[2], Danielle R. Hickey[2], Saiphaneendra Bachu[2], Tianyi Zhang[2], Mauricio Terrones[2,2,2], Joshua A. Robinson[2,2] and Joan M. Redwing[2,2]; [1]Indian Institute of Technology Bombay, India; [2]The Pennsylvania State University, United States

Layered 2D transition metal dichalcogenides (TMDs) and their heterostructures have novel and exotic optical and electronic properties. Current research using transferred exfoliated flakes has demonstrated the rich landscape of possible properties and applications that TMDs and their heterostructures exhibit. A major challenge in harnessing the full potential of these materials is the availability of these materials uniformly over a large-scale. Scalable and adaptable synthesis strategies are necessary to obtain pristine epitaxial TMDs and heterostructures. We have developed an epitaxial growth strategy for layered dichalcogenides MX_2 (M=Mo, W and X= S, Se), based on metal organic chemical vapor deposition (MOCVD). This process uses metal hexacarbonyl and hydride chalcogen precursors to deposit monolayers in a cold-wall reactor.
Epitaxial growth of nearly single crystalline TMDs like WS_2 on 2" sapphire wafers is achieved by a multi-step precursor modulation method. In case of conventional 3D substrates, nucleation density is controlled independently by precursor modulation. The lateral growth of these nuclei is promoted while suppressing additional nucleation to form coalesced monolayer films. In-plane X-ray diffraction demonstrates that the films are epitaxially oriented with respect to sapphire. Controlling the growth temperature and chalcogen flux is crucial in establishing an epitaxial relation and achieving oriented growth. Dark-field transmission electron microscopy (DF-TEM) of transferred WS_2 monolayers show ~95% single orientation coverage with minimal bilayer and inversion domains. The key features observed during the growth of MoS_2, WS_2 and WSe_2 will be discussed.
MOCVD synthesis of TMDs is also investigated on 2D substrates like graphene. In this case, we investigate the effect of defects in epitaxial graphene on the growth of transition metal dichalcogenides like WS_2. The defect density in epitaxial graphene, controlled by exposure to a helium plasma for different durations, control the WS_2 nucleation density as well as nucleation sites. The results indicate that the defect generation, and subsequent sulfur incorporation is higher when the buffer layer was present between the SiC substrate the graphene layers. Another key observation was that the plasma treatment modified the WS_2 nucleation sites from step edges to terraces. This impact on the nucleation site was, however, temperature dependent. Additional details about the role of the buffer layer and the impact on the nucleation site and density will be presented.

SESSION EQ05.01: Perovskites I
Session Chairs: Stefaan De Wolf and Monica Morales-Masis
Monday Morning, November 28, 2022
Sheraton, 2nd Floor, Republic B

10:30 AM *EQ05.01.01
Vapor Phase Deposited Perovskites Henk J. Bolink; University of Valencia, Spain

We will report on the progress on vapor phase deposited perovskites, using novel screening methods and device architectures. The influence of the use of thin organic charge extraction layers, using strong dopants, ionic compounds and other passivators will be described.

11:00 AM *EQ05.01.02
Interactions Between Transport Layer and Active Layer in Organic and Perovskite Solar Cells Julia W. Hsu; The University of Texas at Dallas, United States

Transport layers are essential components of organic and perovskite solar cells (OSCs and PSCs), with functions such as setting up the internal electric field to facilitate charge transport, preventing exciton quenching on the electrodes, and blocking the wrong type of carriers from reaching the electrode. Often transport layers are treated as inert materials in the multi-layered OSCs and PSCs. In this talk, I will highlight a few examples of unforeseen interactions between transport layers and active layers. In OSCs, we find that electron transfer to high work function MoOx hole transport layer (HTL) induces p-doping[1] and highly soluble polyethylenimine (PEI) induced n-doping in the organic active layer,[2] both resulting in lower short circuit current. In PSCs, we find that NiO can significantly lower the decomposition temperatures of $MAPbI_3$[3] and $FAPbI_3$ [4] through an interfacial reaction that stabilizes HI and subsequent NiI_2 formation. SnO_2 and ZnO also react with halide perovskites while TiO_2 appears most stable without UV illumination.[5] The cumulation of these results indicates that the stability of multi-layer devices depends not just on individual layer materials but also their compatibility during processing and operation.

Probing Metal Oxide Surfaces for Stable and Efficient Perovskite Devices Sofia Apergi[1], Selina Olthof[2], Geert Brocks[3,1] and Shuxia Tao[1]; [1]Eindhoven University of Technology, Netherlands; [2]University of Cologne, Germany; [3]University of Twente, Netherlands

With the rapid advance of metal halide perovskites, refining other materials that comprise a perovskite optoelectronic device becomes all the more urgent. Metal oxides are especially important in such devices, as their favorable charge transport properties and superior stability render them ideal charge transport layers. However, interfacing materials naturally adds another level of complexity to the device, which requires careful characterization and optimization. Here, several studies of metal oxide surfaces will be presented, which using a combination of density functional theory calculations with experimental characterizations aim to understand and improve the oxide interface with perovskites. A variety of topics will be covered, including the reactivity of certain oxide surfaces with perovskite precursors [1], the electronic level alignment at interfaces [2] and the passivation of interfaces with molecular engineering [3]. The atomistic insights obtained from these studies provide important basis for further optimizing the performance of these perovskite devices.

SESSION EQ05.02: Transparent Electrodes I
Session Chairs: Stefaan De Wolf and Monica Morales-Masis
Monday Afternoon, November 28, 2022
Sheraton, 2nd Floor, Republic B

1:30 PM *EQ05.02.01
Layered Copper Oxychalcogenides for Next Generation P-Type Transparent Conductors Geoffrey Hyett[1], David O. Scanlon[2], Benjamin A. Williamson[3], Zahida Malik[1] and Daniel W. Davies[4]; [1]University of Southampton, United Kingdom; [2]University College London, United Kingdom; [3]Norwegian University of Science and Technology, Norway; [4]Imperial College London, United Kingdom

Transparent conducting oxides (TCOs) combine low electrical resistivity with visible light transparency, a combination of properties that have made these materials indispensable to modern technology, being found in the screens of smart phones and portable electronics, in photovoltaic panels and in thermally efficient glazing. However all current commercial TCOs are n-type materials - there are no high mobility p-type transparent conductors (p-TCs) and this is acting as an impediment to many critical technologies. Prior work has identified that layered oxychalcogenides have the potential to fill this p-TCs gap, with the *ZrCuSiAs* structured lanthanum oxychalcogenides, LaOCu*Ch* (*Ch* = S, Se and Te), demonstrating band gaps of 2.3 eV to 3.1 eV and reasonably hgh p-type hole mobility. The key feature of these compounds is the anti-litharge structured copper chalcogenide layer where the 3*d* orbitals of the tetrahedral co-ordinated copper(I) hybridise with the chalcogenide orbitals at the top of the valance band to create a highly dispersed band edge. The separation of the copper chalcogenide layer by the lanthanum oxide layer reduces the dimensionality and widens the band gap relative to bulk copper (I) chalcogenides which are not transparent. However although promising, none of the LaOCu*Ch* phases combine a sufficiently large band gap with a sufficiently high hole mobility.

In this paper we will report on our work to identify and optimise new p-type transparent conductors through the synthesis of novel layered oxychalcogenide materials which share the same anti-litharge copper layer found in the LaOCu*Ch* phases, but with more complex and diverse oxide layers to modulate the structure. We have undertaken a combined computational and synthetic search strategy to investigate structures of the type $A_3B_2O_5Cu_2Ch_2$, $A_4B_2O_6Cu_2Ch_2$ and $A_2BO_2Cu_2Ch_2$, where *A* is an alkali or alkaline earth and *B* is a d^0 or d^{10} closed shell transition or post-transition metal. We abbreviate these to the 325, 426 and 212 structure types. We have taken advantage of the leverage available through computational modelling to consider all the possible combinations of 22 different elements across the *A* and *B* sites in these structures, which after selection for charge order, neutrality and tolerance factor refined down to 150 possible combinations which were then assessed for thermodynamic stability. This greatly accelerated the selection process for synthesis allowing us to identify at least 10 new materials including the following 325 copper sulfides, $Ba_3Y_2O_5Cu_2S_2$, $Ba_3Sc_2O_5Cu_2S_2$, $Ba_3In_2O_2Cu_2S_2$ and Ba3$In_3O_5Cu_2S_2$, and copper selenides, $Ba_3Sc_2O_5Cu_2Se_2$, $Ba_3Sc_2O_5Ag_2Se_2$ and $Ba_3In_2O_5Ag_2Se_2$.

These oxychalcogenides and a number of solid solutions between then were synthesized under vacuum using a conventional ceramic synthesis route, at temperatures between 800 °C and 900 °C. Structures were determined by Rietveld refinement of X-ray powder diffraction patterns, and band gaps determined from optical measurements. A comprehensive comparison of experimental and computational results providing the crystallographic and electronic structure of the compounds under investigation has been conducted. We find that the band gaps range from 1.4 V to 3.3 eV, and that it is possible to band engineer these materials through the selectin of different compositions, shifting either the conduction or valance band to control the band gap. We will also report on the transport properties of these compounds, and show that with the diversity of oxide layers available it is possible to control the strain and the geometry in the crucial copper chalcogenide layers, with consequent control of the hole transport properties, and hence their potential as p-type transparent conductors.

2:00 PM EQ05.02.02
Tunneling Junctions on Transparent ITO Electrodes Using Phosphonic Acids for Surface Modification Jane Kardula[1,2], Nahid Torabi[1,2], Lara Clerici[1] and Ryan Chiechi[1,3]; [1]Stratingh Institute for Chemistry, Netherlands; [2]Zernike Institute for Advanced Materials, Netherlands; [3]Department of Chemistry, United States

Since the 1980s, self-assembled monolayers (SAMs) have been used to investigate the electronic properties of molecules in ensemble junctions. They are often formed by contacting a monolayer supported by a planar gold electrode with a conformal metal such as Eutectic Gallium Indium (EGaIn). This material is a non-Newtonian liquid metal alloy, allowing us to form multiple junctions on a single sample in a non-destructive manner. Due to these reasons, replacing the EGain electrode for something transparent is not plausible, so instead we target the planar electrode. Suitable candidates for this are transparent conducting oxides (TCOs). We opted for Indium Tin Oxide (ITO) as it is well known, well studied and important in the field of solar cells and diodes.
We formed monolayers of alkyl phosphonates with varying chain lengths and measured the current-voltage characteristics and observed two different regimes of tunneling decay and possibly two regimes of odd-even effect in the monolayers.

2:15 PM EQ05.02.03
Photonic Curing of Hybrid Transparent Electrodes for High-Throughput Solar Cell Manufacturing Robert Piper, Justin Bonner, Weijie Xu and Julia W. Hsu; University of Texas at Dallas, United States

Realizing high-throughput, low-cost perovskite solar cell (PSC) manufacturing is highly sought-after in photovoltaic (PV) research in recent years. To fully achieve roll-to-roll (R2R) manufacturing of PSCs, it is important to consider the flexible transparent electrode (TE). PET/ITO is a commonly used substrate for making flexible PSCs. When optimizing transparent conducting materials, there is a tradeoff between sheet resistance (R_{sh}) and optical transparency. Because commercial PET/ITO substrates are made with slow (~ 1 m/min) vacuum deposition processes, they tend to be expensive. Therefore, it would be advantageous to develop a high-throughput, R2R compatible, solution-deposition approach for fabricating the TE on PET substrates. While various solution-deposition processes, such as blade coating or slot-die coating, can achieve the desired web speed of > 10 m/min, there is still a need to improve the post-deposition annealing step. One promising post-deposition processing technique is intense-pulsed-light processing, also known as photonic curing. Photonic curing delivers short (0.01 – 100 ms) pulses of broadband (200 – 1500 nm) light from a xenon flash lamp to the samples. Any materials in the sample stack that absorb light will convert the impinging light pulse into heat within the sample, which drives changes in the sample (calcination, phase change, crystallization, etc.). Photonic curing has three main advantages over thermal annealing: 1. Faster processing speed (milliseconds or seconds). 2. Compatibility with plastic substrates. 3. Smaller physical footprint and less wasted energy. Since the light pulses are on for a short time, the intensity can be high while the total energy delivered to the sample is low, minimizing damage to the plastic substrates.

In this work, a hybrid TE material is fabricated on PET substrates using photonic curing. The hybrid TE material contains a layer of silver nanowires (AgNWs) and a layer of metal-oxide (InO_x, ITO, IZO, etc.). The AgNWs increase the light absorbed by the film during the photonic curing process, which leads to higher processing temperatures, possibly improving the conversion of the metal-oxide layer. The AgNWs also enhance the electrical conductivity of the final TE layer after photonic curing. A AgNW and metal-oxide bilayer is formed by spin coating each solution onto the PET substrate sequentially followed by a single photonic curing process. We use average optical transmittance (T_{avg}) from 400 to 700 nm and average R_{sh} to evaluate the TE performance. The following photonic curing parameters are varied to optimize T_{avg} (maximize) and R_{sh} (minimize): Pulse voltage, pulse envelope, number of micro-pulses, duty cycle, number of pulses, and pulse repetition rate. Preliminarily, we also observe a significant impact on the TE properties by the

volume of AgNW deposited during the spin coating deposition step. Using dispense volumes of 80 µL and 20 µL, we achieve samples with T_{avg} = 73%, R_{sh} = 19 Ω/sq, and roughness = 9 nm, and T_{avg} = 83%, R_{sh} = 58 Ω/sq, and roughness = 5.6 nm, respectively, after photonic curing.

This material is based upon work supported by the U.S. Department of Energy's Office of Energy Efficiency and Renewable Energy (EERE) under the Solar Energy Technologies Office Award Number DE-EE0009518.

2:30 PM EQ05.02.04
Computational Prediction and Experimental Realisation of Earth Abundant Transparent Conducting Oxide Ga-Doped $ZnSb_2O_6$ with Unique Band Alignment Joe Willis[1,2,3], Adam J. Jackson[4], Alex M. Ganose[5], Anna Regoutz[1,3], Tim D. Veal[6], Robert Palgrave[1] and David O. Scanlon[1,2]; [1]University College London, United Kingdom; [2]Thomas Young Centre, United Kingdom; [3]Diamond Light Source, United Kingdom; [4]Science and Technology Facilities Council, United Kingdom; [5]Imperial College London, United Kingdom; [6]University of Liverpool, United Kingdom

Transparent conducting oxides have become ubiquitous in modern opto-electronics, yet the number of materials used for transparent conducting applications is limited to a handful of systems that have been known for the last forty years. Subsequently, one is limited by the work-function of these available post-transition metal oxides when building opto-electronic devices. Therefore, it is desirable to discover new transparent conductors with unique band alignments to bring much needed diversity to the field.

In this work, we use hybrid density functional theory and defect chemistry analysis to demonstrate that tri-rutile zinc antimonate, $ZnSb_2O_6$, is an ideal transparent conducting oxide, and identify gallium as the optimal dopant to yield high conductivity and transparency.[1] To validate our computational predictions, we have synthesised both powder samples and single crystals of Ga-doped $ZnSb_2O_6$ which conclusively show behaviour consistent with a degenerately doped transparent conductor. The calculated electron affinity is the largest of all known transparent conductors, which could improve contact efficiency in a range of opto-electronic devices and has tremendous implications for organic photovoltaics.[2]

Nanostructured a-Fe_2O_3 Photoelectrodes with Transparent and Conducting Sb-Doped SnO_2 Films by Atomic Layer Deposition Eunsoo Kim[1,1], Hyunwoo Yang[1,2], Seongrok Seo[1,3], Jong Hyeok Park[4] and Hyunjung Shin[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]North Carolina State University, United States; [3]University of Oxford, United Kingdom; [4]Yonsei University, Korea (the Republic of)

Wide band gap metal oxides, with incorporation of specific dopants, can take on quite moderate electric conductivity while retaining its intrinsic transparency. This seemingly impossible material property has been one of the essential foundations of modern optoelectronic devices. The fabrication of this layer, so called transparent conducting oxide (TCO), has been mostly done by physical vapor deposition techniques such as sputtering or electron beam evaporation. However, emerging devices with complicated structures requires better step coverages for the geometry with high aspect ratio holes and/or trenches. To meet the requirements, we suggest atomic layer deposition of antimony-doped tin oxide (ATO). By alternatively depositing SnO_x and SbO_x layers as matrix and dopant layers, respectively, we could freely control the dopant concentration in a desired level. The as-deposited films didn't show good conducting properties, but after post-annealing process at 550 °C, the resistivity of the films decreased to ~5×10^{-3} Ω cm. All the films with different dopant concentrations showed crystalline rutile phase without any suspicious antimony oxide peaks, even up to 20% antimony incorporation, implying that SnO_2 serves well as a matrix for antimony dopant. The composition of the annealed films, with different antimony sub-cycle ratio in ALD super-cycle, were investigated by subsequent XPS analysis. Also, the plasmonic loss features in Sn 3d peaks showed indirect evidence of the existence of extrinsic free carriers. From the Hall effect measurements, we found that the increased antimony content results in the decrease of mobility with the increased carrier concentration. This trade-off ends up with the optimum dopant concentration of 5%. 36 nm thick ATO nanotube array as a demonstration of nanostructured transparent electrode was successfully fabricated and investigated by conductive atomic force microscopy (CAFM), showing ohmic behavior with Ti contact. This nanostructured transparent electrode was adopted for hematite-based photoanode, which consists of ultrathin(~ 4 nm) α-Fe_2O_3 (deposited also by ALD) as an photo-absorbing layer covering 5µm-long ATO nanotubes' array. The photoanode showed a photocurrent of ~ 1 mA/cm^2 (@1.23V vs RHE) without any co-catalyst layer. The control samples without ATO conducting layers showed almost no photocurrent, implying that the poor carrier transport ability of intrinsic hematite layer is successfully complemented by the conducting ATO layers.

Novel Charge Transport Materials for Improved Efficiency and Stability of Ultraflexible Organic Solar Cells Kenjiro Fukuda[1], Sixing Xiong[2], Jiahen Wang[2,1] and Takao Someya[2,1]; [1]RIKEN, Japan; [2]The University of Tokyo, Japan

Organic photovoltaics, as one of the emerging PVs, has a unique feature of high flexibility by using flexible polymer substrates. By using a substrate and a passivation film with ultimate thinness, ultra-flexible energy harvesting devices can supply powers to wearable sensors on skin or textiles without causing discomfort to wearers [1,2]. The usage of such ultra-thin polymer film typically sacrifices gas barrier properties, and mechanical stresses with small bending radii cause new problems such as delamination at the interface. In this talk, we'll discuss novel charge transport maaterials to achieve both high efficiency and reliability of ultrathin organic solar cells. The topics will include an organic-inorganic hybrid electron transport layers (ETL) enabling much improved mechanical robustness than a conventional oxide ETL [3], suppression of diffusion of ETL materials after a thermal aging process to enhance the stability of OPVs with non-fullerene active layers [4], and usage of liquid metals as solution-processed top cathodes enabling high-performance fully-solution processed organic photovoltaics [5]. In addition to the performance improvement of organic photovoltaic cells, we'll show a lamination strategy of the ultra-thin organic photovoltaics to a complex curved surface [6].

Dielectric Surface-Dependent Photogating Phenomenon and Interface Trap Engineering in C8-BTBT Leading to Photo-Induced Synaptic Applications Somi Kim[1], Jihyun Shin[1], Byung Chul Jang[2] and Hocheon Yoo[1]; [1]Gachon University, Korea (the Republic of); [2]Kyungpook National University, Korea (the Republic of)

Organic phototransistors (OPTs) are being adopted in considerable research field due to their excellent photo-sensing capabilities, high compatibility with flexible substrates, and simple manufacturing processes. To improve the photoresponsive characteristics, previous OPTs studies have focused on the development of organic semiconductor layers. Exploring a suitable dielectric surface, however, is also an important factor in controlling these photoresponsive properties in OPTs. Nonetheless, research on dielectrics is still lacking. In this talk, we present the dielectric-surface-dependent photogating behavior of 2,7-Dioctyl[1]benzothieno[3,2-b][1]benzothiophene (C8-BTBT) phototransistors. Photogating effect was observed depending on the trap states between C8-BTBT and various dielectric interfaces: cyclic transparent optical polymer (CYTOP), poly(methyl methacrylate) (PMMA), aluminum oxide (Al_2O_3), and silicon dioxide (SiO_2). The photogating effect was not observed in hydrophobic dielectric-based OPTs (CYTOP-based OPTs and PMMA-based OPTs), while the photogating effect was observed in hydrophilic dielectric-based OPTs (Al_2O_3-based OPTs and SiO_2-based OPTs), achieving high sensitivity of $>7.34\times10^5$ A A^{-1}, detectivity of $>6.32\times10^{11}$ Jones, and 20 V shift of turn-on voltage under 400 nm light irradiation. The operation principle of photogating effect was elucidated through a comprehensive study, including an analysis of roughness, morphological investigation, hydroxyl group, and surface energy, according to the dielectric surface. Al_2O_3- and SiO_2-based OPTs have more hydroxyl group than CYTOP- and PMMA-based OPTs, resulting in relatively high surface energies and interfacial trap density of states (N_{it}) values. Through the nearly identical surface roughness (Ra) values for each dielectric by AFM analysis, we demonstrated that the photogating effect is dependent on the interfacial charge trap state by the surface energy, not because of the specific morphological variation between each dielectric surface and semiconductor interface. In addition, we implemented an artificial synapses application using the photogating effect. Optoelectronic artificial synaptic operation using SiO_2-based OPTs accomplishes a recognition rate of more than 95%, whereas, despite the same semiconductor, CYTOP-based OPTs accomplish a recognition rate of 0%. As a result, this research suggests that optimizing the dielectric layer surface characteristics is an important component in modulating photoresponsive properties, and through the implementation of artificial synapses, the possibility of applying optoelectronic devices.

4:15 PM EQ05.03.03
Spectrum Profile Simulation of OLED Materials by Time Dependent Density Functional Theory Nobuhiko Akino; Hosei University, Japan

For the design of emissive materials in organic light emitting diodes, it is highly desired to simulate the spectrum profile, that is, not only the peak wavelength of absorption and/or emission, but also its overall spectrum shape. Especially the emission profile is one of the most important material properties as it determines not only the emission color, but also the device efficiency. For example, the material with sharp spectral profile is essential to achieve a better color gamut and also to avoid any loss by the energy filter for the display applications.
In order to study the spectrum profile of materials, the time dependent density functional theory (TDDFT) has been employed [1]. This is one of the most prominent and widely used methods for calculating excited states of medium-to-large molecules, and it is recognized as a powerful tool for studying electronic transition of molecules. The TDDFT code used in this study is based on the real-space and real-time formalism [2]. One of the advantages of this real-space and real-time formalism is that one can keep the code simple and understand physical meanings as directly as possible. Since this formalism is suitable for large-scale parallel computing, we have been developing its MPI parallelized code which can be applied to large molecules depending on the computer resources.
This approach has so far been applied to some typical organic materials such as poly-(9,9'-dialkyl-fluorene) as a fluorescent material [3], tri(2-phenylpyridinato)iridium(III), $Ir(ppy)_3$, as a phosphorescent material [4], and 4CzIPN [5] and DABNA-1 [6] as a thermally activated delayed fluorescent (TADF) materials. The results have been suggesting that although some redshift of the peak wavelength is observed, the simulated spectral profiles agree very well with the experimentally observed profiles [7,8].
In the presentation, some TADF molecules will be studied in order to obtain design rules and possibly new molecules with desired spectrum profile.

Improved Charge Injection of Silver Back Electrodes in Inverted Organic Electronic Devices Using Self-Assembled Monolayers Sneha Sreekumar, Deirdre M. O'Carroll, Marzieh Hydari, Elena Galoppini, Zhongkai Cheng, Hemant Maddali and Krystal House; Rutgers University, United States

OLEDs tend to suffer from low light extraction efficiency when fabricated through conventional methods, in which the devices are built on top of indium-tin oxide on glass. We have developed an inverted method of device fabrication where the device is built on top of the metal electrode, which enables direct patterning of the metal for improved light extraction. However, this method introduces an electronic problem - the creation of a Schottky barrier, where the charge injection at the metal-polymer interface is dependant on the energy difference between the workfunction of the metal and the frontier orbital energy levels of the organic semiconductor. Self-assembled monolayers (SAMs) formed from thiol compounds on metals like Ag and Au electrodes have been used as an important strategy for altering the electronic properties of metal-organic interfaces in organic electronic devices. In this work, we make use of dithiolane compounds that can provide multiple binding sites to the metal, unlike thiol compounds, and, hence, are useful in enhancing the electronic performance of the device. We have fabricated inverted organic semiconducting hole-only devices using Ag back electrodes along with SAMs formed from disulfide lipoic acid-based compounds, in addition to SAMs of a more common long aliphatic chain thiol. Hole-only devices were fabricated on top of the SAM/Ag back electrodes using the organic conjugated polymer F8BT (poly(9,9-dioctylfluorene-alt-benzothiadiazole)) as the semiconducting layer and MoO_3/Au as the top contact layer. . Using ultraviolet photoelectron s spectroscopy and by conducting current density-voltage tests, it was found that the SAMs formed from (±)-α-lipoic acid(α -LA), iso-lipoic acid(i-LA) and (±)-4-phenylbutyl 5-(1,2-dithiolan-3-yl)(PhBuL) pentanoate improved charge injection by either changing the work function of the Ag or altering the physical interaction between the polymer and the metal surface. We found an increase in the current density of the device of 40-50% in the case of α-LA/Ag and i-LA/Ag compared to bare Ag electrodes. We also employed infrared reflective-absorption spectroscopy to further understand the interaction of the SAMs with the conjugated polymer by comparing SAM/Ag and F8BT/SAM/Ag, and found i-LA and α-LA interacts differently with F8BT because i-LA is oriented more out-of-plane compared to α-LA. On depositing F8BT on α-LA/Ag and i-LA/Ag samples, the orientations of both SAMs are altered, indicating intermolecular interactions are occurring between the SAM

and the polymer. This study has led to an understanding of how the nature of the functional groups of the SAM as well as the number of bonds formed between each SAM molecule and the metal electrode influence the performance of organic semiconductor devices. These results are being be further extended to OLED device structures in which we optically engineer the Ag back electrode to include Ag metasurfaces for increased light extraction.

Low-Temperature Fabrication of $BaSnO_3$ Thin-Films via Solution Combustion Sushobhita Chawla[1], Garima Aggarwal[2], Akhilender J. Singh[1] and Balasubramaniam Kavaipatti[1]; [1]Indian Institute of Technology Bombay, India; [2]Uppsala University, Sweden

We have extended the solution combustion technique used to synthesize La:$BaSnO_3$ nanoparticles [1, 2] to develop solution-processed thin films at 130 °C. A colloidal ink of a peroxo/superoxo precursor was spin-coated onto a quartz substrate and yielded ~ 100 nm thick, highly crystalline $BaSnO_3$ films on annealing at 130 °C. This technique allows for facile incorporation of dopants, like La, in the precursor film itself, thereby leading to the synthesis of La:$BaSnO_3$ at such a low temperature. The structure, morphology, optical and electrical properties of the undoped and La-doped thin films have been determined using X-ray diffraction, scanning electron microscopy, UV-Vis spectroscopy and AC Hall measurements. The obtained films show a transmittance of around 70-80 % in the visible range (400–800 nm). In comparison to the insulating $BaSnO_3$, the lanthanum doped films obtained at 130 °C are conducting. The procedure developed can be utilised to directly employ $BaSnO_3$ films in devices having temperature limitations.

Near-Infrared Phototransistor Using Localized Surface Plasmonic Resonance at ITO Nanoparticle/IGZO Interfaces Jusung Chung, Jong Hyuk Ahn, Jong Bin An and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

Recently, photodetectors sensitive to infrared (IR) light are highly desirable for optoelectronic applications such as telecommunications, imaging sensors, remote sensing, and motion detectors. Enhancing the sensitivity, decreasing the price, and minimizing the power consumption are anticipated to be the primary factors in expanding the market for IR photo- detectors and broadening their applications. Oxide semiconductor materials are the promising candidate for channel material of IR photodetector because of their low dark current, low fabrication cost, and capability. However, most oxide semiconductor materials cannot absorb long wavelength visible light and IR because of their large optical bandgap (above 3.0 eV) so that additional light absorbing layer is essential for detecting IR.
In this paper, we suggested indium-tin-oxide (ITO) nanoparticles for near-IR (NIR) absorption layer for indium-gallium-zinc oxide (IGZO) NIR phototransistor. We deposited ITO nanoparticles using electrohydrodynamic (EHD) printing for selective area deposition minimizing contact with source and drain electrode. Nanoparticle was used for optoelectronic device to enhance photoelectric efficiency using localized surface plasmon resonance (LSPR) which is sensitive to their carrier concentration. Metal nanoparticles exhibit extremely intense narrow absorptions in the lower visible wavelength region due to their relatively high carrier concentrations. ITO has lower carrier concentrations than noble metals, resulting in lower plasma frequencies and resonances in the near-infrared spectrum. ITO has wider absorptions than noble metals due to the greater optical losses. When ITO nanoparticles and IGZO interfaces of phototransistor was illuminated under NIR, LSPR and hot electron injection were occurred. IGZO channel layer effectively captured the photoexcited hot electrons and photo current increased.
We compared electrical characteristics of ITO nanoparticle/IGZO NIR phototransistor according to the deposition method, spin coating and EHD printing. ITO nanoparticle/IGZO NIR phototransistor fabricated by spin coating shows high off current because of contacts between ITO nanoparticle and source and drain electrode. In case of EHD printing, ITO nanoparticle was deposited selectively area without electrode contact resulting in superior switching characteristics with 3.67 cm^{2} /V s of saturation mobility, 1.80 x 10^7 of on/off current ratio, and 0.82 V/decade of subthreshold swing. Changes in transfer characteristics according to various wavelengths corresponding to infrared (808, 940, 1342, and 1450 nm) with 190 mW/mm^2 of light intensity were compared to show the light-sensing range of the ITO nanoparticle/IGZO NIR phototransistor. Turn on voltage of ITO nanoparticle/IGZO NIR phototransistor is hardly shifted under the infrared light with wavelength of 940, 1342, and 1450 nm. In case of 808 nm, turn on voltage is negatively shifted from 13 to 11V, which show LSPR occurrence by 808 nm NIR. Next, the change of the transfer characteristics according to the light power density (190, 380, 570, and 760 mW/mm^2) with wavelength of 808 nm was measured and each optoelectronic parameters calculated from change of transfer characteristics were compared. In the case of photoresponsivity, there wasn't a linear relationship with the light power density and was randomly distributed in a certain range (2.5 ± 0.5 A/W). However, As the light power density increased, the turn on voltage shifted negatively so that the difference between photo current and dark current at a constant gate voltage increase. Consequently, maximum photosensitivity increased from 22 to 6.38 x 10^3 as light power density increase from 190 to 760 mW/mm^2.

EQ05.04.03
Optimization of Lithium Intercalation of Sputtered Indium Tin Oxide Thin Films Denisse Cordova Carrizales, Rain Wang, Ari Turkiewicz, Johanna Nordlander, Charles Brooks and Julia Mundy; Harvard University, United States

Indium tin oxide (ITO) is the most widely used transparent conductor for optoelectronics, liquid crystal displays, photovoltaic cells, and touch screens. Generally, optical transparency and high electrical conductivity are mutually exclusive, but the carrier density in a conductor can be optimized to a low enough level to allow for optical transmission in the visible region—this optimization is a central factor of transparent conductivity and has even allowed the creation of transparent superconductors. Previously, ITO thin films grown on glass have been electrochemically doped with Na, Li, K, Rb, Cs, Mg, or Ca ions to create optically transparent superconductors. In this work, we use n-butyllithium to intercalate Li ions into ITO thin films sputtered on technologically relevant substrates. Using x-ray diffraction, atomic force microscopy, and resistance–temperature measurements, we refine ITO sputtering growth parameters and n-butyllithium intercalation parameters to optimally adjust optical transparency and electrical conductivity in lithium-doped ITO thin films for transparent superconductivity.

EQ05.04.04
Tuning Photoconductivity Properties of Co_3O_4 Thin Films Ana Luiza Costa Silva[1], Ariano Rodrigues[1], Renato Jasinevicius[2] and Marcio P. de Godoy[1]; [1]Federal University of São Carlos, Brazil; [2]University of São Paulo, Brazil

The search for new materials for energy conversion has pointed to several promising candidates. However, many of those demonstrate adverse effects such as toxicity and the production of harmful waste – either caused by the material itself or its synthesis processes. Due to its chemical stability, non-toxicity, availability, and optical absorption in the visible range, Co_3O_4 is a strong candidate for clean-related applications in photo-assisted devices. In this study, we investigate the photoconduction behavior of Co_3O_4 semiconductor films grown by the spray pyrolysis technique. An interesting characteristic of Co_3O_4 is its two optical absorption edges: the first one is in the visible range (~ 2.0 eV) and corresponds to Co^{2+} oxidation state; the second one is in the Vis-NIR region (~ 1.5 eV) and corresponds to the Co^{3+} oxidation state. The photoconductivity measurements were performed at room temperature using different wavelengths to tune the absorption edges. Thus, some excitations benefit the charge transfer between $O^{2-} – Co^{2+}$, while other excitations access only the $O^{2-} – Co^{3+}$. Regardless of the excitation energy, the films show a positive photoresponse (PR), with a reduction in PR (up to 73%) for red excitation. Under excitation near the Co^{3+} absorption edge, the as-grown sample shows the absence of a saturation profile in the PR and a persistent PC. Additionally, annealing effects under different atmospheres play a relevant role in the optical and electrical properties of the films. When annealed in an oxidizing atmosphere, long response and recovery times are noted. In contrast, after annealing in Ar or synthetic air, fast responses are observed. The annealing inhibits the persistence effects for red excitations. Therefore, we can attribute that the deep levels mitigated by annealing are located between the Co^{3+} subband and the valence band.

Low Dielectric Adhesive through Thiol-Ene Click-Reaction for High-Frequency Electronic Devices Ji Won Joo and Ho Sun Lim; Sookmyung Women's University, Korea (the Republic of)

With the continuous growth of 5G communication-based high-speed transmission-reception systems, there is a demand for developing a low dielectric material in high-frequency electronic devices. Since the 5G communication system uses a shorter wavelength than the 4G mobile communication, there is a problem with transmission loss because the rate of absorption by materials during the movement of radio waves is high. For this reason, electronic components such as FCCL for 5G mobile communication must exhibit a low dielectric character to reduce transmission loss. Herein, we proposed a fabrication of a low dielectric adhesive through a thiol-ene click reaction between bismaleimide and multifunctional thiol, applicable to advanced electronic devices for 5G communication. The development of the adhesive with a low dielectric constant at a high-frequency range is indispensable while maintaining high adhesion between a copper foil and a low dielectric polymer sheet. We optimized the composition of the adhesive by controlling the ratios of the compounds with alkene or thiol groups. The dielectric constant (ε') measured at 10 GHz ranged from 2.6 to 2.7, which is lower than commercially available adhesives. The peel strength of the low dielectric bond was measured as 1.0 N/mm through a 90° peel test, showing strong adhesion properties between the copper foil and the low dielectric polymer sheet. This low dielectric adhesive could be applied to manufacturing technology of advanced electronic devices for 5G communication in semiconductors, automobiles, mobile phones, and robots.

EQ05.04.06
Hierarchical Metal–Semiconductor–Graphene Ternary Nanostructures with Intimate Coupling for Hydrogen Generation Hayoon Jung and Sang Woo Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

There has been significant interest in heteronanostructures with controlled topologies and configurations for designing efficient photocatalysts. Herein, we present a promising solar energy conversion platform constructed by the intimate contact of graphene, semiconductors (TiO_2), and plasmonic metal nanocrystals (octahedral Au nanocrystals) with well-defined configurations. The complete wrapping of TiO_2 shell around Au nanocrystals and the sequential graphene encapsulation over TiO_2 shell were successfully realized by sol-gel, self-assembly methods, and post-calcination. Through core-shell engineering of the ternary nanostructures, as-prepared graphene-encapsulated octahedral Au nanocrystals@TiO_2 core-shell nanostructures became highly responsive to red light illumination. Accordingly, the ternary nanostructures exhibited superior photocatalytic hydrogen production and photocurrent responses to their binary counterparts, single-component nanomaterials, and physical mixture of the constituents under visible light irradiation ($\lambda > 400$ nm) and even under red light irradiation ($\lambda = 700$ nm). A series of mechanistic studies on photocatalysis indicated that the prominent photocatalytic activity of the hybrid nanostructures is attributed to the hot electron transfer from Au nanocrystals and the subsequent injection of the photogenerated electron to graphene, facilitated through the intimate contact among the constituents. This study can provide new insights in designing heteronanostructures for visible and red light responsive photocatalysis.

EQ05.04.07
Room-Temperature Fabrication of Highly-Oriented β-Ga_2O_3 Thin Film on ZnO/AlO_x-Buffered Cyclo-Olefin Polymer Substrate via Excimer Laser Annealing of Amorphous Thin Film Ryoya Kai[1], Tomoaki Oga[1], Satoru Kaneko[2,1], Akifumi Matsuda[1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

β-form gallium oxides (β-Ga_2O_3) having ultra-wide bandgap (E_g~5 eV) attract much attention in the field of optoelectronic applications such as deep-UV sensor and power-electronics [1]. The combination of polymer substrates and oxide thin films such as transparent conductive oxide (TCO) and Ga_2O_3 has been expected to develop the flexible electric devices with features of wearability and lightness. So far, highly oriented crystalline β-Ga_2O_3 thin films have been prepared mostly on the single crystal substrates such as sapphire (α-Al_2O_3) or Si at relatively high temperatures (~500ºC). On the other hand, in case of film-growth on polymer substrates, it is necessary to lower deposition temperatures because of low thermal stability of polymers. Excimer laser annealing (ELA) applied in this study have been widely used as a low-temperature crystallization process of polycrystalline silicon for thin-film transistors (TFT's) [2]. Previously, we have developed epitaxial β-Ga_2O_3 thin films on sapphire substrates at room temperature (~20ºC) by ELA [3]. In this study, ELA process has been successfully applied to room-temperature fabrication of highly-oriented β-Ga_2O_3 thin films on [c-axis oriented ZnO/amorphous AlO_x] buffered cyclo-olefin polymer (COP) substrates. The structure and properties of the films were characterized via XRD, RHEED and cathode-luminescence spectroscopy.
COP substrates (Zeonor ZF-16, ZEON Co., Japan) with 10×10 mm, thickness of ~188 μm and T_g~163ºC were firstly irradiated in air with vacuum-ultraviolet (VUV) light (172nm) to make the surface clean, flat and hydrophilic before the thin film growth. Thin films were deposited on VUV-irradiated COP substrates by pulsed laser deposition (PLD) technique at room temperature using a focused KrF excimer laser beam (λ=248 nm, E~1.2 J/cm^2). Three kinds of multilayered thin film comprising amorphous aluminum oxide (AlO_x), c-axis oriented crystalline ZnO and amorphous GaO_x were sequentially deposited on COP like GaO_x(~100 nm)/ZnO(~50 nm)/AlO_x(~1 μm)//COP [4]. The thin films were subsequently subject to irradiation of non-focused KrF excimer laser beam (E~0.15 J/cm^2) from the film surface with 300 pulses at room temperature in air. The XRD and RHEED results indicate that solid state crystallization of uniaxial-oriented β-Ga_2O_3 (-201) thin films occurred on the COP substrate, although crystallization of GaO_x thin films after ELA was not observed in case of GaO_x/ZnO//COP and GaO_x/AlO_x//COP thin films. Atomic-scale interface analysis of film/substrate and Ga_2O_3 layer/ZnO layer via high-resolution cross-sectional TEM observation is also to be presented.

Electric Conductivity and Structural Modification of Cobalt Oxide Epitaxial Thin Film at Surface by Excimer Vacuum-Ultraviolet Light Irradiation Kenta Kaneko[1], Hiroki Shoji[1], Tomoaki Oga[1], Yuchi Qiao[1], Satoru Kaneko[2,1], Mamoru Yoshimoto[1] and Akifumi Matsuda[1]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

Cobalt oxide with rock-salt type (CoO) and spinel type (Co_3O_4) crystal structures are known p-type semiconductors, which have attracted interests because of their thin film device applications in optoelectronics such as hole extracting layer in soler cells, electrochromic layers, and so on [1,2]. The p-type conductivity and crystal phase of cobalt oxide have been modified via controlling chemical states of Co-ions by aliovalent doping such as Li^+ as well as O_2 partial pressure during the film deposition [3,4]. Meanwhile, UV-ozone treatment has recently been reported as a post-deposition process to control valence of transition-metal oxide semiconductors without doping impurities [5]. Development and understanding structural and conductivity modification technique which does not depend on aliovalent dopants in cobalt oxide thin films would contribute to improve interfacial properties in optoelectronic multilayer devices. Furthermore, our group have been studied on remarkable enhancement of p-type conductivity in nickel oxide thin films by vacuum ultraviolet (VUV) light irradiation. The VUV-light has larger photon energy compared to conventional mercury lamps, which should have impact on controlling the structure and properties due to its high production efficiency of active oxygen species such as ozone O_3 and atomic oxygen $O(^1D)$. In this study, significant variation of conductivity by 4 digits at the surface of cobalt oxide epitaxial thin films was obtained by VUV-light irradiation using a Xe_2* excimer lamp. In addition, the effects of VUV-light irradiation on structure and its correlation with physical properties of cobalt oxide films were also investigated.
CoO and Co_3O_4 epitaxial films were phase-selectively deposited on atomically stepped α-Al_2O_3(0001) single crystal substrates by pulsed laser deposition (PLD) technique using a KrF excimer laser (λ=248 nm, d~20ns) and a pure CoO sintered target. The CoO and Co_3O_4 thin films growth took place in O_2 partial pressure of ~1.0×10^{-5} Pa and 10^0 Pa, respectively at low temperatures below 100°C. The cobalt oxide thin films were subsequently introduced to VUV-light treatment procedure using a Xe_2* excimer lamp (λ=172 nm, E~65 mW/cm^2 at lamp surface) at room temperature in air. The distance between the lamp surface and the films was fixed at 0.5 mm. The resistivity of as-grown CoO epitaxial films measured by four-point probe method was larger than ~1×10^4 Ωcm, although 120 minutes of VUV-light irradiation reduced the value to ~5×10^{-1}Ωcm without any dopants. Structural analysis by RHEED observation indicated appearance of a new set of diffraction rods with half spacing due to occurrence of doubly periodic structure near the thin films surface by VUV-light irradiation. Further XRD results confirmed a topotactic phase transition from rock-salt type CoO to spinel type Co_3O_4 while retaining the epitaxial structure. The effect of VUV-light irradiation on the structure and conductivity of cobalt oxide thin films in different oxidation states, the thickness dependence of conductivity and structure, and chemical state analysis of cobalt ions would also be discussed in detail.

Hetero-Interfaced Anti-Ambipolar Phototransistor Capable of Distinguishing Wavelength Bands of Light Seongjae Kim, Seongin Hong and Hocheon Yoo; Gachon University, Korea (the Republic of)

Phototransistors that convert light signals into electrical signals are being applied to various fields such as optical communication and image sensors [1-2]. The operation mechanisms of phototransistors have usually been described in terms of photoconductive-effect (PC) and photogating-effect (PG). However, detailed studies still lack, such as the change in photocurrent observed as a function of the position of incident light irradiated to the active layer of the phototransistor. In this presentation, we present the result that the photocurrent changes depending on the location of the light irradiated to the active layer of the phototransistor. The highest photocurrent occurs when the irradiated location is the source region. By utilizing the characteristics of the phototransistor based on the location of the incident light, we implemented a hetero-interfaced anti-ambipolar phototransistor (HI-AA phototransistor), where both source and drain electrodes serve as sources for injecting carriers. Therefore, HI-AA phototransistors can expect excellent photoresponse when the incident light is irradiated to the drain electrode as well as the source electrode. As a result, the HI-AA phototransistor composed of channel layers with different bandgaps has a more varied transfer curve than the single-channel phototransistor depending on the wavelength of the incident light and the irradiated position. Therefore, we can distinguish the wavelength band of the incident light through the change in the transfer curve of the proposed HI-AA phototransistor.

GW-BSE and TDDFT Approaches to the Optical Properties of Organic NIR-II Fluorophores Nguyet N. Pham, Jong S. Park and Seung Geol Lee; Pusan National University, Korea (the Republic of)

Nowadays, organic molecule fluorophores in the second near-infrared window (NIR-II) (1000–1700 nm) have attracted significant attention in life sciences and biomedical applications due to their great resolution and sensitivity. There is a lack of adequate theoretical levels to distribute efficient and accurate estimations of optical and electronic properties of organic NIR-II fluorophores. The standard approach for these calculations previously is time-dependent density functional theory (TDDFT). However, the size and the large excitonic of these compounds are the challenges for computational cost and time. In this work, we used many-body perturbation theory approaches, especially the GW approximation with the Bethe−Salpeter equation (BSE) implemented in Gaussian basis sets based on density functional theory (DFT), to produce the excited state calculations of two NIR molecular fluorophores such as BTC980, and BTC1070, going beyond TDDFT. In this study, we compared TDDFT and GW-BSE calculations through the optical absorption spectra and frontier molecular orbital of these compounds.

Fabrication of Polymer Dispersed Liquid Crystal Based Switchable Glazing via Vacuum Coupling Naila Nasir, Hyeryeon Hong and Yongho Seo; Sejong University, Korea (the Republic of)

Polymer-dispersed liquid crystals (PDLCs), a significant class of materials have diverse applications in optics and electronics. Highly efficient and systematic buildings can be made utilizing the PDLC based switchable glazing as they exhibit switching behavior from opaque to transparent mode in presence of power supply, thus saving the energy and elucidating the privacy issues. In this work we prepared typical PDLC mixture using commercially prepared polymer NOA 65 and liquid crystals (like C7 and E7). The mixture was transferred on ITO glass using the wire bar coater and the cell was fabricated by coupling the glass in vacuum. No film was used between the glass as in typical roll-to-roll process, thus enhancing the transmittance. Via vacuum coupling, PDLC based switchable glazing can be fabricated on glass substrates instead of plastic polymers which degrade with the passage of time reducing the efficiency. The cells were then cured by irradiating UV light (intensity ~ 95.4 $mWcm^{-2}$) leading to polymerization and polymer induced phase separation process. As a result, the liquid crystal forms droplets segregating from polymer matrix. The cells exhibited a switching behavior characterized using oscilloscope and AC voltage driver at different voltages. The transmittance change of ~ 60% - 70% was measured with a driving voltage of 60 ~ 70 V. Thus, by using the vacuum coupling process we can fabricate PDLC based switchable glazing on large scale with maximum transmittance and enhanced stability as it is expected a green refurbishing material of the next generation.

EQ05.04.12
Enhancement of Electrochromic Performance of Sputter Grown WO3 Thin Films Yong Jun Park, Deokyeon Lee and Dong Hun Kim; Department of Materials Science and Engineering, Myongji University, Korea (the Republic of)

Electrochromic devices are expected to improve the quality of human life by being applied to a wide variety of optical devices such as smart windows, automobile head-up displays, sunroofs, and electronic shelf labels. For the electrochromic layers, tungsten oxide (WO_3) thin films have been extensively used due to their advantageous electrochromic performances compared to other electrochromic materials. However, low stability in acid-based electrolytes with low switching speed for coloring/bleaching of WO3 thin film hinders its entry into the market. Therefore, the guarantee of chemical stability and durability of WO3 thin films is exigent for practical application to electrochromic devices as well as enhancement of switching speed.
In this presentation, we will report two strategies to enhance the electrochromic performance of sputter grown WO3 thin films. First, we fabricated multilayers of Nb2O5/WO3 thin films with different thicknesses to prevent the structural evolution during electrochemical process improving the cyclic durability. Bilayer thin films provided distinctly enhanced electrochromic performance, higher transmittance modulation, faster coloring and bleaching responses, and higher CE with considerably enhanced long-term cyclic durability than those of a single-layer WO3 thin films.
Second, we incorporated Ag nanoparticles into WO3 matrix using a composite target. The improved electrical conductivity by incorporating metallic Ag nanoparticles decreased the electrical resistivity compared to that of single WO3 layer resulting the enhanced electrochromic performances, including charge density, transmittance change, coloration efficiency, and switching speed. This study provides an exciting opportunity for fabrication of devices with enhanced electrochemical properties for application in promising next generation electronic devices.

Interface Engineering for Self-Stratifying Structure of Polymer Blends with Different Surface Energy Yoojin Rho and Ho Sun Lim; Sookmyung women's university, Korea (the Republic of)

Self-stratifying coatings can realize a complex multi-layered structure through a one-step process. Thus, self-stratification would be an eco-efficient process since it reduces VOC emissions, time of operation, and processing costs. It could become a promising candidate as an eco-friendly coating in various industries such as automobiles and electronic devices. In this work, we have studied a self-stratifying coating system based on an acrylate/epoxy blend. In particular, we systematically characterized the relationship between the interfacial energy difference and the layer separation. Acrylate copolymers with various surface energy were synthesized by conventional free radical polymerization as controlled the content of fluorinated acrylates. The surface energy varied from 42.9 mN/m to 17.9 mN/m according to fluorinated acrylates content. Kinetically, epoxy resin with a high surface energy of 41.4 mN/m and acrylate copolymer with low surface energy was located on the lower and the upper side of the substrate, respectively. The layer separation can be confirmed by the fact that the surface energy of the self-stratified surface was similar to the surface energy of the acrylate copolymer coated surface. In conclusion, homogeneous blends of acrylate and epoxy resins can be successfully stratified when the surface tension difference is greater than 15 mN/m. In addition, self-stratification can solve the dewetting problem of individually coated two-layer substrates with large surface energy differences.

EQ05.04.15
Ohmic Electron Injection by Solution Processed Interlayers David Trieb, Paul Blom and Gert-Jan Wetzelaer; Max Planck Institute for Polymer Research, Germany

Efficient contacts for charge injection and extraction are of paramount importance in organic electronic devices. Here, we show that inserting a thin organic interlayer between the organic semiconductor and the electrode enables the formation of an Ohmic electron contact. This strategy is demonstrated for electron injection into the high mobility n-type organic semiconductor P(NDI2OD-2T), using a 4 nm layer of TPBi as the organic interlayer. The electron injection is evaluated in electron-only devices. Upon inserting the thin organic interlayer, the electron current increases by three orders of magnitude higher compared to an aluminum contact without interlayer. Upon insertion of the interlayer, the electron current becomes space-charge limited, evidencing the formation of an ohmic electron contact. The function of the interlayer is to decouple the electrode from the organic semiconductor electrostatically, whereas direct contact between metal and semiconductor results in a substantial electron-injection barrier, even when using low-work function metals. With the use of a thin organic interlayer, efficient electron injection is achieved with an air-stable aluminum electrode. Furthermore, we also developed a solution-processed method to deposit the thin organic interlayer on top of the semiconductor. With this solution-processing method, electron injection is equally efficient compared to using evaporated interlayers. Finally, to generalize our procedure, we applied it to different organic interlayer materials as well as different organic semiconductors.

Bi-Dopant Redox Ionic Liquids for Transparent Photo-Electrochromic Windows Jinbo Kim, Hwandong Jang, Byeonggwan Kim and Eunkyoung Kim; Yonsei University, Korea (the Republic of)

Ionic liquids(ILs) have been widely studied due to their exclusive properties such as stabilities, diversities, modifiability of structure. Recently, ILs containing redox active molecules have been applied in electrochemical energy storage devices such as supercapacitors, batteries, and DSSCs.
In this study, we designed the cation structure to explore its effect on the electrochemical property of π-conjugated polymers (CPs) in transparent photo-electrochromic capacitive window (PECW). The potential at electrodes of PECW was precisely controlled, to match the redox reaction and the generated

photo-energy under a light that triggers photocoloration. Capacitance of the PECW was enhanced from bi-dopable system of RILs, which provided p- and n-doping by TFSI and RIL, respectively. The PECW with neutral dye showed high transparency (> 90%) to allow high color contrast (CC > 85%) with a long electrochromic stability. The optimized PECW recorded the high Fig of merit for CC and photocoloration efficiency. The PECW with new RIL provides an integrated model that consists of electrochromic and energy-harvesting layers in one device. Thus the working principle of PECW can be widely applied in energy saving smart windows and multifunctional electrochemical devices.

EQ05.04.17
Effect of Various Hole Transport Layer on the Inverted Quantum Dot Light-Emitting Diodes JunYoung Kim; Gyeongsang National University, Korea (the Republic of)

In this study, we analyzed the hole injection mechanism according to various hole transport layer (HTL) materials and solvents. We compared 3 HTL materials, Poly(9,9-dioctylfluorene-alt-N-(4-sec-butylphenyl)-diphenylamine) (TFB), Poly(9-vinylcarbazole) (PVK), and Poly[bis(4-phenyl) (2,4,6-trimethylphenyl)amine] (PTAA), widely used for HTL. For solvent, Chlorobenzene, P-Xylene, and 1,4-Dioxane were used. We identified which solvent fits each HTL material. In the inverted structure, when each solvent was used on the Quantum Dot(QD), it was confirmed through the solvent washing test that it did not affect the emission layer (EML). As a result of manufacturing the device with the above three materials, it was confirmed that only TFB showed stable luminance. It can be assumed that PVK is caused by too low mobility, and PTAA is caused by high HOMO level compared to Green QD. Since TFB has fast mobility and intermediate HOMO levels between PVK and PTAA, it is considered the most suitable HTL. However, since there is still a large energy barrier between TFB and QD, PVK with a deep HOMO level is thinly placed between TFB and QD to align the energy level. It was confirmed that the device performance was improved. Also, we use PVPy to delay the fast electron injection rate of ZnO as ETL. When the device was manufactured while increasing the thickness to 1.0mg/ml, the leakage current decreased, and the efficiency increased as the thickness increased. Furthermore, the device was manufactured using the various HTLs to evaluate Electroluminescence (EL) characteristics through IVL measurement. In addition, Hole-only Device (HOD) was made to observe the difference in hole conductivity of each HTL material.

Lift-Off Patterning of OLED Active Layer Seunghan Lee[1], Hyobin Ham[2], Chang Hyeok Lim[1], Hyukmin Kweon[3], Do Hwan Kim[3], BongSoo Kim[2] and Moon Sung Kang[1]; [1]Sogang University, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology (UNIST), Korea (the Republic of); [3]Hanyang University, Korea (the Republic of)

Active layer patterning of organic light-emitting diode (OLED) is a key step in achieving full-color display application. Although conventional OLED manufacturing is based on thermal evaporation, solution process-based patterning techniques allows low-cost fabrication of large-area display. In this work, we propose a patterning method for OLED active layer done via a lift-off process. The lift-off process is widely used in conventional semiconductor and display industry, but its applications to OLEDs are limited. This is due to the fundamental issue that process solvents (such as stripper) can dissolve/damage the pre-deposited layer that should be partially lifted-off. In particular, the luminescent small molecules of OLED (such as iridium and platinum complexes) are assembled by weak forces. Herein, we present the use of crosslinkable host and guest organic emitters added with a low-temperature thermal initiator serving as the active layer for OLEDs. The thermally crosslinked active layer shows chemical robustness against subsequent solvent-processes without compromising its luminescence characteristics (indeed we found that the luminescence characteristics are improved upon crosslinking the molecules). More importantly, by initiating the crosslinking reactions below the temperature affecting the chemical/structural properties of photoresist, we can apply the crosslinked active layer to conventional lift-off process to form active layer patterns. Based on this, we successfully fabricate a few microns multicolor patterns with a minimum pattern width of 4um and exceptionally low line-width roughness. We believe that this approach suggests an alternative route to form micrometer-scale patterns of solution processible materials.

Testing Sputter Deposited $Zn_xMg_{1-x}O$:Al Conducting Thin Films in LD Structures as p-GaN Ohmic Contacts and Cladding Layers Aleksandra J. Wójcicka[1], Szymon Grzanka[2,3], Zsolt Fogarassy[4], Adel Racz[4], Erzsebet Dodony[4], Tatyana Kravchuk[5], Iryna Levchenko[3], Eliana Kaminska[3], Piotr Perlin[3] and Michal A. Borysiewicz[1]; [1]Lukasiewicz Research Network - Institute of Microelectronics and Photonics, Poland; [2]TOP-GAN, Poland; [3]Institute of High Pressure Physics, Polish Academy of Science, Poland; [4]Institute for Technical Physics and Material Science, Centre for Energy Research, Hungary; [5]Technion–Israel Institute of Technology, Israel

Transparent conductive oxides (TCO) are materials that at the same time are transparent and conductive. They can be easily deposited using sputtering deposition and other methods to achieve high quality, low resistivity and high transparency films. One of such materials is indium tin oxide (ITO) that has been applied as standard transparent electrode material in electronic applicances throughout the world. Recently there have been works showing its application potential as top cladding layers in GaN-based laser diode (LD) structures. Due to difficulties in growing thick and highly doped AlGaN top cladding layer by means of epitaxial techniques, sputter deposited ITO was studied as an alternative for the highly doped top layer. Due to the high indium content however, alternatives to ITO are being sought, one of them being aluminium-doped zinc oxide (AZO), or ZnO:Al. This material also has the advantage of bandgap tunability by alloying with Mg, that also influences its refractive index value. Since the appropriate refractive index tuning is crucial for high quality mode confinement in a laser structure, such material is well poised for studies allowing it to replace the AlGaN layer.
In this work we study the development of ZnMgO:Al by means of sputter deposition using cosputtering from AZO and Mg sources and a compound $ZnO/MgO/Al_2O_3$ source with different Mg content. We study the behavior of the films and determine the deposition conditions allowing high quality, monocrystalline film growth on Ga-face p-GaN surfaces, as confirmed by HR-TEM images. We show that the material exhibits ohmic behavior in contact to p-GaN and that its resistivity is low, at 1.5×10^{-3} Ωcm for the material deposited with no Mg content. When using a source with 15% Mg, the restivity of the films goes up by a factor of 4 and the Mg content in the films is around 10% with the relation to Zn. Ellipsometric measurements show that the AZO films have a refractive index around 2 for 440 nm that increases to 2.04 for films with 10% Mg. We prepared laser diode test structures and demonstrate here the properties of InGaN laser diodes operating between 420 and 450 nm and study the cladding performance of the films with varying Mg content and deposited by means of both approaches.

This work was supported by the National Centre for Research and Development, Poland, project 'OxyGaN' - M-ERA.NET2/2019/6/2020, by the Hungarian NRDI Fund, grant number 2019-2.1.7-ERA-NET-2020-00002 and by the Israel Ministry of Science, Technology and Space in the frames of the M-era.net Programme.

A Solution Processed Carbon Electrode for High Volume Roll-to-Roll Manufacture of Flexible Perovskite Solar Cells Trystan Watson, David Beynon, Ershad Parvazian, Rahul Patidar, Katherine Hooper and James McGettrick; SPECIFIC, Swansea University, United Kingdom

Recent experiments involving a new carbon electrode demonstrate a true fully roll to roll coated perovskite solar cell via a continous slot die coating method. All previous reports of roll to roll coated perovskite solar cells have completed the device off-line with an evaporated metal contact. The

application of a wet carbon film continuously and compatibly with an underlying perovskite device stack in a moving web at manufacturing speeds is complex but game-changing. The ability to sequentially deposit all layers of the device stack culminating in a fully working device entirely in-line means that the promise of high volume “liquid in/solar cell out” can be realised.

This multifunctional carbon electrode can be safely deposited on top of a layered solar cell without any deformation or dissolution of the underlying layers. The new contact material overcomes issues of solvent incompatibility, interface incompatibility and narrow rheology and heating process windows.

In this talk we will present the development journey of this new electrode material and the recent succesful pilot run of the material. In particular we will show how we formulate a new carbon ink with solvent compatible with the perovskite stack that crucially has suitable boiling point for low temperature, high speed processing coupled with very low toxicity (no work place exposure limit). The solid loading of the ink is optimised for a rheological profile suitable for slot die and we demonstrate the roll to roll slot die coating of the electrode sequentially following the roll to roll coating of the NIP device stack incorporating a low temperature processed p type interlayer. The carbon ink is formulated with solvent system orthogonal with the device stack and with no detrimental action on the perovskite active layer as shown through X-ray diffraction analysis. Electrochemical impedance spectroscopy and steady state photoluminescence analysis reveal that charge transfer at the interface is equivalent to evaporated gold electrodes. Further, the device stack is demonstrated to have no detrimental effect on stability, unencapsulated cells retained 90% of original PCE at atmospheric temperature for 1000 hours and outperform gold electrode cells at elevated temperature.

This work introduces the very first entirely roll to roll devices achieving efficiency matching evaporated gold electrodes. This first fully roll-to-roll coated perovskite prototype promises the possibility of transferring to industrially efficient PV production in the near future.

EQ05.04.23
A Study on Single-Layer Graphene/germanium Interface—Schottky Junction Cesar A. Diaz Mendoza and Fernando Lazaro Freire Junior; Pontificia Universidade Católica do Rio de Janeiro, Brazil

The graphene/semiconductor interface is a building block of advanced electronic devices. Herein, we investigated the interfacial electronic structure of single-layer graphene on germanium substrates from a fundamental perspective. Direct synthesis of single-layer graphene on (100) and (110) faces of Ge was conducted via chemical vapour deposition. The interaction of π electrons of graphene with the Ge substrate was evidence, confirming its electronic coupling with the semiconductor substrate. Moreover, each Ge crystalline orientation obtained relevant features associated with the Schottky contact nature, interface dipoles, band alignment, and energy barrier heights. Such results are essential for new graphene/germanium systems applications, particularly for its integration into the complementary metal-oxide-semiconductor technology.

EQ05.04.24
Self-Powered Near-Infrared Organic Photodiode with Functional Interlayer Yongju Lee, Hyojeong Choi, Hyowon Jang, Swarup Biswas and Hyeok Kim; Univerisity of Seoul, Korea (the Republic of)

The electromagnetic spectrum consists of ultraviolet (100-400 nm), visible (400-750 nm), and infrared (750-2500 nm) regions, among others. The visible region contains the wavelengths that can be seen by the human eye, and infrared light is outside the red edge of this band when the light emitted from any source or heating element is spectrally dispersed. In the infrared band, the electromagnetic waves with the shortest wavelength are referred to as near-infrared rays (750-1000 nm). An organic photovoltaic capable of generating light in the near-infrared wavelength band was fabricated herein through bandgap matching of the photoactive polymer for sensing in the near-infrared region. In addition, the organic photovoltaic was optimized through a newly synthesized functional intermediate layer; this layer constitutes a hole-transport layer that transfers the holes generated by the photoactive layer to the cathode easily. The material traditionally used for the hole-transport layer is PEDOT:PSS, which has the advantages of excellent heat resistance as well as high electrical conductivity and transparency. However, PEDOT:PSS also has drawbacks, such as cost inefficiency, strong acidity, and high hydrophilicity. We have synthesized a polypyrrole polystyrene sulfonate (PPY:PSS) as a hole-transport material that overcomes these disadvantages and optimized it by adjusting the ratio of PPY to PSS. Next, poly[4,8-bis(5-(2-ethylhexyl)thiophen-2-yl)benzo[1,2-b;4,5-b]dithiophene-2,6-diyl-alt-(4-(2-ethylhexyl)-3-fluorothieno[3,4-b]thiophene-)-(2-carboxylate-2-6-diyl)]:phenylC70butyric acid methyl ester (PTB7-th:$PC_{70}BM$) active-layer-based organic photovoltaic was fabricated. Thus, an organic photodiode capable of sensing more effectively in the near-infrared region was developed by inserting the functional interlaye

EQ05.04.25
Multifunctional Sensing on a Monolithic Optoelectronic Chip Jixiang Jing[1], Hou Yong[1], Kwai Hei Li[2] and Zhiqin Chu[1]; [1]The University of Hong Kong, Hong Kong; [2]Southern University of Science and Technology, China

Miniature biosensors which have significant potential in portable applications in various scenarios and designs with features of convenient, reliable, economic, high sensitive, and capable of real-time measurement are highly desirable in nowadays. Herein, we demonstrate a highly refractive index-sensitive sensor based on a micro-scale III-nitride chip that contains a light emitter (LED) and a photodetector (PD). As the LED and PD of the device contains the same InGaN/GaN multi-quantum wells, the PD can directly respond to the emission of the LED. And the flip-chip assembly of the chip enables the exposed sapphire substrate to be in direct contact with external mediums, and the refractive index sensing capability is governed by the change of critical angle and Fresnel reflection at the sapphire/medium interface. Particularly, we demonstrate the monolithic chip exhibits a sensitivity of 7.77 μA/RIU and a resolution of 6.4×10^{-6} RIU at the LED current of 10 mA.
Furthermore, we apply this integrated chip-sensor into detecting different salinity contents, where this sensor shows excellent sensitivity of salinity as 2721.05 nA/(mol/L) (or 465.57 nA/%) and a response time of 0.243 s. In addition, a polymer-based anti-fouling coating on the surface of the sensing chip has been established to significantly improve its long-term stability in mimicked marine water. Additionally, as existing approaches of quantitatively monitoring cellular activities such as fluorescent staining and impedance-based methods are often hindered by their multiple time-consuming preparation steps, sophisticated labeling procedures, and complicated apparatus. Hence, for the first time, we utilize this chip-sensor to quantitatively monitor the progression of different intracellular processes in a label-free manner. As a proof-of-concept demonstration, we explored its applications in 1) cell adhesion dynamics monitoring, 2) drug screening, and 3) cell differentiation studies, highlighting its potential in broad fundamental cell biology studies as well as in clinical applications.

Electrochemiluminescence Devices Exploiting a Floating Electrode Hyeono Yee, Jong Ik Lee, Keonhee Jung, Seunghan Lee, Dong Mok Park and Moon Sung Kang; Sogang University, Korea (the Republic of)

Electrochemiluminescence (ECL) has been recently exploited to form alternative light-emitting devices referred to as electrochemiluminescence devices (ECLDs). The ECL-based light emitting device offers excellent on/off contrast properties due to the self-emissive technology that generates light by itself.

However, ECLDs have two critical issues, low luminance efficiency and short lifetime. Enhancing the luminance can be typically attained by applying a higher voltage, but this, in turn, induces more side reactions and reduces lifetime. Herein, we introduce a novel ECLD structure exploiting a floating electrode, a third electrode in the device without connection to the external power source, placed on top of an ECLD containing two coplanar parallel electrodes. Based on the electric field rearrangement based on the floating electrode, the novel ECLD structure features enlarged emisison area (more than 10 times, depending on the geometry of the device), compared to an ECLD in conventional parallel electrode structure. More importantly, the lifetime of the device is extremely increased because excessive current leading to the side reaction and degrades the operational electrodes can be expensed at the formation of additional EDLs near floating electrode.

Halide Perovskite Interface Chemistry—Interphases, Redox and Electrochemistry Ross Kerner[1], Moses Kodur[2], David P. Fenning[2], Barry P. Rand[3], Joseph J. Berry[1] and Kai Zhu[1]; [1]National Renewable Energy Laboratory, United States; [2]University of California, San Diego, United States; [3]Princeton University, United States

Metal halide perovskites have many attractive advantages as semiconductors and optoelectronic materials owing to their rich and unique chemical properties. However, their molecular and ionic constituents readily participate in reduction/oxidation (redox) and Brønsted acid-base reactions in solution as well as the solid-state. Interactions with other materials range from catastrophic to very subtle; the latter are challenging to characterize, yet have significant impacts that ultimately dictate device performance. In this talk, we present several detailed examples of reactivity with oft-assumed compatible materials such as ITO, NiO_x, SnO_x, organic hole transport layers, and noble metals with an emphasis on voltage-induced electrochemical reactions that can destroy performance (corrosion) or result in added functionality (doping). We further describe electrochemical tools to characterize and/or predict chemical compatibility between contact materials and perovskites via methods that are accessible to most research laboratories and industrial entities. The applications of these methods range from accelerating fundamental, mechanistic revelations in the laboratory to providing excellent quality controls built into commercial production lines, and will play a crucial role in enabling technological development and deployment of halide perovskite devices at scale.

9:00 AM *EQ05.05.02
Charge Selective Contacts for Halide Perovskite Semiconductors Philip Schulz[1,2]; [1]Centre National de la Recherche Scientifique, France; [2]Institut Photovoltaique d'Ile de France (IPVF), France

It has been well documented in previous reports that optoelectronic properties of perovskites can be altered by the substrate (or selective contact) underneath [1], however so far, we do not dispose of any conclusive picture explaining this effect. In the conventional solar cell stack, a thin perovskite layer is usually buried between charge selective layers, making it very challenging to probe its properties.
Here, we fabricated a functional lateral heterojunction device, which consists of a substrate with two laterally arranged selective contacts (TiO_x as an electron transport layer and NiO_x as a hole transport layer), onto which a continuous methyl ammonium lead iodide ($MAPbI_3$) perovskite layer is deposited. Taking advantage of now exposed perovskite surface, we used a series of surface sensitive techniques and advanced optical characterisation techniques, such as ultraviolet and X-ray photoemission spectroscopy (UPS/XPS), X-ray absorption spectroscopy, Kelvin probe force microscopy, and hyperspectral imaging, to measure how substrate selectivity is affecting the optoelectronic properties of the perovskite.
We find evidence suggesting that the contact selectivity is inducing a carrier concentration gradient in the perovskite layer across the junction connected to the functionality of the lateral device. Furthermore, we are able to show, that by varying selectivity of the contacts through different oxidation levels we can alter the magnitude of this gradient, which in turn influences built in potential within the sample and hence the device performance [2].
This study provides a baseline for tailoring the selectivity of the contact materials for enhancing performance of perovskite solar cells and opening an avenue for new device architectures including buried cells terminals [3].

Interfacial Energetics in Organic and Hybrid Solar Cells—Low-Light, Oxides, Light-Soaking and More! Joel Luke[1], Tianhao Lan[1], Charlie Henderson[1], Yi-Chun Chin[1], Luiza Correa[2], Matyas Daboczi[1], Izabela Bicalho[2], Heejoo Kim[3], Kwanghee Lee[3], Diego Bagnis[2] and Ji-Seon Kim[1]; [1]Imperial College London, United Kingdom; [2]Oninn, Brazil; [3]GIST, Korea (the Republic of)

Interfacial energetics play a key role in defining the operation and performance of organic and perovskite photovoltaics. Of particular importance is the interface between the photoactive layer (PAL) and the hole transport or electron transport layers (HTL and ETLs). This interface affects charge extraction, and influences charge recombination mechanisms in devices. Understanding and optimising these interfaces is therefore of prime importance to improving device efficiencies and achieving market realisation. Here we present several examples of how interfacial energetics affect device performance and determine the slow processes observed in these devices under illumination (i.e. light-soaking effects).
Organic photovoltaics (OPVs), now exceed 18% power conversion efficiency at 1 sun illumination. However, efficiencies still lag behind Si and perovskite solar cells which limits the potential market for OPVs. One promising route to market for OPVs is for targeted low-light and indoor applications where illuminance is orders of magnitude smaller than 1 sun. Under low-light OPVs perform significantly better than silicon solar cells. However, devices considered in the literature so far employ materials or fabrication methods which are not suitable for large scale-up.
We demonstrate the commercial viability of OPVs for low-light applications by utilizing a fully scalable device architecture with upscalable OPV materials. We show superior device performance to silicon and discuss important optimisation parameters. Critically, we identify and characterise a critical light-soaking (LS) effect that is ruinous for low-light performance. Using surface photovoltage (SPV) and energetics measurements we find that this LS effect results from poor electron extraction at the electron transport layer (ETL)/photoactive layer interface due to high density of mid-gap states in the ZnO ETL and poor energetic alignment. We effectively remove this LS effect by employing SnO_2 nanoparticles as ETL, which we then use to demonstrate scale-up potential by fabricating a 21.6 cm^2 module (1).

We further investigate the properties of the ETL and look at controlling the LS effect by controlling the properties of ZnO. Here we characterise this oxide and compare it to other oxides using wavelength and atmosphere dependent SPV measurements to develop our understanding of these oxide interlayers and their role in device performance.
Additionally, we apply energetics measurements to perovskite solar cells, to understand how the interface between interlayers and perovskite affects device performance (2,3). Perovskite solar cells are also an exciting PV technology due to rapid improvements in power conversion efficiencies, now exceeding 25%. To further improve performance, it is necessary to improve V_{OC} which is sensitive to the choice of interlayer and the recombination processes at the interface.
Here, we look at a range of interlayers, and control their properties e.g. the doping level, or energetics, to modulate the interface with the perovskite. Doing so we are able to pinpoint an interlayer dependent light-soaking effect in large-area blade-coated perovskite cells, and suggest how to avoid this. We also investigate the energetics of an integrated organic/perovskite solar cell, demonstrating the loss mechanisms involved at the different interfaces, and how these affect device performance.
In summary, this presentation will highlight the importance of understanding the energetics and interfaces in a range of optoelectronic devices, and also the key role of SPV measurements to achieve this.

9:45 AM EQ05.05.04
Identifying Field Effect Passivation as the Origin of the Voltage Enhancing LiF Interlayer at the Perovskite/C_{60} Interface Dorothee Menzel[1], Amran Al-Ashouri[1], Alvaro Tejada[1,2], Igal Levine[1], Jorge A. Guerra[2], Bernd Rech[1,3], Steve Albrecht[1,3] and Lars Korte[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Pontificia Universidad Católica del Perú, Peru; [3]Technische Universität Berlin, Germany

In metal halide perovskite (MHP) solar cells with p-i-n architecture, the electron selective contact is often realized using the fullerene C_{60}. However, the C_{60}/perovskite interface is known to limit the open circuit voltage (V_{oc}) of the solar cells. This might be caused by non-radiative recombination, an unfavorable conduction band offset at the interface, or a combination thereof [1]. It has been shown that with an ultra-thin interlayer of LiF the V_{OC} can be enhanced by around 50 meV [2], due to reduced non-radiative recombination [3]. Yet, the exact passivation mechanism is still a question of ongoing research.
In this contribution we investigate the effect of such a thin LiF interlayer on the interface of a state-of-the-art multi cation multi halide perovskite composition, $Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})_3$ (CsMAFA, E_G = 1.63 eV), and thermally evaporated C_{60} by means of photoelectron spectroscopy [4]. MHPs exhibit a characteristically low density of states at the valence band maximum (VBM) [5]. To access the energetic position of the VBM and defect states within the band gap, we employ a rarely used technique: near-UV photoemission spectroscopy in constant final state mode (CFSYS). CFSYS allows to directly trace the density of occupied states with a very high dynamic range of up to seven orders of magnitude. Previously, we were thus able to reveal the VBM and to quantify occupied states in the band gap of CsMAFA [6]. Furthermore, with the low photon energies used here, the information depth is strongly enhanced to 5 – 10 nm and thus, it is possible to study the buried interface of CsMAFA and C_{60}.

We refine our description of the perovskite's valence band [6] to also model the superposition of the perovskite and C_{60} density of occupied states for thin C_{60} layers. From a sample with 5 nm C_{60} thickness, we can then directly determine the offset between the perovskite VBM and the C_{60} HOMO-edge to 0.55 eV. Furthermore, considering the band gap of the MHP and C_{60}, the LUMO edge is found 0.26 eV below the perovskite CBM. This unfavorable line-up potentially contributes to the V_{OC} limitation by the C_{60} interface. Interestingly, we find that introducing the LiF interlayer leads to an *enhanced* defect density in the first monolayers of C_{60}, which would lead to an increased trap assisted recombination, thus lower V_{oc} in a cell. Our CFSYS data shows, that this is overcompensated by a reduced hole density in the vicinity of the perovskite/C_{60} interface, which can be caused by a small dipole and probably a positive fixed charge. Linking to established solar cell technologies, we propose that the LiF evokes a field effect passivation reducing the absolute non-radiative charge carrier recombination and leading to the improved V_{oc}.

Theory-Based Insights into Interfacial Effects Influencing the Performance and Stability of Thin-Film Photovoltaics Joel B. Varley; Lawrence Livermore National Laboratory, United States

The transformation and utilization of solar energy with photovoltaics is becoming an increasingly cost-effective renewable energy source to supplant fossil-based alternatives. Rapid and parallel advances in storage solutions like batteries or in chemical bonds via (photo)electrochemical (PEC) processes are further accelerating this transformation. Underpinning all of these technologies are the creation and optimization of complex interfaces required for the desired separation and transfer of charge carriers, chemical reactivity, and stability. First-principles based calculations offer one avenue for providing insight into many of the fundamental details of these heterointerfaces that can so strongly influence device performance. Here we detail many examples of particular relevance to thin-film photovoltaics, such as the choices for particular absorber compositions and heterojunction partners of other layers like buffer layers and transparent contacts, and common deposition and post-processing treatments. Using hybrid density functional theory calculations, we will

discuss how these choices, as well as the role of alloying in different layers, can steer important device variables such as band gap, band offsets, doping and stability. These properties are often interrelated and can complicate device optimization. We will primarily illustrate how understanding these effects have led to gradual improvements in conventional thin-film photovoltaics (e.g. those based on $Cu(In,Ga)(S,Se)_2$ and CdTe), but will discuss how they are also relevant to alternative absorbers like wider-bandgap chalcopyrites and the hybrid perovskites.
This work performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344 and partially supported by the Department of Energy office of Energy Efficiency & Renewable Energy (EERE) and by the HydroGEN Advanced Water Splitting Materials Consortium, established as part of the Energy Materials Network under the EERE Hydrogen and Fuel Cell Technologies Office.

Size Tunable High-Efficiency Micro-LED Array Grown on Sapphire Nano-Membrane Template Jungel Ryu, Jehong Oh, Sohyeon Park, Yongjo Park and Ho Won Jang; Seoul National University, Korea (the Republic of)

Micro-LED displays are emerging displays with a lot of potential advantages over conventional display technologies. They are new displays with high pixel density, high brightness, superior stability, low energy consumption and most importantly, no limitation in size, capable of covering from micro-displays for AR/VR/MR to large area displays for consumer TV. Recent demonstrations by companies and institutes shows that development of micro-LED technology is in progress. However, further research is needed before they are commercialized. The current micro-LED fabrication process contains singluation of LED film into micro-scale using plasma etching. During the etching process, the active layers are inherently damaged, resulting in degradation in quantum efficiency. Another obstacle is the unacceptable loss of LED film known as kerf loss. The mentioned problems become more crucial as the chip size shrinks, affecting the cost of the micro-LED displays. It is highly desired to establish a scheme to fabricate high-efficiency micro-LEDs without a singulation process.
To fabricate micro-LEDs with self-passivated structures, we proposed a unique growth template called sapphire nano-membrane (SNM). The SNMs are 3D bridge structures consisted of 100 nm thick single crystalline Al_2O_3. The fabrication process of the SNM array started with photolithography to make photoresist (PR) pattern on a sapphire substrate. Then, an amorphous Al_2O_3 layer with a thickness of 120 nm was deposited by atomic layer deposition. Second photolithography and wet etching by H3PO4 solution was conducted to make a discrete SNM array. After removal of PR using acetone, the template was annealed at 1100 °C for 2 hours in air to crystallize the amorphous Al_2O_3 into single crystalline Al_2O_3 through solid phase epitaxy.
An array of discrete micro-LEDs surrounded by a major (0001) plane, and (11-20) and (1-101) planes at sidewalls was grown on SNM template using MOCVD. Self-passivated structure of the fabricated micro-LEDs, with MQWs sandwiched between n-GaN at the core and p-GaN at the outer shell, were confirmed with TEM and STEM. The size of micro-LEDs was controlled by adjusting the width and space of the SNM array. By placing several SNMs closely, larger micro-LEDs were obtained via lateral overgrowth and merge of the GaN. Structural and optical properties of the fabricated micro-LEDs were analyzed to confirm the compliant substrate effect of the SNM. Micro-Raman spectroscopy result showed reduced strain on the GaN and consequent reduction of threading dislocations were confirmed with panchromatic CL analysis. Micro-PL result showed improved internal quantum efficiency and spatially resolved CL analysis showed different spectrums emitted from various facets.
After the growth of LED structures, p-contact metal was formed using e-beam evaporation followed by flip-chip bonding to a target substrate with an electrode array. Utilizing ultra-thin profile of the SNM, micro-LED array was massively transferred to the target substrate via mechanical lift-off process. The micro-LEDs showed improved electrical properties with lower leakage current level compared to dry-etched micro-LEDs. Moreover, our devices showed reduced quantum confined stark effect with negligible wavelength shift depending on the current density change. We assume that it is due to relaxed strain which resulted in reduced band bending. The improved properties were observed regardless of the chip size, implying that the size effect problem in micro-LED display could be controlled using the SNM technique. We believe that results presented in this work would provide a significant step towards the commercialization of micro-LED displays.

11:15 AM EQ05.06.03
Resonant Capacitors with Single Injection Contacts for Bright Light Emission Across the Spectrum Vivian Wang and Ali Javey; University of California, Berkeley, United States

The range of luminescent materials that can be used in light-emitting devices is typically limited due to material processing and band alignment concerns. We have found that a single device architecture can be used to generate electroluminescence from a wide range of materials simply by depositing the luminescent material on top of a metal-oxide-semiconductor capacitor across which pulsed voltages are applied. By using a carbon nanotube network as the top injection contact, emission spanning the ultraviolet to infrared energy range can be produced using materials such as organic molecules and colloidal quantum dots, even when the lateral charge transport is poor or the film is non-uniform. Charge injection is achieved across different band alignments through transient band bending at the contact, rendering the device generic in the sense that emitter-specific charge injection layers are not needed. Importantly, light emission can be observed at voltages near the optical gap of the emissive material by employing a thin high-k gate oxide layer. Due to the capacitive nature of the device, the device can be driven resonantly to reduce the input voltage even further and achieve high power efficiency. Thus, bright emission can be achieved without complex device structures by using alternating carrier injection from a single contact. Facile fabrication of devices with emission across a broad spectral range may enable new opportunities in optoelectronics.

11:30 AM EQ05.06.04
Visualizing NIR Using Monolithic QD Optoelectric Upconversion Devices in Transmissive Mode Tae Hyun Kwon and Moon Sung Kang; Sogang University, Korea (the Republic of)

Exploiting of near infrared (NIR) wave is under significant advances in emergence technologies related to night vision, bioimaging, wafer inspections, and security systems. The full use of NIR in such technologies eventually requires converting the "invisible" NIR electromagnetic wave to "visible (Vis)" signal. This can be attained from optoelectric upconversion device, comprising a Vis light-emitting diode (LED) tandemly stacked onto an NIR photodiode (PD). In this work, we fabricate an efficient optoelectric upconversion device based on quantum dots (PbS quantum dots for NIR detection and CdSe quantum dots for Vis output signal). Employing a semi-transparent top electrode, we demonstrate a transmissive-mode device where NIR irradiated through the bottom electrode is upconverted to Vis under bias, which is then emitted through the top electrode. Moreover, not only an upconversion device comprising a single LED stacked onto a single PD (1PD-1LED configuration) is demonstrated, but we also fabricate a tandem device comprising a single PD sandwiched between two LEDs (1PD-2LED configuration). Unlike the upconversion device in 1PD-1LED configuration where only either the electrons or holes generated from photoexcitation are exploited in generating light, the upconversion device in 1PD-2LED configuration allows converting both electrons and holes to Vis. This approach will make significant impact on improving the efficiency of optoelectric upconversion and can provide wider possibility of applications.

Leveraging DFT Atomic-Scale Modeling and Simulation Approaches for Designing Ultrathin 2D-TMD Based Optoelectronic Devices Ugonna C. Ohiri; Northrop Grumman Corporation, United States

Two-dimensional (2D) materials are emerging materials which exhibit very intriguing physical, electronic and optoelectronic properties, such as the ability to grow these thin film materials on a variety of heterogeneous substrates, high refractive indices in the visible-IR wavelength regime, and tunable bandgap engineering with respect to the number of stacked 2D layers.

For example, Group-6 Transition metal dichalcogenides (TMDs) monolayer/bilayer materials (e.g., MoS_2, WS_2, WSe_2, $MoSe_2$, $MoTe_2$) demonstrate good semiconducting behavior (e.g., direct bandgap performance in the range of 1-2 eV), strong light-matter interactions, and good detection performance in the visible-near IR regime. Black Phosphorous (bP) and Group-10 Noble TMDs (e.g., PdS_2, $PdSe_2$, PtS_2, and $PtSe_2$) have attracted more recent attention as these materials demonstrate higher carrier mobility, wider tunable bandgaps, and can offer great potential for developing next-generation mid-infrared optoelectronic devices.

Here, we report on a deep dive exploration into using density functional theory (DFT) approaches for modeling and simulating various Group-6 and Group-10 2D materials, and the ability to tune the electronic and optical performance when Group-6 and Group-10 TMDs are hetero-structured with each other. These DFT modeling and results will shed light on novel and scalable strategies needed to fabricate Group-6 and Group-10 2D-based heterojunction devices; this presentation will also address critical issues which still need to be addressed for physically realizing these devices into the commercial scale.

SESSION EQ05.07: Transparent Electrodes II

1:30 PM *EQ05.07.01
Hydrogen Behavior at Crystalline/Amorphous Interface of Indium Oxide and Its Role in Carrier Transport, Photoconductivity and Crystallization Julia E. Medvedeva; Missouri University of S&T, United States

Revealing the microscopic behavior of hydrogen in wide-bandgap metal oxides that have been employed as transparent electrodes in many optoelectronic devices, including highly efficient silicon heterojunction solar cells, and that recently became competitive in large-area flexible displays, represents a formidable problem. In oxides, hydrogen may passivate under-coordinated oxygen or metal atoms, forming covalent or ionic H bonds, respectively, and the resulting macroscopic properties depend on the relative formation, distribution, and behavior of the competing H defects. Although the structure and properties of substitutional and interstitial H defects in crystalline oxides, primarily, in In_2O_3, SnO_2 or ZnO, have been studied theoretically, the results cannot be transferred to disordered phases. The ionic nature of metal-oxygen bonding renders a substantial disorder within the short-range structure of the amorphous oxide phases that feature large fractions of under-coordinated oxygen (O) and metal (M) atoms. The wide coordination distributions and strong distortions in the M-O and O-M polyhedra dramatically increase the number of possible locations for hydrogen and the diversity of its immediate neighbor environment. The latter affects the formation, activation and stability of various H defects as well as H mobility through the disordered structure. Therefore, quantum-mechanical and statistically-significant calculations are required to elucidate the complex H behavior in wide-bandgap amorphous oxide semiconductors.
In this work, the role of crystalline-amorphous interfaces in the resulting microscopic behavior of hydrogen in indium oxide is investigated using *ab-initio* molecular dynamics simulations and hybrid density functional calculations. The results of this computationally-intensive work reveal that disorder plays a decisive role in H-induced extended bond reconfiguration which: (i) significantly outweighs the energy gains from passivation of under-coordinated oxygen atoms and nonbonding O–p-orbitals; (ii) stabilizes H defects with ionic bonding (In-H-In) even in the stoichiometric amorphous oxide; (iii) improves the morphology of disordered oxide that widens the conduction bandwidth---in accord with the observed improved mobility; and, most strikingly, (iv) favors the formation of covalent OH bonds that introduce deep trap defects, limiting the number of free carriers.
The results help explain a puzzling experimental observation of atypical semiconductor behavior in H-doped indium oxide, namely, a decreasing number of free carriers as temperature raises. Furthermore, the crystalline/amorphous interfacial model developed in this work in order to establish the structural characteristics of the interface and their effect on the formation, stability, distribution, and properties of H defects, is indispensable to resolve the controversial experimental observations regarding the H role in crystallization, namely, faster crystallization rates upon H doping, yet, decreasing grain sizes with increasing H concentration. Our statistically-significant calculations combined with molecular-dynamics simulations at various temperatures help identify the H defects and defect complexes that are responsible for H pinning, switching and segregation, governing the complex crystallization processes in indium oxide. Last but not least, the results of this work help predict which defects in H-doped indium oxide will be sensitive to photo-illumination and may contribute to the observed negative bias illumination stress instability behavior in thin film transistor devices, one of the major drawbacks hampering commercialization of the wide-bandgap amorphous oxide semiconductors.

2:00 PM EQ05.07.02
Doping and Mobility Limits of Cuprous Iodide Joe Willis[1,2,3], Qi Zhou[1] and David O. Scanlon[1,2]; [1]University College London, United Kingdom; [2]Thomas Young Centre, United Kingdom; [3]Diamond Light Source, United Kingdom

The quest for p-type transparent conducting materials has challenged researchers for decades. Initial efforts focused on designing p-type transparent conducting *oxides*, such as $CuAlO_2$,[1] which generally display good transparency, but fail to reach competitive levels of conductivity. This is because the valence bands of such materials are dominated by highly localised oxygen p states, which trap hole polarons and severely limit the charge carrier mobility.[2] In recent years, research has moved more towards *non-oxide* materials that have greater delocalisation of the states at the valence band maximum in an effort to improve p-type conductivity.[3-5]

One such material is cuprous iodide (CuI), which has an optical band gap just shy of 3 eV and displays intrinsic p-type conductivity that can be improved upon intentional doping.[6] The relatively disperse valence band maximum is formed from the broad overlap of Cu 3d and I 5p orbitals that suggests high hole mobility is possible.

In this work, we investigate Se-doping in CuI using hybrid density functional theory. We compare defect formation energies to both experimentally and computationally determined values from the literature, and examine effects of the dopant on the electronic structure. We compute the charge transport properties of CuI using the AMSET package,[7] and determine the upper limit of hole mobility. We find that the relatively low dielectric response of CuI

ultimately prevents hole mobility exceeding around 40 $cm^2 V^{-1} s^{-1}$ when degenerately doped.

Transparent Ohmic Contacts to p-GaN by AZO with Subcontact Layers Aleksandra J. Wójcicka[1], Zsolt Fogarassy[2], Tatyana Kravchuk[3], Cecile Saguy[3], Eliana Kaminska[4], Piotr Perlin[4], Szymon Grzanka[5] and Michal A. Borysiewicz[1]; [1]Lukasiewicz Research Network - Institute of Microelectronics and Photonics, Poland; [2]Institute of Technical Physics and Materials Science, Centre for Energy Research, Hungary; [3]Technion–Israel Institute of Technology, Israel; [4]Institute of High Pressure Physics, Polish Academy of Science, Poland; [5]TOP-GAN, Poland

Thanks to its wide band gap engineered by alloying with Mg and In and its built-in piezoelectric field, gallium nitride (GaN) is the material widely used in optoelectronics, for the fabrication of light emitting diodes (LEDs) and laser diodes (LDs) as well as in high frequency electronics for the preparation of high electron mobility transistors (HEMTs). The steady improvement in the already mature epitaxial technology has enabled interesting device developments, however there are also processing concerns which should be taken into account when optimizing a device. One of such is the design of appropriate contact layers for current biasing of the devices. In the case of LEDs and LDs, it is now being regarded that optically active materials are preferred over metals due to the possibility of their usage for enhancing light confinement or extraction.
In this work we analyze the application of a transparent conducting oxide (TCO) ZnO:Al, or AZO deposited by sputtering as the top contact to p-GaN epitaxial layers and if it is possible to improve its performance by introducing ultrathin subcontact layers at the interface and appropriate surface processing. We see that AZO forms an ohmic contact after annealing at 800°C. What is relevant, the application of subcontact layers of Au and Ni lowers the contact forming temperatures to 600°C and 650°C, respectively and substantially increases the currents under the same bias. These metals were applied since the Ni/Au bilayer is the standard low-resistivity ohmic contact to p-GaN. We analyze the interfacial layer using high resolution TEM, XRD and SIMS to try to understand the mechanism of contact formation. For the Ni we see the formation of NiO spots in cross-section TEM and NiO peaks in the XRD suggesting the presence of NiO is needed for the contact to form. However when we fabricate a sample with NiO directly at the interface instead of Ni, we don't observe ohmic I-V characteristics. This might mean that a more intimate reaction at the interface might take place, which we try to deconvolute using cross-sectional scanning tunnelling microscope. The scheme with Au also yields ohmic behavior however no clear mechanism for this has been yet found. We analyze the influence of the thickness of the Ni and Au layers on the contact formation and also apply an ultrathin Ni/Au bilayer to try to undestand the role of each element in contact formation. What is specific, we anneal the contacts in nitrogen instead of the commonly used air, as the oxygen source for the contacts to form is the AZO film itself, as seen from the NiO formation. We also assess the length of the temperature formation step and its influence on the performance.
Finally, we demonstrate light emission from LD structures with the AZO-based contacts and determine their influence on the emission of the light from the diode structure.

Transport Properties of $AlSbO_4$—A Rutile Structured Wide Band Gap Oxide for Optoelectronic Applications and Beyond Bonan Zhu and David O. Scanlon; University College London, United Kingdom

Transparent conducting oxides (TCOs), combing two seeming mutually exclusive properties, are essential components for a range of optoelectronic applications. Existing materials such as indium-doped tin oxides (ITOs) require raw materials that are limited in supply (e.g., In). Hence, cost-effective alternatives are in urgent need[1]. Having the same rutile lattice, $AlSbO_4$ can be seen as a cation mutated version of SnO_2 with Sn (IV) replaced Al (III) and Sb (V). Sb based systems are interesting as Sb (V) is isoelectronic to Sn(IV) and In (III) which are known to yield strongly dispersive conduction bands[2]. In this work, a thorough computational investigation is conducted to assess the potential of $AlSbO_4$ as a TCO. Despite the early experimental report of a fully cation-disordered structure[3], Monte-Carlo simulations based on cluster expansions show a relatively high order-disorder transition temperature of about 1800 K. The 0 K ground state structure is also obtained and found to contain a wide direct band gap of ~4 eV, and an electron effective mass of 0.38 m_e at the conduction band minimum. Band alignment calculations suggest a large electron affinity and ionisation potential, which can be attributed to the strong overlap between Sb 2s and O 2p states, making it a potential contact material. The dopability of this system will also be discussed. Beyond potential TCO applications, a low lattice thermal conductivity is found with the ordered ground state structure, and the possibility of further reduction in conductivity through disordering makes it a potential candidate material for thermal barrier coating.

Nanostructured Inorganic and Organic Materials for Next Generation Solar-Based Energy Technology Andrea Rubino[1], Andrea Camellini[1], Luca Rebecchi[1,2], Michele Ghini[1] and Ilka Kriegel[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Università degli Studi di Genova, Italy

The next generations of optoelectronic devices for energy production will have to comply with increasingly stringent requirements to promote sustainable development. The main directives concern efficiency, environmental compatibility and easy access on a global scale. In terms of materials, all this translates into the need for abundant, non-toxic, stable compounds with the best optoelectronic properties. An equally intriguing direction concerns the design of composite structures in which it is possible to combine the characteristics of several elements in order to exploit new functionalities. Among the

most promising and widespread materials in various fields of optoelectronics we find the nanocrystals of transparent conductive oxides [1]. The advantages in the use of these nanomaterials derive from the successful convergence of optical transparency/absorption and conductivity and from the easy processability in solution for the formation of thin films. However, recent studies have opened new stimulating perspectives on the use of these metal oxides, especially in the field of light-powered devices. The possibility of increasing their charge density through photodoping makes these materials potential candidates for solar conversion technology, but also for energy storage [2,3]. Another family of compounds at the forefront of emerging energy applications are the quantum dots of graphene (GQD). In this case, their attractive optical and electronic properties come with a very low environmental impact and incredible versatility in terms of functionalization [4]. The synthetic control of these organic structures makes it possible to manipulate and enhance their photo-response and adapt them, for example, to the extraction of positive or negative charges on demand. In such a context, the subsequent charge transfer process is a key aspect in the improvement of the performance and possible multi-charge mechanisms can be a significant upgrade in materials design for advanced light-driven technologies as photovoltaics, photo-catalysis or photo-rechargeable batteries. In this study, we spectroscopically analyzed the behavior of Indium Tin Oxide nanoparticles with respect to the possible photo-induced charge accumulation. Furthermore, we present the potential charge transfer properties of these nanomaterials by means of chemical titration with an oxidizing compound (electron-acceptor) [5]. We extended the same characterization to some GQDs designed to be able to delocalize different charges. The aim of this work target the possible implementation and integration of both materials (creating, for example, composite hetero structures) and multiple charge transfer mechanisms (both electrons and holes) for the development of energy conversion and storage systems.

Addressing the Stability and Reliability Challenges in Perovskite Solar Cells via Interfacial Tailoring Nitin P. Padture; Brown University, United States

Most commercial devices, including photovoltaics (PVs), have gone through a familiar research and development trajectory — increasing performance, upscaling, improving stability, and enhancing mechanical reliability — before making it to the marketplace successfully. In this context, perovskite solar cells (PSCs) are likely to be no exception, but little attention has been paid to the latter issue of mechanical reliability. In fact, enhancing the mechanical reliability of PSCs is particularly important and challenging because the low formation energies of MHPs that makes them easy to solution-process renders them inherently poor in mechanical properties: they are compliant (low Young's modulus), soft (low hardness), and brittle (low toughness). To address this perhaps final hurdle in the path towards PSCs commercialization, several rationally designed interfacial tailoring approaches are used. These include grain-coarsening, grain-boundary functionalization, and interfacial engineering. Most importantly, these approaches are designed such that they not only enhance the PSCs mechanical reliability but also increase performance and improve stability. The scientific rationales for these approaches are discussed, together with the presentation of the current results.

Energy Band Alignment in between Perovskites with Different A-Site Molecules and NiO Interlayers for Highly Efficient and Stable Inverted (*p-i-n*) Perovskite Solar Cells Hyoungmin Park, Sooeun Shin and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

To date, most highly efficient perovskite solar cells (PSCs) are based on a normal (n-i-p) structure. However, even normal structure PSCs show higher power conversion efficiency (PCE), the advantage of relatively high stability and applicability to tandem devices draw tremendous attention to the inverted (p-i-n) structure of PSCs. Notoriously, most of inverted PSCs are based on polymer hole transporting layers (HTLs), which restrict the further development of stability due to their hygroscopic and acidic properties. Unlike polymer HTLs, PSCs based on oxide HTLs such as NiO, CuO_x and $CuCrO_3$ demonstrated more stable than polymer HTLs. Among oxide HTLs, NiO is the most attractive and widely accepted as a potential candidate for HTL in the inverted PSCs. However, surface redox reaction at the surface defects, especially at Ni^{3+} what are detrimental reaction sites with cations and/or halides induced voltage loss, series resistance and band alignment miss-match remained to be solved. In addition, surface properties depending on NiO fabrication methods constrict reproducibility of the inverted PSCs based on the composition of formamidine (FA) cations which show better device performance due to broad light absorption compared to methylammonium (MA), which are before mainstream of perovskite absorbers. Furthermore, to the best of our knowledge, direct deposition of pure-$FAPbI_3$ or more than 95% of $FAPbI_3$ on NiO HTLs was not reported yet. Therefore, a suggestion of appropriate deposition techniques of NiO and analysis of the interfaces between NiO/Perovskite layers still much to be investigated. Among various deposition methods, we choose atomic layer deposition (ALD), because of their pin-hole free, uniform and conformal characteristics. To investigate NiO/Perovskite interface, we fabricated inverted PSCs with three perovskite composition (1) pure $MAPbI_3$, (2) $(CsPbI_3)_{0.05}(FA_{0.83}MA_{0.17})_{0.95}Pb(I_{0.83}Br_{0.17})_3$, and (3) $FAPbI_3$ with trace amount of MACl (hereafter MA, CsFAMA and FA). As the amount of FA cation increased from MA to FA composition, PSCs showed a gradual increase of J_{sc} up to 23 mA/cm^2 in FA base PSCs. However, open-circuit voltage (V_{oc}) showed the decreasing trends from average V_{oc} around of 1.05 V in MA and 0.99 V and 0.97 V in CsFAMA and FA, respectively. We compared X-ray/Ultraviolet photoemission spectroscope (XPS, UPS) and Kelvin Probe work-function measurement focusing on energy band matching between NiO/Perovskite interfaces. As a result, we figure out that voltage loss dependence on FA cation ratio is caused by energy level miss-marching between NiO/perovskite interface. In addition to energy band mismatch, in all cases of perovskite compositions, Ni^{3+} defects induced a non-radiative recombination, which could restrict further performance enhancement. We also modified the NiO surfaces with organic substances containing both Lewis bases and pseudo halides. Synergetic effect of Ni^{3+} defects' passivation and suppressed nonradiative recombination significantly enhances the device performances, in particular, *FF* and V_{OC}. Not only device performance, but also reproducibility of PSCs with MA, CsFAMA and FA composition were increased. Furthermore, the fabricated PSCs were additionally passivated with ALD-grown SnO_2 on top of electron transport layer (ETL). Finally, ALD NiO and ETL dual passivated inverted PSCs showed the enhanced photovoltaic

performances and increased stability. In summary, this study demonstrates facile surface defect passivation and energy level alignment optimization to boost charge extraction of NiO/Perovskite interfaces by Lewis base/Ionic molecules. In addition to NiO surface modification, we adopt ALD SnO_2 layer on top of ETL to enhance electron transport and device stability.

4:15 PM EQ05.08.03
Electronic Structure and Charge Transport at Heterogeneous Functional Interfaces in Solar Energy Conversion Devices Ana B. Muñoz-Garcia and Michele Pavone; University of Naples Federico II, Italy

Solar energy conversion devices are pivotal for the ongoing ecological transition toward a sustainable economic and social development. From re-emerging dye-sensitized solar cells for indoor light-recycling and building integrated photovoltaics [1] to the high-performance perovskite solar cells [2], the conversion of light into electricity involves charge transport across several constituent materials. The heterogeneous functional interfaces among these different materials are key for an efficient and effective conversion process. In this context, the complexity of multi-layered devices hinders a complete and conclusive understanding based on experimental outcomes. For this reason, computational modeling tools based on atomistic and first-principles approaches are at the forefront in the current revolution of materials design and optimization.
Here we will discuss how DFT-based approaches are able to unveil the charge transfer mechanism in several interfaces between optically-active materials and charge-collector layers in different electrochemical environments: (i) at hybrid solid-liquid interface with promising Cu-based molecular redox-couples in dye sensitized photo-anodes [3] and (ii) at heterogenous interface between lead halide perovskite and molecular/inorganic hole transport materials [4,5] and passivation ligands [6].
Our results provide new insights on the structure-property-functional relationships of different functional materials/interfaces and outline new design principles for further improvements of the corresponding devices.

Hole Transport Materials Based on PEDOT Derivatives for Perovskite Solar Cells Qiuming Yu; Cornell University, United States

Poly(3,4-ethylenedioxythiophene):poly(styrene sulfonate) (PEDOT:PSS) has been widely used as a hole conducting polymer in many optoelectronic devices, such as light-emitting diodes (LEDs), photodetectors, and solar cells. As a benchmark hole transport material, PEDOT:PSS has the advantages such as solution processability, high transparency, and good flexibility. However, relatively low electrical conductivity and poor electron-blocking capacity of PEDOT:PSS are detrimental to the operational parameters of perovskite solar cells, including open-circuit voltage (Voc), short-circuit current density (Jsc), and fill factor (FF). We proposed a new strategy to modify the electronic, structural, and surface morphological properties of PEDOT:PSS by introducing a hydroxymethyl (−MeOH) or chloromethyl (-MeCl) functional group to ethylenedioxythiophene (EDOT) to form hydroxymethylated-3,4-ethylenedioxythiophene (EDOT-MeOH) or chloromethylated-3,4-ethylenedioxythiophene (EDOT-MeCl) monomers and to further polymerize them to water-soluble poly(hydroxymethylated-3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT-MeOH:PSS) or poly(chloromethylated-3,4-ethylenedioxythiophene):polystyrene sulfonate (PEDOT-MeCl:PSS) using the oxidative chemical polymerization method. The introduced functional groups can either modify the work function or the conductivity of PEDOT-MeOH:PSS and PEDOT-MeCl:PSS. We systematically varied the amount of the ferric oxidizing and basic agents and reaction temperature and time in polymerization to control the reaction kinetics, the chain length, and the oxidation state of polymers. We also varied the amount of PSS used in polymerization to control the doping level and work function of synthesized PEDOT-MeOH:PSS and PEDOT-MeCl:PSS. Furthermore, we added ethylene glycol (EG) in the synthesized PEDOT-MeOH:PSS and varied annealing conditions such as in polar solvent environment and EG washing for PEDOT-MeCl:PSS to further tune the microstructures, electrical conductivities and work function of PEDOT-MeOH:PSS and PEDOT-MeCl:PSS thin films. We used Raman scattering spectroscopy to study the backbone structural changes among the benzoid and quinoid conformations and their impacts on the surface morphologies using atomic force microscope (AFM), electrical conductivity using four-probe measurement, and work function using ultraviolet photoelectron spectroscopy (UPS) and cyclic voltammetry (CV). The surface chemical compositions were obtained by x-ray photoelectron spectroscopy (XPS) to confirm the presence of PEDOT-MeCl on the thin film surface. The inverted structured $MAPbI_3$ perovskite solar cells with PEDOT-MeOH:PSS treated with EG exhibited the enhanced Voc and Jsc because of the enlarged work function and electrical conductivity. Elongated photoluminescence lifetime of $MAPbI_3$ on PEDOT-MeCl:PSS indicated the strong interaction between Cl- and perovskites. Additionally, the inverted structured $MAPbI_3$ perovskite solar cells with PEDOT-MeCl:PSS annealed in polar solvent vapor exhibited the enhanced Voc and Jsc because of significantly reduced trap states at the HTL/perovskite interfaces. This work opens the way to develop new hole transport materials for highly efficient inverted perovskite solar cells and other optoelectronic devices with low-cost and solution processability.

Optical Probes of Triplet Exciton Sensitization of Silicon Narumi Wong, Collin F. Perkinson, Alice Q. Wu, William Tisdale, Moungi Bawendi and Marc Baldo; Massachusetts Institute of Technology, United States

To match the growing global energy demand while meeting space and cost limitations, efficiencies of solar cells need to improve. However, the efficiencies of crystalline silicon solar cells, the current industry standard, are approaching the maximum theoretical limit. One method of going beyond this limit is to sensitize the silicon (Si) by using a material that can perform singlet exciton fission (SF), a carrier multiplication process that can create two triplet excitons (electron-hole pairs) from a single photon. Successful transfer of these two triplet excitons to silicon can result in increased photocurrent

and improved efficiencies.

Recent work has shown coupling between Si and the archetype SF material tetracene (Tc) in the presence of passivating interfacial layers of Hafnium oxynitride [1]. Excitation spectra show a boost in the photoluminescence from Si when Tc is photoexcited that may be caused by energy transfer or changes in the silicon passivation [1]. To experimentally distinguish between these phenomena and understand the complex dynamics of excited states and charges at silicon/SF interfaces, we have developed a spectroscopy technique that is robust to the weak and intensity-dependent photoluminescence from silicon. Using combinations of biasing optical pumps and selective modulation of SF rates using a magnetic field, we study structural variations at the interface to probe the mechanism of coupling at Hafnium oxynitride interfaces and other rationally-designed heterostructures. We demonstrate positive contributions from tetracene to silicon photoluminescence that suggest a key role for charge transfer states in realizing solar cell efficiency enhancements from singlet exciton fission.

Interfaces in Perovskite Optoelectronics – Role of Energy Level Alignment and Interface Chemistry Selina Olthof; University of Cologne, Germany

Optoelectronic devices, such as solar cells, are typically multi-layer stacks in which the absorber layer is sandwiched between metal oxide and/or organic transport layers in order to facilitate charge extraction or block unwanted charge carriers. In perovskite-based devices, the role of this energy level alignment remains to be elusive, and I will present some of our own results based on photoelectron spectroscopy analysis, as well as reports from literature. The effect of energetic alignment on the device performance can more easily be understood in case of inorganic-inorganic interfaces, as for example used as recombination layers in monolithic tandem solar cells. Therefore, I will also present our analysis of a highly efficient Sn_x-InO_x interconnect, employed in a record-breaking organic-perovskite tandem solar cell.
However, the energetic alignment and device efficiency are not the only important aspects to consider in a solar cell, device stability is almost equally important. We show that material combinations developed for other thin film technologies (such as organic semiconductors) cannot straight forward be transferred to perovskite devices, as the direct contact to metal oxides can trigger chemical reactions that lead to a partial or to a complete decomposition of the perovskite film. Post treatment of the substrate, or the insertion of thin organic interlayers, can be necessary to stabilize the interface and achieve better stability.

9:00 AM EQ05.09.02
Fully Vacuum Deposited Perovskite Solar Cells in Substrate Configuration Abhyuday Paliwal and Henk J. Bolink; Institute of Molecular Sciences, University of Valencia, Spain

Vacuum-deposition of perovskite solar cells (PSCs) in substrate configuration on metal thin films and foils is advantageous. Due to the high conductivity of the bottom-metal electrode, the possibility of depositing thick and narrow metal grids on the top transparent electrode for facilitating loss-free charge extraction, and the intrinsic scalability of the vacuum-deposition methods, large-area cells, or subcells for modules can be fabricated with relative ease. However, despite the above, the number of reports focusing on the fabrication of PSCs in substrate configuration remains scarce. In this work, we demonstrate the complete fabrication of inverted PSCs in substrate configuration by vacuum-deposition methods. The resultant devices (~0.05 cm^2) having a co-evaporated formamidinium methylammonium lead iodide (FAMAPI, E_g of ~1.54 eV) perovskite demonstrate a maximum power conversion efficiency (PCE) of ~19%, which is comparable to the maximum PCE of ~19.5 % obtained in the superstrate configuration devices and is the highest value reported for a PSC in substrate configuration. The devices in substrate configuration exhibit higher short circuit current density values despite the parasitic absorbance from the front fullerene-C_{60} layer (> 0.5 mA/cm^2). Furthermore, we discuss the reflection losses in the above two device configurations based on the insights obtained from the transfer matrix-based optical simulations. Next, we observe that the encapsulated devices of both the configurations exhibit similar thermal stability at 85 °C (on a hotplate) in an N_2 environment, reaching a t_{80} (time to reach 80% of the original PCE) of ~800 hours. Finally, via systematic characterization, we study and identify the degradation mechanisms occurring in the devices and propose recommendations for enhancing their thermal stability. We believe our findings may contribute to the development of large-area, efficient, and thermally stable fully vacuum-deposited PSCs.

9:15 AM EQ05.09.03
Revealing Hole Transporting Properties of Transition Metal Oxides Deposited via Atomic Layer Deposition as Bi-Functional Interlayers to Highly Efficient Perovskite Solar Cells (>23%) Hyoungmin Park, Seonghwa Jeong, Seongrok Seo, Sooeun Shin, Eunsoo Kim and Hyunjung Shin; Sungkyunkwan University, Korea (the Republic of)

Power Conversion Efficiency (PCE) of Perovskite Solar Cells (PSCs) is over 25.7%. Despite solar cell's high PCE, low device stability coming from the inherent stability of perovskite absorber remains to be solved and restrict PSCs' commercialization. Currently, the state-of-the-art PSCs used $FAPbI_3$ (Formamidinium lead tri-iodide) as the main composition. Although pure $FAPbI_3$-based PSCs show higher PCE due to a wider absorption spectrum owing to a lower band gap than $MAPbI_3$ (Methylammonium lead tri-iodide), a spontaneous phase transition from photoactive α-$FAPbI_3$ to non-photoactive δ-$FAPbI_3$ is pointed as a significant challenge. In addition to phase transition issue, low device's stability because of 2,2',7,7'-tetrakis[N,N-di(4-methoxyphenyl)amino]-9,9'-spirobifluorene (Spiro-OMeTAD) which is mainly used as hole transporting layer(HTL) in n-i-p normal structure PSCs is also raised as a challenge. Oxide hole transporting layers (HTL) can be strong candidates. However, the oxide transporting layers generally require high processing temperature and the lack of p-type characteristics inhibits application to PSCs as HTLs. Transition metal oxide (TMO) such as TiO_2, WO_X, MoO_X and V_2O_{5-X} are also recognized as a solution, but the control of hole transporting properties related to oxidation state of metals in TMO and a proper ohmic junction with organic layer and/or suitable deposition methods without damaging the perovskite absorber layer should be solved in advance. Motivated from here, we adopt atomic layer deposition (ALD) to fabricate TMO as HTLs with low temperature process and intentionally induce oxygen deficient traps to form empty *d*-bands to induce and further enhance hole transporting properties. With their oxygen deficient trap assisted hole transporting properties as an HTL, we fabricated n-i-p normal structure PSCs of $FAPbI_3$ and Spiro-OMeTAD with ALD grown TMOs (TiO_2, MoO_X and V_2O_{5-X}) on top of Spiro-OMeTAD to enhance device stability. During fabrication, we adopt funnel like 2D perovskite passivation layers for defect passivation and

enhance perovskite's stability coming from hydrophobic characteristics. [1] As a result, highly efficient PSCs of PCE of over 23% with TMOs are fabricated with pin-hole free hole transporting and protection bi-functional ALD layers. [2,3] The stability of PSCs with ALD TMO layer is over 90% initial PCE after ~ 570 hrs and maintained 94.9% of initial PCE after 130 hrs operating condition without UV cut-off filter. In conclusion, this study demonstrates the application of TMOs as hole transport/protective bi-functional HTLs and ALD as an optimal deposition method without damaging the underlying perovskite absorber. Furthermore, this study shows the possibility that ALD TMO can be also applicable to tandem device fabrication and stable PSCs' commercialization.

9:30 AM EQ05.09.04
Gate/Light Co-Tunable Negative Differential Resistance Behaviors from Small-Molecules Heterostructure Seongjae Kim, Yunchae Jeon and Hocheon Yoo; Gachon University, Korea (the Republic of)

Negative differential resistance (NDR) is a characteristic in which the current decreases as the voltage increases. Recently, these new characteristics have been applied in various fields such as multi-value logic devices and switching circuits [1-3]. In this study, we present an ambipolar transistor that controls NDR characteristics through light and gate voltage bias co-tunability. We fabricated the proposed small-molecules heterostructure device by stacking dinaphtho[2,3-b:2′,3′- f]thieno[3,2-b]thiophene (DNTT) on top of N,N′-ditridecyl-perylene-3,4:9,10-tetracarboxylic diimide–C13 (PTCDI-C13). The proposed device shows the electrical characteristics of a typical ambipolar transistor in the dark. When light is irradiated, photocarriers move in the sub-bandgap, resulting in NDR behaviors depending on the gate/light control. While the gate voltage bias was increased from 0 V to 30 V with 10 V increments, the peak voltage was measured at 41 V, 51 V, 60 V, and 69 V, which showed a proportional increase with the gate voltage dependency. In addition, as a result of measuring with different wavelengths of light at a fixed gate voltage (V_G = 10 V), NDR characteristics were shown in all wavelength ranges from λ = 400 to 1,100 nm, and light-tunable characteristics according to the wavelength of light were confirmed. The peak to valley ratio (PVCR) exhibited a maximum of 2.02 A/A at λ = 1,000 nm light illumination. We also fabricated an array of 9 × 9 NDR devices to test the reproducibility and uniformity of the induced NDR. All 81 devices constituting the array showed light-induced NDR and gate-shiftable characteristics. Finally, we detected the text image by mapping the PVCR of 81 devices when the text image pattern was irradiated on the 9×9 NDR device array.

10:15 AM EQ05.10.01
Elucidating the Growth Kinetics of *h*MBE-Grown $SrTiO_3$ via ReaxFF Benazir Fazlioglu Yalcin[1], Adri C.T. van Duin[1] and Roman Engel-Herbert[1,2]; [1]The Pennsylvania State University, United States; [2]Paul-Drude-Instit für Festkörperelektronik, Germany

Titanium(IV) isopropoxide (TTIP), a commonly used metal-organic substance, has tremendous industrial applications since its thermal decomposition produces TiO_2 as a final product. Therefore, it has come into focus as an indispensable component of hybrid molecular beam epitaxy (*h*MBE) systems to grow titanate structures such as $SrTiO_3$.[1] To have a better understanding of the reaction kinetics of the growth process, reactive force field molecular dynamic simulations (ReaxFF-MD) constitute as a powerful tool which is based on a bond order-based force field that provides a unique opportunity to observe chemical reactions with the continuous bond formation and breaking together with allowing for large simulation sizes.[2,3] The decomposition pathways and surface interactions can realistically be captured and tracked in the low-pressure conditions present in the deposition experiments. In this study, a $SrTiO_3$ (001) structure was simulated using ReaxFF molecular dynamics simulations in such a way that one surface of $SrTiO_3$ is TiO_2 terminated while the other surface is SrO terminated. TTIP molecules and Sr atoms were placed randomly around the $SrTiO_3$ structure to mimic the *h*MBE growth conditions. Performing the ReaxFF-MD simulations in the presence of TiO_2- and SrO-terminated SrTiO (001) surfaces revealed that the particular surface chemistry of the $SrTiO_3$ growth front dramatically affected the initialization of the TTIP decomposition process. While the metal-organic precursor TTIP was found to be rather stable with a pronounced tendency to thermally desorb from TiO terminated SrTiO (001) surfaces, its decomposition on SrO terminated surfaces was much pronounced, providing first insights into the intricacies of the hybrid MBE growth process. The major observations that were made based on these simulations are as follows:

1) Sr atoms had a clear tendency to go to the surface with TiO_2 termination, 2) TTIP molecules were attracted by the SrO surface and no TTIP can be observed in the vicinity of TiO_2-termination which confirmed the experimental finding that TTIP breaks down at a 40% higher rate on SrO than on bare TiO_2.[4] 3) As soon as the Sr atoms started making bonds with the TiO_2 surface, TTIP molecules were attracted by Sr atoms and got incorporated into the surface to decompose and to grow the $SrTiO_3$ structure.

The conclusions that were drawn from the simulations of TTIP decomposition on $SrTiO_3$ play a critical role in understanding the growth kinetics of *h*MBE in more detail. At this level, one can ask questions such as what are the decomposition reactions of TTIP on $SrTiO_3$? Do the bonds of the TTIP molecule tend to break between C-O or Ti-O leaving the remaining molecule oxygen-deficient? Does the temperature have any contribution to the types of bond dissociation reactions? How does the steric hindrance of TTIP affect the growth? Can TTIP be replaced by a better-suited Ti-based metal-organic precursor? What is the ideal amount of TTIP molecules that need to be supplied on an 8x8 atom surface? All these questions can be answered via ReaxFF-MD simulations and will be discussed in this talk in detail.

Calcium Titanate Orthorhombic Perovskite-Nickel Oxide Heterogeneous Solar Blind UVC Photodetectors with Unprecedented Long-term Stability Exceeding 500 Days and Their Applications to Real-Time Flame Detection Subin Lee, Taehyun Park, Jaehyun Hur and Hocheon Yoo; Gachon University, Korea (the Republic of)

As the frequency of fires has increased in recent years, the demand for efficient fire monitoring systems has increased. To realize sensitive and wide-range fire monitoring, flame detection based on Ultraviolet-C (UVC) photodetector can be considered a promising approach. Here, we demonstrate a self-powered and real-time flame detector by means of calcium titanate perovskite (CTO) and nickel oxide (NiO) heterostructure. The proposed UVC photodetectors achieve a high solar-blinded rejection ratio (at UVC light/ UVA light) of 80.22 A/A and an on/off switching current ratio of 120 A/A under UVC light and dark states. Furthermore, we emphasize that significantly robust and stable operation of long-term stability is accomplished due to the clean interface between CTO and NiO junction. The proposed UVC photodetectors maintained their UVC sensing operation behavior unchanged even for more than 500 days. Comprehensive investigation including UV-visible spectrophotometer, X-ray photoelectron spectroscopy, capacitance-voltage analysis, atomic force microscope, scanning electron microscope, and electrochemical impedance spectroscopy was performed, which shed light on the operation mechanism in the proposed UVC photodetectors. Furthermore, by controlling the junction properties between the two materials, this study obtained a photovoltaic effect that allows the device to operate at zero voltage bias conditions without external bias. Finally, this study successfully demonstrates real-time flame detection using the proposed CTO and NiO heterostructure. During the test, the UVC photodetectors exhibited a systematic current change in response to the flame intensity variation, enabling quantitative analysis of fire monitoring, and presenting a new possibility for prompt and accurate fire detection.

10:45 AM EQ05.10.03
Optical Control and *In Situ* Detection of Trapped Carrier Dynamics in $BiVO_4$ Photoanodes Zhu Meng[1], Shababa Selim[1], Ernest Pastor[2], Andreas Kafizas[1], James R. Durrant[1] and Artem Bakulin[1]; [1]Imperial College London, United Kingdom; [2]Institut de Ciències Fotòniques, Spain

In solar water splitting cells, the photon-to-current conversion efficiency is often governed by carrier transport in photoelectrodes. While defects in metal oxides are widely known to play a role in this transport, their multifactorial influence on charge dynamics in photoelectrochemical cells remains largely unexplored. Here we apply a novel 'pump-push-photocurrent' (PPPC) approach to observe the trapping and de-trapping of carriers at intrinsic oxygen vacancies (OVs) of the photoanode bismuth vanadate ($BiVO_4$). In PPPC, re-activating carriers in OV state with near-IR light produces additional photocurrent, aiding electron extraction after de-trapping. We observe that carrier trapping in $BiVO_4$ first occurs on ~10 ns time scale, followed by ~20 ms delayed transport-assisted trapping. At the external biases below 0.8 V, OVs states directly affect the device photocurrent via carrier trapping and recombination. The recombination of OV-trapped carriers is suppressed at higher bias (> 1.0 V vs Pt) due to the better spatial segregation of electron and hole space charge layers. These observations show that external bias has multiple effects on device performance via oxygen vacancies, which can be instrumental for development of $BiVO_4$ photoanodes and photocatalyst materials.

A High-Throughput Approach to Determining Energy-Dependent Impact Ionization Probabilities Ryan N. Hall[1], Norbert Krause[2], Francois Ladouceur[1] and Fiacre Rougieux[1]; [1]University of New South Wales (UNSW), Australia; [2]Silanna Pty Ltd, Australia

Introduction
Impact Ionization plays a critical role in a wide range of devices, including avalanche photodiodes, LED devices, power transistors, and MOSFETS. Carrier generation by Impact ionization is also used in the contacts of emerging wide bandgap optoelectronic devices [1] to efficiently inject carriers, mitigating the doping challenges associated with conventional wide bandgap material systems.

The impact ionization probability is a critical parameter in the search for novel wide-bandgap materials. However, current impact ionization models can be poorly predictive, often assuming a parabolic band dispersion relation or failing to take advantage of recent advances in ab-initio electronic structure calculations. On the other hand, advanced models require the calculation of the transition matrix elements which comes at an immense computational cost, precluding high-throughput studies for material screening and prediction.

For high-throughput material screening, there is a critical need for a fast and accurate model for the impact ionization threshold. In this study, we bridge this critical gap and develop a high-throughput computational method to calculate the impact ionization threshold as a function of the primary carrier momentum and from this, the energy-dependent probability of impact ionization for ultra-wide bandgap semiconductors.

Methodology
The threshold for impact ionization was determined by minimizing the energy of the primary carrier subject to energy and momentum conservation. The band structures were acquired from the Materials Project database, enabling a high-throughput computational study of up to 76,000 materials. These band structures were computed via density functional theory (DFT) using the generalized gradient approximation (GGA). A scissor correction was first applied to the Materials Project band-structure data, utilizing experimental bandgaps where available, and by linear regression of the GGA error elsewhere. The band-structures were then interpolated in k-space, applying the symmetry operations of the associated Brillouin zone (BZ), before implementing interpolation by radial basis functions (RBF), using a basis set of cubic splines. The minimization problem comprises nine continuous variables (the k-point coordinates for each of the non-primary carriers) and three discrete variables; their band indices. Minimization was achieved through brute force over the band combinations and by basin-hopping with sequential least squares programming (SLSQP) for the continuous variables. The impact ionization threshold was computed for primary carriers along high symmetry k-space paths and additionally for some number of random primary momenta (k-points) within the first BZ for k-space interpolation. An energy-dependent impact ionization density of states was computed by integrating the states where the threshold is less than the given carrier energy over the constant carrier energy surface of the band structure. Dividing this by the total DOS gives the energy-dependent impact ionization probability.

Results
In this work, we developed a new model to rapidly calculate the impact ionization threshold of wide bandgap semiconductors based on DFT-calculated band structures. We validate the impact ionization thresholds against measurements in the literature showing that the impact ionization probability is a reliable estimator for the impact ionization scattering rate for high-throughput material screening and prediction. We then use our model to calculate impact ionization probability curves for several conventional ultrawide bandgap material systems including GaN, AlN, β-Ga2O3, and MgO, and show a range of

interesting asymmetry in electron/hole impact ionization rates that could be exploited to make more efficient optoelectronic devices.

High-Resolution Mapping of Strain Partitioning and Relaxation in InGaN/GaN Nanowire Heterostructures Bumsu Park[1,2], Jongil Kim[3], Christoph T. Koch[4], Martin Wolz[5], Lutz Geelhaar[5] and Sang Ho Oh[1,3]; [1]Sungkyunkwan University, Korea (the Republic of); [2]CEMES-CNRS, France; [3]KENTECH, Korea (the Republic of); [4]Humboldt-Universität zu Berlin, Germany; [5]Paul-Drude-Instit für Festkörperelektronik, Germany

Growing an $In_xGa_{1-x}N$/GaN multi-quantum well (MQW) heterostructure in nanowire (NW) form is expected to overcome limitations inherent in conventional light-emitting diodes (LED) based on the planar heterostructure. The epitaxial strain induced in an $In_xGa_{1-x}N$/GaN MQW heterostructure can be relaxed through the sidewalls, which is beneficial to LEDs because a much larger misfit strain with higher indium concentration can be accommodated with reduced piezoelectric polarization fields. The strain relaxation, however, renders a highly complex three-dimensional strain distribution within the small volume of the heterostructure.

Here we show that combined use of scanning transmission electron microscopy (STEM) and dark-field inline holography (DIH) strain mapping can comprehend the strain distribution within an axial $In_{0.3}Ga_{0.7}N$/GaN MQW heterostructure embedded in GaN NWs by providing the complementary strain maps which can cover the entire NW, and reveal fine details near the sidewalls. The InGaN QDs feature a faceted hollow dome shape, surrounded by an approximately 10 nm-thick epitaxial GaN shell layer. To quantitatively evaluate the strain partitioning and relaxation, FEM strain mapping was carried out in a systematic way by changing the geometry and shape of the InGaN QDs and also with including the GaN shell.

The overall strain distribution within the NW heterostructure is reproduced well by the geometric phase analysis (GPA) of high-resolution STEM images. Due to the strain partitioning between the InGaN QD and the GaN QB, the compressive in-plane strain in InGaN is reduced but the tensile strain arises in the GaN. The DIH strain mapping allowed the details of local strain distribution to be distinguished with much higher spatial resolution and strain sensitivity. The DIH in-plane strain map shows that the strain across the InGaN QDs is not uniform but tensile and compressive strain alternates in the GaN QB and the GaN shell, respectively, which is consistent with FEM calculations. In addition, while exhibiting almost similar in-plane strains within the QD central plate, interestingly, the out-of-plane strain profiles show a locally different distribution in the growth direction. The piezoelectric polarization calculated using the measured in-plane as well as out-of-plane strain indicates a significant reduction in the piezoelectric field compared to that of an equivalent planar heterostructure. The presence of the opposite sign of strain in the GaN QB and shell across the narrow inclined InGaN facet induces a dramatic reduction of the polarization charges and, therefore, a reduced piezoelectric field. This moderated piezoelectric field at the side facet of the InGaN QD can change the direction of the local piezoelectric field and increase the internal quantum efficiency.

11:30 AM EQ05.10.06
Electronic Structure at β-Ga_2O_3(001)/NiO(001) Interface—A Computational Study Cheng-Wei Lee[1,2], Andriy Zakutayev[2,1] and Vladan Stevanovic[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

β-Ga_2O_3 is a promising ultra-wide band-gap oxide (E_g ~4.9 eV) due to its excellent n-type performance. Furthermore, high-quality and low-cost bulk single crystal can be grown from melt, making it particularly attractive for device fabrication and commercialization. However, no *p*-type doping has been realized for β-Ga_2O_3, preventing realization of homoepitaxial *p-n* junction devices. Instead, heterojunctions are needed. β-Ga_2O_3(001)/NiO(001) heterojunction was recently shown to have better rectifying performance than β-Ga_2O_3/Ni Schottky diodes[1]. Experimental J-V curve indicates existence of interfacial states, but their identity remains unclear. To study the electronic structure of the heterojunction, we utilize the structure-matching algorithm (actual atom-to-atom matching algorithm) developed by Therrin *et al.*[2] and found that the experimentally observed orientations of (001) and (111) are among the top three NiO surfaces that best match the Ga_2O_3 (001) substrate. Moreover, another critical challenge of modeling such heterojunction lies on the selection of proper XC functionals that can correctly describe the band gaps of β-Ga_2O_3 and antiferromagnetic rock-salt NiO simultaneously. Hybrid functionals like HSE06 are known to reproduce the band gap of β-Ga_2O_3 when an adjusted mixing parameter (α=0.32) is used. But HSE06 requires a significantly smaller mixing parameter (α=0.19) to reproduce the band gap of NiO (~3.5 eV). The nature of homogeneous screening for HSE06 makes it challenging to find a mixing parameter that can describe the electronic structure of the whole heterojunction correctly at the same time[3]. For NiO, the CBM is mostly composed of localized Ni *d* orbital, which can be adjusted via on-site potential[4] while keeping the mixing parameter that reproduces the band gap of Ga_2O_3 well. In this talk, we will show that the HSE06+U method can simultaneously reproduce the respective band gaps of β-Ga_2O_3 and NiO within the interface. As a result, we can identify in-gap interfacial states that affect the band alignment and the position of the Fermi energy. We can also extract the differences in valence and conduction band edges, which differ from values estimated using the electron affinity rule. Our findings reveal the potential interfacial defects and provide the basis for future improvement on its rectifying performance.

Ultra-Thin Metal Capping Layer-Induced Oxygen Deficient Interface for Visible Light Absorption in Indium–Gallium–Zinc Oxide Phototransistors Kyungmoon Kwak, Kyungho Park, Hyukjoon Yoo, Jusung Chung and Hyun Jae Kim; Yonsei University, Korea (the Republic of)

With the advent of next-generation technologies such as the internet of things (IoT) and artificial intelligence (AI), broadband photo sensor technology is considered one of the most significant sensors to recognize vast amounts of the optical signal and allow users to interact with surroundings anywhere via an optical signal. Recently, amorphous oxide semiconductor (AOS) thin-film transistors (TFTs) have gained considerable attention as promising candidates for photosensors due to their excellent characteristics, such as high field-effect mobility, low off-current, high transparency, and large-scale deposition capability. Among AOS materials, indium-gallium-zinc-oxide (IGZO) based TFTs exhibit superior performance and stability. However, there is a critical limitation in detecting visible light by an IGZO phototransistor because of its wide band gap of more than 3 eV. To solve this issue, studies have been reported to broaden the absorption wavelength by adopting an additional absorption layer, such as nanowires, quantum dots, and nanoparticles. However, these studies have the drawbacks of requiring complicated processes and not being suitable for commercialization.
In this research, we propose IGZO phototransistors with an ultra-thin aluminum capping layer (UACL). The UACL is used to generate subgap states in the interface between IGZO and the UACL that allow visible light to be absorbed. To fabricate IGZO phototransistors with the UACL, the IGZO channel was deposited by radio frequency (RF) magnetron sputtering on a SiO_2 (120 nm)/Si substrate. The length and width of the channel were defined as 150 and 1,000 μm, respectively. After the channel layer deposition, indium-tin-oxide (ITO) source and drain electrodes were deposited by RF magnetron sputtering

via shadow mask. Sequentially, the UACL was finely patterned between the source and drain electrodes by RF magnetron sputtering with RF power of 80 W. The deposition time and the shadow mask width of the UACL were adjusted from 0 to 50, 70, 90 seconds, from 50 to 75, 100 μm, respectively. After all deposition processes, IGZO phototransistors with the UACL were simultaneously annealed at 300°C for 1 hour in the air.
The optoelectronic characteristics of IGZO phototransistors with the UACL were enlarged to absorb visible light by modulating the thickness and width of the UACL. It was confirmed that the IGZO phototransistors with the UACL had the highest photoresponse characteristic at the UACL thickness of 10 nm and width of 50 μm. Specifically, we achieved IGZO phototransistors with photoresponsivity of 651.55 A/W, photosensitivity of 1.08×10^8, and detectivity of 1.19×10^{12} Jones under 5 mW/mm^2 of green visible light using. The reason for improved optoelectronic characteristics of IGZO phototransistors with the UACL could be assumed that oxygen vacancies and subgap states are generated at the interface between the IGZO layer and the UACL. In general, aluminum (Al), a material with a low standard electrode potential (SEP) and strong oxygen affinity, showed the characteristic of binding to oxygen ions. Therefore, the UACL attracts oxygen ions in the IGZO and generates oxygen vacancies that serve as subgap states. For this reason, IGZO phototransistors with the UACL enable to absorb broadband wavelength over UV visible light. The aforementioned mechanism of the subgap states generated in the interface between the UACL and IGZO is also discussed along with X-ray photoelectron spectroscopy (XPS) and technology computer-aided design (TCAD) simulation analyses. Finally, we revealed that optoelectronic characteristics of IGZO thin film are easy to control substantially depending upon the thickness and dimension of the UACL. This controllability is critical for expanding the range of applications and fine-tuning performance from phototransistor to photo memory, such as neuromorphic devices that use persistent photoconductivity (PPC).

Site-Selective Atomic Layer Deposition for Surface Defect Amelioration Alex Martinson; Argonne National Laboratory, United States

While ALD is most commonly employed in uniform conformal growth, more selective precursors and processes may allow for more precise synthetic strategies including targeted reaction at subtly unique surface sites including those that lead to electronic defects. The adsorption free energies for molecular and dissociative adsorption of H_2O on TiO_2 and In_2O_3 were calculated to evaluate this strategy as a viable route to step edge and oxygen vacancy selectivity. We predict that selective hydroxylation is possible on several step edges and vacancy sites and further computationally evaluate three metalorganic ALD precursors for their compatibility with the selective hydration strategy. Experimental evidence for delayed nucleation of ALD on rutile (001), (110), and (100) TiO_2 single crystals corroborates predictions of surface dehydration that enables site-selective synthesis.

Predicting Thermochemistry and Stability of Metal/Oxide Interfaces Cheng-Wei Lee[1,2], Andriy Zakutayev[2,1] and Vladan Stevanovic[1,2]; [1]Colorado School of Mines, United States; [2]National Renewable Energy Laboratory, United States

Assessing thermochemical stability of metal (and other) contact materials with wide-gap oxides is relevant for device design and fabrication. Experimental databases of standard formation enthalpies can be used for this purpose but are mostly limited to binary oxides. On the other hand, computational databases include not only the binary but also most of the multi-component compounds documented in ICSD and beyond. Building on these and using β-Ga_2O_3 as an example, we perform thermochemical stability analysis based on one of the existing computational databases (NREL MatDB[1]) to predict the stability of metal/β-Ga2O3 interfaces. β-Ga_2O_3 has great n-type performance as power electronics and electron affinity (EA) around 4.0 eV. Based on the Schottky-Mott rule, metals with work functions (WF) around 4.0 eV will be candidates for Ohmic contacts for β-Ga_2O_3. From the stability analysis, we found that Cd, In, Sn, Tl, Pb, and Bi are stable β-Ga_2O_3 and the difference in WF from 4.0 eV is ≤ 0.3 eV. But we also notice that these metal candidates have low melting temperatures (<400 °C) and require very low oxygen partial pressure ($<10^{-10}$ atm) to remain thermochemically stable with β-Ga_2O_3. Our results are also consistent with recent experimental findings[2] that the commonly used Ti contact is not stable with β-Ga_2O_3 at elevated temperature (~400 K). To generalize our results to other oxides, we found a correlation between the metal WF and the formation enthalpy of its oxides: Smaller the WF in magnitude (closer to vacuum level), larger the formation enthalpy per oxygen in magnitude. Such correlation suggests that if a metal oxide's EA is smaller or close to the WF of its corresponding metal, other metals with WF close to its EA will likely oxidize in contact with the metal oxide. This suggests that an alternative approach beyond the Schottky-Mott rule is generally needed to select a stable ohmic contact with wide-gap oxides.

Tunable Bandgap in Molecular 2D Conductor Composites Raphael Pfattner[1,2], Jinghai Li[1], Elena Laukhina[2], Rossella L. Zaffino[1], Nuria Aliaga-Alcalde[1], Marta Mas-Torrent[1,2], Vladimir Laukhin[1], Jaume Veciana[1,2] and Sergi Riera-Galindo[1]; [1]Materials Science Institute of Barcelona (ICMAB-CSIC), Spain; [2]Networking Research Center on Bioengineering, Biomaterials and Nanomedicine (CIBER-BBN), Spain

The first BEDT-TTF=bis(ethylenedithio)-tetrathiafulvalene based quasi two-dimensional organic superconductor β-(BEDT-TTF)$_2I_3$ was reported back in 1984.[1] Soon it became clear that ion radical salts derived from BEDT-TTF exhibit tunable electronic band structures. Therefore, such molecules are excellent building blocks for engineering a rich and diverse family of organic crystalline metals and semiconductors. Such systems can be further tuned by choosing the nature of the IRSs enabling high sensitivity towards strain, pressure, humidity, temperature or even contact-less radiation sensing *i.e.* bolometers.[2-4] Composites exhibit unique synergistic properties emerging when components with different properties are combined. The tuning of the energy bandgap in the electronic structure of the material allows designing tailor-made systems with desirable mechanical, electrical, optical, and/or thermal properties.[5] Here, we discuss an emergent insulator−metal transition at room temperature in thin-films comprised of polycarbonate/molecular-metal composites. Temperature-dependent resistance measurements allow monitoring of the electrical bandgap, which is in agreement with the optical bandgap extracted by optical absorption spectroscopy. The semiconductor-like properties of our films, made with bis(ethylenedithio)-tetrathiafulvalene (BEDT-TTF or ET) α-ET_2I_3 (nano)microcrystals as two-dimensional molecular conductor on one side and insulator polycarbonate as a second ingredient, are attributed to an emergent phenomenon equivalent to the transition from an insulator to a metal. This made it possible to obtain semiconducting films with tunable electrical/optical bandgaps ranging from 0 to 2.9 eV. A remarkable aspect is the similarity close to room temperature of the thermal and

mechanical properties of both composite components, making these materials ideal candidates to fabricate flexible and soft sensors for stress, pressure, and temperature aiming at applications in wearable human health care and bioelectronics.

Interface Engineering for Enhancing the Performance of Perovskite and Sb2SSe3 Solar Cells Lydia H. Wong; Nanyang Technological University, Singapore

In this talk, I will present our group's efforts in enhancing the performance of perovskite solar cell by interface engineering. In the first example, Cu-S and Al-CuS is used as hole transporting layer and found to enhance the stability of perovskite solar cell due to the Pb-S bond at the interface. In the second example, SnO/CdS electron transporting layer is shown to facilitate directional growth of the higher mobility [hk1] planes of $Sb_2(S,Se)_3$, resulting in power conversion efficiency of >9%.

8:30 AM *EQ05.12.02
High Performance Si and Cu(In,Ga)Se_2 Tandem Solar Cells Based on Wide-Bandgap Perovskites Prepared with Anion-Engineered 2D Additives
Daehan Kim[1], Passarut Boonmongkolras[1], Hojin Lee[1], Inyoung Jeong[2], Kihwan Kim[2] and Byungha Shin[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Korea Institute of Energy Research, Korea (the Republic of)

To reach ultrahigh efficiency beyond the Shockley-Queisser limit for single-junction devices, there have been growing interests in applying a perovskite top cell in tandem with a Si or Cu(In,Ga)Se_2 (CIGS) bottom cell. The ideal bandgap for the tandem configuration is ~1.67 to 1.75 eV for the top cell and 1.12 eV for the bottom cell, which, fortuitously, is the bandgap of both Si and CIGS. The bandgap of perovskites can be tuned by (partial) replacement of iodine anions with bromine or chlorine. However, the replacement of I with Br by more than 20%, which is necessary to enlarge the bandgap to ~1.7 eV, leads to stability issues under illumination through phase separation that forms I-rich and Br-rich structures. One approach to stabilize the perovskite is to create a two-dimensional (2D) phase in which sheets of $[PbX6]^{2-}$ octahedra are separated by an excess number of long-chain molecules that act as a passivation agent. While most of the recent studies have focused on the cation components of the 2D additives, we developed a 2D-3D mixed wide bandgap (1.68 eV) perovskite using a mixture of thiocyanate (SCN) with the more conventional choice, iodine. Through a careful application of atomic resolution transmission electron microscopy, we demonstrated that electrical and charge transport properties as well as the physical location of 2D passivation layers can be controlled with anion engineering of the 2D additives. This approach not only improved device performance but also extended light stability. For a perovskite device, we achieved a PCE of 20.7% that retained > 80% of its initial efficiency after 1000 hours of continuous illumination in working conditions. Taking advantage of the highly efficient and stable wide bandgap perovskite, we have achieved a power conversion efficiency of 26.7% from monolithic two-terminal Si/perovskite tandem solar cells and over 23% from monolithic two-terminal CIGS/perovskite tandem solar cells, the integration details of which will be discussed.

9:00 AM EQ05.12.04
Controllable Aggregation of Conjugated Polymer Monolayer—From Field-Effect Transistors to Integrated Circuits Mengmeng Li; Institute of Microelectronics, Chinese Academy of Sciences, China

In spite of their great potentials in bottom-up organic electronics, it is challenging to fabricate conjugated polymer monolayer field-effect transistors due to intricate crystallization and film formation of conjugated polymers. Here, we demonstrate transistors based on a single molecular layer of a conjugated polymer. The resulting polymer monolayer transistors are highly reproducible and exhibit field-effect mobilities reaching 3 $cm^2 V^{-1} s^{-1}$. The high performance is attributed to the strong interactions of the polymer chains present already in solution leading to pronounced edge-on packing and well-defined microstructure in the monolayer. The high reproducibility enables the integration of discrete unipolar polymer monolayer transistors into inverters and ring oscillators. Real logic functionality has been demonstrated by constructing a 15-bit code generator in which hundreds of self-assembled polymer monolayer transistors are addressed simultaneously. Our results open prospective pathways for bottom-up organic electronics.

9:15 AM EQ05.12.05
Lowering in Resistivity and Ultra-Flattening of AZO Thin Films on Cyclo-Olefin Polymer Substrates via Substrate-Surface Modification for Flexible Optoelectronics Tomoaki Oga[1], Ryoya Kai[1], Hisashi Miyazaki[2], Satoru Kaneko[3,1], Akifumi Matsuda[1] and Mamoru Yoshimoto[1]; [1]Tokyo Institute of Technology, Japan; [2]National Defense Academy, Japan; [3]Kanagawa Institute of Industrial Science and Technology, Japan

ZnO and Al-doped ZnO (AZO) thin films can achieve relatively low resistivity even on amorphous substrates such as oxide glasses. Therefore, in combination with flexible transparent polymer substrates, these conducting thin films are expected to be used in wearable or flexible optoelectronic devices. The thermoplastic cyclo-olefin polymer (COP) used in this study is promising as a flexible substrate for wearable optoelectronics due to its very low moisture absorption, high transparency, and relatively high grass transition temperature (about 150°C), in contrast there are concerns about its thermal properties and surface roughness in comparison with oxide substrates. It might be useful for the growth of highly crystalline oxide thin films on polymeric substrates to modify of the polymer substrate surface to control oxide nucleation and growth direction. It might be useful to modify the polymer substrate surface for growth of highly crystalline oxide thin films on polymer substrates, leading to control of oxide nucleation and growth direction at low temperatures applicable for polymer materials. So far, we reported the atomic-scale patterning on the polymer surfaces having 0.3 nm-high atomic-steps and ultra-flat terraces, by applying thermal nanoimprinting using atomically stepped sapphire (α-Al_2O_3) molds [1]. Significant decrease in the surface roughness and crystallinity improvement was found for the ZnO thin films deposited on the surface-morphology-controlled polymer substrates subject to

nanoimprinting [2]. The insertion of an oxide buffer layer on the polymer substrate will be expected to promote oriented crystal growth of ZnO thin film deposited on it. In this study, we investigate the influence of the oxide buffer layer inserted on the ultra-flat polymer substrate upon the crystal growth and electrical property of ZnO thin films in pulsed laser deposition (PLD) at room-temperature.
Firstly, the surface topography of COP sheets used as the substrates was modified by thermal nanoimprinting (2 MPa, 180°C, 5 min, 10^3 Pa) using a sapphire mold with a 0.3 nm-high atomic step and terrace pattern, followed by PLD using a KrF excimer laser (λ=248 nm, d~20 ns) to form oxide buffer layers such as Al_2O_3. Subsequently, Al-doped ZnO (AZO; Al: 2 wt%) thin films (t~200 nm) were grown at RT by PLD under O_2 gas at 10^{-3} Pa. The AZO thin films grown on the surface-pretreated COP substrates showed very smooth surface without irregularities. The root mean square roughness in 3 μm squares of the AZO thin film on the pretreated COP substrate was reduced from 1.3 nm for the sample on the untreated substrate down to 0.4 nm. The XRD analysis of the diffraction peak attributed to AZO (001) indicated that the crystallinity and growth orientation of AZO thin films on the surface-pretreated substrate were clearly improved compared to the sample grown on an untreated COP substrate. The electrical resistivity of the AZO thin films deposited on the surface-modified COP substrates was decreased to 2.8 x 10^{-4} Ωcm, approximately 30% lower than the films on the untreated substrates. Thus, physical and chemical pretreatments of COP substrate surfaces improved surface smoothness and electrical properties of AZO thin films even on the polymer substrates.

First Principles Phase Diagram Calculation and Theoretical Investigation of Electronic Structure Properties of $ZnO_{1-x}Se_x$ for Photoanode Applications Arini Kar, Balasubramaniam Kavaipatti and Dayadeep S. Monder; Indian Institute of Technology Bombay, India

Terminal solid solutions in the $ZnO_{1-x}Se_x$ system ($0 \le x \le 0.15$, $0.95 \le x \le 1$), exhibit extreme bandgap reduction attributable to band anti-crossing (BAC). In this work, we perform a theoretical investigation of extreme alloying in this system ($0 \le x \le 1$). The temperature-composition phase diagram of $ZnO_{1-x}Se_x$ is obtained via cluster expansion method and Monte Carlo simulations. For $0 \le x \le 0.15$, a solid solution in the wurtzite structure and for $0.8 \le x \le 1$, a solid solution in the sphalerite structure is obtained. The alloy system exhibits a miscibility gap in the range $0.15 \le x \le 0.8$. Only the solid solutions are seen to obey bandgap reduction predicted by BAC. The band gap of the alloys, calculated using the delta-sol method shows a bowing behaviour as predicted by the BAC model. Difference in the electronegativities of O and Se atoms in the lattice leads to hybridization of O-2p and Se-4p electronic states. Interaction between these electronic states also leads to a split in the valence band edge at O-rich end and a split in the conduction band edge at the Se-rich end. The effective mass, estimated from the density of states, of holes at the O-rich end and that of electrons at the Se-rich end, increases with alloying. These fundamental insights will help in employing suitable alloy compositions for optimal photocurrent density when these materials are used as photoanodes.

Metal Nanostructure Embedded ITO Deposition and Modified Top Transparent Electrode for Emerging Thin-Film Photovoltaics Ananta Paul, Vikas Sharma, Saurabh Gupta, Sudhanshu Mallick and Dinesh Kabra; IIT Bombay, India

The conventional structure of transparent devices is finished with metal oxide as a sputtering damage protection layer and top electrode in general Indium doped tin oxide (ITO). The geometry is designed and investigated considering the inverted solar cell structure (PIN). The work considered is to modify this oxide-electrode junction with the insertion of ultrathin metal in between tin oxide and ITO. In this study, we investigated the effect of process temperature and different metal insertions on the performance of SnO_2/metal (Al/Au/Ag)/ITO (SMI) multilayer film. The damage protection layer SnO_2 is prepared by atomic layer deposition. The thermal evaporation system evaporated the metal. The top ITO layer is deposited by RF magnetron sputtering system at different temperatures (25°C, 50°C, and 100°C). Transparent tin oxide SnO_2/metal (Al/Au/Ag)/ITO (Hybrid) multilayer electrodes have been prepared on conventional soda-lime glass substrates. The thickness of SnO_2, M (Al/Au/Ag), and ITO metal films in the multilayered structure was constant at 10, 1, and 200 nm, respectively. The hybrid multilayer electrode films' structural, electrical, and optical properties are investigated. The variation of transmittance and sheet resistance values are dependent on the intermediate metal layers (Al/Ag/Au) and can be tuned accordingly. These hybrid films show a very high average transmittance of >75% in 300 to 1200 nm and roughness below or average 3 nm. With the observation, we can state that we can tune the electrode properties such as transparency in a particular wavelength and control the electrical conduction by controlling the mobility and carrier number.

UV Light Blocking and Conversion by Porous Europium-Doped Titanium Dioxide (TiO2-Eu) Thin Films for Potential Protection of Photovoltaic Devices Kamila Zhumanova and Timur Atabaev; Nazarbayev University, Kazakhstan

In recent years, transparent thin films capable of screening and converting UV photons into visible spectrum gained significant interest in the protection of photovoltaic devices. We investigated the optical properties and UV screening capability of europium-doped titanium oxide (TiO_2-Eu) thin films deposited by the spin-coating method from a solution precursor for the first time in this study. We showed that TiO_2-Eu thin films demonstrate europium concentration-dependent optical properties, and the quantum yield (QY) of the optimized sample was found to be ~ 10.2 %. Transmittance and photoluminescence measurements suggested that TiO_2-Eu thin film can effectively block UV photons (~ 30.5 % at 320 nm) at glass substrate and convert them to red emission thanks to $^5D_0 \rightarrow {}^7F_j$ (j = 0, 1, 2, 3, and 4) Eu (III) electronic transitions. Photodegradation experiments with Methylene blue (MB) dye revealed that TiO_2-Eu thin films offer better UV protection as compared to uncoated samples. We strongly believe that porous TiO_2-Eu thin films can be effectively utilized as a UV blocking and light conversion coating.

Spin Coated Indium Tin Oxide for Application as a Transparent Superconductor in Quantum Devices Madison S. King[1], Emma K. Batson[2], Karl Berggren[2] and Stephanie Hurst[1]; [1]Northern Arizona University, United States; [2]Massachusetts Institute of Technology, United States

The use of solid-state qubits in quantum technologies has created a need for efficient electro-optical transduction to avoid loss that comes with transmitting data at microwave frequencies over optical fibers in a quantum network [1]. Through the integration of superconducting electronics and quantum photonics, efficient transduction and read out of qubits can be achieved. The use of a transparent superconducting material is ideal to avoid efficiency loss in these circuits due to photon absorption. It has been demonstrated that indium tin oxide (ITO), a transparent semiconductor, behaves as a superconductor with a transition temperature (T_c) between 2 – 4 K when doped to a charge carrier concentration of 10^{21} cm^{-3} [2, 3]. This work is a part of collaborative effort to characterize the structure, composition, and electro-optical properties of superconducting ITO thin films prepared by two different methods. Our prior work has shown that commercially available ITO can be electrochemically reduced, permitting superconductivity. This process has been found to generate a rough nanoparticle layer on the surface of the ITO thin film [4].
Here we present the characterization of ITO thin films with applications as a transparent superconductor prepared by a spin coating method. Atomic force microscopy (AFM), scanning electron microscopy (SEM), and X-ray photoelectron spectroscopy (XPS) measurements provide details on surface and cross-section characteristics of the ITO thin films. The transparency of the thin films has been quantified through ellipsometry along with UV-visible spectroscopy and their T_c values determined.

Enhanced Electro-Thermal Properties of Gallium Doped Zinc Oxide (GZO) Thin-Films Transparent Heater Using 3D Printed Mask Technique
Jasmine Beckford, Makhes Behera, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

There is a growing popularity of incorporation of transparent conducting oxide in domestic applications such as car defrosters, smart windows, and other devices. We fabricated and investigated the different properties of thin film transparent heaters (TFTH) which are made by a 3D printed mask. Gallium doped zinc oxide (GZO) transparent conducting oxide thin film is used as active material and deposited on glass substrate via pulsed laser deposition (PLD) technique. The thin films are ultra-smooth in nature and displayed excellent structural, electrical, optical, and thermal properties. The temperature dependent resistivity is measured using linear four probe methods, and the samples are highly conducting and showed low sheet resistance values. Optical transmission spectra revealed that the samples exhibit high optical transparency value of (>85%). These TFTH also demonstrated excellent joule heating effect. GZO based TFTH performed a consistent joule heating effect for many repeatable measurements with temperature reaching over 50 °C with a low input voltage of 8 V. These findings are encouraging for the use of GZO as a transparent conducting oxide material for applications in low-cost optoelectronics.

Electro optic (EO) polymers containing nonlinear chromophore and polymer matrix have attracted great attention due to their large EO activity. Versatile optical devices based on EO polymers like optical switch, optical modulator and so on are already reported. Compared to 1310 and 1550 nm wavelength, the EO activities at the shorter end of near-infrared range (from 800 nm to 1000 nm) for short-distance or frees-pace optical interconnects have seldom been studied due to the challenge of absorption band. The work here provides a systematic study on how the molecular engineering affects the properties of these EO polymers, as well as photonic devices. By doping chromophores up to 50 wt%, the electro-optic coefficient as a function of the concentration is examined. To suppress intermolecular interaction at higher loading concentration, site isolating groups are attached to the chromophores. Along with guest host polymers, covalently bonded polymers are also probed. They show much higher long-term temperature stability compared to guest host polymers, which is a critical figure of merit for high-density photonic device array.
The advances in EO polymers make nanophotonic devices wide-band, high frequency and low energy consumption. Optical filter is an indispensable tool for nano-optic platform. Within our cooperation, the EO polymer as active material is integrated between thin-film mirrors which are prepared by ion beam sputtering. The Fabry-Perot interferometer alike device shows a promising frequency filtering and different wavelength range compared to silicon photonics.
The aim of this research is to study nanophotonic EO devices starting from theoretical material design, and up to device characterization. The material data bank built by us offers a good base for optical devices over a wide range of wavelength and under extreme working conditions.
Key words: electro optic polymer, chromophore, optical device.

High-Efficient Photoelectrochemical Water Splitting of the Three-Dimensional ZnO Nanostructure
Nanzheng Ji[1], Lingya Yu[2], Wenhan Cai[2], Chun-Yu Lee[1], Yongchun Xiao[1], Shujing Sun[1], Kun-Ching Shen[3] and Chenlong Chen[1]; [1]Chinese Academy of Science Fujian Inet, China; [2]Chinese Academy of Science Fujian Inst, China; [3]Fuzhou university, China

In recent years, ZnO has attained focus in water splitting applications due to the benefits of low cost, ease of fabrication, and high chemical stability. Here, we proposed a three-dimensional (3D) inclined ZnO nanowire structure via an Au catalyst-assisted vapor-liquid-solid method. This ZnO nanostructure exhibited better photoelectrochemical performance as compared with the ordinary 1D ZnO nanowires because of the increased area for the light-receiving and catalyst reaction. Furthermore, the 3D ZnO structure was doped with nitrogen using a post-annealing process, the photocurrent density of the *N*-doping ZnO was significantly increased from 1.68 mA/cm^2 to 2.82 mA/cm^2 at 1.23 V vs. RHE, and the photon-to-current conversion efficiency at 400 nm wavelength reached 7.3%. The strategy of appropriate *N*-doping can effectively increase carrier concentration of samples, and the carrier concentration of the sample annealed for one hour reaches the maximum of 6.54×10^{18}. In this study, the photoelectric properties of ZnO materials were considerably enhanced by constructing a 3D ZnO nanostructure and N doping.

"Slide-Tronics" Moshe Ben Shalom; Tel Aviv University, Israel

A ferroelectric system is presented, only two atoms thick. Its intrinsic electric polarization emerges once stacking diatomic hexagonal layers with parallel lattice orientations. Interestingly, the symmetry of these bilayer crystals translates a minute planner shift between the layers, by one inter-atomic spacing, to a vertical flipping of the structure and its out-of-plane polarization. Owing to the interfacially-confined charge redistribution in these systems, we named the phenomena interfacial ferroelectricity. I will discuss the origin and consequences of this confinement from a real and momentum space perspective and the unique polarization switching mechanism by domain wall sliding observed in our experiments.

High-Order van der Waals Superlattices and Artificial Quantum Solid Beyond Mechanical Exfoliation and Restacking Xiangfeng Duan; University of California-Los Angeles, United States

The advent of two-dimensional atomic crystals (2DACs) and van der Waals heterostructures (vdWHs) has inspired a new thinking on heterostructure construction beyond the limits of lattice matching requirement. However, the vdWHs explored to date have been largely limited to relatively simple systems with a small number of building blocks. The preparation of high-order vdW superlattices with a larger number of alternating units is exponentially more challenging due to the limited yield and scalability of the commonly used exfoliation-and-restacking strategy. Here I will discuss strategies to create high-order vdW superlattices (vdWSLs). First, by exploiting a capillary-force-driven rolling-up process, we show a series of synthetic VDWHs can be transformed into high-order vdWSLs with alternating atomic layers of widely variable material compositions, electronic band offset dimensions, chirality and topology. Alternatively, we further introduce a molecular intercalation approach to prepare a new family of hybrid superlattices consisting of alternating layers of covalently bonded 2D atomic layers and self-assembled molecular layers, which opens the door to exploit highly versatile molecular design strategies to tailor solid-state materials, enabling artificial materials with designable structural motifs and tunable electronic properties beyond the reach of conventional crystalline solids. We will particularly highlight a recent example of a new class of chiral molecular intercalation superlattices with robust chiral-induced spin selectivity.The formation of high-order vdW superlattices defines a rich artificial materials platform to unlock previously inaccessible physical limits and enable new device concepts beyond the reach of the existing materials.

Weyl Semimetal Phase in 2D Tellurium Under High Pressure Peide P. Ye; Purdue University, United States

Relativistic Weyl fermion quasiparticles in Weyl semimetal bring the electron's chirality degree of freedom into the electrical transport and give rise to various exotic phenomena. A topological phase transition from topological trivial phase to topological non-trivial phase offers a route to controllable topological electronic devices. Here, we report the Weyl semimetal phase in hydrothermally grown two-dimensional (2D) Tellurium (Te) induced by pressure (up to 2.47 GPa). The highly tunable chemical potential in 2D Te provides a comprehensive understanding of the pressure-dependent electron band structure. The pressure-induced insulator to metal transition, two-carrier transport, and the non-trivial π phase shift in quantum oscillations are observed in the 2D Te Weyl semimetal phase. Our work demonstrates the pressure-induced bandgap closing in inversion asymmetric narrow bandgap semiconductors and opens the door for the electronic transport study on the topological phase transition process.

Excitonic Three-Level System for Quantum Interference in Transition Metal Dichalcogenide Monolayers and Bilayers Jonas M. Bauer, Sebastian Bange, John M. Lupton and Kaiqiang Lin; Universität Regensburg, Germany

Combining atom-like quantum interference phenomena with optoelectronic devices has been a long-standing goal. Few solid-state systems exhibit such quantum interference effects like electromagnetically induced transparency (EIT). We have discovered a new excitonic species, the high-lying exciton (HX), in transition metal dichalcogenide monolayers with almost twice the band-edge A-exciton energy and with a linewidth as narrow as that of band-edge excitons [1]. The coincidence of such high-lying excitonic species at around twice the energy of band-edge excitons explains the efficient exciton-exciton annihilation in TMDC monolayers, and forms a three-level system that enables the excitonic quantum-interference phenomenon revealed in optical second-harmonic generation (SHG) [2]. High-lying excitons in bilayer WSe_2 can be widely tuned by twisting [3] and by the Stark effect, which gives control over the excitonic quantum interference and the corresponding optical nonlinearity. In a monolayer WSe_2 transistor device, an electrical gate controls both the oscillator strength and the detuning of the excitonic transitions and thus the Rabi frequency of the strongly driven three-level system, enabling excitonic quantum interference to be electrically switched on and off in a deterministic fashion.

Nonlinear Interactions of Dipolar Excitons and Polaritons in MoS_2 Bilayers Charalambos Louca[1], Armando Genco[2], Salvatore Chiavazzo[3], Thomas P. Lyons[1,4], Sam Randerson[1], Chiara Trovatello[2], Peter Claronino[1], Rahul Jayaprakash[1], Kenji Watanabe[5], Takashi Taniguchi[5], Stefano Dal Conte[2], David Lidzey[1], Giulio Cerullo[2], Oleksandr Kyriienko[3] and Alexander Tartakovskii[1]; [1]The University of Sheffield, United Kingdom; [2]Politecnico di Milano, Italy; [3]University of Exeter, United Kingdom; [4]RIKEN Center for Emergent Matter Science, Japan; [5]National Institute for Materials Science, Japan

Coherent superposition of light and matter allows for the realisation of half-light half-matter quasiparticles called polaritons. Nonlinear interactions between excitons strongly coupled to light are key for accessing quantum many-body phenomena in polariton systems[1]. Atomically-thin two-dimensional semiconductors provide an attractive platform for strong light-matter coupling owing to many controllable excitonic degrees of freedom[2]. Among these, the recently emerged exciton hybridization opens access to unexplored excitonic species, with a promise of enhanced interactions[3]. In this work [4], we employ hybridized interlayer excitons (hIX) in bilayer MoS_2 to achieve highly nonlinear excitonic and polaritonic effects. Such interlayer excitons possess an out-of-plane electric dipole as well as an unusually large oscillator strength [5]. The latter allows us to realise dipolar polaritons (dipolaritons) in bilayers in optical microcavities with large Rabi splitting. We observe coupling strengths comparable to monolayer intralayer excitons and as much as half of that of intralayer excitons in bilayers.

The dipolar nature of hIX and polariton states in MoS_2 homobilayers results in approximately 8 times stronger nonlinearity compared with the their monolayer intralayer exciton [6] counterparts. Namely, we observe saturation and blueshift at much lower exciton densities, which can be explained by the enhanced exciton-exciton coulomb interactions in this system.

We, also, find a further strong enhancement of interaction under simultaneous excitation of inter and intralayer excitons that share the same valence band. Specifically, we observe intralayer excitons blueshift while hIX redshift with the bleaching of hIX occurring at an order of magnitude lower densities than separate illumination. Thus, we report on an overall enhancement of the nonlinearity by nearly two orders of magnitude. Simultaneous excitation provides access to an unprecedented nonlinear regime which we describe theoretically by analysing the excitonic many-body physics and the inter-species cross interactions. We refer to this effect as hole-crowding, and note that, to our knowledge, it was never considered before, requiring specific conditions matched only in TMD bilayers. The presented insight into many-body interactions provides new tools for accessing few-polariton quantum correlations which are highly sought after for fundamental studies and applications in polariton logic networks .

The Axial Higgs Mode in RTe_3 Yiping Wang[1], Ioannis Petrides[2], Grant McNamara[1], Mofazzel Hosen[1], Shiming Lei[3], Yueh-Chun Wu[4], James L. Hart[5], Jun Yan[4], Di Xiao[6], Judy Cha[5], Prineha Narang[2], Leslie Schoop[3] and Kenneth Burch[1]; [1]Boston College, United States; [2]Harvard University, United States; [3]Princeton University, United States; [4]University of Massachusetts Amherst, United States; [5]Yale University, United States; [6]University of Washington, United States

Charge density wave (CDW) systems can host a variety of emergent modes whose properties are linked to a change or breaking of symmetry; a well studied example is the Higgs (amplitude) mode that breaks translational symmetry. Despite its close resemblance to superconductivity and first prediction in 1955, all CDW to date have revealed s-wave condensation with a scalar Higgs. Uncovering the symmetry properties of collective modes is challenging, usually necessitating very low temperatures and requiring going beyond typical spectroscopic or scattering techniques. Here, we present the study of room temperature Raman spectra of the CDW system RTe_3 (where R = La or Gd) and reveal the existence of an axial Higgs mode. We use a polarization-resolved inelastic scattering technique to obtain the Raman tensor associated to the Higgs mode, elucidating the axial vector representation (i.e. a pseudo-angular momentum) and the unconventional nature of the CDW in RTe_3.

Frank van der Merwe Manufacturing of Bilayer Graphene with 'Smart' Processes Haozhe Wang; California Institute of Technology, United States

While the number of exciting physical phenomena observed in bilayer graphene increases, a significant gap persists in transforming these discoveries into practical applications, owing to the small-scale samples obtained via top-down approaches. We realized a layer-by-layer (that is, Frank-van der Merwe) growth mode in large-scale bilayer graphene, with no island impurities, which is unprecedented in any van der Waals-stacked materials. Machine learning is adopted to assist spectroscopy, enabling the 'smart' characterization following the chemical vapor deposition. Rather than random sampling on large-area materials, we adapted K-means algorithms to analyze Raman mapping data for precise characterization of stacking order and layer number of graphene. After growth, a transfer is necessary to move bilayer graphene from the growth substrate to a destination substrate with a mandatory sacrificial support layer. This process induces residuals, wrinkles, and cracks, thus deteriorating 2D materials from their intrinsic properties. We utilized the Marangoni effect, also known as the 'tears of wine', to enable 'smart' transfer by building a surface tension gradient in transfer liquids. We demonstrate our autonomous Marangoni-flow transfer technique can transfer bilayer graphene without a support layer, resulting in residue-free bilayer graphene.

4:00 PM EQ06.02.09
Strong and Localized Luminescence from Interface Bubbles Between Stacked hBN Multilayers HaeYeon Lee[1,2], Soumya Sarkar[3], Kate Reidy[2], Abinash Kumar[2], Julian Klein[2], Kenji Watanabe[4], Takashi Taniguchi[4], James LeBeau[2], Frances M. Ross[2] and Silvija Gradečak[3]; [1]Columbia University, United States; [2]Massachusetts Institute of Technology, United States; [3]National University of Singapore, Singapore; [4]National Institute for Materials Science, Japan

Van der Waals (vdW) layered materials and their heterostructures exhibit extraordinary physical properties while readily allowing out-of-plane deformation, which is of great interest for flexible and conformal electronics. A unique approach to understand the role of mechanical deformation on optoelectronic properties of vdW materials is to take advantage of the bubbles that are formed during the fabrication of vertical vdW heterostructures. Potential applications of bubbles in vdW heterostructures in optoelectronics and photonics have been recently reported due to their unique structure, the resulting strain, and the pressure in the bubble (vdW pressure), however, have been limited to monolayers. Strain engineering of vdW multilayers should present new opportunities in optoelectronics since multilayers of vdW materials exhibit robust optical performance, their bending is different from that seen in a monolayer or in classical plate theory, and multilayers circumvent issues related to exfoliation and manipulation of monolayers.
Here, we demonstrate strong and localized luminescence in the ultraviolet region from interface bubbles between stacked multilayers of hexagonal boron nitride (hBN). Compared to bubbles in stacked monolayers, bubbles formed by stacking vdW multilayers show distinct mechanical behavior. We combine experimental measurements and theoretical modeling to elucidate geometry and strain across the bubble, providing insights into bending of vdW multilayers. We then demonstrate a novel approch to modify the bubble geometry by utilizing the polymeric material confined within the bubbles, resulting in strong luminescence and formation of optical standing waves. We observe a strong phonon-coupled luminescence locally from the hBN bubble regions and examine the origin of the optical emission. Our results open a new route to design and modulate microscopic-scale optical cavities in ultraviolet region with controlled dimensions *via* strain engineering in vdW materials, which we suggest will be relevant to both fundamental mechanical studies and stretchable optoelectronic and photonic applications.

4:15 PM EQ06.02.08
Magic-Angle Graphene for Highly Efficient Tunable 2D Photonic Surfaces and Waveguide-Coupled Modulators Tao Fang, Xiaoxin Wang and Jifeng Liu; Dartmouth College, United States

Tuning the refractive index of optical materials via external stimuli (e.g. electric field, temperature, etc.) has broad applications from optical communications to display technologies. While conventional semiconductor quantum well modulators can achieve a fast and reversible optical tunability, the refractive index change is small ($\Delta n, \Delta k << 0.1$). Phase change materials can achieve large $\Delta n > 1$, yet the response is much slower due to the phase transition rate limitation. Tunable 2D photonic surfaces provide a unique opportunity in their atomic thickness and a large refractive index change ($\Delta n, \Delta k > 1$) comparable to phase change materials, while simultaneously offering a response time even faster than conventional semiconductors, enabling unique opportunities in tunable photonic devices. Magic angle graphene (twisted bilayer graphene with the twist angle around 1.1°) is famous for its topological insulator and unconventional superconductivity behavior. However, until now, few studies have been conducted on its applications in photonics to benefit from its unique band structures.
In this research, we extract the optical conductivity and dielectric function of the magic angle graphene by tight-binding model and Kramers-Kronig relations. We then calculated the refractive index of the magic angle graphene at different Fermi levels upon electrical gating. Interestingly, while regular monolayer graphene changes from a semimetal ($n \sim k$) to a dielectric material ($n >> k$) upon gating at near infrared (NIR) spectral regime, magic angle graphene behaves in the opposite fashion in that its changes from a semimetal to a good metal ($n << k$). This behavior gives magic angle graphene a unique application prospective in photonics.
As a demonstration, we use finite element model to design magic-angle graphene based optical devices. We report 2D surface photonic modulators based on coupling between magic angle graphene and regular single-layer graphene to best utilize their opposite behavior upon electrical gating. This modulator can work both in reflective mode and transmission mode, and the former can be applied to efficient modulating retroreflectors for free-space optical communication and light detection and ranging (LiDAR) applications. With optimized parameters and dielectric materials in an optical slot-antenna coupled cavity (SAC), the broadband reflection difference in 1500-2000 nm wavelength range between the on and off states can reach 70%, with a low insertion loss of 0.7 dB and a high extinction ratio of 7 dB almost independent of incident angles. This performance far exceeds our previous design optimization of surface-incident modulator based on regular single layer graphene in a similar optical SAC structure, which only achieved an extinction ratio of 1.62 dB [1]. This device structure also enables a low driving voltage for free-space optical modulation, as opposed to their commercial bulk $LiNbO_3$ counterparts that require more than 100 V to drive [2].
Our second design is the magic-angle graphene on silicon waveguide electroabsroption modulator. This waveguide could work at the wavelength around 1550 nm with an on-off ratio larger than 14 (>11 dB extinction ratio) and transmission loss less than 0.013 dB. To increase the absorption difference, we compared slot waveguide vs. channel waveguide structures. According to the previous work on graphene coupled silicon waveguide electroabsroption

modulator, our device can work in a similar infrared region, but our simulation results showed a larger modulation 0.22 dB than their results 0.1 dB. Finally, the device concept for such large refractive change 2D photonic system may also extend to other 2D materials and other electromagnetic wave range. Currently, tunability of flat metalenses and other optical components is of great interest for these 2D surface photonic systems.

4:30 PM EQ06.02.07
Magnetotransport Properties of MBE-Grown $NiTe_2$ Zuzanna W. Ogorzalek[1], Bartlomiej Seredynski[1], Slawomir Kret[2], Wiktoria Zajkowska[2], Rafal Bozek[1], Mateusz Tokarczyk[1], Michal Baj[1], Michal Grzybowski[1], Wojciech Pacuski[1], Janusz Sadowski[1,2,3] and Marta Gryglas-Borysiewicz[1]; [1]University of Warsaw, Poland; [2]Institute of Physics, Polish Academy of Sciences, Poland; [3]Linnaeus University, Sweden

The recent discovery of topological semimetals (TSMs) with linear Dirac cone-shaped band dispersion, opened a new path of research in condensed matter physics. In some special TSMs, called type-II TSMs, the Dirac cone is strongly tilted as a result of broken Lorentz symmetry. As a consequence many peculiar physical phenomena, such as angle-dependent chiral anomaly [1], exotic superconductivity [2] and large, positive magnetoresistance [3] appear. Here we focus on the $NiTe_2$ which has recently been shown to be type-II Dirac TSM with Dirac nodes much closer to the Fermi level (EF) than in other type-II Dirac transition metal di-tellurides (TMDT), which opens possibility to exploit phenomena associated with Dirac carriers in transport [4]. There are a number of methods to obtain high quality crystalline TMDT materials including self-flux method [4-6] and molecular beam epitaxy [7]. The latter method is relatively novel and yet seems promising due to an in-situ monitoring of the growth process with reflection high energy electron diffraction.
In this paper, we present a study of the magnetotransport properties of MBE-grown $NiTe_2$ layers. Hall effect measurements were performed in magnetic fields up to 12 T and in temperature range from 300 K to 1.4 K. Samples were grown on semi-insulating GaAs (111)B, which provides the same crystal symmetry and the lattice parameter close to that of $NiTe_2$. The growth conditions were adjusted by the substrate temperature and modification of Ni and Te fluxes, which enabled variation of the room temperature resistivity by two orders of magnitude. The resistivity of the samples dropped when temperature was decreased, however the residual resistivity ratio stays relatively low, reaching 10 for the best samples. Possible scattering mechanisms, keeping the value of the low temperature resistivity relatively high, will be discussed. They are of key importance as the Dirac surface states have been observed by ARPES in our $NiTe_2$ samples, but still, no clear impact of relativistic carriers on electronic transport has been concluded up to now.

Zerovalent-Metal Intercalated MoS_2 Hybrids for Optoelectronics Ashwin Ramasubramaniam; University of Massachusetts-Amherst, United States

The intercalation of layered compounds is a promising route for scalable synthesis of 2D heterostructures with novel emergent optoelectronic properties. Here, we investigate, via first principles calculations, the intercalation of zerovalent metals within the van der Waals gap of bulk MoS_2. Specifically, we focus on Cu-MoS_2 and Sn-MoS_2 hybrids that can accommodate Cu and Sn, ranging from clusters to continuous 2D layers within the vdW gap of MoS_2. We study the evolution of the Cu-MoS_2 and Sn-MoS_2 hybrids with increasing metal content and examine the consequences for intercalation energetics and optoelectronic properties as the intercalated metals evolve from disordered clusters to contiguous layers. We identify emergent interfacial plasmons (1-2 eV range) that are unique to these intercalated materials, arising from resonant 2D metallic states within the MoS_2 band gap. Our calculations are shown to be in good agreement with experiments and help explain the enhanced infrared absorption of the Cu-MoS_2 and Sn-MoS_2 hybrids. Overall, our results indicate that intercalation of zerovalent metals in layered materials offers a facile and scalable approach for designing hybrid 2D heterostructures with tunable optoelectronic properties for device applications.

9:00 AM EQ06.03.02
Linear Bulk Photovoltaic Effect in Strain Gradient-Engineered MoS_2 Jie Jiang and Jian Shi; Rensselaer Polytechnic Institute, United States

The theoretical Shockley-Queisser limit of photon-electricity conversion in conventional *p-n* junction could be potentially overcome by the bulk photovoltaic effect that uniquely occurs in non-centrosymmetric materials. Using strain gradient engineering, the flexo-photovoltaic effect, i.e., strain gradient-induced bulk photovoltaic effect, can be activated in centrosymmetric semiconductors significantly expanding material choices for future sensing and energy applications. Here, we propose a strain gradient engineering approach based on the structural inhomogeneity and phase transition of a two-dimensional/three-dimensional (2D/3D) hybrid system. We report an experimental demonstration of the flexo-photovoltaic effect in an archetypal 2D material MoS_2 transferred on a VO_2 microbeam. The experimental bulk photovoltaic coefficient in MoS_2 is orders of magnitude higher than that in most non-centrosymmetric materials. Our findings unveil the fundamental relation between the flexo-photovoltaic effect and a strain gradient in low-dimensional materials, which could potentially inspire the exploration of novel optoelectronic phenomena in strain gradient-engineered materials. The MoS_2/VO_2 hybrid structure sheds light on emerging phenomena and brings new opportunity in 2D/3D interfaces.

Excitonic Properties in 2D Silver Phenlychalcogenolates Woo Seok Lee, Yeongsu Cho, Eric R. Powers, Watcharaphol Paritmongkol, Tomoaki Sakurada, Heather J. Kulik and William Tisdale; Massachusetts Institute of Technology, United States

Silver phenylselenolate (AgSePh) and silver phenyltelluroate (AgTePh) are novel hybrid organic-inorganic two-dimensional (2D) semiconductors. AgSePh and AgTePh are synthesized in the form of three-dimensional crystals consisting of 2D layers bound together by van der Waals forces. Unlike 2D layered perovskites and transition metal dichalcogenides, AgSePh and AgTePh feature strong covalent bonding between organic and inorganic components, forming truly hybrid organic-inorganic semiconductors. However, AgSePh and AgTePh exhibit strikingly different excitonic properties despite having the same crystal structure. Whereas AgSePh exhibit narrow, fast luminescence with minimal Stokes shift, AgTePh exhibits comparatively slow, significantly broadened luminescence with large Stokes shift. In this presentation, we will present the synthesis, structural and optical properties of AgSePh and AgTePh films. Furthermore, we will discuss different physical mechanisms underlying light emission in AgSePh and AgTePh. Using time-resolved and temperature-dependent optical spectroscopy, combined with sub-gap photoexcitation studies, we will show that exciton dynamics in AgTePh are dominated by intrinsic self-trapping behavior, whereas dynamics in AgTePh are dominated by interaction of free-excitons with extrinsic defect states. Finally, we will discuss the origin of exciton self-trapping in AgTePh using density functional theory calculations.

Large Scale Atomically Thin Semiconductor Films for Electronics and Optoelectronics Jiwoong Park; University of Chicago, United States

Two dimensional (2D) electron transport has been one of the most important topics in science and technology for decades. It was originally studied in 3D semiconductors and then continued in 2D van der Waals (vdW) crystals. In this talk, I will start with the large-scale processes for generating 2D crystalline semiconductor transition metal dichalcogenide (TMD) films and superlattices that could be used to fabricate atomically thin integrated circuits cleanly. These large scale TMD films also display novel optical properties depending on the geometry of the film itself and on the geometry of the incident light. I will discuss two examples. First, TMD films grown with nanoscale textures produce optically isotropic films with strongly enhanced absorption. Second, TMD monolayers can be used to form three-atom-thick waveguides with a long (~ 1 cm) propagation length that can be used to generate a novel 2D photonics platform.

10:30 AM EQ06.03.05
Proximity Exchange in 2D Magnets Deduced from a Cr(o-tolyl)$_4$ Magnetic Sensor Kathleen R. Mullin and James M. Rondinelli; Northwestern University, United States

Molecular color centers, like Cr(o-tolyl)$_4$, show promise as a more flexible platform for magnetic sensing with many similarities to more frequently studied quantum magnetic sensors, like diamond NV centers. Using these molecules in thin film geometries would allow for the sensing of magnetic fields over a wide range of distances, angstroms to micrometers, from the analyte. This is particularly important for 2D magnetic materials, such as CrI_3, that have shown large discrepancies in magnetic fields measured by different methods. Past studies have suggested proximity exchange, that occurs between the magnetic substrate and a very close sensor, may be responsible for the discrepancies. To that end, we used density functional theory calculations to understand how the molecular color center, Cr(o-tolyl)$_4$, adsorbs on a monolayer CrI_3 substrate and how proximity exchange, or wavefunction overlap, impacts the excited states in the Cr(o-tolyl)$_4$ molecule at different distances from the substrate. Magneto-static modeling is used to predict dipolar interactions between the magnetic sensor and the substrate. By combining these models, we show that at short distances proximity exchange dominates in molecule-substrate interaction, but at further distances the molecule would act as a typical magnetic sensor, with magneto-static effects dominating changes to the energies of the excited state. Our models effectively demonstrate how a molecular color center could be used to measure the magnetic field of a 2D magnet and the role of important distance-dependent interactions that contribute to the field.

Towards Compact Phase-Matched and Waveguided Nonlinear Optics in Atomically Layered Semiconductors Chiara Trovatello[1,2], Xinyi Xu[1], Fabian Mooshammer[1], Yinming Shao[1], Shuai Zhang[1], Kaiyuan Yao[1], Dmitri N. Basov[1], Giulio Cerullo[2] and P.J. Schuck[1]; [1]Columbia University, United States; [2]Polytechnic University of Milan, Italy

Nonlinear frequency conversion provides essential tools for light generation, photon entanglement, and manipulation. Conventional nonlinear optical crystals display moderate second-order nonlinear susceptibilities ($|X^{(2)}|\approx$1-30 pm/V) and perform well in benchtop setups with discrete optical components. However, such crystals do not easily lend themselves to miniaturization and on-chip integration. Two-dimensional transition metal dichalcogenides (TMDs) possess huge nonlinear susceptibilities ($|X^{(2)}|\approx$100-1000 pm/V) and, thanks to their deeply sub-wavelength thickness, offer a unique platform for on-chip nonlinear frequency conversion and light amplification. However, due to their atomic thickness, they display a notably lower second harmonic generation (SHG) efficiency ($\eta_{SHG}=I_{2\omega}/I_{\omega}\approx10^{-11}$ at I_{ω}=30 GW/cm^2) compared to standard nonlinear crystals ($\eta_{SHG}=I_{2\omega}/I_{\omega}$=1-50%).

The nonlinear conversion efficiency of a TMD could be scaled by increasing the propagation length through the active medium. This is attainable by increasing the number of layers in the TMD sample. However, the nonlinear optical properties of semiconducting TMDs critically depend on their crystallographic symmetry, i.e., 2H (hexagonal) or 3R (rhombohedral). 2H-MoS_2 is naturally centrosymmetric, giving an opposite dipole orientation among consecutive layers. This results in a vanishing nonlinear susceptibility ($|X^{(2)}| = 0$) for crystals with even number of layers and precludes efficient conversion in multilayer 2H-TMDs. In contrast, 3R-MoS_2 naturally combines broken inversion symmetry ($|X^{(2)}| \neq 0$) and aligned layering, representing ideal candidates to boost the nonlinear gain with minimal footprint. The nonlinear optical response of 3R-MoS_2 has been explored in some recent pioneering studies[1,2], so far focusing on thinner crystals, reporting the quadratic enhancement with the number of layers at the 2D limit, and showing a maximum SHG enhancement of $\approx10^2$ occurring at specific thickness windows. Pushing towards general application, however, requires higher nonlinear enhancements and thus larger layer number, which in turn leads to more intricate interferences and interactions within the crystal.

Here we measure SHG from multilayer 3R-MoS_2 crystals with variable thickness, using a custom transmittance microscope, and we achieve record nonlinear enhancement from a van der Waals material, $>10^4$ stronger than a monolayer, revealing the intrinsic single-pass upper limits of the material. We provide a comprehensive model, which explains the second-order nonlinearity of 3R-MoS_2 including its phase mismatch and its intrinsic interference effects. We report the first measurement of the coherence length along the ordinary axis, elucidating the role of phase-matching at excitation photon energies close to the telecom band. Furthermore, along the extraordinary axis, we achieve broadly tunable SHG in a waveguide geometry, revealing the coherence length in such a structure for the first time. Upon edge coupling the fundamental wavelength on one side of the flake we detect the SH emission from the opposite edge within our field of view. We observe the characteristic SHG signal modulation with increasing path length, allowing us to quantify the out-of-plane coherence length in 3R waveguide structures. In addition, we also characterize the anisotropic linear optical properties by imaging the propagation of waveguide modes in real space using near-field nano-imaging, identifying the conditions for phase-matched SHG in waveguide geometries[3].

Our results highlight the potential of 3R-stacked TMDs for integrated photonics, providing critical parameters for designing highly efficient on-chip nonlinear optical devices including periodically poled structures, optical parametric oscillators and amplifiers, and quantum circuits.

Dual COVID-19 and Influenza Virus Detection via Antibody-Functionalized Graphene Field-Effect Transistors Deji Akinwande; The University of Texas at Austin, United States

The advent of pandemic caused by SARS-CoV-2 (COVID-19) has highlighted the requirement of sensor devices capable of carrying out rapid differential diagnosis of various viruses that may manifest similar physiological symptoms but demand tailored treatment plan. Annually, the world undergoes multiple cycles of seasonal Flu infection which now poses a bigger challenge, exacerbated by the pandemic. In this work, we demonstrate liquid-gated graphene field-effect transistor (GFET) based rapid biosensing device capable of making differential diagnosis between Influenza and COVID-19 viruses. The device consists of four onboard GFETs arranged in a quadruple architecture, where each quarter is functionalized with specific antibody to utilize the antibody-antigen reaction on graphene's surface to indicate the presence of either Influenza or COVID-19. The graphene bio-sensors were successfully tested against a range of concentrations of both the viruses, indicating extremely high sensitivity. Unlike the standard polymerase chain reaction-based testing kits which have a turn-around time of at least three hours, graphene bio-sensors offer a response time of about 10 seconds, hence enabling rapid diagnosis. The antibody functionalized graphene bio-sensor is a suitable platform for the rapid diagnosis of existing and future infectious diseases.

Charge Transfer in Janus 2D Semiconductors and Janus Heterostructures Fabricated by Low-Energy Selenium Implantation Yu-Chuan Lin[1,2]; [1]The Pennsylvania State University, United States; [2]Oak Ridge National Laboratory, United States

Janus transition metal dichalcogenide (TMD) monolayer is relatively new in the family of two-dimensional (2D) materials. In 2D Janus TMDs, such as MSSe (M= W, Mo), one M atomic layer is sandwiched by S and Se atomic layers. This asymmetry perpendicular to the basal plane of 2D Janus TMD results in a built-in dipole moment pointing from Se to S layers. Many theoretical studies have predicted many exciting aspects of 2D Janus TMDs, including electronic band structures, spin properties, piezoelectric, and photocarrier transfer. First, the preparation and properties of 2D WSSe and MoSSe prepared by selenium implantation will be discussed.[1] The plasma plumes of pulsed laser deposition offer controllable hyperthermal kinetic energies to synthesize metastable 2D materials that conventional thin film techniques cannot achieve. Using the plasma plumes, we replace the top S atoms in 2D WS_2 and MoS_2 with Se atoms and convert them to Janus structures. Second, transient absorption measurements reveal that the excitons in 2D Janus TMDs form faster than those in their pristine counterparts by about 30% due to their enhanced electron−phonon interaction by the newly introduced built-in dipole moment.[2] Finally, we study the charge transfer properties of bilayer heterostructures formed by Janus and regular TMDs with photoluminescence and time-resolved pump-probe measurements.[3] The results from three heterostructures with atomic layer sequences of S–W–Se/S–W–S, Se–W–S/S–W–S, and S–W–Se/Se–W–Se reveal that charge transfer from regular to Janus TMDs is ultrafast and independent of the direction of the built-in electrical field (Janus field). On the other hand, the charge transfer from Janus to regular TMDs is directional and controlled by the Janus field: When the current direction is along the field, the charge transfer is ultrafast and efficient, while the field blocks the charge transfer with an opposite charge current direction. The understanding of ultrafast and directional charge transfer between Janus and regular TMDs shows that the Janus structures can be used to make 2D heterostructures with efficient and directional charge transfer properties.

Towards Strain-Tunning Correlations in van der Waals Heterosrtuctures Marshall A. Campbell[1,2], Sean Doan[1], Vignesh Chandrasekaran[2], Michael T. Pettes[2] and Luis Jauregui[1]; [1]University of California, Irvine, United States; [2]Los Alamos National Laboratory, United States

Two-dimensional (2D) materials and heterostructures offer a rich environment to study and probe quantum phenomena such as electron correlations, superconductivity, ferromagnetism, and topological effects with great tunability. Controllable in-situ strain in 2D materials offers a novel pathway to control those correlated effects. Transition metal dichalcogenides are one class of 2D materials known for their capability of electronic band tuning and promising photonic applications as they exhibit a direct gap at the monolayer limit. While several studies have been performed on commensurate TMD structures, few strain studies have been performed on twisted structures due to the difficulty in fabricating high-quality samples and the techniques available to apply controllable strain. Here, we present a strain study on twisted homobilayers of WSe2 on hexagonal Boron nitride (BN). The twisted WSe2 structure exhibits a moire lattice that alters the electronic band structure and phonon modes. Placing the twisted homobilayers of WSe2/BN structure on flexible polyethylene terephthalate (PET) substrates enables the application of tunable tensile strain along the axis of substrate bending and orthogonal compressive strain due to the Poisson effect. This provides a controllable method to strain the moire superlattice. We then perform ultralow frequency Raman spectroscopy, photoluminescence spectroscopy, and lifetime measurements to characterize any changes with strain. We observe changes in the low-frequency phonon modes which we attribute to changes in the moire wavelength. Furthermore, we extract the strain applied to the homobilayer WSe2 by a Gruneisen parameter analysis on phonon mode shift in the E2g and A1g modes. We measure an applied strain of roughly 1% in our samples. We carry on this analysis to observe shifts in the photoluminescence energy and exciton lifetime. We observe a small decrease in the exciton lifetime, but no significant shift in exciton energy at room temperature. Knowing the exact amount of strain applied to a moire lattice is pivotal to characterizing the strain-tunability in these structures. Our methods allow the characterization of the amount of strain applied and the modification of the moire patterns via low-frequency Raman measurements. Our results could pave the way toward strain-tunable electron interactions in strongly correlated systems and the study of strain-driven phase transitions in van der Waals heterostructures.

SESSION EQ06.04: 2D Electronic and Photonic Devices II

MoS_2 Transistors for Back-End-of-the-Line Si Integration Tomas Palacios; MIT, United States

This paper describes our recent work on developing both the material synthesis and the fabrication technology needed to integrate single-layer molybdenum disulfide (MoS_2) devices at the back-end-of-the-line of fully fabricated Silicon CMOS chips. These devices could significantly improve the performance of future Si chips by enabling compact three-dimensional microsystems with shorter interconnects, lower leakage currents, and increased memory.

2:00 PM EQ06.04.02
Transition Metal Dichalcogenides p-n Junctions Fabricated by Plasma-Assisted Edge Doping Luca Anzi, Andrea Tagliabue, Nikil Paithankar and Roman Sordan; Polytechnic University of Milan, Italy

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) have raised great research interest due to their attractive optical and electronic properties. Their semiconducting nature and the low dimensionality make them the perfect candidate for new-generation electronic devices. MoS_2 and WSe_2 are the most promising TMDCs for the fabrication of 2D electronic circuits. However, a reliable technique to modify the carrier type and concentration in these semiconductors is still missing. Three different techniques have been used so far to dope TMDCs: charge transfer, electrostatic, and plasma-assisted doping. Charge transfer doping has been widely used due to a simple fabrication procedure. However, the lack of controllability and the induced carrier scattering make this method unsuitable for small scale devices. Electrostatic doping exploits external gate electrodes and has been used, e.g., to realize a lateral p-n junction with a controllable barrier height and carrier concentration. However, this method cannot be used in realistic applications due to the increased circuit complexity and power consumption. Plasma treatments with fluorinated gases or N_2 have been used to p-dope the MoS_2 surface by substituting S atoms with energetic F or N ions. However, the etching of the surface exposed to the plasma increases the surface roughness, which drastically affects the transport properties of the doped flakes. For this reason, the obtained p-n junctions exhibited relatively low forward current, limiting their use in realistic applications.

Here we demonstrate high-quality p-type MoS_2 and WSe_2 obtained by plasma-assisted edge doping. Ribbons of width of ~ 100 nm were patterned by e-beam lithography on wide-area flakes of MoS_2/WSe_2. The flakes, which initially exhibited an overall n-type behavior, were subsequently etched by SF_6 plasma. The etching incorporated an excess of F atoms at the edges of the ribbon caused by the plasma substitution of S/Se atoms. Due to their acceptor nature, the F atoms increased the concentration of holes in the proximity of the edges. In narrow enough (width < 100 nm) ribbons, the doping from the edges extended through the entire width, leading to an overall p-type conduction. At the interface between the ribbon and the wide part of the flake, a p-n junction was formed due to the opposite carrier type of the two sides.
The edge doping technique preserved the surface integrity of the TMDC flakes. We obtained high-quality MoS_2 p-n junctions with an on/off ratio of ~ 10^4 and forward current of ~ 50 A/m (normalized to the ribbon width). Such p-n junctions were used to fabricate realistic electronic circuits, e.g., wave rectifiers and amplitude demodulators.

The presented technique for the p-type doping of MoS_2 and WSe_2 could be, in principle, adapted to control the doping type and concentration of any TMDC by choosing a suitable plasma treatment.

2:15 PM EQ06.04.03
Reduced Dopant-Induced-Scattering in Remote Charge Transfer Doped MoS_2 Field-Effect Transistors Juntae Jang[1], Jae-Keun Kim[2], Kyungjune Cho[3], Keehoon Kang[1] and Takhee Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Max Planck Institute of Microstructure Physics, Germany; [3]Korea Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) transition metal dichalcogenide (TMDC) semiconductors such as molybdenum disulfide (MoS_2) hold great promise for next-generation electronic devices [1, 2]. From a practical point of view, surface charge transfer doping (SCTD) is known to be an effective method to modulate the electrical properties of 2D semiconductors. However, although SCTD is a facile and non-destructive method, it could also introduce charged impurities that can hinder charge transport [3].
In this study, we overcome the shortcomings of SCTD through demonstrating a remote charge transfer doping by simply inserting a thin hexagonal boron nitride (h-BN) layer (< ~3 nm thickness) between MoS_2 channel and the n-type molecular dopants, benzyl viologen (BV), which was sufficient for achieving a significant charge transfer [4]. First, we characterized the electrical properties of MoS_2 field-effect transistors (FETs) with h-BN interlayer (denoted as “remotely doped” device) and without h-BN (denoted as “directly doped” device) before and after doping with temperature-dependent gated four-point probe measurements which can minimizes the effect of phonon scattering and the varying charge injection behaviors due to the BV doping. As a results, we identified a significantly larger enhancement in the mobility of remotely doped device relative to its pristine (un-doped) state than that of directly doped device under similar carrier concentration conditions since the spatial separation of thin h-BN interlayer between BV and the MoS_2 FETs channel suppresses the charged impurity scattering which could be additionally introduced by the SCTD. Next, we conducted the quantitative analysis of the remote doping method in comparison with the conventional direct doping method and our mechanistic study supports the efficient suppression of the dopant-induced charged impurity scattering in the remotely doped MoS_2 channel, corroborated by our theoretical predictions.
Our mechanistic study of the novel doping method promotes the remote charge transfer strategy as a promising way for achieving a wide doping range without compromising the carrier mobility, which is required for high performance emerging electronic and optoelectronic devices based on 2D materials.

Carbon Nanotube Transistors for a Future 3D Logic Technology Qing Lin, Carlo Gilardi, Subhasish Mitra and H.S. Philip Wong; Stanford University, United States

Carbon Nanotube (CNT) Field-Effect Transistors (CNFETs) are promising candidates for future high-performance and energy-efficient digital logic. Gate-All-Around (GAA) CNFETs with doped extensions and multiple layers of high-density CNTs are projected to show up to 7× Energy-Delay Product (EDP) benefits vs. Si FET at the 2 nm technology node [1]. Moreover, CNFETs have already been integrated into silicon industrial manufacturing facilities at relaxed nodes (e.g. through DARPA 3DSoC program, at ADI, and SkyWater Technology Foundry), thus illustrating compatibility with existing fab process

infrastructures [2-3].

Many fundamental building blocks of the CNFET technology have already been demonstrated. In the very near future, it will be possible to integrate all the building blocks achieved thus far to demonstrate a MOSFET-like structure with 35-nm contacted gate pitch, and 20-nm active width that is projected to have performance that far exceeds Si transistors for a 2-nm node logic technology while at the same time can be fabricated in multiple 3D device layers for a future logic technology.

In this talk, I will describe the journey of the worldwide CNT research community that leads up to this important juncture. I will discuss the remaining challenges for CNFET to mature into a manufacturing-ready technology.

Effect of Plasma Etching on the Transport Properties and Electrical Stability in Transition-Metal Dichalcogenide Field-Effect Transistors
Mohammad Nouri and William S. Wong; University of Waterloo, Canada

The application of two-dimensional (2-D) layered transition metal dichalcogenide (TMDC) for high-performance large-area memory applications requires establishing long-term electrical stability through an understanding of the carrier transport and the effect of the materials processing on the device behavior. A novel approach for creating arrays of thin-film and few-layer molybdenum disulfide (MoS_2)-based field-effect transistors was achieved through a mechanical exfoliation and a dry etching process. The current-voltage (I-V) and electrical stability characteristics showed that the etching process can effectively remove intrinsic bulk defects within the TMDC layers and create few-layer device structures. The as-transferred thin-film transistor (TFT) structures, having thicknesses of ~ 90 nm, were found to have a trap density of approximately 3×10^{10} cm^{-2} per monolayer. This defect density was observed to decrease when the layers were removed using a SF_6/O_2 plasma etching process, resulting in a positive threshold voltage shift in the transistor operation. The process was effective in removing bulk defects in the MoS_2 layers causing a positive threshold voltage shift of +40V with a final threshold voltage of -12V for a 3 nm thick layer. Conversely, the measured transport properties and electrical stability was found to degrade when the thickness of the MoS_2 layer was < 15 nm. This observed degradation was due to the etched backchannel layer moving closer to the active channel region as the TMDC layer was thinned. The transport properties of the transistor were affected by surface states along the backchannel contributing to carrier scattering as the thickness of the semiconductor approached the accumulation layer in the transistor. The same surface states acted as trap centers in the semiconductor degrading the electrical stability of the devices. This effect was becoming more pronounced as the proximity of the TFT backchannel surface approached the active channel region during etching. Finally, the effect of passivation layers on the etched backchannel will be presented for an array of TDMC devices for large-area memory applications.

4:15 PM EQ06.04.07
Giant and Tunable Fano Resonance Induced by Two-Dimensional Metals Kunyan Zhang[1], Rinu A. Maniyara[1], Yuanxi Wang[2], Maxwell Wetherington[1], Thuc Mai[3], Timothy Bowen[1], Chengye Dong[1], Slava Rotkin[1], Angela R. Hight Walker[3], Vincent Crespi[1], Joshua A. Robinson[1] and Shengxi Huang[1,4]; [1]The Pennsylvania State University, United States; [2]University of North Texas, United States; [3]National Institute of Standards and Technology, United States; [4]Rice University, United States

Quantum interference between phonons and other quasiparticles brings about fascinating physical phenomena. As an example of phonon coupled to a scattering continuum, Fano resonance is characterized by an asymmetric line shape in the scattering spectrum. Here, we report the giant Fano resonance of folded longitudinal optical phonons in SiC after the intercalation of atomically thin metals, with a resonance strength two orders of magnitude higher than prior reports. A range of physical characteristics, including surface termination, temperature, and excitation wavelength, were used to tune the degree of Fano resonance. The tuning mechanisms were studied by first-principles calculations, which reproduced the intricate phonon behaviors. Our work presents the plethora of tuning knobs for the phonon-related Fano resonance, which paves the way toward constructing quantum interference effects in the nanoscale limit.

High-Performance Ambipolar $MoTe_2$ Field-Effect Transistors Zhiying Wang[1], HaeYeon Lee[1], Yang Liu[1], Jordan Pack[1], Song Liu[1], Luke Holtzman[1], Kenji Watanabe[2], Takashi Taniguchi[2], Cory Dean[1], Qianhui Shi[3] and James Hone[1]; [1]Columbia University, United States; [2]National Institute for Materials Science, Japan; [3]University of California, Los Angeles, United States

Two-dimensional (2D) monolayer semiconductors such as transition metal dichalcogenides (TMDs) host a variety of emergent quantum properties and have attracted intense attention in electronics and optoelectronics. For both fundamental studies and novel electronic applications, it is a critical prerequisite to achieve low-resistance contacts on monolayer (ML) TMDs. Semiconductor Molybdenum Ditelluride ($MoTe_2$) is an attractive material platform in various ways including its ambipolar behavior due to its smaller bandgap of 1.2 eV compared with other TMDs materials and small energy required for the phase transition. However, due to air-instability of ML $MoTe_2$ and weak Mo-Te bonding, it is challenging to fabricate high performance ML $MoTe_2$ transistors with low contact resistance. Therefore, there is a lack of fundamental studies of ML $MoTe_2$ and its applications.

Here, we present several techniques to fabricate electrical contacts on ML $MoTe_2$: (1) direct deposition of semimetal on ML $MoTe_2$ (2) insertion of

monolayer spacer as a tunneling barrier between metal contact and ML $MoTe_2$ and (3) pre-pattern high work function metal contact. High quality $MoTe_2$ is used for our study, which is synthesized by self-flux method and exhibits defect density as low as 1 x $10^{11}/cm^2$. We compare electric performance of ML $MoTe_2$ field effect transistor fabricated by using different approaches mentioned above. Among those approaches, we have achieved ML 2H-$MoTe_2$ field effect transistor with low contact resistance which is an order of magnitude lower than the previous report for both electrons and holes at room temperature, by further optimizing the pre-pattern contact structure and device fabrication process. Our results can allow us to have comprehensive insight of the Landau level sequence and correlated states by accessing both electrons and holes region from a single device. It also provides new opportunities in optoelectronics using ML $MoTe_2$, which is comparable with silicon with similar band gap.

Novel Nanospike Array Electrodes for Enhanced-Performance 50 NM-Channel MoS_2 Thin-Film Transistors Yuchen Zhou, Chankeun Yoon, Xin Xu, Kelly Liang and Ananth Dodabalapur; University of Texas at Austin, United States

There has been a great deal of research interest in scaling down the channel lengths in MoS_2 thin-film transistors (TFTs). However, when the channel length reaches the nanometer scale, transistors start experiencing short channel effects, including low on/off ratio, degraded subthreshold swing, and drain-induced barrier lowering (DIBL), etc. This abstract introduces an alternative to overcome short channel effects for transistors with channel lengths below 100 nm. Conventionally, MoS_2 TFTs have been fabricated with flat edge source and drain electrodes. By changing the shape of the source/drain electrodes into nanospike-like structure, transistors can overcome short channel effects and regain gate control. Furthermore, patterning the source and drain contacts into nanospike array electrodes can improve the on-current of the transistors as well. 50 nm-channel length MoS_2 TFTs with nanospike array electrodes were fabricated along with the conventional flat edge electrodes for direct comparison.
The 17 nm thick source/drain electrodes (Cr/Au) were patterned on 90 nm of SiO_2 coated silicon substrates using electron beam lithography (EBL). Mechanically exfoliated 5 nm few-layer MoS_2 and 20 nm thick hBN were transferred onto the preformed contacts. A 100 nm thick Au top gate was patterned with EBL and thermally evaporated. The nanospike tips are 200 nm wide equilateral triangles with a 1 μm long rectangular base extending orthogonally from conventional flat electrodes. The channel length, defined as the distance between the tips of the source and drain spikes, is approximately 50 nm. The total channel width is 3.4 mm with 5 pairs of nanospikes spaced evenly from each other.
Nanospike electrodes provide a unique bias-dependent charge flow pattern, which is responsible for the improved performance. Enhanced electric field results in increased charge injection from the tips of the nanospike electrodes and improves channel length scaling to sub-50 nm while maintaining excellent current modulation. The spacing between each pair of nanospikes also plays an important role. Larger spacing accentuates the formation of individual charged nanoribbons between source and drain, and the increased channel width from having larger spacing also helps improve the on-current as well. The transfer characteristics of nanospike TFTs demonstrate an on/off ratio of ~10^7 while this ratio is typically 10^2 or less for devices with flat edge electrodes. Increased drain current (35 μA/μm vs. 25 μA/μm) and reduced contact resistance (40 kΩ μm vs. 52 kΩ μm) are also observed for the nanospike devices.
The 50 nm MoS_2 TFTs was connected in series with a 15 kΩ resistor to assess the characteristics of an inverter. With a supply voltage of 2 V, the circuit is on with an output voltage of 2 V at negative input voltages and an output voltage of near 0 at positive input voltages. The circuit gain was calculated to be approximately 3.75. The intrinsic gain ($g_m r_o$) of the device reaches 300 in the subthreshold regime, which is much higher than the intrinsic gain that can be achieved by silicon under subthreshold condition. The high intrinsic gain is a result of reduced DIBL and improved sub-threshold swing due to charged nanoribbon formation and enhanced gate control. This opens up the possibility for high performance subthreshold circuits with low power dissipation for applications such as neuromorphic computing and energy efficient logic. In summary, the use of nanospike array source/drain electrodes shows a step towards scalable, multi-functional, and high-performance MoS_2 TFTs.

Towards Accurate Ionic Relaxation Algorithms for Two-Dimensional Chalcogenide van der Waals Materials Mahmoud el-Attar and Nageh K. Allam; American University in Cairo, Egypt

Recently, two-dimensional (2D) layered materials, known as van der Waals (vdW) materials, have attracted remarkable attention due to their unique electrochemical and physical properties. Transition metal dichalcogenides (TMDs) are 2D materials, which commonly exist in three polymorphs (1T, 2H, and 3 R) in a honeycomb structure (hexagonal lattice). From a structure relaxation point of view, the 1T phase has less structural symmetry along the z-direction, rendering it more challenging than the 2H counterpart. Herein, the importance of enabling vdW forces as well as the associated challenges during the simulation of 1T polymorph are tackled. The two most widely used ionic relaxation methods (conjugate gradient and RMM-DIIS) were used for six TMDs (TaS_2, $TaSe_2$, MoS_2, $MoSe_2$, WS_2, WSe_2), and the results were compared to those reported in the literature. Moreover, a newly designed advanced conversion algorithm (TPSCA) is developed by incorporating shell scripts, DFT electronic relaxation, and Python coding. The developed algorithm is tested for 1T-TaS_2 to confirm the obtained results and get better insights into the dependence of the energy on the different combinations of those parameters.

EQ06.05.02
***Ab Initio* Studies of Thermodynamic and Electronic Properties of $MoSi_2N_4$ Edges** Atharva S. Burte[1], Ashwin Ramasubramaniam[1], Omar Abdelrahman[1] and Andre Muniz[2]; [1]University of Massachusetts Amherst, United States; [2]Universidade Federal do Rio Grande do Sul, Brazil

Recently, a novel 2D nitride, $MoSi_2N_4$, was successfully fabricated by chemical vapor deposition methods. This 2D nitride displays excellent mechanical and thermal stability and exhibits semiconducting behavior within the bulk. Drawing parallels with other 2D materials that have been studied for optoelectronics and catalysis, we anticipate that the edges of $MoSi_2N_4$ could host interesting electronic and chemical properties. Here, we present a density functional theory study of the electronic and thermodynamic properties of $MoSi_2N_4$ edges. We developed a ternary phase diagram, identifying a region of chemical potentials wherein $MoSi_2N_4$ is stable over competing elemental or binary phases. Based on this phase diagram, we determined the thermodynamic properties of a wide range of armchair and zigzag edges. Using this detailed thermodynamic analysis as a basis, we identify the most favorable edge structures and elucidate the electronic structures of these favorable edges. Our analysis suggests that low-energy edges of $MoSi_2N_4$ could be of potential

interest in (opto)electronic and/or electrocatalytic applications.

Tunable Optical Pulling Forces Enabled by Bilayer van der Waals Materials Ziqiang Cai; Northeastern University, United States

Light induced forces can be used to manipulate nanoparticles, which have led to various applications in nanotechnology and bioengineering. Among all kinds of light induced forces, the optical pulling force can transport objects towards the source rather than pushing them away, providing a new degree of freedom in particle manipulation. It has been demonstrated that by using hyperbolic metamaterials and photonic crystals, the scattered light possesses increased momentum in the forward direction compared with the incident light, giving rise to optical pulling forces [1, 2]. However, once these photonic structures are fabricated, their properties cannot be tuned, thus the optical force cannot be in-situ changed. On the other hand, people have demonstrated that the momentum topology of the polaritons in graphene/α-MoO_3 bilayer structure can be changed from the hyperbolic to elliptical via tuning the Fermi level of graphene [3].
In this work, we numerically demonstrate that by utilizing the tunable property of graphene/α-MoO_3 bilayer structure, under plane-wave illumination, the direction of optical force exerted on the nanoparticle can be switched between pulling and pushing in a broad frequency range (from 851 cm^{-1} to 952 cm^{-1}) while only tuning the Fermi level of graphene. In the simulation, the carrier mobility and maximum Fermi level of graphene are 3000 $cm^2/(Vs)$ and 0.6 eV, respectively, which are achievable in experiment. We point out that such phenomenon can be used in in-situ optical force tuning without changing the light source. We believe that our work can provide more degrees of freedom in applications related to particle manipulations.

Direct Observation of Stacking Faults and Stacking Domains in the van der Waals Magnet CrI_3 Myeongjin Jang[1], Sol Lee[1], Fernando Cantos-Prieto[2], Ivona Košić[2], Jong Chan Kim[3], Jun Yeong Yoon[1], Loukya Boddapati[4], Francis Leonard Deepak[4], Hu Young Jeong[3], Elton J. Santos[5], Efrén Navarro-Moratalla[2] and Kwanpyo Kim[1]; [1]University of Yonsei, Korea (the Republic of); [2]Universitat de Valencia, Spain; [3]Ulsan National Institute of Science and Technology, Korea (the Republic of); [4]International Iberian Nanotechnology Laboratory, Portugal; [5]University of Edinburgh, United Kingdom

Van der Waals (vdW) stacking is a powerful technique to achieve desired properties in condensed matter systems under the paradigm of layer-by-layer crystal engineering. Here, we show that recently discovered 2D vdW CrI_3 magnets stabilize natural twisted stacking domains in their crystal structure. By using cross-sectional high-angle annular dark-field scanning transmission electron microscopy and electron diffraction, we unveil that multilayer CrI_3 displays an overall monoclinic structure with occasional rhombohedral stacking faults at room temperature. In addition, the appearance of unusual 120° twisted faults along the stacking direction break up the continuity of the structure into twisted domains with a mode thickness of 10 nm. Remarkably, the monoclinic domains show no hint of the structural phase transition to the rhombohedral stacking down to 95 K but the relative populations among different twisting directions display the strong temperature dependence. Our findings indicate that multilayer CrI_3 presents a high degree of domain stacking disorder, shedding light into the longstanding question of its structural phase transition.

EQ06.05.05
Alternating Doping Level in Epitaxial WS_2 Monolayer on Zigzag Au Substrate Using Scanning Tunneling Microscopy Jeong Won Jin[1], Bumsub Song[2], Soo Ho Choi[2], Ki Kang Kim[1] and Young Hee Lee[2]; [1]Sung Kyun Kwan University, United States; [2]IBS-Cinap, Korea (the Republic of)

Monolayer transition metal dichalcogenides (TMDs) have been extensively investigated owing to their unique physical properties, such as atomically thin nature and tunable electronic properties. Especially, monolayer TMDs require the presence of substrates, which inevitably induces drastic changes to the properties of adlayer materials in various ways including charge doping and strain. Here, employing scanning tunneling microscopy and spectroscopy (STM/S), we characterize the epitaxial WS_2 monolayer grown on the high-index Au surface which was recently introduced as a unique platform for single-crystalline TMD synthesis. Interestingly, alternating doping level of WS_2 ranged from neutral to strong *n*-type with atomically sharp boundaries is observed, and a direct correlation with the zigzag-like morphology of the Au substrate is revealed by STS mapping. From the Fourier analysis, two major superstructures between the WS_2 and substrate are found. This implies that different interlayer coupling may lead to the alternating doping level.

EQ06.05.06
Electrically Tunable Two-Dimensional Homojunctions for Self-Powered Photodetection Tengyu Jin and Wei Chen; National University of Singapore, Singapore

Photodetectors play an important role in the future “Internet-of-Things” information society. Two-dimensional (2D) materials-based photodetectors have attracted intense interest from both academic and industrial fields, thanks to their outstanding performances and related interesting electrical, and optoelectronic phenomena. However, controlling the electronic properties of the 2D materials by incorporating impurity dopants is inherently difficult due to the limited physical space in the atomically thin lattices. Here, we report a successful reconfigurable WSe_2 optoelectronic device with a simple localized floating gate structure that allows reversible electrostatic doping of the channel. Fitting the *I–V* curve of the lateral p-n homojunction diode formed in this way with the Shockley diode equation reveals an ideality factor of 1.25 and a series resistance of 0.42 MΩ, which are beneficial for highly-efficient photodetection. Under the illumination of a 525-nm laser, the diode manifests high-performance self-powered photodetection. The photocurrent depends linearly on input power, giving an almost constant responsivity (*R*) value of ~ 0.17 A/W, which is outstanding compared with other 2D materials-based homojunction devices. A maximum EQE of ~ 51%, FF of ~ 67%, and PCE of ~ 5.62% can also be obtained for the p–n homojunction. In addition, the homojunction demonstrates a wide detection spectral range from violet (405 nm) to the near-infrared region (the cutoff near 1,100 nm) and maintains a high *R* for all the wavelengths. This work opens up a promising pathway toward high-performance optoelectronics based on locally electrostatic doped 2D semiconductors.

EQ06.05.07
Electrical Improvement Using $PtTe_2$/$PtSe_2$/$PtTe_2$ Edge Contact Synthesized by Molecular Beam Epitaxy Hyeon-Sik Kim, Jaehun Jeong, Gihyeon Kwon, Hyunjun Park and Mann-Ho Cho; Yonsei University, Korea (the Republic of)

As the dimensions of channel materials decrease, the importance of the interface between semiconductor and contact metal increases significantly. One-dimensional (1D) edge contact is considered as one of the keys to improve problems resulting from the interface between two-dimensional (2D) transition-metal dichalcogenides (TMDs) and contact metal, overcoming the problems of surface contact, such as surface damage and orbital hybridization. Although several studies have investigated edge contact, there are some problems such as inevitable etching damage and a limited area. Herein, a tellurization method is applied to a specific lateral region to fabricate $PtTe_2$/$PtSe_2$/$PtTe_2$ edge-contact field-effect transistors (FETs) without etching damage. X-ray

photoelectron spectroscopy, Raman spectroscopy, and annular dark-field scanning transmission electron microscopy are used to verify tellurization completion, which is evidenced by the complete transformation of $PtSe_2$ to $PtTe_2$ by the substitution of Se atoms with evaporated Te atoms. Furthermore, tellurization is applied to a specific lateral region by utilizing the hexagonal boron nitride to black the detachment of Se atoms and the interdiffusion of evaporated Te atoms. Finally, the 1D edge-contact FETs fabricated by tellurization shows a higher on–off ratio and carrier mobility than the surface-contact FET, owing to the reduction in contact resistance. Therefore, the fabrication method of the $PtSe_2$-based 1D edge-contact device with free contact resistance can be applied to achieve various 2D TMD-based electrical devices with a high on–off ratio and carrier mobility, which has yet to be demonstrated in large-area TMD-based electrical devices.

EQ06.05.08
Aharonov-Bohm and Quantum Hall Interferometers in Graphene Rings Cynthia I. Osuala, Zitao Tang, Eui-Hyeok Yang and Chunlei Qu; Stevens Institute of Technology, United States

Two-dimensional monolayer graphene exhibits many interesting physical and chemical properties, representing a powerful platform for the development of sensors with various unique advantages [1]. The interference of the electron matter-wave in a mesoscopic graphene ring has important interferometric applications such as the engineering of electron Sagnac gyroscopes [2] and Aharonov-Bohm interferometers [3,4]. Both applications are based on the same mechanism [5] - the electron picks up a different phase while moving along the two arms of the graphene ring with the relative phase being proportional to the applied rotation velocity or the magnetic field.

We will present our theoretical investigations of the Aharonov-Bohm oscillations in a graphene ring structure in the presence of a magnetic field. For a weak magnetic field, the differential conductance oscillates with a fast frequency due to the Aharonov-Bohm effect; as the magnetic field is further increased, the system enters the quantum Hall regime and the conductance diagram in the plane of Fermi energy and magnetic field exhibits the Hofstadter butterfly fractal structure. The dependence of the electric conductance on the radius of the graphene ring, the width of the arms, the position of the leads, the defects on the edge and in the bulk, the spin-orbit interaction, the electric potentials of the side gates, and the thermal fluctuations are systematically studied for a single graphene ring and a few coupled graphene rings. The optimal structure for the control of the quantum transport properties and for the engineering of interferometric devices will be discussed. Our theoretical results and analysis will be useful for graphene transport experiments and the development of graphene interferometers.

The Ferroelectric Floating Memory (FFM) with the Reconfigurable Operating Voltage Sangyong Park[1,2] and Jin-Hong Park[1,1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of)

Ferroelectric field-effect-transistor (Fe-FET) is a promising candidate for a synaptic device of the neuromorphic system due to its compatibility with the conventional CMOS structure, fast operation speed, and facilitating conductance control. The electrical characteristics of the synaptic device are mainly determined by the intrinsic properties of the material and fixed after the fabrication process is completed. However, to support the multiple target applications, reconfigurable electric characteristics are required. In this paper, we introduce an alternative ferroelectric memory device, named ferro-floating memory (FFM), that changes the operating voltage region and the dynamic range by using dual operating mechanisms (ferroelectric switching and tunneling mechanisms). The ferro-floating memory (FFM) uses the electrically isolated semiconducting van-der-Waals ferroelectric material, indium selenide (In_2Se_3), as both the ferroelectric memory and charge storage layers. The two operating mechanisms are individually operated because the ferroelectric switching voltage is lower than the tunneling voltage. The electrical potential of the ferro-floating layer is controlled by injecting the charges into the ferro-floating layer with sufficient gate voltage to occur tunneling. The changing of the electrical potential in the ferro-floating layer modulates the channel surface potential and shifts the threshold voltage. As a result, the operating voltage region of the ferroelectric switching operation can be reconfigured by storing the charges in the ferro-floating layer. We experimentally implemented the ferro-floating memory with van-der-Waals materials and confirmed dual-mode operation by the electrical measurement and scanning Kelvin force microscopy (SKFM). The hysteresis of the double sweep I_d-V_g curve is successfully shifted as tunneling voltage is applied. Finally, we apply the dual-mode operation of the ferro-floating memory to the controlling of the threshold voltage variations in an artificial neural network. The effect of controlling variation is verified using our in-house image recognition simulator.

Nanomechanical Characterization of an Antiferromagnetic Topological Insulator Amit Vashist[1], Shuwan Liu[1], Su Kong Chong[2], Dongwook Kim[1], Rohit Kumar[1], Seng Huat Lee[3], Kang L. Wang[2], Zhiqiang Mao[3], Feng Liu[1] and Vikram V. Deshpande[1]; [1]The University of Utah, United States; [2]University of California, United States; [3]The Pennsylvania State University, United States

The antiferromagnetic topological insulator $MnBi_2Te_4$ (MBT) exhibits an ideal platform to study exotic topological phenomena and magnetic properties. The transport signatures of magnetic phase transitions in the MBT family materials have been well-studied. However, their mechanical properties and magneto-mechanical coupling have not been well-explored. We use nanoelectromechanical systems to study the intrinsic magnetism in MBT thin flakes via their magnetostrictive coupling. We investigate mechanical resonance signatures of magnetic phase transitions from antiferromagnetic (AFM) to canted antiferromagnetic (cAFM) to ferromagnetic (FM) phases versus magnetic field at different temperatures. The spin-flop transitions in MBT are revealed by frequency shifts of mechanical resonance. With temperatures going above T_N, the transitions disappear in the resonance frequency map, consistent with transport measurements. We use a magnetostrictive model to correlate the frequency shifts with the spin-canting states. Our work demonstrates a technique to study magnetic phase transitions, magnetization and magnetoelastic properties of the magnetic topological insulator.

Vanadium Doping/Alloying in Molybdenum Disulfide Monolayers—Characteristic Raman Modes and Tunable Electronic and Magnetic Properties Da Zhou[1], Mingzu Liu[1], Yen Thi Hai Pham[2], Aaryan Oberoi[1], David Sanchez[1], Ke Wang[1], Andres Fest[1], Alexander J. Sredenschek[1], Na Zhang[1], Humberto Terrones[3], Saptarshi Das[1], Manh-Huong Phan[2] and Mauricio Terrones[1,1,1]; [1]The Pennsylvania State University, United States; [2]University of South Florida, United States; [3]Rensselaer Polytechnic Institute, United States

Transition metal doping/alloying is a powerful tool to tailor the optical, electronic, and magnetic properties of semiconducting transition metal dichalcogenides (TMDs). In particular, vanadium doping in tungsten disulfide (V-WS_2) and tungsten diselenide (V-WSe_2) monolayers have demonstrated p-type doping[1,2] and ferromagnetism at room temperature[1,3]. Recently, the synthesis of vanadium-doped molybdenum disulfide (V-MoS_2) monolayers had also been reported using powder chemical vapor deposition (CVD) with the study of their optical and electronic properties.[4,5] Their emergent Raman modes have been explained by the introduction of vanadium atoms into the MoS_2 lattice. However, no systematic study on the origin of these Raman modes as a function of vanadium doping concentration has been reported to date. The magnetic properties of these monolayers were also not investigated. To address these gaps, here we use a liquid precursor CVD method[6] to grow V-MoS_2 monolayers with doping levels ranging from 0.1 to 8 at%. We then combine Raman spectroscopy using different excitation wavelengths, high-resolution scanning transmission electron microscopy (HR-STEM), and first-principles density functional theory (DFT) calculations to study the interaction of vanadium dopants and sulfur vacancies and how they contribute to the emergent Raman modes. Furthermore, vibrating sample magnetometry (VSM) measurements at room temperature revealed an optimal ferromagnetic signal when the vanadium doping concentration was moderate (2-3 at%). In addition, we fabricated field effect transistors (FETs) on the V-MoS_2 with different vanadium doping concentrations and found the emergence of p-type behavior as the vanadium concentration increased. Our work lays the foundation for future studies on defect engineering for tunable electronic/magnetic properties in magnetic atom doped/alloyed TMD systems.

Nanoporous MoS_2 Field-Effect Transistor-Based Biosensor for Ultrasensitive and Selective Biomolecular Detection Junoh Shim[1], Heekyeong Park[1,2], Seungho Baek[1], Anamika Sen[1] and Sunkook Kim[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Harvard University, United States

In this work, we incorporate an ultrasensitive and selective biological FET (bio-FET) created by nanoporous molybdenum disulfide (MoS_2). We construct the nanoring of MoS_2 nanopores via block copolymer (BCP) and analyze them by Raman, scanning transmission electron microscopy, and X-ray photoelectron spectroscopy spectra. After fabricating MoS_2 nanopore rings-based bio-FET, we identify edge-selective functionalization by the Au nanoparticle tethering test and the change of electrical property of the bio-FET. And we achieve the ultrahigh sensitivity with the limit of detection of 1 ag/mL for cortisol detection by using MoS_2 nanopore edge rings-based bio-FET. Also we verify the selectivity by performing several control experiments with other biomaterials. This work suggests a probability that nanoporous MoS_2 bio-FET would furnish platforms for biosensors with ultrahigh sensitivity and selectivity.

EQ06.05.17

The High Sensitivity of the Magnetic Exciton in a Non-Magnet Doped van der Waals Antiferromagnet Junghyun Kim[1,2], Jonghyeon Kim[3], Woongki Na[4], Pyeongjae Park[1,2], Hyeonsik Cheong[4], Jae Hoon Kim[3] and Je-Geun Park[1,2]; [1]Center for Quantum Materials, Seoul National University, Korea (the Republic of); [2]Department of Physics & Astronomy, Seoul National University, Korea (the Republic of); [3]Department of Physics, Yonsei University, Korea (the Republic of); [4]Department of Physics, Sogang University, Korea (the Republic of)

The antiferromagnetic van der Waals (vdW) $NiPS_3$ is a rare material for studying the exciton physics based on the magnetically ordered system. The extremely narrow linewidth of the exciton peak arising coherently from the Zhang-Rice singlet and triplet states was observed by the photoluminescence (PL) and the optical absorption in the single crystal $NiPS_3$ [1]. The locality of NiS_6 cluster based on the cluster model calculation was expected to show a stability of the coherent behavior against to the disturbance in the magnetically ordered system. Here, we newly synthesized the antiferromagnetic vdW $Ni_{1-x}Cd_xPS_3$ which have the non-magnetic dopant Cd replaced in the Ni sites homogeneously throughout the whole crystal. The lattice constant c extracted from the XRD pattern expanded linearly, changing by 0.6 % from x = 0 to 0.1, following the Vegard's law. From the PL and absorption measurement, we observed that the coherent behavior of magnetic exciton peak shows high sensitivity to the dopant concentration where the Neel temperature relatively maintained showing a linear decrement. Here, we emphasize that we showed the decoherence behavior from the linewidth and peak suppression starts to change drastically even in the magnetically ordered ground state where the non-magnetic dopant broke the spin order locally. Additionally, we simulated the magnetic ground state for doped systems and the magnon linewidth broadening was compared with that from the optical probes. We expect that our work will provide novel magnetic systems with spin ordering for a deeper understanding of the magnetic exciton.

Adhensive Functionalization and Lamination of 2D Materials for Flexible Device Fabrication. Ningxin Li[1], Rui He[2], Olunloyo Olugbenga[3], Tara Jabegu[1], Hedi Ma[1], Diren Maraba[1], Aisha A. Okmi[1], Kai Xiao[3], Gangli Wang[1], Pei Dong[2] and Sidong Lei[1]; [1]Georgia State University, United States; [2]George Mason University, United States; [3]Oak Ridge National Laboratory, United States

In modern microelectronics, flexible device fabrication with two-dimensional (2D) materials which show excellent bendability, and ductility is leading a new trend. The sustainable deformation level of 2D materials before rupture is an important degree that determines the performance of the microelectronic device. Despite the respective progress, strain engineering is lagging due to a major challenge: providing strong adhesion between 2D materials and substrate to avoid slippage. Here, we report a method by employing (3-Mercaptopropyl) trimethoxysilane (MPTMS) for surface functionalization to ensure mechanical strain transferring. By applying different tension strain, we noticed the Raman spectrum shows a red shift of 12.9 cm^{-1} for monolayer MoS_2 under the maximum strain value at 1.50%. Meanwhile, the magnitude of the Raman spectrum red shift is inversely proportional to the thickness of the 2D

materials. Compared with other physical encapsulation methods, our way provides strong adhesion to the interface through atomic level chemical bonding, reducing the negative impact of slippage effectively which inherits the mechanical flexibility of 2D materials. Moreover, such a strong bonding method allows not only the isolated samples to transfer, but also the complete micro-devices. As such, the difficulty of fabricating devices on flexible substrates can be overcome simultaneously, which develops the flexible micro-device fabrication technology.

Strain Manipulation and the Role of Magnetism for Charge Density Waves in Monolayer VTe_2 Do Hoon Kiem, Min Yong Jeong, Hongkee Yoon and Myung Joon Han; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Vanadium ditelluride (VTe_2), which is one of the transition metal dichalcogenides (TMDCs), has an intriguing interplay of spin, charge, and lattice degrees of freedom. Motivated by our recent work on crystalline bulk VTe_2 [1], we theoretically investigated the interplay between spin, charge, and lattice in monolayer VTe_2. To understand the controversial experimental reports on several different charge density wave (CDW) ground states, we paid special attention to the 'hidden' role of antiferromagnetism as direct experimental detection may be challenging. Our first-principle calculations show that the 4x1 CDW and the corresponding lattice strain are accompanied by a 'double-stripe' AFM spin order in its ground state. This magnetic phase has the lowest total energy as well as dynamic phonon stability, which supports the group of previous experiments. Interestingly, this ground state is only stabilized by assuming an underlying spin order. Other previously reported phases were found to have significantly high total energy or unstable phonon profiles. By discovering interesting and previously unknown interactions between magnetism and other degrees of freedom, we propose possible strain engineering. The monolayer VTe_2 exhibits a phase transition first to a different CDW structure by applying a tensile strain, and then finally to a ferromagnetically ordered one.

EQ06.05.21
Optical Control of Spin Defects in a van der Waals Magnetic Semiconductor Samuel W. Song[1], Julian Klein[1], Rami Dana[1], Zdenek Sofer[2], Frances M. Ross[1] and Rafael Jaramillo[1]; [1]Massachusetts Institute of Technology, United States; [2]University of Chemistry and Technology Prague, Czechia

The van der Waals material CrSBr stands out as a promising 2D magnetic semiconductor due to its high antiferromagnetic ordering temperature $T_{Néel} \approx 135$ K, near-infrared direct bandgap $E_g \approx 1.55$ eV, and air-stability. In addition to its bulk magnetic order, CrSBr also exhibits a low-temperature magnetic order that is hypothesized to originate from the ferromagnetic polarization of defects [1,2]. A detailed understanding of the mechanisms underlying this defect-induced magnetic order is still needed to fully characterize and better engineer the material's magnetic response.

In this work, we demonstrate optical control of the defect-induced magnetic order in CrSBr single crystals using magneto-optic superconducting quantum interference device (SQUID) magnetometry, which provides high-sensitivity magnetic susceptibility measurements under a controllable external light source. We observe an increase in the zero-field susceptibility of the defect-induced order after exposure to above-bandgap excitation using 405 nm (3.06 eV) illumination. This effect is further amplified upon subsequent excitation using 880 nm (1.41 eV) illumination, which was chosen due to the increased sensitivity of defect absorption at sub-bandgap frequencies [1]. Moreover, we anneal the samples at 400°, 600°, and 800°C to increase defect concentration, which we verify through scanning tunneling microscope (STM) imaging and susceptibility measurements showing increased onset temperatures for the defect-induced magnetic order. For a sample annealed at 800°C, the peak in the enhanced susceptibility (near 70 K) is comparable to or even larger than that of the critical Néel transition at 135 K. From our results, we hypothesize that interactions in the magnetic subsystem of disordered defects arise from the interplay between defect charge states and light-induced carriers, thereby allowing control via illumination. Further exploration of the history-dependence of this interplay relation may lead to the realization of optical control of magnetic interactions between solid-state defect state spin qubits. More broadly, our findings establish CrSBr as an outstanding candidate for further research into tunable optical control of magnetism in 2D semiconductors, with potential applications in spintronics, quantum sensors, and opto-magnetic devices.

A Computational Thermodynamic Approach to Modeling the Efficiency of 2D Materials in Space Solar Cells Using a Novel 7-Junction Configuration Calista Wilk and Peide P. Ye; Purdue University, United States

Approximately 3 billion people have never used the internet due to its costs and inaccessibility, particularly in developing countries. To provide these areas with affordable internet, reducing the cost of building and launching satellites has become paramount in the assessment of their design, particularly their solar cells. While three-dimensional semiconductor materials like gallium arsenide (GaAs) have been the main material used in these cells to convert solar energy into electrical energy, two-dimensional (2D) materials like tellurene have demonstrated properties that warrant consideration. This research evaluates the potential of a novel 7-junction space solar cell configuration consisting of manganese phosphorus trisulfide, tungsten disulfide, rhenium disulfide, molybdenum disulfide, molybdenum ditelluride, bismuth oxyselenide, and tellurene to replace current 3-junction configurations using GaAs-based materials. Thermodynamic expressions, including the efficiency of a Carnot heat engine and a geometric optimization approach using the Shockley-Queisser triangle, were analyzed to derive equations for two properties critical to a space solar cell: efficiency and specific power. Computational simulations were run, and the results indicate that a 7-junction space solar cell configuration using 2D materials can enable a maximum efficiency gain of 12%, a mass reduction by over one-fifth, and a specific power output improvement of 54% at lower costs compared to GaAs-based space solar cells. The implications of this study point to the performance and cost feasibility of satellite usage for a broad range of applications, with social and environmental significance.

Bandgap Study of Titanium Oxynitride Photoactive Material System Abiodun Odusanya and Dhananjay Kumar; North Carolina A&T State University, United States

A TiNxOy (TiNO) material system has been synthesized in thin-film form using a pulsed laser deposition method. X-ray photoelectron spectroscopic measurements have been carried out to determine the elemental composition of the partially oxidized films to show partial oxidation of TiN to TiNO. In addition, the bandgaps were experimentally measured using UV-Vis. In this paper, we performed a theoretical study through Density Functional Theory (DFT) calculations to theoretically assess the role of oxygen content on the changes in bandgap as well as the variation of the lattice parameter with

increasing oxygen composition. We compared these variations with the experimental data. In our calculations, we systematically evaluate the electronic structures within the context of accompanying perturbation in the defect chemistry associated with the charge balance necessary to accurately determine the corresponding bandgap and lattice parameter of TiNO thin films. Due to the potential application of these TiNO systems which possess excellent photoactive characteristics, this study may open up a new compositional and processing strategy to realize novel optical devices.

2D Amorphous Carbon Dielectric Prepared from Solution Precursor for Nanoelectronics Qing Cao; University of Illinois at Urbana-Champaign, United States

Two-dimensional (2D) semiconductors and semimetals could enable performance and scaling of solid-state electronic devices beyond the limits of those built on their conventional bulk counterparts. However, their suitable accompanying 2D dielectric, ideally in the highly disordered amorphous form to avoid nonuniformity and defects associated with grain boundaries similar to SiO_2 for silicon, has not been identified, which prevents nanoelectronic devices based on low-dimensional nanomaterials from fulfilling their potential. The synthesis of 2D amorphous dielectrics and their integration into electronic devices are challenging due to the metastable nature of amorphous phases. Here we present a scalable and solution-based strategy to prepare large-area and freestanding 2D amorphous carbon monolayers and multilayers as novel dielectrics, from coal-derived carbon quantum dots as precursors. The synthesized 2D amorphous carbon can be transferred to various substrates and is mechanically robust enough to be suspended over cavities without tearing. Structures are fully characterized by Raman, atomic-force microscopy (AFM), X-ray spectroscopy (XPS), and atomic-resolution transmission electron microscopy (TEM). Resulting from their unique amorphous atomic structures, the prepared 2D amorphous carbon demonstrates robust dielectric properties with resistivity higher than 10^9 Ω/cm and dielectric strength above 20 MV/cm. When utilized as gate dielectrics in graphene transistors, 2D amorphous carbon helps to achieve a low leakage current density below 10^{-4} A/cm^2 with an extremely scaled thickness down to three atomic layers (~1.6 nm) for enhanced electrostatic coupling. Meanwhile, their dangling-bond-free van der Waals interface with graphene leads to mobility twice as high as that of 2D devices employing SiO_2. When implemented as ion-transport media in memristors, the ultrathinness of 2D amorphous carbon bilayer enables forming-free operations of non-volatile memory cells with low voltage (<0.4 V), fast switching time (<20 ns), and low energy consumption (<20 fJ per operation), without sacrificing endurance and retention. The large-number rings in their amorphous Zachariasen regions provide well-defined pathways for the filament formation to minimize device spatiotemporal variability.

Continuous Liquid Metal Printing of High Mobility 2D Oxide Heterostructure Transistors Andrew B. Hamlin, Simon Agnew, Anand P. Tiwari and William J. Scheideler; Dartmouth College, United States

We introduce a new roller-based Continuous Liquid Metal Printing (CLMP) process for low-temperature, in-air deposition of 2D metal oxides, including InO_x and GaO_x. Our R2R compatible printing method uses Van der Waals forces to transfer high-quality, large area (> 30 cm^2) 3.5 nm conductive oxide films generated by a self-limiting Cabrera-Mott oxidization mechanism in < 3s. We apply the CLMP method to fabricate InO_x / GaO_x heterostructure thin film transistors (TFTs) at a maximum process temperature of 200 °C. The CLMP 2D GaO_x layers were designed to provide a modulation doping effect at the back-channel of the 2D InO_x, enhancing the free carrier concentration as well as the electronic mobility. The nature of this InO_x / GaO_x heterointerface was further investigated by AFM, Kelvin probe measurements, photoelectronic spectroscopy in air (PESA), and Raman spectroscopy. XRD and TEM characterization reveal that the 2D GaO_x layer is amorphous as deposited, while the 2D InO_x exhibits large, plate-like grains, an electronically advantageous unique property of CLMP InO_x. An average linear mobility improvement from μ_0 = 12.5 cm^2/Vs to μ_0 = 17.5 cm^2/Vs is observed in comparing pure InO_x channels with InO_x / GaO_x heterostructure TFTs. These heterostructure devices exhibit accumulation mode operation and an average I_{on}/I_{off} of 10^7. In summary, our work utilizes a breakthrough high-speed Van der Waals printing to fabricate semiconducting 2D oxide heterostructures for applications to displays, photodetectors, and flexible inorganic electronics.

9:15 AM EQ06.06.03
Atomic Layer Deposition Integration of Amorphous Boron Nitride with 2D Semiconductors Cindy Y. Chen[1], Yu-Chuan Lin[1], Riccardo Torsi[1], Ke Wang[1], Haiying Wang[1], Bangzhi Liu[1], Jessica Kachian[2] and Joshua A. Robinson[1]; [1]The Pennsylvania State University, United States; [2]Intel Corporation, United States

2D transition metal dichalcogenides (TMDs) exhibit unique electronic and optical properties and are actively under investigation as transistor channel materials to combat the critical limit in continued transistor scaling. While 2D TMDs are hailed as having no out-of-plane bonding, these systems are rarely defect-free, and the atomic thickness leads to a high susceptibility to environmental factors that reduce layer stability and electronic performance. Encapsulation with insulators is an effective method to not only prevent 2D TMD oxidation and degradation in ambient environment, but also provide a suitable dielectric environment for enhancing 2D device performance. For instance, hexagonal boron nitride (hBN) at the interface between 2D TMD and the oxide substrate can improve the carrier mobility up to an order of magnitude due to dielectric screening from charged impurities and the suppression of surface optical phonon scattering, both of which are commonly present in conventional 3D oxide substrates. Motivated by the robust dielectric properties of BN, we explore atomic layer deposition (ALD) of ultrathin (2-10 nm) BN as a wafer-scale, non-water-based, low-temperature process for 2D TMD encapsulation. Two routes of ALD, plasma-enhanced (PE) and thermal (Th), are explored to understand the impact of ALD precursor and processing parameters on the resulting chemical, structural, and dielectric properties of BN. ThALD, utilizing sequential injections of NH_3 and BCl_3, results in fully amorphous BN (aBN), whereas the increased energy from N_2 plasma generation in PEALD yields nanocrystalline BN with higher surface roughness. Furthermore, using Mo-based TMDs as a test 2D TMD system, we find significant improvement in the thermal and chemical stability of aBN-capped 2D TMD after prolonged periods (> 1 month) of time in ambient air. Finally, we will discuss the impact of aBN encapsulation on the electronic and optical properties of a range of TMDs, with discussion of implications on using aBN as a robust dielectric for 2D-based electronics.

Doping 2H-$MoTe_2$ with a Monolayer Oxide Anjaly Rajendran, Rishi Maiti, Luke Holtzman, Song Liu, Katayun Barmak and James Hone; Columbia University, United States

Direct bandgap van der Waals semiconductors are excellent candidates for optical devices like photodiodes and light emitting diodes due to excellent optical properties and scope for miniaturization. Among these, monolayer Molybdenum Telluride (2H-phase) is a promising material for fabricating optical devices that can work in the Infrared (IR)/ Near-infrared (NIR) regions pertaining to its band gap of 1.1 eV. However, its air sensitive nature makes it extremely hard to find appropriate dopants to form a p-n junction --- heart of any photodetector.
In this work, we demonstrate p-type doping of 2H-$MoTe_2$ using a monolayer of Tungsten Oxyselenide (TOS) --- an amorphous, stable, and high work-function oxide obtained by self-limiting oxidation of WSe_2. Compared to other p-type doping techniques, this method allows first-passivation-then-doping mechanism that allows to preserve the underlying 2H-$MoTe_2$. We characterize the doping in $MoTe_2$ using Raman, PL, and electrical characterization that shows degenerate doping of $MoTe_2$ using TOS. This is further supported by charge-balance simulations that indicate > 10^{13} cm^{-2} doping density. In conclusion, we demonstrate a stable, controllable, degenerate p-type doping technique to dope 2H-$MoTe_2$ using tungsten oxy selenide (TOS).

Manipulation and Characterization of Interlayer Exciton Electroluminescence in Atomically Thin Semiconductor Heterostructures Philip Kim; Harvard University, United States

Atomically thin semiconductor heterostructures based on transition metal dichalcogenides (TMDs) offer an electrically tunable platform for developing coherent on-chip optoelectronic devices. Interlayer excitons (IEs) in these systems form out-of-plane dipoles and exhibit long lifetimes owing to the spatial separation of electrons and holes. The bosonic nature of excitons and strong dipolar interactions make them ideal candidates for searching for Bose-Einstein condensation in 2D materials. In this presentation, I will discuss creating high densities of cold, controllable excitons as an essential step toward studying the phase diagram of dipolar exciton gases in MoSe2/WSe2 atomically thin heterostructures. Via electrostatic gating, we spatially modulate the vertical electric fields to create a quasi-1D trap for the diffusive IEs, enabling control over the spatial diffusion profile and local IE densities. By electrically modulating density, we reveal a universal linewidth broadening at a critical density in good agreement with the Mott density, independent of the local electrostatic profile. In the second part of the talk, I will demonstrate coherent light emission from the IEs formed by electrically driven carrier injection. We observe a threshold in the electroluminescence of interlayer excitons as we increase the applied forward bias with a balanced injection of electrons and holes. We further characterize the nature of this transition by performing measurements of the second-order correlation function. Strong photon number correlation has been characterized near the threshold IE emission, signaling the quantum correlation of IEs in this regime.

Interacting Opto-Moiré Quantum Matter Xi Wang; University of Washington Seattle, United States

Transition metal dichalcogenide (TMD) heterobilayers with tunable periodic moiré potentials have emerged as a desirable platform for studying quantum many-body interactions. Strong excitonic responses in TMDs allow optical access to the wealth of correlated physics. In this presentation, I will discuss our recent studies of interactions between moiré excitons and charge carriers trapped in moiré potentials. New excitonic many-body ground states are discovered, which can be tuned by moiré carrier fillings and layer stacking. The integration of optical excitation further enriches the phase diagram of moiré quantum matter. We have observed that the spin-spin interactions between moiré trapped holes can be drastically tuned by optical excitation power, pointing to the excitons mediated long-range exchange interaction between moiré trapped carriers. Our work provides the framework for understanding and engineering electronic and excitonic states in moiré quantum matters.

A Quasiparticle Soup—Phonons, Magnons and Spin-Orbit Excitons in CoTiO3 Angela R. Hight Walker; National Institute of Standards and Technology, United States

$CoTiO_3$ has recently been in the spotlight due to its promise of exotic magnetic behavior especially topological magnons. It is a semiconductor with a band gap of ~2.25 eV with the Co^{2+} in edge-sharing octahedra form a stacked honeycomb lattice along the c-axis, with an easy-plane, A-type, antiferromagnetic ordering below 38 K. The spins in each honeycomb plane, which is perpendicular to the c-axis, are ferromagnetically aligned, while the planes are antiferromagnetically aligned with each other. There is significant bond-dependent exchange coupling, which is quite unique for 3d ions. Our magneto-Raman spectroscopic capabilities enable diffraction-limited, spatially resolved optical measurements while simultaneously varying the temperature, laser wavelength and magnetic field to study the photo-physics of layered quantum materials like $CoTiO_3$. Additionally, coupling to a triple grating spectrometer provides access to low-frequency (down to 6 cm^{-1}, or 0.75 meV) phonon and magnon modes, which are sensitive to magnetic order and interactions. Two magnons are clearly identified and studied as a function of temperature and magnetic field, both parallel and perpendicular to the c-axis. Wild phonon behavior is seen which is corroborated by recent neutron scattering measurements and will be discussed.

2:00 PM EQ06.07.02
Exciton-Charge Auger Limit Photovoltaic Performance of 2D Semiconductor Devices Timothy L. Atallah[1,2], Peng Chen[3,2], Zhaoyang Lin[2], Peiqi Wang[2], Sung-Joon Lee[2], Jungqing Xu[4], Zhihong Huang[2], Xidong Duan[5], Yuan Ping[4], Yu Huang[2], Justin R. Caram[2] and Xiangfeng Duan[2]; [1]Denison University, United States; [2]UCLA, United States; [3]Southern University of Science and Technology, China; [4]University of California, Santa Cruz, United States; [5]Hunan University, China

Two-dimensional semiconductors remain of great interest due to their exotic photophysical and magnetic properties: for example while they are inorganic semiconductors they exhibit strong exciton binding energies due to limited dielectric screening. Furthermore, doping has dramatic impacts on 2D device properties due to planar confinement. However, since they are largely interfacial in nature, devices from 2D materials often are plagued with extrinsic limitations such as chemical disorder or contact effects which limits our ability to observe the intrinsic semiconductor properties within devices. Our work shows we can correlate the exciton lifetime from time resolved photoluminescence to the short circuit photocurrent as function of electrostatic doping

within our Van der Waals contacted tungsten diselenide diode showing that at high doping the charge collection is diffusion limited due to the exciton-charge Auger process. This further supported by our scanning imaging photocurrent microcroscopy measurements. Hence we are able to correlate the photophysics directly with device performance and show the importance of prestine and non-destructive contacts and the control of charge density to achieve a high quality 2D device.

2:15 PM EQ06.07.03
Probing Charge Transfer of A*β*-Proteins Examined Using Two-Dimensional Materials as Raman Spectroscopic Platform Wujoon Cha[1,2], Chaejeong Heo[1,2], Sang Hyub Lee[1,2], Seok Jun Yun[3], Byeong Wook Cho[1,2], Taewoo Ha[1,2] and Young Hee Lee[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of); [3]Oak Ridge National Laboratory, United States

We report distinguished charge transfer of amyloid-*β* (A*β*) proteins at different aggregation stages with two-dimensional (2D) materials that can potentially be critical for understanding the fibrillization mechanism and developing an early-stage diagnostic method of Alzheimer's disease. We previously identified notable variations in conductance of A*β* proteins in monomer, oligomer, and fibril forms measured by THz spectroscopy, suggesting significant changes in electronic structures as A*β* fibrillizes [1]. In this work, we show that A*β*s exhibit distinct charge-transfer behavior depending on their aggregated states when interacting with monolayer graphene and molybdenum disulfide (MoS_2). In particular, we found that small and soluble A*β* monomers *p*-doped both graphene and MoS_2 sheets while large and insoluble A*β* fibrils *n*-doped them. These findings provide critical insights into the electronic properties of A*β*s that could be essential to identifying the onset of neurotoxic A*β* fibril formation and developing a rapid, label-free diagnosis based on two-dimensional materials.

In Alzheimer's disease (AD), the accumulation of senile plaques, dominantly composed of fibrillized A*β*s in the cerebral cortex, has been identified as the primary indication of degeneracy. Therefore, early diagnosis of AD is strongly dependent on the ability to detect the emergence of toxic A*β* oligomers and fibrils. It has been suggested that charge transfer plays a key role in the formation and the interaction of proteins [2]. Although A*β* states can be identified based on 'fingerprints' of vibrational modes observed with optical spectroscopies, there is a gap in knowledge about the electronic properties of A*β* that varies significantly as A*β* fibrillizes. To address this gap, we used Raman spectroscopy to probe A*β* proteins interacting with two-dimensional materials that are sensitive to molecular charge transfer.

Graphene, an atomically thin semimetal, and monolayer MoS_2, a semiconductor with a direct bandgap, react sensitively to charge-transfer-induced doping. The shifts in the carrier concentrations and in the Fermi levels can be distinguished from the characteristic Raman bands in graphene (G and 2D) and in MoS_2 (E_{2g} and A_{1g}) [3,4]. Here, we conducted Raman spectroscopy on monolayer graphene and MoS_2 added with A*β* proteins at different fibrillization stages - monomer, oligomer, and fibril. The graphene and MoS_2 sheets were prepared *via* chemical vapor deposition and transferred on a Si/SiO_2 300-nm substrate separately. Then,10 μM protein solutions were loaded and dried in air for subsequent Raman spectroscopy. A statistically significant (p-value < 0.0001) distinction was shown for doping due to monomers and fibrils. Taking the effects of buffer media into account, we observed that, in both graphene and MoS_2, monomer withdrew electrons and *p*-doped while fibril injected electrons and *n*-doped on average. This was evidenced by the upshift(downshift) of G and 2D band, sharpening(broadening) of G band, and decrease(increase) of 2D to G intensity ratio for graphene with monomer(fibril). Similarly, in MoS_2, A_{1g} frequency increased(decreased) and width stiffened(softened) by monomer(fibril). The changes in carrier concentrations were calculated based on the relative positions of the signature Raman bands. In turn, we estimated that the monomers and fibrils shifted the graphene Fermi level by approximately -1.0 eV and +1.9 eV, respectively. The contrary charge-transfer behavior suggests that the electronic states of A*β*, such as its highest occupied (HOMO) and lowest unoccupied (LUMO) molecular orbital levels, shift significantly as A*β* fibrillizes. The transition point from *p*-doping to *n*-doping can serve as a marker for the onset of toxic A*β* aggregates.

Application of 2D Materials in Photonic Sensing and Electronics Thomas Mueller; Technische Universität Wien, Austria

The materials that have enabled the information technology revolution over the past decades will soon reach their physical limits. Novel nanomaterials and technologies have therefore become a major focus of current solid-state device research, with two-dimensional (2D) materials being one of the most promising candidates. While much progress has been made on an individual device level, only a few studies have looked into more complex systems. In this talk I will present realizations of electronic and photonic systems, comprising a large number of 2D material-based devices. In particular, I will discuss photosensors that are able to simultaneously sense and process optical images without latency. We achieved both supervised and unsupervised learning and successfully trained the sensors to classify and encode images, that are optically projected onto the chip. Further, I will share our latest results on the heterogeneous integration of 2D materials with arbitrary substrates, including paper, for applications in electronics and integrated photonics. I will present investigations of 2D device variability, its physical origins, and how it affects system performance.

4:00 PM *EQ06.07.05
Coupling of Magnetic and Optical Properties in Transition Metal Phosphorous Trichalcogenide Efrat Lifshitz; Technion-Israel Inst of Tech, Israel

In recent years, van der Waals magnetic materials gained a renascence of interest due to their potential implementation in modern quantum technologies. The current study focuses on the study of *the transition metal phosphorous tri-chalcogenides semiconductors,* having a general chemical formula MPX_3 (M=1st row transition metals, X=chalcogenides). A single MPX_3 (M=transition metal, X-chalcogenide) layer comprises a honeycomb arrangement (Neel, stripe, or zigzag) of the metal ions, producing an anti-ferromagnetism (AFM). The study tackled a few scientific questions: (1) What mechanism sustains the long-range AFM, and whether the type of magnetic arrangement can be manipulated? Previous work proposed a dominancy of spin-exchange coupling among next metal neighbors. To examine this assumption, we examined the magnetic and magneto-optical properties of a benchmark compound, $MnPS_3$, embedded with different diamagnetic cations (e.g., Zn^{2+}). The results designated a sustain of AFM, however, with a reduction of the Neel temperature with the increase of the dopant concentration, followed by a switch of a magnetic arrangement from Neel to Zigzag in layers at Mn: Zn ratio of 1:1, and a complete loss of AFM arrangement with the dominancy of Zn ions. The gradual transitions with the increase of Zn content were reflected in shifts and polarization of the magneto-PL spectrum, exposing a magnetic-optical solid correlation. (2) Do other moments (e.g., spin-orbit) dictate spin arrangement? To address this question comparison of magneto-optical properties among a few different compounds ($MnPS_3$, $FePS_3$) has been explored. The study designated a unique behavior in $FePS_3$ compared to the two others, exposing new magnetic phenomena that have not been demonstrated before, supposedly related to strong spin-orbit and an inversion of symmetry breaking (see attached a representative emission spectrum). A full description of the observations

will be discussed at the meeting. The experimental observations were corroboration by considering the electronic properties in the framework of DFT+U studies.

Detection of Circularly Polarized Light with Chiral Molecule Functionalized MoS_2 Ye Wang, Yan Wang, Yiru Zhu and Manish Chhowalla; Univerisity of Cambridge, United Kingdom

Emission and detection of circularly polarized photons are essential for quantum computing, spintronics, biosensing, and three-dimensional displays. Thus, materials that can emit and detect circularly polarized light are crucial for enabling new technologies. Here, we demonstrate chemical vapor deposited (CVD) atomically thin semiconductor (MoS_2) coupled with chiral thiol-based amino acids for circularly polarized light (CPL) photodetection. The functionalization was carried out by dipping the CVD MoS_2 sample in a solution of amino acids (concentration = 7.6 mmol in deionised (DI) water). Circular dichroism (CD) spectra show temperature-independent bands between 200 to 500 nm, indicating induction of chirality on functionalized MoS_2. We estimate the degree of functionalization to be 5~7%. The photodetection measurements performed at excitation wavelength of $\lambda = 405$ nm on the functionalized CVD MoS_2 devices show an anisotropy factor (*g* factor) of ~ 10^{-1} at room temperature for left and right CPL detection. The results suggest that while MoS_2 is non-chiral, functionalization with chiral molecules allows differentiation of different polarizations of light.

4:45 PM EQ06.07.07
Optical Emission in Hafnium Disulphide (HfS_2) Related to Iodine (I_2) Intercalation Natalia Zawadzka[1], Tomasz Wozniak[2], Marcin Strawski[1], Igor Antoniazzi[1], Zahir Muhammad[3], Weisheng Zhao[3], Roman Stepniewski[1], Adam Babinski[1] and Maciej R. Molas[1]; [1]University of Warsaw, Poland; [2]Wroclaw University of Science and Technology, Poland; [3]Hefei Innovation Research Institute, Beihang University,, China

Hafnium-based transition metal dichalcogenides (TMDs) including hafnium disulphide (HfS_2) have attracted recently more attention of researchers due to their very effective electrical response [1]. This justifies a need to uncover their basic optical and electrical properties.

Along the line of research, we report on optical emission from HfS_2 bulk crystal grown by chemical vapor transport method. The photoluminescence (PL) is investigated in a broad range of temperatures (5-300 K).

The low-temperature emission consists of a series of well-resolved emission lines apparent in the energy range of 1.3-1.5 eV. In order to identify the observed emission lines, classical correlations between the PL intensity at the energies of different emission lines [2] is analysed. A series of spectra measured at different spots of the sample is used in the analysis. The analysis allows to identify two zero-phonon emission lines in the spectrum which intensities are strongly anticorrelated. The zero-phonon lines are accompanied by several phonon replica. The replica involving accoustic (LA, TA) and optical (E_u(TO)) phonons and their combinations are identified.

The observed emission is related to excitons (most likely neutral and charged) in HfS_2 bound to a localizing potential due to neutral iodine molecules (I_2). The I_2 molecules were introduced into the crystal during its growth as iodine is used as a transport agent in the process. The molecules are intercalated in van der Waals gaps between covalently bonded HfS_2 layers. The presence of iodine in the investigated samples was confirmed by secondary ion mass spectroscopy and the sample de-iodization results in the spectrum disappearance which further supports our attribution. Similar low-temperature PL, related to intercalated halogen molecules was previously observed in 2H polytypes of tungsten sulphides/selenides [3].

The space localization of the bound excitons leads to their delocalization in the momentum space. This explains a strong coupling to phonons from a whole Brillouin zone. We note that the energies of phonon replicas in the PL spectra correspond to maxima of the total density of phonon states in bulk HfS_2, rather than to the energies of phonons from particular high-symmetry points of the Brillouin zone.

In conclusion we present for the first time the low-temperature excitonic emission in bulk HfS_2. We analyze the observed PL spectrum using classical correlation method and we identify two “families” of lines attributed to neutral and charged excitons bound by a potential due to iodine molecules in van der Waals gaps. Our attribution is supported by the observation of iodine in the investigated samples by means of secondary ion mass spectroscopy.

SESSION EQ06.08: Quantum Properties and Applications I
Session Chairs: Monica Allen and Qiong Ma
Thursday Morning, December 1, 2022
Sheraton, 2nd Floor, Back Bay B

8:30 AM *EQ06.08.01
New Optical Features and Biosensing Applications of Engineered 2D Materials Shengxi Huang; Rice University, United States

Engineering of 2D materials, such as defect and structural engineering, offers enormous opportunities to realize new material properties. In this talk, I will introduce a nitrogen substitutional defect in 2D transition metal dichalcogenides and new photoluminescence features generated at various wavelengths. I will also discuss how various 2D materials, including the natural and artificially engineered ones, can be used for biosensing to achieve high sensitivity and high multiplexity.

9:00 AM EQ06.08.02
Giant Effective Zeeman Splitting in a Monolayer Semiconductor Realised by Spin Selective Strong Light-Matter Coupling Daniel Gillard[1], Thomas P. Lyons[2,1], Charly Leblanc[3], Jorge Puebla[2], Dmitry Solnyshkov[3,4], Lars Klompmaker[5], Ilya Akimov[5,6], Charalambos Louca[1], Pranaba Muduli[7,8], Armando Genco[1,9], Manfred Bayer[5,6], Yoshi Otani[2,7], Guillaume Malpuech[3] and Alexander Tartakovskii[1]; [1]The University of Sheffield, United Kingdom; [2]RIKEN, Japan; [3]Institut Pascal, France; [4]Institut Universitaire de France, France; [5]Technische Universität Dortmund, Germany; [6]Russian Academy of Sciences, Russian Federation; [7]The University of Tokyo, Japan; [8]Indian Institute of Technology Madras, India; [9]Politecnico di Milano, Italy

Strong coupling between light and the fundamental excitations of a two-dimensional electron gas (2DEG) are of foundational importance both to pure physics and to the understanding and development of future photonic nanotechnologies (Smolka et al, 2014; Efimkin et al, 2017; Back et al, 2017; Sidler et al, 2017; Tan et al, 2020; Klein et al, 2021; Roch et al, 2019). Here we study the relationship between spin polarization of a 2DEG in a monolayer semiconductor, $MoSe_2$, and light-matter interactions modified by a zero-dimensional optical microcavity. We find pronounced spin-susceptibility of the 2DEG to simultaneously enhance and suppress trion-polariton formation in opposite photon helicities. This leads to observation of a giant effective valley Zeeman splitting for trion-polaritons (g-factor > 20), exceeding the purely trionic splitting by over five times. Going further, we observe clear effective optical non-linearity arising from the highly non-linear behavior of the valley-specific strong light-matter coupling regime, and allowing all-optical tuning of the polaritonic Zeeman splitting from 4 to > 10 meV. Our experiments lay the groundwork for engineering topological phases with true unidirectionality in monolayer semiconductors, accompanied by giant effective photonic nonlinearities rooted in many-body exciton-electron correlations.

Our experiments demonstrate the simultaneous manifestation of strong and weak coupling regimes between a photonic mode and a many-body correlated matter excitation consisting of an exciton dressed by electrons in an effective ferromagnetic phase, resulting in a giant Zeeman splitting between trion-polariton modes. We additionally show that laser illumination acts to depolarize the 2DEG via a process of trion valley pseudospin relaxation and subsequent radiative recombination. The resulting Rabi splitting transfer between the two polarization components induces energy renormalization to which we associate large effective interactions. While in this work an EuS film was used to introduce additional free electrons into the flake, similar results should be observed in any $MoSe_2$ monolayer in which the itinerant carrier density can be raised arbitrarily to give the trion sufficient oscillator strength. Magnetic 2-dimensional materials may also be used to induce 2DEG spin polarization without the need for strong external B-fields (Lyons et al, 2021). Moreover, we note that extremely high laser powers, often pulsed and quasi-resonant, are typically needed to enter regimes of polariton non-linearity, while here the strongest effective interactions occur under low power non-resonant continuous-wave laser excitation. Our work therefore highlights doped $MoSe_2$ as a flexible system in which to realize and apply ultrastrong low-threshold non linearities, for instance towards TMD-based all-optical logic gates (Amo et al, 2010), or to explore nonlinear topological photonics (Smirnova et al, 2020).

Scanning Tunneling Microscope Characterization of Chalcogen Site Defects in Flux Grown WSe_2 Madisen Holbrook, Luke Holtzman, Song Liu, Katayun Barmak, Abhay N. Pasupathy and James Hone; Columbia University, United States

Within the family of two dimensional (2D) materials, transition metal dichalcogenides (TMDs) have gained much research interest due to their potential for filling the semiconductor role in 2D devices. Defects play a critical role in modifying semiconductor electronic properties, both detrimental by limiting device performance, and beneficial as a tool to engineer the electronic properties. The extreme 2D nature of TMDs leads to a strong sensitivity to defects from confinement and reduced screening.[1] A number of different atomic defects have already been experimentally observed in TMDs, but connecting each defect species with their impact on the electronic properties is critical. Recent studies have shown that defect concentrations below 10^{11} cm^{-2} are achievable for TMD single crystals synthesized by a self-flux growth method, [2] but the identity of these defects still remains unclear. Of the possible defects in TMDs, chalcogen vacancies are shown to be the most energetically favorable with the lowest formation energy,[3] but previous studies have shown that oxygen passivated vacancies are the most abundant defect in CVD grown samples. Here we report the characterization of chalcogen site defects in flux grown WSe_2 using scanning tunneling microscopy and spectroscopy (STM/S). We study the electronic and structural properties of the defects in both bulk and monolayer as-grown WSe_2. We further induce vacancies by thermal annealing in UHV, and oxygen passivate them to show how the defects influence the WSe_2 electronic properties. Our study sheds light on the how one of the most abundant defects in TMDs, chalcogen site defects, can be used to engineer the electronic properties of TMDs.

9:30 AM BREAK

10:00 AM EQ06.08.05
Single Photons from Atomically Thin h-BN/WS_2 Heterostructured Bubbles Elena Blundo[1], Salvatore Cianci[1], Federico Tuzi[1], Djero Peteers[2], Eirini Parmenopoulou[1], Giorgio Pettinari[3], Antonio Miriametro[1], Takashi Taniguchi[4], Kenji Watanabe[4], Marco Felici[1] and Antonio Polimeni[1]; [1]Sapienza University, Italy; [2]Technische Universiteit Eindhoven, Netherlands; [3]National Research Council, Italy; [4]National Institute for Materials Science, Japan

Two-dimensional (2D) crystals represent a vast class of materials with exceptional properties that most often contrast with those of their bulk counterpart. An exemplary case is that of transition metal dichalcogenides (TMDCs), which feature a direct bandgap in the monolayer (ML) form, while they are indirect bandgap semiconductors as soon as their thickness exceeds one layer. Indeed, very high emission efficiency characterizes TMDC MLs in the visible/infrared range. In addition, the robustness of TMDC MLs to mechanical deformations (strain) has been exploited as a tuning "knob" to tailor the optical and electronic properties of 2D crystals [1]. At the same time, strain is also at the basis of the appearance of quantum emitters (QEs) in the photoluminescence (PL) spectra of deformed MLs brought to cryogenic temperatures, a property that has sparked the interest of the nanophotonics and quantum information community.
Starting from the observation that the majority of the QEs seemed to appear in spontaneously strained ML regions, such as at the edges of exfoliated flakes [2] or in naturally occurring wrinkles [3], different methods were employed to generate ordered arrays of “strained” emitters that is an essential step for their integration in photonic devices. So far, top-down approaches were mainly used (see a review in [1]), whereby the deposition of MLs on patterned substrates followed by the exposure to highly energetic charged particles [4] generates spatially controlled emitters.
Here, we present an innovative bottom-up straining method, which avoids etched substrates and allows the control over the position and properties of QEs. Indeed, we show that *low-energy* (10 eV) hydrogen-ion irradiation of *bulk* WS_2 flakes can be exploited to engender localised strains. More specifically, protons penetrate through one layer, leading to the production and accumulation of molecular hydrogen in the first interlayer region. The trapped gas coalesces, causing a local blistering of the material, and thus the formation of ML-thick WS_2 micro/nano-bubbles [5]. The bubbles can be made ordered via lithographic methods [5] and host complex strain fields [6], which drive peculiar interaction phenomena between the ML electronic states [7,8]. However, the bubbles completely deflate for temperatures below the gas-to-liquid transition temperature of H_2 (33 K) [5], thus nullifying strain and hindering the appearance of QEs at cryogenic temperatures. We show that by capping the WS_2 bubbles with few-layer-thick h-BN it is possible to preserve the bubble

shape even at temperatures below 33 K, leading to exciton localization in regions of the bubbles, where the strain gradient is maximum. As a result, the micro-PL spectra of the h-BN-capped bubbles at 5 K feature emission lines as narrow as about 1 meV and spectrally isolated. Finally, autocorrelation measurements performed with a Hanbury Brown & Twiss setup demonstrates the quantum nature of the light coming from the bubbles. This finding provides us with a new route to create ordered arrays of site-controlled QEs with the exciting perspective of coupling them with the nano-mechanical resonator represented by the bubbles' membrane.

Two-dimensional (2D) materials such as monolayer WSe_2 have prospective applications in quantum information science because of their capability to host single-photon emitters (SPEs). However, chemical functionalization remains an unexplored parameter space in the design and control of SPEs based on 2D materials, whose atomically thin structure should yield strong tunability with interfacial modifications. Moreover, SPEs in 2D materials are typically generated using a single mechanism such as strain. Here, we report a chemomechanical approach to modify SPEs by using a synergistic combination of localized mechanical strain and non-covalent functionalization with aryl diazonium chemistry. Following a facile diazonium treatment, the dense defect-related emissive states of strained monolayer WSe_2 are simplified into spectrally-isolated SPEs with high photon purity. Our work significantly broadens the possibilities in the parameter space of designing 2D materials-based SPEs by utilizing molecular heterojunction and chemical functionalization approaches.

10:30 AM *EQ06.08.07
Semimetal Device Technology for 2D Semiconductor Electronics Yuxuan Cosmi Lin; Corporate Research, TSMC San Jose, United States

2D semiconductor has emerged as promising candidates for the channel materials in a future ultimately scaled transistor technology. A number of challenges still remain both in terms of material processing and device technologies. The weak interlayer coupling and the unique mesoscopic physics of semimetal/2D semiconductor heterostructures have shown great promises to address some of these fundamental challenges and have demonstrated viable pathways towards scalable and high-performance electronic device technologies based on 2D semiconductors. This talk will summarize our recent research efforts on the material processing and device technologies for semimetal/2D semiconductor electronics. First, I will discuss a wafer-scale semi-automated dry transfer process for monolayer CVD transition-metal dichalcogenides (TMDs) utilizing the weakly coupled interface between semimetal (Bi) and TMDs. Second, our recent progress on semimetal contacts (Bi, Sb) to 2D TMDs for high performance n-type field effect transistor (nFET) technologies will be covered. The thermal stability of these contact technologies will also be evaluated. Finally, I will talk about our computational efforts on the searching of pinning free semimetallic p-type contacts to 2D TMDs.

SESSION EQ06.09: Quantum Properties and Applications II
Session Chairs: Shengxi Huang and Yuxuan Cosmi Lin
Thursday Afternoon, December 1, 2022
Sheraton, 2nd Floor, Back Bay B

1:30 PM *EQ06.09.01
Quantum Properties and Applications of Ultrapure 2D Materials James Hone; Columbia University, United States

This talk will review four areas relevant to the use of 2D materials for achieving novel quantum states and technologies. (1) Synthesis of ultra-pure crystals of transition metal dichalcogenide semiconductors and metals; (2) Studies of quantum transport in semiconducting WSe_2; (3) Novel superconductivity in bilayer $MoTe_2$; and (4) Applications of 2D heterostructures in superconducting qubits.

2:00 PM *EQ06.09.02
Atomic Layer Etching—Towards the Atomic Limit in Scalable Manufacturing Austin J. Minnich; California Institute of Technology, United States

The figures of merit of photonic and electronic devices based on both 2D and 3D materials are increasingly limited by imperfections introduced in nano fabrication. Further advances in capabilities demands subtractive manufacturing methods with vastly improved precision compared to that of typical methods such as wet etching or plasma-based reactive ion etching. In this talk, I will describe our development of plasma-thermal atomic layer etching which enables engineering of the surfaces of photonic and electronic materials with atomic monolayer precision. Possible extensions to 2D materials will also be discussed.

2:30 PM *EQ06.09.03
Creating and Probing New Phases in Layered Quantum Materials Qiong Ma; Boston College, United States

Over the past decade, van der Waals monolayer crystals and heterostructures have been increasingly recognized as a highly-tunable material platform to create and control novel quantum phases. Remarkably, we can create moiré superlattices with the lattice constant continuously tuned over a wide range, providing artificial potential modulation that is effectively felt by electrons. This has led to a plethora of low-temperature emergent phases in lattices made

out of pure carbon, including magnetism, topology, and superconductivity. In this talk, I will show an unexpected spontaneously ordered electronic phase in graphene moiré superlattices with practical device functionalities, persisting all the way up to room temperature. Also, in order to sensitively detect the symmetry properties of such new electronic orders, I will introduce nonlinear electromagnetic responses in various forms and give an example in which the nonlinear properties are employed not only to detect but also to control an emergent electronic phase with definite chirality in a layered correlated semimetal.

3:00 PM BREAK

3:30 PM EQ06.09.04
Deep-Ultraviolet Photoluminescence Excitation Spectroscopy of Hexagonal Boron-Nitride Crystals Su-Beom Song[1,2], Sangho Yoon[1,2], So Young Kim[1,2], Sera Yang[1,2], Seung-Young Seo[1], Soonyoung Cha[2], Hyeon-Woo Jeong[1], Kenji Watanabe[3], Takashi Taniguchi[3], Gil-Ho Lee[1], Jun Sung Kim[1,2], Moon-Ho Jo[1,2] and Jonghwan Kim[1,2]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of); [3]National Institute for Materials Science, Japan

hBN is an indirect and wide bandgap vdW semiconductor forming the indirect gap of ~ 5.96 eV. Despite the indirect bandgap, hBN emits series of strong luminescence lines via strong electron-phonon coupling. Although the physical origin of S-series is verified as phonon-assisted emission from the indirect bandgap of AA' stacked hBN, the physical origin of D-series is largely elusive yet. Cathodoluminescence imaging of D-series has identified that the structural origin is stacking fault in hBN. However, the physical origin of D-series emission is still ambiguous. Here, we employ deep-ultraviolet photoluminescence excitation (PLE) spectroscopy to probe light absorption properties of electronic states for the emission lines of D-series. Our PLE spectra unambiguously demonstrate that all emission lines in D-series originate from inherent stacking faults in hBN crystals.

3:45 PM EQ06.09.05
CVD-Grown Graphene Rings Toward Aharonov-Bohm Oscillations Zitao Tang[1], Siwei Chen[1], Abdus Salam Sarkar[1], Na Liu[1], Stefan Strauf[1], Grzegorz Hader[2], Chunlei Qu[1] and Eui-Hyeok Yang[1,1]; [1]Stevens Institute of Technology, United States; [2]US army DEVCOM, United States

The Aharonov-Bohm effect (AB Effect) demonstrates that the orbital wave function of a charged particle picks up a different phase when it moves along two different paths in the presence of an external magnetic field. The AB effect has been studied in various semiconductors, including GaAs, InP, InAs, AlGaSb, phosphorene, and Bi_2Se_3 [1–3]. More recently, the AB effect was also demonstrated in mechanically exfoliated graphene nanostructures [4–6]. While these results revealed intriguing electron transport properties in graphene nanostructures, relying on graphene produced using sticky tapes limits its scalability for future practical applications.

Here, we present the fabrication of CVD-grown graphene nanorings and their electron transport measurement under magnetic fields toward achieving AB oscillations. We first fabricated graphene channels to measure the sheet resistance (approx. 1165 Ω) and the mobility (approx. 3400 $cm^2/V*s$), which were found comparable to the values found in the literature [7]. We then fabricated the graphene rings and loaded the device inside an ultra-low vibration cryogen-free cooling closed-cycle cryostat at 4 K for the magnetoresistance measurement under the out-of-plane external magnetic fields up to +/-2T. The side gate voltage of up to 1 V was also applied to the graphene ring. The results showed low-frequency oscillations from which the AB oscillations were not extracted, and it is likely due to the large universal conductance fluctuations present in the current device.

We are currently working on modifying and improving the device design based on inputs from modeling to isolate the AB oscillations from the noise floor at 4K (note that AB oscillations in exfoliated graphene rings were detected only below 3.5K in the past [4, 6]). In addition, we will encapsulate the device with hBN to improve the environmental stability of electronic properties and room-temperature mobility [8]. We will also consider incorporating Si_3N_4 or Al_2O_3 as the substrate for graphene rings to reduce the back gate leakage/charging effect. The new results will be included in the presentation at the meeting.

4:00 PM EQ06.09.06
Imaging Conductance with Atomic Scale Resolution in van der Waals Heterostructures Jawaher Almutlaq[1], Ondrej Dyck[2], Bevin Huang[1], Hyowon Moon[1], Chitraleema Chakraborty[1], Stephen Jesse[2] and Dirk Englund[1]; [1]Massachusetts Institute of Technology, United States; [2]Oak Ridge National Laboratory, United States

Transition metal dichalcogenides (TMDs) are naturally favored for e-beam imaging due to their atomic thickness, semiconducting nature, and heavy atoms that are easy to see under scanning probe techniques. In this project, we use STEM Secondary Electron Beam Induced Current (SEBIC) to image and probe the electrical conductivity and connectivity of the active layers in quantum devices. SEEBIC is an emerging electron microscopy technique for probing the electronic band structure of a material by spatially mapping secondary electrons (SEs) [1,2]. The image signal generated with this technique depends on the device and material parameters including SE generation and emission, work function, and conductivity. The measurement requires special sample preparation and a unique substrate with an electron transparent window for STEM. The method has been initially demonstrated to probe graphene and now it is extended to probe more complex multi-layer Van der Waals (VdW) heterostructures. Our results show that we can distinguish the excitonic and conductive layers and see the WSe2 monolayer with atomic resolution even though it is buried between layers of h-BN and graphene, while regions of h-BN and graphene could be identified using electron energy loss spectroscopy (EELS). The correlation between local atomic structure and the emergent electronic properties is of paramount importance in the design and fabrication of device architectures. The facilitation of direct measurement and visualization of such properties is expected to provide a critical window into the operational physics of devices spanning sensing, optoelectronics, and quantum information processing.

Engineering Charge Density Waves Using Interleaved Polytype Heterostructures Suk Hyun Sung[1], Yin Min Goh[1], Nishkarsh Agarwal[1], Noah Schnitzer[2], Ismail El Baggari[3], Kai Sun[1], Lena F. Kourkoutis[2] and Robert Hovden[1]; [1]University of Michigan, United States; [2]Cornell University, United States; [3]The Rowland Institute at Harvard University, United States

1T-TaS_2 is a prototypical charge-ordered van der Waals (vdW) material that hosts several charge density wave (CDW) phases that spontaneously break crystal symmetries, mediate metal–insulator transitions and compete with superconductivity [1–4]. CDWs in TaS_2 are two-dimensional (2D) and reside within each vdW layer. These low-dimensional quantum states are promising candidates for novel devices [5–8], efficient ultrafast non-volatile switching [9,10], and suggest elusive chiral superconductivity [9,10]. Unfortunately, 2D charge ordering is fragile, and extrinsic and thermal disorder quickly degrades long-range order. Here, we engineer 2D-CDW states by controlling disorder via endotaxial interleaved polytype heterostructures of TaS_2. Furthermore, we explore the temperature vs disorder phase space of octahedrally coordinated TaS_2 using in-situ S/TEM to offer a deeper understanding of the system.

Disorder—both extrinsic and thermal—significantly degrades CDWs. Nie, Tarjus, and Kivelson showed that 2D incommensurate (IC)-CDWs in cuprates are long-range ordered only at the zero-disorder limit [11]. Here, we employ endotaxial polytype engineering to substantially decrease disorder to access new regions of the phase diagram where fragile low dimensional quantum states become stable. For example, we show that for octahedrally coordinated TaS_2 the long-range ordered C-CDW (stable < 200 K for 1T) is stable all the way up to ~350 K in interleaved polytype heterostructures [12]. Above ~350 K, the polytype heterostructure recovers long-range order in the IC phase. Furthermore, the hexatic-IC phase exists even above 620 K; in 1T-TaS_2, CDWs completely vanish at ~540 K [13]. Using *in-situ* electron microscopy we can control amount of disorder by directly observing layer-by-layer polytype transformations [12].

In summary, we demonstrate that polytype engineering can stabilize fragile phases such as an ordered IC phase even at high temperatures. In addition, we now provide a schematic phase diagram of octahedrally coordinated TaS_2.

Momentum-Dependent Oscillator Strength Crossover of Excitons and Plasmons in Two-Dimensional $PtSe_2$ Mark Kamper Svendsen[1], Jinhua Hong[2], Thomas Pichler[3], Kazu Suenaga[2] and Kristian S. Thygesen[1]; [1]Technical University of Denmark, Denmark; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]University of Vienna, Austria

The 1T-phase layered PtX_2 chalcogenide has attracted widespread interest due to its thickness dependent metal–semiconductor transition driven by strong interlayer coupling. While the ground state properties of this paradigmatic material system have been widely explored, its fundamental excitation spectrum remains poorly understood. Here we combine first-principles calculations with momentum (q) resolved electron energy loss spectroscopy (q-EELS) to study the collective excitations in 1T-$PtSe_2$ from the monolayer limit to the bulk. At finite momentum transfer, all the spectra are dominated by two distinct interband plasmons that disperse to higher energy with increasing q. Interestingly, the absence of long-range screening in the two-dimensional (2D) limit inhibits the formation of long wavelength plasmons. Consequently, in the small-q limit, excitations in monolayer $PtSe_2$ are exclusively of excitonic nature, and the loss spectrum coincides with the optical spectrum. The qualitatively different momentum dependence of excitons and plasmons enables us to unambiguously disentangle their spectral fingerprints in the excited state spectrum of layered 1T-$PtSe_2$. This will help to discern the charge carrier plasmon and locally map the optical conductivity and trace the layer-dependent semiconductor to metal transition in 1T-$PtSe_2$ and other 2D materials.

4:45 PM EQ06.09.09
Intrinsic Supercurrent Non-Reciprocity Coupled to the Crystal Structure of a van der Waals Josephson Barrier Jae-Keun Kim[1], Kun-Rok Jeon[2], Pranava Sivakumar[1], Jaechun Jeon[1] and Stuart S. Parkin[1]; [1]Max Planck Institute of Microstructure Physics, Germany; [2]Chung-Ang University, Korea (the Republic of)

The non-reciprocal behavior in dissipative current flows, known as the diode effect, has played a central role in modern electronic devices and circuits. In conventional schemes, non-reciprocity along the current direction arises from spatial inhomogeneity. Recently, it has been shown that when inversion and time-reversal symmetries are both broken, and in combination with a spin-orbit interaction (SOI), even spatially homogeneous systems can provide for diode functionality. By implementing this magneto-chirality with superconductors and matching the superconducting gap with the SOI energy, one can achieve a directional, non-dissipative, supercurrent flow, which is a prerequisite for the realization of future superconducting quantum devices. To date, only a few methods have been developed to intrinsically and/or extrinsically break the inversion symmetry and its mechanisms, especially whether intrinsic or extrinsic, remain elusive.
Here we demonstrate a substantial supercurrent non-reciprocity in a van der Waals (vdW) vertical Josephson junction (JJ) formed with a T_d-WTe_2 barrier and $NbSe_2$ electrodes that clearly reflects the intrinsic crystal structure of T_d-WTe_2. In combination with time-reversal symmetry breaking by the applied magnetic field, an inherently inversion symmetry breaking of WTe_2 barrier can provide a non-reciprocal supercurrent in $NbSe_2$/WTe_2/$NbSe_2$ vdW JJs. The

magneto-chiral characteristics with respect to a mirror plane of WTe_2 strongly support the crystal structure reflected supercurrent non-reciprocity in $NbSe_2/WTe_2/NbSe_2$ vdW JJs. The diode efficiency of the JJs show linear scaling behavior with WTe_2 barrier thickness up to critical thickness, which is predicted theoretically for ballistic JJ. It shows that the supercurrent non-reciprocity of the JJs can be likely related to charge transport mechanism in the barrier. Our results show that 2D materials promise vertical Josephson diodes with high efficiency and tunability. Our approach can be extended to other low-symmetric and twisted vdW systems for accelerating the development of 2D superconducting devices and circuits.

SESSION EQ06.10: Quantum Properties and Applications III

Large-Area Single-Crystal 2D Films for Electronic Device Applications Ki Kang Kim[1,2]; [1]Institute for Basic Science, Korea (the Republic of); [2]Sungkyunkwan University, Korea (the Republic of)

Two-dimensional (2D) materials including graphene, hexagonal boron nitride and transition metal dichalcogenide have been highlighted due to unusual intrinsic physical and chemical properties such as high exciton binding energy and large magnetic resistance, which allows unprecedented electronic applications. To realize the intrinsic material properties and industrial applications, wafer-scaled single-crystal 2D films are highly required. Here, we present the recent progress of single-crystal growth for 2D materials in a wafer scale via the self-collimation on liquid substrate and the epitaxial growth on atomic sawtooth surface. The detailed growth mechanism is discussed accordingly.

8:45 AM EQ06.10.02
Modelling Defective MoS_2 and Au Interfaces in 2D Memristors by Combining DFT with Green's Function Surface Calculations Gabriele Boschetto[1] and Aida Todri-Sanial[1,2]; [1]LIRMM, University of Montpellier, CNRS, France; [2]Technical University of Eindhoven, Netherlands

Atomically thin single-layer molybdenum disulfide (MoS_2) is a two-dimensional material with highly desirable mechanical, electronic, and optical properties. In addition, its reduced dimensionality and ultra-thin size could enable the fabrication of a new generation of very compact and low-power devices beyond conventional CMOS technology.
In this context, 2D memristors for neuromorphic computing applications [1] based on single-layer MoS_2 present several advantages with respect to conventional devices based on transition metal oxides: good flexibility, high transparency, and the potential to work when applying low voltages (0.1 - 0.2 V), thus allowing the fabrication of very compact and energy-efficient devices.
However, the working mechanism of 2D memristors is still far from being understood: the resistive switching may non-trivially depend on several factors, such as device architecture, metal electrodes, and the quality of the MoS_2 film. Small and extended defects in MoS_2 films, which are introduced during the material growth, are thought to play a crucial role not just in the properties of MoS_2 itself but also in the quality of the metal contact.
Indeed, at present, MoS_2 films are far from being pristine, and there is still much debate around the role of defects in the physics of the device.
Thus, to shed light onto the physics of metal-MoS_2 interfaces, we carry out atomistic computer simulations in the framework of density functional theory (DFT). We employ surface calculations based on the Green's function formalism to construct realistic interfaces and compute surface properties [2]. To model the metal electrode, we choose Au as it is commonly one of the most popular choices, and it has been successfully used to develop 2D memristors [3]. As we aim to bridge the gap between materials' properties and device physics, we investigate the effect of common defects on MoS_2 (i.e., vacancies and substitutions) on the physics and chemistry of Au-MoS_2 interfaces [4].
To the best of our knowledge, this is the first attempt to thoroughly model defective MoS_2 interfaces with DFT coupled with the Green's function formalism.
Ultimately, our study constitutes the first step of a more comprehensive multi-scale modelling approach, in which the aim is to construct a full atomistic-to-device level model that can aid us in elucidating the working mechanism of 2D memristors based on single-layer MoS_2.

High-Quality Exfoliation and Integration of Large-Area Transition Metal Dichalcogenide Monolayers with Wafer Bonder Wenjing Wu[1,2] and Shengxi Huang[1,2]; [1]Rice University, United States; [2]Penn State University, United States

Transition metal dichalcogenides (TMDCs) monolayers and their heterostructures have attracted tremendous research interests in the past decades, for their remarkable physical properties. However, producing such two-dimensional (2D) monolayers with both desired lateral scale and film quality still needs effort. Here, we report a nifty and generic way to achieve high quality large-area TMDC monolayers and their assembly from bulk crystals, with improved control over cracks and strain based on the Au-assist exfoliation technique. Wafer bonder is used during the process for: 1) applying controllable and uniform force to integrate monolayers onto desired substrates, 2) supporting a high vacuum (HV) environment to eliminate air bubbles between layers, and 3) maintaining the desired temperature. Both optical and electrical characterizations of different TMDC monolayers confirm the high quality over a centimeter scale. This high-throughput method could be beneficial to the fundamental physical studies as well as the electronic and photonic applications of the TMDC materials.

9:15 AM EQ06.10.04
Conformal Growth of Hexagonal Boron Nitride on Silicon-Based Nano-Trenches with High-Aspect Ratio Jiye Kim[1], Chang-Won Choi[1], Seokho Moon[1], Doh Kyung Yeon[1], Hokyeong Jeong[2,1], Jaewon Kim[3,1], Jaerim Kim[1], Dongwa Lee[1], Si-Young Choi[1] and Jong kyu Kim[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]Samsung Electronics Memory Division, Korea (the Republic of); [3]Samsung Advanced Institute of Technology, Korea (the Republic of)

Hexagonal boron nitride (h-BN) has emerged as a prospective dielectric material for future silicon (Si)-based electronics. Despite notable advances in h-BN synthesis, there are remaining challenges toward real-world applications at the industrial level. h-BN grown on catalytic substrates by using chemical vapor deposition (CVD) should be transferred onto a target substrate, which inevitably induces various deformations of the transferred h-BN such as tears, wrinkles, and incorporation of impurities. Moreover, it is extremely difficult to form a conformal and intact contact between h-BN and a target substrate with 3-dimensional complicated nanostructures, as is the case for CMOS devices, through such a transfer process, which should be addressed for taking advantage of h-BN in the future Si electronics technologies.
Here, we present the direct growth of h-BN film on an array of Si-based nano-trenches with a pitch of 60 nm and the aspect ratio of 7:1 by metal-organic chemical vapor deposition (MOCVD). Few-layer h-BN with a thickness of ~1.67 nm was conformally grown along the nano-trenches consisting of SiO_2 and Si, with an excellent step coverage. The conformal growth mechanism of MOCVD-grown h-BN will be discussed with a combination of state-of-the-art spectroscopic analyses and theoretical calculations. The boron and nitrogen precursors act as the key factor of conformal growth, which can easily diffuse into the nano-trenches and chemisorb on the SiO_2 surface.

9:30 AM EQ06.10.05
EllipsoNet—Deep-Learning-Enabled Optical Ellipsometry for Complex Thin Films Ziyang Wang[1], Yuxuan Lin[2], Kunyan Zhang[1], Wenjing Wu[1] and Shengxi Huang[1]; [1]The Pennsylvania State University, United States; [2]University of California, United States

Analysis of optical spectroscopy data often requires intensive model fitting. Reflectometry and ellipsometry are commonly used methods to measure the optical dielectric functions or the complex refractive indices of optical thin films such as 2D materials. However, the available fitting models are extremely computational intense, require calibrations from human-expert and very specific to the optical structures of the samples. The substrate structures need to be simple (a single, thick, and transparent substrate is ideal) and perfectly defined. In addition, ellipsometry also requires expensive setup. In this study, we developed a deep learning method based on an encoder-decoder convolutional neural network that is capable of extracting refractive indices of thin films including 2D materials on arbitrary complex multilayer substrates named EllipsoNet. EllipsoNet is trained with numerically generated data. Without any prior knowledge of stack materials or human intervention, EllipsoNet can predict the complex refractive indices of thin films from experimentally obtained optical reflectance with high accuracies. Kramers-Kronig relations are spontaneously learned by the model without purposely teaching. This approach enables the in-situ optical characterization of functional materials and components in actual complex optoelectronic devices, a task previously not feasible with traditional reflectometry or ellipsometry methods.

10:15 AM *EQ06.10.06
Multiscale Simulation of 2D Electronic Devices—From Contact Design to Machine-Learning-Guided Device Optimization Tong Wu[1], Ning Yang[1], Han Wang[2] and Jing Guo[1]; [1]University of Florida, United States; [2]University of Southern California, United States

In nanoscale logic and memory devices based on new materials, atomistic scale features of materials and interfaces can play an important role in determining device characteristics and performance. Atomistic simulations of a practical logic or memory device, however, are computationally expensive, which hinders efficient device design. A multiscale approach to device simulation can address the above challenge and achieve physical accuracy and computational efficiency at the same time in device simulations. We have developed a multiscale simulation approach and machine-learning-guided design optimization methods to investigate the metal contacts to 2D materials, 2D-material-based nanoscale transistors, and ferroelectric tunneling junction (FTJ) memory devices, as described below.
To understand and explore low contact resistance to 2D materials, a multiscale simulation approach is developed to simulate the contact transport properties between a semimetal to a monolayer two-dimensional (2D) transition metal dichalcogenide (TMDC) semiconductor [1]. The results elucidate the mechanisms for low contact resistance between semimetal and TMDC semiconductor contacts from a quantum transport perspective. The simulation results compare favorably with recent experiments. Furthermore, the results show that the contact resistance of a Bismuth-MoS_2 contact can be further reduced by engineering the dielectric environment and doping the TMDC material to . The quantum transport simulation indicates the possibility to achieve an ultrashort contact transfer length of ~1nm, which can allow aggressive scaling of the contact size.
At the device level, scaling of transistors near the physical limits imposes significant technological and design challenges. Identifying and understanding optimum designs and trade-offs between multiple design targets, including speed, power or energy, and variability, is necessary. By integrating machine-learning-based optimization methods into device simulation, we developed a multiobjective device design method that can automatically and efficiently identify the most promising device designs that can simultaneously satisfy multiple design objectives [2] for 2D-material-based field-effect transistors (FETs) near the scaling limit. The multiobjective design framework performs gradient-free efficient global optimization based on an active learning method. Optimum designs with the trade-off between transistor speed, power, and variability are identified automatically for 2D FETs by applying the multiobjective design framework. It is shown that the International Roadmap of Devices and Systems (IRDS) target of 2025 and 2028 technology nodes can be met by the identified designs of 2D FETs [2].
The multiscale simulation approach is further applied to simulate 2D-material-based memory devices. Atomically thin van der Waals (vdW) heterojunctions are investigated for ferroelectric tunnel junction (FTJ) device application by combining multiscale simulations from atomistic *ab initio* to quantum transport device simulations with experimental studies [3]. The simulation reveals that low quantum capacitance of graphene, weak electronic hybridization of vdW bonds, and high interface quality free of dangling bonds can lead to extremely large vdW interface barrier height modulation at the graphene-2D ferroelectric (FE) interface [3].

10:45 AM EQ06.10.07
Unraveling the Correlation Between Raman and Photoluminescence in Monolayer MoS_2 Through Machine Learning Models Ang-Yu Lu[1], Luiz G.P Martins[1], Pin-Chun Shen[1], Zhantao Chen[1], Ji-Hoon Park[1], Mantian Xue[1], Jinchi Han[1], Nannan Mao[1], Ming-Hui Chiu[1,2], Tomas Palacios[1], Vincent Tung[2,3] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]King Abdullah University of Science and Technology, Saudi Arabia; [3]The University of Tokyo, Japan

Two-dimensional (2D) transition metal dichalcogenides (TMDCs) with intense and tunable photoluminescence (PL) have opened up new opportunities for optoelectronic and photonic applications such as light-emitting diodes, photodetectors, and single-photon emitters. Among the standard characterization tools for 2D materials, Raman spectroscopy stands out as a fast and non-destructive technique capable of probing material crystallinities and perturbations

such as doping and strain. However, a comprehensive understanding of the correlation between photoluminescence and Raman spectra in monolayer MoS_2 remains elusive due to its highly nonlinear nature. Here, we systematically explore the connections between PL signatures and Raman modes, providing comprehensive insights into the physical mechanisms correlating PL and Raman features. Our analysis further disentangles the strain and doping contributions from the Raman spectra through machine learning models. First, we deploy a DenseNet to predict PL maps by spatial Raman maps. Moreover, we apply a gradient boosted trees model (XGBoost) with Shapley additive explanation (SHAP) to bridge the impact of individual Raman features in PL features, allowing us to link the strain and doping of monolayer MoS_2. Last, we adopt a support vector machine (SVM) to project PL features on Raman frequencies. Our work may serve as a methodology for applying machine learning in 2D material characterizations and providing the knowledge for tuning and synthesizing 2D semiconductors for high-yield photoluminescence.

11:00 AM EQ06.10.08
Transition Metal Dichalcogenides—Self-Flux Synthesis, Characterization and Defect Computations Luke Holtzman[1], Song Liu[1], Preston A. Vargas[2], Madisen A. Holbrook[1], Richard Hennig[2], James Hone[1] and Katayun Barmak[1]; [1]Columbia University, United States; [2]University of Florida, United States

Two-dimensional transition metal dichalcogenides (TMDs) have emerged as a highly attractive class of materials due to their novel optical and electronic phenomena, scalability to sub-nanometer sizes, and potential for electronic and optoelectronic applications. Chemical vapor deposition (CVD) and chemical vapor transport (CVT) have been used to grow monolayers and bulk crystals, respectively, quickly and at high yields. However, these techniques produce highly defective TMDs, negatively impacting the novel properties [1-4]. An alternative synthesis method is self-flux crystal growth, which has been shown to grow bulk TMDs with point defect densities several orders of magnitude lower than those from CVD and CVT [5]. The self-flux-growth uses high-purity elemental precursors limiting impurities and occurs inside of a vacuum sealed quartz ampule. The transition metal dissolves in the excess liquid chalcogen flux at an elevated temperature, then the mixture is slowly cooled to allow for growth of high-quality crystals.
In this work, we use the self-flux method to synthesize five different TMDs: $MoSe_2$, WSe_2, WTe_2, 2H-$MoTe_2$, and 1T'-$MoTe_2$. Temperature profiles for growth of the four stable phases are largely similar; however, for the metastable 1T'-$MoTe_2$ phase, the ampule is removed from the furnace at 900 °C and rapidly quenched instead of slow cooling to room temperature. The material and phase are confirmed using a combination of Raman spectroscopy and x-ray diffraction. The point defect density is determined by counting point defects in several scanning tunneling microscopy (STM) images taken from across a cleaved bulk TMD's surface. To identify the defect chemical identities in self-flux TMDs, density functional theory calculations were used to simulate STM images for various intrinsic defects, and after comparison to experimental images, the simulations suggest the presence of chalcogen vacancies in $MoSe_2$ and WSe_2, and both metal and chalcogen vacancies in 2H-$MoTe_2$. Additionally, ab initio modeling is used in conjunction with experimental thermodynamic data to calculate temperature dependent thermal equilibrium defect densities for intrinsic defects of the four stable self-flux TMDs. In WSe_2, the thermal equilibrium defect density of selenium vacancies at the self-flux growth conditions was calculated to be two to three orders of magnitude less than experimental values determined by STM images, suggesting thermal equilibrium has not been reached, and kinetic or residual impurity factors drive increased point defect densities in self-flux TMDs.

11:15 AM EQ06.10.09
Printed Memristors on Paper Jinrui Chen, Mingfei Xiao, Nasiruddin Macadam and Tawfique Hasan; University of Cambridge, United Kingdom

Paper is a low-cost, flexible, and biodegradable substrate that could address the ever-growing e-waste problem. It is 10,000 times cheaper than silicon, and 300 times cheaper than the widely used plastic substrate polyimide. However, the progress in electronics on paper-based substrates in the last decade has largely remained focused on transistors and rudimentary sensors. We present the first ever memristor on consumer-grade printing paper. Our MoS_2-based inkjet-printed memristors with Ag and Au electrodes can be fabricated at < 120-celsius degrees. The devices exhibit excellent resistive switching behavior, with a high (10^6) ON-OFF ratio, and < ±0.5 V operation voltage. Using an intermediate layer of polyethyleneimine, we demonstrate more than 6 stable resistive states and controllable transition from volatile to non-volatile state. We further demonstrate synaptic and neuron functions by integrating the devices into RC circuits. Our versatile memristor platform opens exciting opportunities in artificial synapses for neuromorphic electronics on biodegradable substrates.

11:30 AM EQ06.10.10
Chemical Exfoliation of Tin Monosulfides for Thin Film FETs on Flexible Substrates Abdus Salam Sarkar, Sarah Erickson, Siwei Chen and Eui-Hyeok Yang; Stevens Institute of Technology, United States

Low crystal symmetry and structural in-plane anisotropic orthorhombic group IV_A-VI metal monochalcogenides (MMCs) have recently emerged as novel electronic materials. [1-3] They have a chemical formula, MX (M=Si, Ge, Sn and X=S/Se), with uniquely distorted layered structures. Among them, earth-abundant tin (II) monosulfides (SnS) show rich fundamental physics and anisotropic optical, electrical and mechanical responses originating from their low crystal symmetry [1]. However, the successful isolation of atomically thin SnS single/ultrathin layers is challenging due to strong interlayer interactions attributed to the lone-pair electrons of sulfur (S), which, in turn, makes it difficult to realize low-cost, printed field-effect transistors (FETs).
Here, we present a top-down liquid-phase exfoliation (LPE) approach to overcome the challenge by synergistically utilizing the thermal and ultrasound energies that induce hydrodynamic force in the solution, giving rise to the systematic isolation of highly crystalline SnS nanosheets [4, 5]. In the LPE method, tin (II) sulfide granular (>99.99%) trace metals were dissolved in acetone in a glass vial sealed with Teflon tape, followed by cavitation using ultrasonication at 50 W and 40 kHz for 20 hours. After the sonication process, the obtained dark brown solution was centrifuged at 8000 rpm for 15 minutes. The isolated SnS nanosheets were characterized using an atomic force microscope (AFM), transmission electron microscope and Raman/PL spectroscopy. The AFM analysis of isolated SnS dimensionality revealed Gaussian distribution in thicknesses. The average sheet thickness of the nanosheets was ~0.90 nm, affirming the isolation of monolayers or bilayers with high crystallinity. The room temperature Raman spectra of SnS nanosheets exhibited four optically active phonon modes consistent with those of ultrathin layers. The phonon modes peaked at ~100, and ~190, ~210 cm^{-1} correspond to A_g (1), A_g (2), A_g (3) vibrational modes, respectively, while the peak at ~160 cm^{-1} to B_{3g} orthorhombic mode.
The SnS nanosheets formulate a functional ink that can be subsequently deposited by spin/spray coating onto Si/SiO_2 and PET substrates. This chemical exfoliation technique enables large-scale isolation of electronic grade SnS nanolayers for a wide range of applications, including extended area nanoelectronic devices printed from solution to create field-effect transistors (FETs) and phototransistors for flexible electronic applications. Currently, we

are fabricating these FET arrays, which will be included in the presentation at the meeting.

Low-Energy Ion Implantation—Range Comparisons Between Theory and Experiment Michael Titze[1], Jonathan Poplawsky[2], Alex Belianinov[1] and Edward Bielejec[1]; [1]Sandia National Laboratories, United States; [2]Oak Ridge National Laboratory, United States

The continued decrease in size of microelectronic devices has created a need for shallower implanted dopant layers. With the recent discovery of two-dimensional (2D) materials, the ultimate limit for shallow layer implant is incorporating material into a single monolayer. Multi-specie focused ion beams (FIB) can operate with a variety of ion species and enable direct-write implantation of specific ions tailored for an exact application. Prior to any ion irradiation experiment, the range of ions in the material needs to be calculated, often predicted by using freely available Stopping and Range of Ions in Matter (SRIM) simulation.
SRIM simulations are in excellent agreement with experiment for high energy light ions, however, for low energy heavy ions, discrepancies between SRIM and observed experimental values have been reported. We use Rutherford backscattering spectrometry (RBS), Secondary ion mass spectrometry (SIMS) and Atom-probe tomography (APT) to measure the depth of heavy ions in silicon following FIB implantation with energies from 1 – 150 keV. The resolution limit of RBS and SIMS is on the order of nanometers, comparable to the implantation depth for few keV ion implants, requiring the use of APT for measuring lowest energy implants because APT is capable of almost angstrom resolution in the 100 direction of single crystalline Si. The difference between SRIM and experimental result is < 10 nm for all investigated ion energies, however due to the low overall range of the ions, the relative error is larger for lower ion energies with 1 keV as the minimum energy investigated showing > 500 % relative discrepancy.

Engineer Confined Phononic Light-Matter Waves in van der Waals Materials Siyuan Dai; Auburn University, United States

The manipulation of light at small scales is one of the ultimate goals for modern optics. For this purpose, polaritons—hybrid light-matter waves that propagate in a confined length scale—are typically involved. Recent results of polaritons in van der Waals materials reveal a series of advances, including atomic-scale localization, dynamic tunability, relative low-loss, and topologically protected states. These advances are attributed to the unique physical properties in reduced dimensions and the configurability through van der Waals heterostructuring. In this talk, I will show the engineered merits of photo-lattice waves—phonon polaritons—by van der Waals stacking, structuring, and twisting. Phonon polaritons in van der Waals heterostructures exhibit dynamic tunability, various wavefronts, and new energy-momentum dispersions.

2:30 PM EQ06.11.04
Experimental Quantum Transport in Strained Graphene and SWCNTs – Towards NOEMS Alexandre R. Champagne; Concordia University, Canada

We report new measurements of ballistic charge conductivity in strained suspended graphene, and observe the previously predicted [1] strain-induced scalar and vector potentials. To do so, we built an experimental platform for *in-situ* strain-engineering of quantum transport in 2D materials. This instrumentation permits low temperature (0.3 K) transport in 0 to 9 Tesla magnetic fields. The tunable uniaxial strain (up to 3%) is completely decoupled from the gate-tunable charge density, permitting quantitative understanding of strain effects. We show slippage-free mechanical clamping of high aspect-ratio graphene crystals, where atomically ordered edges are unnecessary for quantitative straintronics. We study in detail transport in a ballistic graphene channel whose length is 90 nm and width is 600 nm. By applying strain in this device, we observe that the strain-induced scalar potential shifts its low energy band structure downward by up to 30 meV. We also show precise control of the gauge vector potential which reversibly suppresses the conductance. We discuss our ongoing experimental progress towards quantum strain engineering in SWCNTs, and present calculations showing their potential for valleytronics and other applications.

We conclude with an overview of a project to integrate *suspended* 2D materials in planar optical cavities towards achieving fully tunable nano-opto-electro-mechanical (NOEMS) systems. We developed a nitrocellulose-based (nail polish) method to manipulate very gently and suspend individual ultra-thin 2D materials [2]. Using this method, we assembled optical cavities able to a widely tune Raman scattering and absorption in bilayer graphene. [1] A. C. McRae, G. Wei, and A. R. Champagne, Phys. Rev. Applied 11, 054019 (2019). [2] I. G. Rebollo, F. C. Rodrigues-Machado, W. Wright, G. J. Melin, A. R. Champagne, 2D Mater. 8, 35028 (2021).

Photon Addition Quantum Module for Enhanced Sensing and Imaging Pankaj K. Jha[1], Hamidreza Akbari[1], Souvik Biswas[1], Claudio Parazzoli[2], Barbara Capron[2], Benjamin Koltenbah[3] and Harry A. Atwater[1]; [1]California Institute of Technology, United States; [2]North West Quantum Science, United States; [3]The Boeing Company, United States

Single photon sources (SPSs) are one of the building blocks for quantum technologies, including optical quantum computing, quantum communications, and sensing and metrology [1]. Recently, color centers in hexagonal boron nitride (*h*BN) have emerged as a promising candidate for SPS at room temperature [2], which can be localized with nanometric precision [3] as well as exhibit near-lifetime and tunable quantum emission [4]. Here, we show that these *h*BN emitters can be used as a quantum module for photon addition quantum technology for enhanced sensing and imaging applications [5]. In this work, we investigated emission characteristics of an *h*BN quantum emitter pumped off-resonantly with a 532 nm pulsed laser. We quantified the Mandel-Q parameter over several orders of magnitude of observation time scale by tagging every photon and applying temporal gating. We observed the transformation of sub-Poissonian statistics of intensity fluctuations measured over the shorter (tens of nanoseconds) times to super-Poissonian over the longer (tens of microseconds) times. Next, in addition to the pump laser, we triggered the excited quantum emitter quasi-resonantly with a very weak (at the level of single photons) tunable dye laser. De-excitation of the *h*BN quantum emitter can be triggered by the dye laser or occur spontaneously. Using the Hanbury Brown-Twiss setup, we measured two photon counts with and without the *h*BN quantum emitter. We compared the experimental results to those calculated using a light-emitter interaction model. Our experimental results may open the door to using *h*BN quantum emitters for probabilistic coherent amplification of weak optical and thermal signals for applications in sensing and imaging.

Disentangling Many-Body Effects in the Coherent Optical Response of a 2D Semiconductor Chiara Trovatello[1,2], Florian Katsch[3], Qiuyang Li[1], Xiaoyang Zhu[1], Andreas Knorr[3], Giulio Cerullo[2] and Stefano Dal Conte[2]; [1]Columbia University, United States; [2]Polytechnic University of Milan, Italy; [3]Technische Universitat Berlin, Germany

Monolayer transition metal dichalcogenides (1L-TMDs) have received increasing attention because of their enhanced light-matter interaction and tightly bound excitons[1]. Measuring and modeling the transient behavior of optically excited carriers and excitons is essential for exploiting TMDs in optoelectronic devices with decreased size[2]. Transient absorption spectroscopy has been extensively used to study exciton scattering processes on an ultrafast timescale. While it has been shown that on a ten- to hundred-ps timescale, the exciton decay dynamics is dominated by thermal effects[3], **the physical origin of exciton dynamics on a ps and sub-ps timescale is still under debate**. In this temporal window, many-body effects lead to a renormalization of the bands, inducing a transient energy shift of the excitonic resonance. Simultaneously, the increase of the electronic temperature after photo-excitation, due to multiple electronic scattering events, broadens the excitonic linewidth. Broadening and shift of the excitonic peak overlap in time with an abrupt absorption reduction due to phase-space filling effect (i.e., Pauli blocking mechanism)[4]. All these processes are difficult to disentangle, and their dynamical interplay determines the complex shape of the transient absorption spectra of TMDs across the bandgap at early time delays (i.e., during and immediately after the pump and probe temporal overlap). In the literature, transient exciton energy shifts have been roughly estimated from pump-probe measurements with contrasting results, e.g., different signs and values depending on the pump energy.

In this work, we measure the transient optical response of 1L-WS_2 on SiO_2 across its optical bandgap. The sample is photoexcited on- and out-of-resonance with respect to the A exciton, and at variable pump fluences below the exciton-Mott transition. In order to capture the origin of the different transient signal shapes, **we fully disentangle absorption reduction, energy shift and broadening of the excitonic peak from the transient optical response, using Kramers-Kronig constrained variational analysis to extract the absorbance spectrum from the measured transient reflectivity** ($\Delta R/R$) as a function of pump-probe delay.

The absorption spectra show a linear variation of all the A exciton peak parameters (i.e. intensity, energy and linewidth) with the pump fluence. We find that **many-body effects are strongly enhanced for resonant excitation**, resulting in a transient blue shift of the A exciton. The shift progressively decreases as the pump is detuned from the resonance and turns into a small red shift when the energy of the pump is close to the B excitonic resonance. The energy shift originates from Coulomb-induced bandgap renormalization while the asymmetric broadening is related to excitation induced dephasing mechanism. **Microscopic calculations based on excitonic Heisenberg equations of motion quantitatively reproduce the non-linear absorbance spectra of the material**.

In conclusion, we provide a more complete picture of the transient optical response of 1L-WS_2 which can finally explain the strong differences observed in the pump-probe spectra following on- and off-resonant excitation. Our combined experimental and theoretical studies give important insights into the complex interplay between many-body correlations and excitonic interactions determining the non-equilibrium response of 1L-TMDs.

Interlayer Drag Effects in Graphene-Based Electronic Double-Layer Systems Changgan Zeng; University of Science and Technology of China, China

A closely spaced but electronically isolated electronic double-layer system is a fascinating platform to study interlayer quasiparticle interactions and to reveal intriguing interlayer correlated states. Recent progress in the development of graphene and other two-dimensional (2D) electronic systems has sparked renewed interest in the study of interlayer interactions based on vertical 2D heterostructures. Especially, the highly tunable electronic properties of component layers, together with the accessibility of ultra-small interlayer separation, enable the investigation of the drag effect in previously inaccessible regimes.
In this talk, I will present our recent progresses on the interlayer drag experiments in several graphene-based electronic double-layer systems, including: 1) The demonstration of signature carrier-density-dependence of drag resistance between massless and massive fermions in heterostructures consisting of monolayer graphene and bilayer graphene separated by hBN spacer [1]. 2) The discovery of a new type of quantum interference effect in inter-layer Coulomb drag, with the interference pathway comprising different carrier diffusion paths across the two constituent graphene layers [2]. 3) The discovery of a giant and highly-tunable drag effect between graphene and superconducting $LaAlO_3/SrTiO_3$ heterointerface, wherein a brand-new mechanism of Josephson-Coulomb drag is proposed [3]. These results have important implication for investigating interlayer-coupling-induced fascinating physics via utilizing newly-emerging 2D electronic systems.

Symmetry Engineering in Nanostructures of Transition Metal Dichalcogenides Yoshi Iwasa[1,2]; [1]The University of Tokyo, Japan; [2]RIKEN CEMS, Japan

Symmetry often plays crucial roles in the properties and functions of materials. In bulk materials, symmetry is basically determined by the space group of single crystals. In sharp contrast, in nanomaterials, symmetry can be controlled as designed. For instance, graphene and bilayer graphene have totally different symmetry, and needless to say, rolling them into tublar structures makes their symmetry reduced to chiral.
In this presentation, we discuss one of the symmetry sensitive properties, bulk photovoltaic effect, in nanotubes [1], van der Waals (vdW) heterostructures [2], and strained [3] transition metal dicalcogenides (TMD). Bulk photovoltaic effect is the photovoltaic effect of uniform materials without p-n junctions, which have been known as a characteristic property of ferroelectric or polar bulk materials. Monolayer TMD has a trigonal structure, which is a noncentrosymmetric but nonpolar structure. Therefore no bulk photovoltaic effect for random light polarization is expected. However, TMD can be changed to polar structures by making tubular structures, vdW heterostructures with twofold rotational symmetry, or strained 3R structure, and thus bulk photovoltaic effect emerges. The light intensity dependence of photocurrent exhibits a crossover from linear to route mean square dependence, in agreement with the quantum mechanical shift current mechanism. Importantly, the observed photocurrent density is rather large comparing to those in bulk polar materials. The present result may indicate a novel route to create new functionalities based on nanostructures through symmetry engineering.

Intercalation Dynamics, Charge Transfer and Defect Correlation in Transition Metal Dichalcogenides/Sapphire Interfaces Jill Serron[1], Albert Minj[1], Valentina Spampinato[1], Alexis Franquet[1], Yevhenii Rybalchenko[1,2], Marie-Emmanuelle Boulon[1], Steven Brems[1], Henry M. Silva[1], Yuanyuan Shi[1], Benjamin Groven[1], Renan Villarreal[2], Thierry Conard[1], Paul van der Heide[1] and Thomas Hantschel[1]; [1]IMEC, Belgium; [2]KU Leuven, Belgium

Due to their unique properties, offering prospects in multitudinous applications, two-dimensional (2D) materials have received significant interest in the research community. A pivotal factor to consider is their sensitivity to atmospheric gas species, as experimental observations have shown consistently that defective transition metal dichalcogenides (TMDs) layers interact with oxygen, water, and ambient gasses[1,2]. Undoubtedly, as commonly used characterization techniques are often performed in an ambient or inert environment, they can contribute to unreliable quality checks. Although, a clear insight on the interaction mechanism with water and ambient has been established for graphene, the key role atmospheric adsorbates play in modifying the material properties of layered TMDs has not yet been fully understood. Therefore, in this work scanning probe microscopy techniques, such as Conductive - Atomic Force Microscopy (C-AFM), Kelvin Probe Force Microscopy (KPFM) and Scanning Tunneling Microscopy (STM) along with Time of Flight – Secondary Ion Mass Spectrometry (ToF-SIMS), are carried out in (ultra-)high vacuum to identify the intercalated adsorbates in the MoS_2/sapphire and WS_2/sapphire systems and to explore the complexity of the adsorption-desorption mechanism. Contact mode experiments reveal a conductivity increase with the removal of intercalated species. Re-exposure to atmospheric ambient proves intercalation to be a rapid process happening in the order of minutes. Our experimental data suggests that the intercalated species are water molecules at the interface, which is supported by ToF-SIMS findings. Moreover, the collected C-AFM data shows a local decrease in conductivity in the water intercalated regions, indicating that a charge transfer occurs to the adsorbates, depleting the *n*-type 2D layer. On the contrary, contact potential differences obtained by KPFM seemingly imply an improvement of *p*-doping over time. However, when considering the 2D screening of substrate interface charges[3], this trend can rather be quantitatively interpreted as an enhancement in *n*-doping, which is in consonance with the C-AFM findings. Besides verifying that intercalation takes place at the interface, STM uncovers that the confined water layer (5.6 Å) is comprised of three phases: an ice, a quasi-liquid, and a triple water layer[4]. Lastly, time dependent STM has established a distinct interdependence between water intercalation and the presence of defects. Either defects form selectively and gradually in water intercalated areas or water intercalation is facilitated by pre-existing defects associated to local inhomogeneities in growth. Regardless, this discovery must be factored when evaluating the degradation of device performance with aging. Our work shows that TMD/sapphire samples are prone to water intercalation, which heavily affects the electronic properties, potentially leading to material degradation.

Twisted van-der-Waal's (vdW) Hetero-Bilayer Stacking Using Polymer to Polymer Transfer Abdulaziz Almutairi[1], David Schmitt[2], Jan Philipp

Bange[2], Wiebke Bennecke[2], Giuseppe Meneghini[3], Daniel Steil[2], D. Russell Luke[4], R. Thomas Weitz[2,5], Sabine Steil[2], G. S. Matthijs Jansen[2], Samuel Brem[3], Ermin Malic[3,6], Marcel Reutzel[2], Stefan Mathias[2,5], Antonio Lombardo[7,7] and Stephan Hofmann[1]; [1]The University of Cambridge, United Kingdom; [2]Georg-August-Universitat Gottingen, Germany; [3]Philipps-Universitat, Germany; [4], Georg-August-Universitat Gottingen, Germany; [5]University of Gottingen, Germany; [6]Chalmers University of Technology, Sweden; [7]University College London, United Kingdom

Two dimensional layered (2D) materials exhibit outstanding properties that make them excellent candidates for electronic and optoelectronic applications [1]. The lack of surface dangling bonds allows deterministic stacking different 2D materials to form heterostructure without the constrains of lattice matching. These heterostructures are usually referred as van-der-Waals (vdW) heterostructures, and they characteristics resulting from the interaction between their constituent layers. Hence, vdW heterostructures have been extensively used in different type of electronic devices from tunneling field effect transistors (TFETs) to photodetectors (PDs) [2]. In addition, the ability to combine 2D material deterministically permits to stack 2D materials with controlled twist angle between layers resulting in the formation moiré superlattices [3], which in return opens the door for more complex device architecture.

Interface quality between layers has a significant impact on the overall properties of the resulting vdW heterostructure. Therefore, major focus has been dedicated to developing transfer techniques that produce vdW heterostructures with clean interface [4,5]. However, most techniques developed are situational and requires several complicated steps. In fact, most techniques rely on using a polymeric stamp to transfer/stack 2D materials. Hence, techniques that works by stacking on a target substrate faces the issue of dealing with polymer residual on surface of each transferred layer. Whereas approaches that utilize stacking vdW heterostructure on the stamp by picking up layers from different substrates are limited by the size of the flakes exfoliated on holding substrates. This is a major concern for 2D materials such as transition metal dichalcogenides (TMDs) where monolayer flake size is limited if exfoliated on SiO_2.

Here, we investigate polymer to polymer stacking to realize bilayer vdW heterostructures. This approach allows relatively large flakes stacking while maintain relatively clean interface. For this study, WSe_2/MoS_2 hetero-bilayer system was stacked using polydimethylsiloxane (PDMS) to PDMS transfer technique with 9.8±0.8° twist angle. The interface quality was investigated using multidimensional time- and angle-resolved photoelectron spectroscopy (trARPES). Even though PDMS stamps are known for their persistent residuals, the WSe2/MoS2 heterostructure demonstrated the formation of interlayer exciton (ILX) which is characteristic of vdW hetero-bilayers and additionally showing a distinct ILX momentum fingerprint which is a direct hallmark of the moire superlattice [6]. This suggests the forming of clean interface between the two 2D materials. While the technique does not produce blister free heterostructure, polymer to polymer stacking represents a facile stacking technique to produce clean interfaces in hetero-bilayers when advanced approaches are not feasible.

9:30 AM EQ06.12.05
Room Temperature Multiferroicity in Transition Metal Dichalcogenide Bulk Single Crystals Gabriel Cardenas-Chirivi[1,2], Karen Vega-Bustos[2], Jhon Pazos[1], Mario A. Macias Lopez[2], Oscar Herrera[1], Camilo Espejo[3], William López-Pérez[3], Jose Augusto Galvis[1] and Paula Giraldo-Gallo[2]; [1]Universidad Central, Colombia; [2]Universidad de los Andes, Colombia; [3]Universidad del Norte, Colombia

The search for new and better multiferroicity is arduous. Ferroic orders such as ferroelectricity and ferromagnetism must coexist simultaneously [1]. Nonetheless, ferroelectrics tend to be insulators as a need to preserve electric polarization (free charges in metals screen this effect) while ferromagnets are metals in their majority [2]. Coupling among the multiple degrees of freedom allows that the order parameters of one state can be controlled by tuning parameters different from their conjugate variable. Historically, it has been found mainly in 3-dimensional complex oxides and perovskites, such as $Cr2O_3$ [3], $YMnO_3$ [4], $BiFeO_3$ [5], among others, or in heterostructures of ferroelectric/ferromagnetic thin-films [6]. Recent advancements in the field of 2D-multiferroics have been done, as for example in the halide compound NiI_2 and Fe-doped In_2Se_3 [7,8]. However, this state has still been elusive for the most widely studied and characterized family of 2D compounds, the transition metal dichalcogenides (TMDs), in spite of theoretical predictions in this respect [9,10]. In this study, we report the first experimental realization of multiferroic states in TMDs via doping, at room temperature, in bulk single crystals. We observe a coexistence of ferromagnetism and ferroelectricity, revealed in the observation of magnetic hysteresis loops and piezoresponse force microscopy (PFM) measurements, resistive switching effects, Density functional theory (DFT) calculations, and substantial piezoelectricity with similar effective coefficients than its undoped monolayer counterparts [11]. This work opens the possibility of building devices for new nanoelectronic and spintronic applications.

Amorphous BN Growth Using CVD and Measurement of RRAM Properties Using the Same Dokyeong Yun; Sungkyunkwan University, Korea (the Republic of)

In this paper, a large array resistive memristor device was manufactured by adjusting the crystal properties of the film by adjusting the growth conditions. It is composed of Au/amourphous/Au as a two-terminal resistive switching device with a Metal/Insulator/Metal (MIM) vertical structure. Changes in the state, thickness and crystal structure of the film were analyzed by adjusting various growth conditions, and it can be seen that it has Boron Nitride characteristics through Raman spectrometers measurement and TEM image. When a voltage is applied to a non-conductive material, RRAM generates a filament through which ions can aggregate and current can flow, Similarly, RRAM with high electrical characteristics was implemented by adjusting growth conditions.

Imaging the Local Band Topology in Magic-Angle Graphene Eli Zeldov; Weizmann Institute of Science, Israel

Topology is a key element governing the electronic and magnetic properties of 2D moiré materials. The topological electronic bands are classified by their Chern number C, which is considered to be a global topological invariant. The Chern number is governed by the Berry curvature that leads to orbital magnetization. Utilizing a scanning superconducting quantum interference device on a tip (SQUID-on-tip), we image the Berry-curvature-induced equilibrium orbital magnetization, thus providing new means to resolve the local band topology on the nanoscale [1]. At integer filling \nu=1, we observe a zero-field Chern insulator, which rather than being described by a global topologically invariant C, forms a Chern mosaic of microscopic patches of C = 1, 0, or 1, the boundaries of which carry chiral edge states. Upon further filling, we find a first-order phase transition due to recondensation of electrons from valley K to K', leading to irreversible flips of the local Chern number and magnetization, and to the formation of valley domain walls giving rise to hysteretic anomalous Hall resistance. The findings shed new light on the structure and dynamics of topological phases in moiré devices.

The aim of all human action is to rearrange the world into a more preferable state. The field of engineering, with ever increasing degrees of precision, seeks to arrange matter such that desirable functional properties are elicited. With routine fabrication procedures edging into the single digit nanometer scale, one begins to wonder about the bottom.1 This talk will discuss current efforts at controllably attaching atoms to single and bilayer graphene using an electron beam in a scanning transmission electron microscope. The effects of source and sample temperature on defect and adatom diffusion will be discussed. In addition, the effects of temperature on the rate of healing, desorption, and effective damage rate will be elaborated with a view toward refined top down control. Demonstrations of patterning single atoms and atomic clusters as well as the direct writing of chains of Sn atoms into graphene will be presented.[2]

From Metals to Doped Semiconductors—Exploring the Formation and Unique Phenomena in 2D Systems Joshua A. Robinson; The Pennsylvania State University, United States

Two-Dimensional materials are now a main-stay in the sciences, with an ever increasing footprint across the technological world. After the first decade of proof-of-concept studies and demonstration of large area "pristine" 2D semiconductors, our research efforts now aim to advance controllable doping and establish universal methods to identify the doping and carrier concentration in 2D layers. Furthermore, heterogeneous stacking and doping of 2D materials also allows for additional band structure engineering. In this talk, I will discuss recent breakthroughs in two-dimensional atomic layer synthesis and properties, with am emphasis on doping 2D semiconductors, and combining 2D metals with topological insulators to create unique platforms for next generation quantum applicaitons.

De-Wrinkling of the 2D Black Phosphorus Using Electron Beam Irradiation Manpreet Kaur, Himanshu Tyagi and KIRAN S. HAZRA; Institute of Nano Science and Technology, India

The two dimensional van der waals nanomaterials are sensitive to formation of surface corrugations (wrinkles and ripples) during the handling of materials in any scientific experiment. Especially, Black Phosphorous (BP) is affected by formation of such surface corrugations due to their high surface reactivity. The interface disorders such as interface coulomb contaminations, charge traps and local fluctuations in strain, polarised carrier puddles, dielectric screening and suppression of electron transport occur due to such surface corrugations. While numerous efforts have been made to de- wrinkle the flake, the issue is far from resolved. Here, we demostraste the de wrinkling process that utilizes electron beam of transmission electron microscope (TEM) for ironing out the wrinkles and ripples of BP flake. Experimental outcomes show the enhancement in crystallinity of the flake under e-beam irradiation due to the evolution of lattice ridden with line defects and declinations into the uniformly spaced parallel lattice planes. The overexposure to e-beam causes buckling of flake and thus the de- wrinkling process is optimized by crucially controlling the electron fluence rates or the exposure time. The hitherto undeveloped electron beam based de-wrinkling of 2D flakes with nanoscale precision is prospective to open up innovative prospects for progress of 2D nanomaterials with reproducible optoelectronic properties.

8:45 AM EQ06.14.03
A Brand New Type of Heterostructure—Dual Additives-Assisted Chemical Vapor Deposition for High-Performance W-Doped MoS_2/MoS_2 Heterostructures Qing Zhang[1,2], Dechao Geng[3], Wei Chen[1,2] and Wenping Hu[1,3]; [1]Joint School of National University of Singapore and Tianjin University, International Campus of Tianjin University, China; [2]Department of Chemistry, National University of Singapore, Singapore; [3]Department of Chemistry, Tianjin University & Collaborative Innovation Center of Chemical Science and Engineering, China

Chemical techniques for modifying the intrinsic optoelectronic properties of transition metal dichalcogenides (TMDs) have provided tremendous flexibility for multi-functional electronics. The innovative product created by combining two chemical strategies, substitutional doping and heterostructure, is predicted to tune TMD band topologies over a wide range. However, because of the advanced equipment and the unavoidable cross-contamination problem, the regulated synthesis of doped material/pure material heterostructures remains a challenge. To address the issues, a simple dual additives-assisted chemical vapor deposition (DACVD) approach is proposed to synthesis a new type of heterostructure formed by W-doped MoS_2 and pure MoS_2 in a controlled manner. Molten salts lower the melting point of metal oxide precursors, while oxygen plasma pre-treatment on the substrate creates a defect-free surface that allows only pure MoS_2 to be deposited. Following that, doped materials are grown in sub-sequential layers in a controlled manner. The doping ratio can reach as high as 17%. The multilayered pyramid structure reduces contact resistance sufficiently, thus the mobility of multilayer heterostructure is superior to that of conventionally CVD-produced monolayer MoS_2 and multilayer MoS_2. Furthermore, the heterostructure exhibits diode-like characteristics, with a rectification ratio of up to 3.5×10^3. This work provides ideas and experimental cases for the preparation and application of novel heterostructures.

8:50 AM *EQ06.14.04
Intelligent Infrared Sensing Enabled by Tunable Moiré Quantum Geometry Fengnian Xia; Yale University, United States

In optical sensing, traditionally different types of optical sensors are utilized to measure different physical properties of light. The spectrometer, polarimeter and power meter are used to determine the incident light spectrum, polarization state and power, respectively. It appears that measuring of all the physical properties with a single device is not feasible. Here we introduce a new sensing scheme which challenges this conventional wisdom leveraging the reconfigurable quantum geometric properties in twisted double bilayer graphene (TDBG) and artificial intelligence.
We show that the nonlinear infrared bulk photovoltaic response is largely determined by the quantum geometric properties of Bloch electrons (i.e., Berry connection and curvature). Moreover, due to the tunable quantum geometric properties and the bandstructures in TDBG, the bulk photovoltaic responses in dual-gated TDBG are dependent on the wavelength, the polarization states of the light, and the top and bottom gate biasing voltages of the TDBG device. Utilizing such unique properties of such dual-gated TDBG devices, we were able to generate a photoresponse map as a function of top and bottom gate biases for each incident light with specific power, wavelength and polarization state. Furthermore, we utilized the measured results to train a convolutional neural network (CNN), which was then leveraged to interpret the photoresponse map measured under the unknow excitation light. We showed that such a trained CNN was able to decipher the physical properties of the unknown incident infrared light measured with a single TDBG device.
Our work represents a novel sensing scheme which is ultimately compact but is able to realize the functions of multiple table-top instruments. Moreover, the results also suggest a new pathway for nonlinear infrared photonics research.

The Overcome Defect at ZnO Thin Film Interface by Self-Assembly of Molecule Buffer Layer Kim Taehyeon; Sungkyunkwan university, Korea (the Republic of)

Tuning defect is very important for top gate devices to control it well. Especially ZnO thin film, which is deposited by ALD (atomic layer deposition) method, have surface defect formation so that it's hard to control top-gate devices.
So, in this study, we introduced self-assembly of molecule(SAM) buffer layer. it's very powerful for adjusting charge transports in ZnO thin film by reducing the trap density at interface. we also report the robust fabrication of ZnO top gate field effect transistors (TG-FET) arrays by using thin SAM buffer layer Al2O3 as top gate oxide. Our devices have 12 times higher mobility than origin ZnO thin film and 100,000 higher on/off ratio than device without buffer layer. Using this new platform, we demonstrated a large scale of transistors arrays with high mobility.

Probing Magnetism in Cobalt-Intercalated $MoTe_2$ Whan Kyun Kim[1,2], Ga Young Cho[1] and Woo Jong Yu[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Samsung Electronics, Korea (the Republic of)

Recently, as 2D materials with long-range ferromagnetic order such as Fe_3GeTe_2, $Cr_2Ge_2Te_6$, $CrTe_2$, VSe_2, and CrI_3 have been experimentally proven, research on magnetic devices based on them has been actively conducted. On the other hand, various studies have been conducted on magnetic properties generated by defects or implanting magnetic dopants into 2D transition metal dichalcogenide (TMD) with semiconducting or metallic properties. However, from the viewpoint of magnetism, the intercalation method that inserts an additional element between the van der Waals (vdW) planes of TMD has rarely been explored. Intercalation for 2D layered materials can be applied using vapor phase methods, solid phase diffusion, and wet chemical methods. In this study, Co, the 3d transition metal, was inserted between the vdW layers of 2H-$MoTe_2$ by applying 2 step-intercalation, which was sequentially performed Li-intercalation and Co-intercalation based on the wet chemical method.
n-Butyllithium diluted in hexane has been widely adopted as a reagent for preparing lithium intercalation complexes. Since the reaction is possible at room temperature, only Li ions can be intercalated, excluding by-products. 2H-$MoTe_2$ with n-type semiconducting behavior undergoes a phase transition to 1T'-$MoTe_2$ by Li-intercalation for 48 hours. It was confirmed that Li-intercalated $MoTe_2$ with metallic properties had ohmic contact with the metal electrode. As Li-ions are injected between each $MoTe_2$ layer, the vdW gap is also increased compared to the pristine. After Li-intercalation, the phase transition to 1T'-$MoTe_2$ was confirmed by measuring I-V characteristics and the transfer curve. We observed that the source-drain current increased from 20nA to 82nA at 1V due to Li-ion insertion, and current modulation was minimized when applying the back gate voltage.
Next, the intercalation method of Co, a zero-valent transition metal formed by disproportionation redox reaction, was applied to Li-intercalated $MoTe_2$. Dicobalt octacarbonyl, $Co_2(CO)_8$, was used as a precursor to providing zero-valent Cobalt (Co(0)) through redox reaction. This redox reaction is carried out in acetone used as a solvent during intercalation for 30 minutes at a reaction temperature of 50ºC. Longitudinal magnetoresistance (MR) was measured in a cryogen-free probe station (Lake Shore CRX-VF) with a superconducting magnet by applying an out-of-plane magnetic field at a temperature from 200K to 300K. Our sample showed the MR ratio of 7% at 200K and 4% at 300K around ±2T. We demonstrate that $MoTe_2$ intercalated with Co has a ferromagnetic order in which resistance changes by an external magnetic field. This study has opened new horizons to the future field of 2D vdW-based magnetic devices.

Doped Diamond Deposition for Quantum Applications—Opportunities and Challenges Shannon S. Nicley[1,2] and Jonas N. Becker[1,2]; [1]Michigan State University, United States; [2]Fraunhofer USA Center Midwest (CMW), United States

Diamond is a highly attractive material as a solid-state host for a class of crystal defect spin-based qubits, which exhibit high stability even under ambient conditions. Carbon-12 isotopically purified diamond is also spin free, allowing for exceptionally long coherence times. We will introduce the challenges and opportunities in this field and present the results of our ongoing efforts to improve the charge state stability of defects through the controlled growth of doped diamond and our efforts to identify new defects in diamond with long coherence times and high-quality optical interfaces.

11:00 AM *EQ07.01.02
Cubic Boron Nitride/Diamond Heterostructures Grown by Ion Beam-Assisted Molecular-Beam Epitaxy David F. Storm, Sergey Maximenko, Andrew Lang, Neeraj Nepal, Tatyana Feygelson, Bradford Pate and David Meyer; US Naval Research Laboratory, United States

Cubic boron nitride has several electronic and thermal properties which make it an attractive candidate for high power and high temperature electronic applications: an ultra-wide band gap (6.4 eV, indirect); a high thermal conductivity, second only to diamond; and its capacity to be doped both *n*- and *p*-type. Further, its structural and electronic similarity to diamond hold the potential for novel electronic devices based on c-BN/diamond heterostructures. However, there are numerous challenges associated with growing device-quality layers of c-BN, including the existence of multiple phases of BN; the metastability of the cubic phase at pressures and temperatures typical of vapor-phase growth; and the absence of large-area bulk c-BN crystals, which necessitates heteroepitaxial growth on non-native substrates.

Single crystal epitaxial cubic boron nitride films were grown on (100) oriented IIa diamond substrates by ion beam-assisted molecular-beam epitaxy (MBE) in a custom MBE system equipped with an Ar ion source, a N_2 plasma source, and an electron beam evaporator for supplying elemental boron. Fourier transform infrared spectroscopy indicates these films are fully cubic, and the phase identification is corroborated by x-ray photoelectron spectroscopy. Transmission electron microscopy confirms the presence of an epitaxial c-BN film with isolated misfit dislocations and no indication of h-BN. The interface between the c-BN layer and the diamond substrate is structurally abrupt, and no interlayer between the c-BN film and diamond substrate is seen. It was found that trace amounts of impurities, such as Mg, facilitate the growth of c-BN on diamond by ion-assisted MBE. [1]

11:30 AM EQ07.01.03
Growth Process of 2-In-Diameter High-Quality CVD Diamond on Ir/Sapphire Substrate Compared with Ir/MgO Substrate Makoto Kasu[1], Ryo Masaki[1], Koji Koyama[2] and Seong W. Kim[2]; [1]Saga University, Japan; [2]Adamant Namiki Precision Jewel Co., Ltd., Japan

Diamond is expected to be high power and high efficient devices, superior to SiC and GaN, because diamond possesses higher critical field strength, and thermal conductivity. For the power-device application, the inch-diameter high-quality diamond wafer has been a big challenge. Recently, we have demonstrated the growth of the highest-quality 2-inch-diameter (001) diamond on a (11-20) sapphire substrate.
In this study, we investigate the crystal properties of diamond wafer mainly by XRD in both out-of-plane and in-plane conditions, and observe the surfaces of the Ir buffer layer, bias-enhanced nucleation (BEN)-treated Ir surfaces, and diamond surfaces grown at the initial stage with different diamond growth times on both the (11-20) sapphire and (001) MgO substrates by AFM, XTEM, and EDX. We grew diamonds on Ir/ sapphire and Ir/MgO substrates.
We found that Ir buffer layers had compressive stress, diamond layers had tensile stress. Ir buffer layers were concave and diamond layers were convex. However, the magnitude of compressive stress in Ir buffer on sapphire was much less than that on MgO, and the magnitude of tensile stress in diamond grown on Ir/sapphire was much less than that on Ir/MgO. This is a key to the success of a 2-inch diameter high-quality diamond wafer grown on Ir/sapphire.
The (001) Ir buffer surface exhibits atomically flat terraces with atomic steps. However, after the BEN treatment, a ridged surface appears, and diamond island growth begins from the bottom of the ridges during the diamond CVD growth. On Ir/sapphire, quadrangular-pyramid diamond three-dimensional (3D) islands with {111} sidewalls grow first. Subsequently, the sidewall facet changes from {111} to {011} and preferentially coalesced in the <010> direction. In contrast, on Ir/MgO, quadrangular-pyramid diamond 3D islands with {111} sidewalls grow first. Subsequently, the columnar growth proceeds. Consequently, the coalescence of diamond 3D islands on Ir/MgO requires a longer time than that on Ir/sapphire. These different growth processes on Ir/sapphire and Ir/MgO substrates lead to lower threading dislocation density and narrower XRC FWHM for the diamond grown on Ir/sapphire substrates.

11:45 AM EQ07.01.04
Preparation and Analysis of Oxidation on (100) Single-Crystal Diamond Surface Ricardo Vidrio[1], Daniel Vincent[1], Benjamin Bachman[2], Cesar Saucedo[2], Maryam Zahedian[1], Zihong Xu[1], Timothy A. Grotjohn[3], Shimon Kolkowitz[1], Junyu Lai[4], Jung-Hun Seo[4], Robert J. Hamers[2], Keith G. Ray[5], Zhenqiang Ma[1] and Jennifer Choy[1]; [1]University of Wisconsin–Madison, United States; [2]UW-Madison, United States; [3]Michigan State University, United States; [4]University at Buffalo, The State University of New York, United States; [5]Lawrence Livermore National Laboratory, United States

Applications for oxidized single crystalline diamond surfaces are found in various fields of study, such as controlling the surface conductivity of diamond-based electronics, stabilizing near-surface color centers, and enabling functionalization of the diamond surface for chemical sensing. There are a multitude of oxidation approaches for diamond and diamond-like materials, with similar techniques on identical carbon materials reporting inconsistent oxygen coverages. In this work, several surface treatment methods were performed on (100)-single-crystal diamonds to establish protocols for ensuring that oxidized diamond surfaces can be prepared consistently and analyzed. Our findings indicate that two chemical parameters on the surface, graphitic carbon and molecular contaminants, prove crucial towards interpreting the oxygen coverage on the diamond surface and can account for the inconsistency found in literature.
Diamond surfaces were treated using wet chemical oxidation (which includes exposure to oxidizing acids and hydrogen peroxide, and treatment of a hydrogen-terminated surface with carboxylic acids), photochemical oxidation via UV-illumination, and an atomic layer deposition (ALD) technique using water vapor pulses. Surface analyses were performed primarily with X-ray Photoelectron Spectroscopy (XPS), as well as atomic force microscopy (AFM), and ultraviolet photoelectron spectroscopy (UPS).
XPS peak deconvolution on H-terminated diamond samples shows the presence of C-C, C-H, ether bonds, and Csp2 bonding carbon in the bulk. H-terminated diamond surfaces with a subsequent acid treatment show similar results, except for a lower C-H intensity and the addition of a carbonyl peak. All other oxidation methods show only the presence of ether, carbonyls, C-C and Csp2 bonded carbon from C1s peak deconvolution. The results show that the O1s surface content tends to be strongly correlated to the presence of surface contaminants and graphitic content. Out of the three wet chemistry oxidation methods, it was found that a tri-acid mixture of sulfuric, nitric, and perchloric acids yielded the least contaminants, with less than 0.1 at %, when compared to the other wet chemical methods. Similarly, the dry oxidation methods, such as the ALD water vapor pulses and the photochemical UV/Ozone treatment, exhibited contaminants at less than 0.7 at % while having O1s at % values of 6 – 7%. However, the O1s peak area showed strong correlation with respect to the intensity of the deconvoluted graphitic peak in the C1s narrow scan. Given the dependence of O1s at % to surface contamination, we

suggest a series of experimental best practices to ensure repeatable and high purity oxygen-terminations on diamond. Furthermore, we advocate that any future reporting of O1s at % content on diamond surfaces have a detailed description concerning the severity of surface contamination and graphitic content. We identify the tri-acid clean, ALD water vapor pulses, and the UV/Ozone illumination as the prime techniques to ensure clean diamond surfaces with O1s at % between 4.8 and 7.1%. Preliminary computational results show that a full monolayer coverage of carbonyl bonds on the Csp3 diamond surface correspond to 6.0 O1s at %. However, these results consider only Csp3 carbon bonds on the diamond and do not account for any Csp2 sites that tend to be prolific on the surface. Future work will look at computational modeling efforts to ascertain how the monolayer coverage changes as a function of different functionalizations on the surface.

SESSION EQ07.02: Sensing I

1:45 PM *EQ07.02.01
Chemical Sensors Based on Diamond—From Lab to Field Applications Emmanuel Scorsone[1,2]; [1]Université Paris-Saclay, France; [2]Commissariat à l'énergie atomique et aux énergies alternatives, France

Diamond has been grown in some laboratories by either HPHT process or Plasma-Enhanced Chemical Vapor Deposition (MP-CVD) since a few decades. Single crystal diamond exhibits outstanding properties including a high optical transparency over a broad electromagnetic spectrum, high thermal conductivity approx. five times higher than copper, and acoustic wave velocity close to 19 000 $m.s^{-1}$. It displays also remarkable mechanical properties with e.g. a Young's modulus exceeding 1000 GPa along with high resistance to fracture, to name a few. Some of these properties remain also remarkable in its polycrystalline form when compare to most other materials. Furthermore, diamond can be doped e.g. with nitrogen or boron during growth, offering electrical properties from semiconducting to quasi-metallic regimes. When heavily doped with boron (~2.10^{21} cm^{-3}), the so-called Boron Doped Diamond (BDD) electrodes become attractive electrodes featuring a high potential window > 3V in water and low double-layer capacitance. Moreover, diamond is extremely resilient to corrosion and more generally to chemical attacks. It is also biocompatible, which makes it very attractive for *in-vivo* sensing applications. Finally, the carbon nature of the diamond offers wide opportunities for surface grafting of chemical or biochemical functional groups through highly stable covalent carbon-carbon bonding. One can take advantage of these properties to enhance the analytical performances and stability of chemical/biochemical sensors and this has motivated our research over the last 15 years.
Our work focuses mainly on polycrystalline diamond thin films that can be grown typically on 4 inches silicon substrates, thus offering access to some clean-room processes and potentially large-scale production. As examples, diamond based MEMS devices (microcantilevers, SAW sensors) take advantage both of the mechanical properties of diamond, along with steady carbon interface for convenient bio-functionalization. Our work here focused mainly on the detection of odorant molecules, using biomolecular receptors involved in olfaction in Nature as sensitive layers, including Odorant Binding Proteins (OBPs), Major Urinary Proteins (MUPs) and Olfactory Receptors (OR). Multisensor array instrumentations were developed around this concept, for applications ranging from breathe analysis to security applications. Beside, heavily doped diamond electrodes were developed successfully both as macro- and micro-electrodes for biomedical, pharmaceutical or foodstuff analysis applications. These applications benefit both from the high analytical performances of diamond electrodes in particular due to their low background signals and high reactivity, and high stability and reliability. BDD electrodes offer also significant advantages in electrochemiluminescence (ECL) techniques, which are being investigated for various applications ranging from foodstuff analysis to narcotics detection. A key benefit of BDD electrodes for all of the above applications is certainly that they can be electrochemically reactivated following fouling, sometimes directly in the analytical medium, to maintain high reactivity thus opening the way to reusable sensors and online monitoring.

2:15 PM EQ07.02.02
Proposal of a Common Gate Method Suitable for Multi Sensing Using Diamond Electrolyte Solution Gate FETs Reona Nomoto[1], Hirotaka Sato[1], Yu H. Chang[1] and Hiroshi Kawarada[1,2]; [1]Faculty of Science and Engineering, Waseda University, Japan; [2]The Kagami Memorial Research Institute for Materials Science and Technology, Waseda University, Japan

In this study, we report the pH sensitivity utilizing common-gate Diamond Electrolyte Solution Gate FETs (SGFET)[1].
Since the introduction of SGFETs , the development of multi-ion sensors including pH sensor has been a great interest. Most of the multi-ion monitoring systems utilizing the FETs employ common-source FETs . However, the systems with the common-source FETs have the following drawbacks. In order to operate the common-source multiple sensors, it is required to immerse multiple reference gate electrodes in sample solution and to apply a different gate voltage (V_{GS}) for each FET. Consequently, simultaneous sensing of various ions at various points is not practically performed. Moreover, Ag/AgCl glass electrodes, which are commonly used as the gate electrodes, are difficult to miniaturize, resulting in a larger sensing system with more glass electrodes for detection of a wider variety of ions at many locations . Therefore, multi-sensing with a plurality of FETs at a common gate is desirable. Here, we propose biosensing measurement using a common gate FET that can be sensed by sharing one gate electrode with a plurality of FETs.In general, common-gate FETs are often used as cascade amplifiers and contribute to high output impedance in electronic circuits. The gate of the common-gate FETs is grounded, that is, gate bias is not applied. Instead, source voltage V_{SG} and drain voltage V_{DG} are applied and control drain current I_D. Sensing is also performed by changing only the source voltage V_{SG} and the drain voltage V_{DG}. Therefore, even when a plurality of FETs is used for common gate, only one gate electrode is completed.
In this study, we have investigated whether multi-sensing is actually possible using common-gate SGFETs composed of one gate and plural source drain (SD) probesand the pH sensitivity of SD probes sis independently measured.
In this experiment, we utilized two n-channel SGFETs (SGFET 1, SGFET 2) with different threshold voltages. The $I - V$ characteristics of the common-gate SGFETs were measured in the following two ways: 1) measuring each SGFET independently and 2) measuring two both SGFETs operated simultaneously with a common gate electrode.
A Carmody buffer solution was used for each pH solution (pH 2 - 12), and a gate electrode (Ag/AgCl) and SGFET were immersed in the Carmody buffer solution. The I_D - V_{SG} characteristics of the SGFET were measured in the range of V_{SG} = 0 to -2V at V_{DG} = 0 V from pH 2 - 12. From I_D - V_{SG} characteristics, the V_{SG} - pH characteristics were obtained from the source voltage V_{SG} at a certain drain current value I_D, and the pH sensitivity was calcurated from the slope of the V_{SG} - pH characteristics. At common gate, the n-channel SGFET showed high pH sensitivity comparable to the Nernst response (About 59 mV/pH) with -49.4 mV/pH and -48.2 mV/pH. Next, The pH sensitivity of the two SGFETs obtained by multisensing is shown in comparison with the previous results. The pH sensitivity of SGFET1 was -49.4 mV/pH, and the pH sensitivity of SGFET1 in multisensing was -49.7 mV/pH. The pH sensitivity of SGFET2 was -48.2 mV/pH, and the pH sensitivity of SGFET2 in multisensing was -48.0 mV/pH.
It can be seen that the characteristics hardly change when measured with one SGFET and when a voltage is applied to two SGFETs simultaneously and

multi-sensing is performed. The I_D - V_{SG} characteristics of two SGFETs has measured at the same time. From this result, we have shown how simultaneous applying gate voltage to two SGFETs affects the individual characteristics. We confirmed that multi-sensing is possible from the experimental results that , multiple ions can be sensed simultaneously by using FETs having different ion-sensitive films.

2:30 PM BREAK

SESSION EQ07.03: Quantum Applications I
Session Chairs: Philippe Bergonzo and Junko Ishi-Hayase
Monday Afternoon, November 28, 2022
Sheraton, 2nd Floor, Independence East

3:00 PM EQ07.03.01
Diamond for Quantum Technology Applications Paul Quayle[1], Ramón Díaz[1], Thanh Tran[1], Sandra Cita[1], Alex Grotjohn[1], Danyell Morris[1], Luis Hernandez[1], Keith Evans[1] and Timothy Grotjohn[2]; [1]Great Lakes Crystal Technologies, United States; [2]Michigan State University, United States

The performance of nitrogen-vacancy (NV) center diamond is dependent on the crystalline properties of the substrate and N-doped epitaxial layer. The crystallinity of the substrate and epi-layer in terms of lattice curvature, extended defect concentration and chemical purity determines the baseline characteristics of the final devices, which have immense potential to impact a variety of magnetic field and electric field sensing applications. These technologies are enabled by the negatively charged NV^- center in diamond which has a spin state that can be optically probed and manipulated. The extreme sensitivity of this spin-state to magnetic fields allows for unprecedented capabilities in magnetic and electric field sensing. In this presentation, we report on the assessment of NV center diamond produced by Great Lakes Crystal Technologies. Samples were synthesized at a variety of conditions to investigate optimum growth conditions. Ensemble NV center dephasing times are correlated with defect characteristics measured using birefringence microscopy and lattice curvature measured by x-ray diffraction mapping. UV-visible and Fourier-transform infrared spectroscopy is used to compare parasitic acceptor-like defects concentrations. Results are reported for samples grown using both natural and isotopically purified carbon sources.

3:15 PM EQ07.03.02
Control and Sensing of Dark-Spin Bath Polarization via a Single Probe Qubit Yuxin Wang[1], Mykyta Onizhuk[1], Jonathan Marcks[1], Benjamin Soloway[1], Paul C. Jerger[1], Nazar Delegan[2,1], F. J. Heremans[2,1], David Awschalom[1,2,1], Giulia Galli[1,1,2] and Aash Clerk[1]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

The central spin model, where a single qubit interacts with a collection of neighboring bath spins, provides a paradigmatic model for understanding qubit decoherence in a great variety of quantum platforms ranging from superconducting circuits to solid state defect spins. It is common to treat such spin environment as a classical fluctuating noise source, which can be readily characterized using standard qubit noise spectroscopy techniques. However, a realistic spin bath forms a dynamical object that can be perturbed by evolution of the central spin. Here, we theoretically propose techniques that utilize a single qubit to both polarize and probe its surrounding spin bath. Making use of an effective quench induced by the qubit onto the bath [1], we further show how our method allows a model-free estimation of the effective bath temperature. We discuss how our protocols can be directly implemented using a single NV center spin qubit in diamond, which can interact with either ^{13}C nuclear spins or substitutional nitrogen electron spins (P1 centers). We also present numerical calculations based on cluster correlation expansion (CCE) to benchmark our protocols' performance.

3:30 PM EQ07.03.03
Surface-Activated Direct Bonding of Diamond (100) and Sapphire with High Transparency for Quantum Devices Tetsuya Miyatake[1], Toshiki Iwai[1], Tetsuro Ishiguro[1], Kenichi Kawaguchi[1], Yoshiyasu Doi[1], Shintaro Sato[1], Jeffrel Hermias[2], Salahuddin Nur[2] and Ryoichi Ishihara[2]; [1]Fujitsu Limited, Japan; [2]Delft University of Technology, Netherlands

Diamond single crystals with color centers have attracted attention for their application in quantum photonic devices. Owing to the size limitation of diamond substrates, bonding a small diamond substrate to a large mother wafer is crucial for developing large-scale integrated devices. To access the quantum states of color centers using an optical technique, bonding the diamond with a transparent material with low optical loss in the visible region is desired. Sapphire is a promising candidate as a transparent material as it is a single crystal with a large optical bandgap. However, the direct bonding of a diamond substrate with (100) surface orientation is an unexplored challenge for sapphire wafers. In fact, such direct bonding has not been easy for Si wafers [1-5]. Herein, we report the successful direct bonding of diamond (100) substrates and sapphire (1000) wafers using the atom beam–assisted surface-activated bonding method and clarify its mechanism with detailed structural characterizations.
CVD-grown diamond (100) substrates with a size of 4×4 mm^2 and a thickness of 0.5 mm were used in the experiments. We systematically investigated the relationship between the surface properties and the bonding strength. It was found that atomic-level surface flatness (roughness below 0.1 nm) in a micron-sized area and submicron-level global flatness (roughness below 0.2 μm) in the whole area are important to achieve stable bonding. The diamond and sapphire surfaces were activated using fast atom beam (FAB) irradiation in a vacuum chamber for 600 s, although the diamond/Si bonding studies used the wet-chemical activation process for the diamond surface [1-5]. Subsequently, the substrates were brought into contact under a pressure of 20 MPa at room temperature, resulting in full bonding. No graphite layers were observed on the activated diamond surface through Raman spectroscopy. Thus, a highly transparent bonding interface was realized. Cross-sectional transmission electron microscopy and energy dispersive X-ray spectroscopy revealed that an amorphous AlO_x layer with a thickness of 150–200 nm existed between the diamond and the sapphire single crystal. This intermediate amorphous layer was likely formed during the FAB treatment. The shape of the amorphous layer was deformed to fit the monolayer steps of the diamond surface, indicating its effectiveness as an adhesive layer. This bonding method was effective for the diamond substrates with various impurity concentrations, including very high–purity substrates suitable for quantum devices. Furthermore, it was confirmed that the light emitting from the color center was efficiently extracted from the sapphire side. The shear strength measurement showed that the diamond/sapphire-bonded wafer had a shear strength of 14.41 MPa, approximately nine times higher than that for diamond/Si wafers [1],[2], making it sufficient for device processes. To summarize, we have successfully bonded diamond (100) and sapphire with high transparency, realizing a promising technique for diamond integrated device applications.

Synthesis of Spin Defects in Low Dimensionality and Heteropolytypic Platforms for Quantum Applications Nazar Delegan[1,2], Jonathan Marcks[2], Xinghan Guo[2], Katherine Harmon[1], Sean Sullivan[1], Martin Holt[1], Stephan Hruszkewycz[1], Alex High[2], David Awschalom[2,1] and F. J. Heremans[1,2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States

Wide band-gap semiconductor hosted, optically addressable point-defects are a versatile platform for a number of quantum information science (QIS) applications. These spin qubits are inherently sensitive to their local crystalline, charge, and nuclear spin environments making them ideal for quantum sensing applications. Recent advances in host material growth, nanofabrication, and deterministic defect creation have enabled the ability to engineer the local environment surrounding these spin qubits via the control of host material polytype, isotopic engineering, and host dimensionality. Herein, we present on these advances, highlighting novel low dimensionality (*1*) and heteropolytypic (*2*) quantum platforms. These advances will be presented in the context of deterministic integration of these quantum systems with other classical or quantum systems, as a means for local defect control, and as probes of local spin-bath dynamics.

8:30 AM *EQ07.04.01
Virus Capture by Nanodiamond Modified Membranes Henry Bland[1], Isabella Centeleghe[2], Soumen Mandal[1], Evan Thomas[1], Jean-Yves Maillard[2] and Oliver A. Williams[1]; [1]Cardiff University School of Physics and Astronomy, United Kingdom; [2]Cardiff University, United Kingdom

Nanoscale contaminants such as viruses, industrial dyes and pharmaceutical by-products present serious challenges to health in the water supply, drug manufacture and blood filtration. Of the existing filtration platforms, only ultrafiltration or reverse osmosis can achieve high retention levels of such nanoscale pathogens. These systems are expensive and complex, being mostly limited to centralised water treatment systems. This has led to the development of adsorptive depth filtration (ADF) where contaminants are targeted by van der Waals / electrostatics forces, hydrophobic interactions etc driving contaminant adsorption to the membrane surface. A key advantage of such a technology is that retention is not achieved through size exclusion, allowing much higher flow rates and smaller pressure differentials. It can also enable the removal of nanoscale contaminants by charge whilst allowing larger bodies to pass though the filter. Such approaches are used in blood filtration, virus capture during drug manufacture and virus preconcentration in water monitoring.

In this work[1], quartz filters were modified with hydrogenated diamond nanoparticles, reversing the zeta potential of the membranes from negative to positive across a wide pH range. Untreated quartz filters demonstrate log0.2 (35%) retention of viruses (MS2 bacteriophage) whereas the diamond modified ones exhibit at least log6.2 (>99.9999%) reduction from feed waters. This is due to the MS2 bateriophage exhibiting a low isoelectric point, in common with the overwhelming majority of viruses. Thus, is has a negative zeta potential in water and is attracted to the positively charged diamond modified membrane. The modified membrane was also tested with far smaller contaminants such as acid black 2 dye and demonstrated >90% higher retention over the unmodified filter. Finally, the diamond modified filter was compared to commercially available electropositive filter membranes where it demonstrated a consistently higher positive zeta potential over a larger pH range. Thus, diamond modified filters offer higher zeta potentials vs pH and thus higher virus retention over current ADF technologies. These filters are also stable over a wider temperature range and flow than the currently available technology.

Surface Modification of Nanodiamond for Tailored Interaction in Biological Media Viktor Merz[1], Julia Puck[1], Elisabeth Mayerhoefer[2] and Anke Krueger[2]; [1]Julius-Maximilians-Universität Würzburg, Germany; [2]Stuttgart University, Germany

The surface of nanoparticles plays a major role in their interaction with biological systems and media. Especially undesired nonspecific adsorption e.g. of proteins as well as unwanted agglomeration in physiological fluids hamper the application of nanoparticles in biomedicine and related fields. This holds true for nanodiamonds, too.
Here, we present several strategies involving covalent surface functionalization of nanodiamond with peptides, hydophilic/lipophilic hybrid systems, zwitterions and oligoethers which enable the formation of stable colloidal solutions of nanodiamond even at high ionic concentrations and prevent the formation of a protein corona when such nanodiamonds are exposed to serum proteins.[1]
Complex architectures combining different of these elements have been investigated for their effect on the dispersibility, colloidal stability and inhibition of protein adsorption.
First in vitro experiments confirm the low toxicity and high biocompatibility of these functionalized nanodiamonds.
Such functionalized nanodiamonds can now be used to introduce specific functional moieties, which can then selectively interact with their environment, a prerequisite for sensing, imaging and drug delivery.

Advances in Preparation and Understanding of Ultrasmall Nanodiamonds Stepan Stehlik[1,2], Ales Vlk[2], Martin Ledinsky[2], Michel Mermoux[3] and Evgeny Ekimov[4]; [1]University of West Bohemia, Czechia; [2]Institute of Physics, AS CR, Czechia; [3]Univ. Grenoble Alpes, Univ. Savoie Mont Blanc, France; [4]Institute of High Pressure Physics, Russian Academy of Sciences, Russian Federation

Understanding of diamond properties in ultrasmall region of few nanometers is important, yet challenging task. Since spectroscopic characterization reflects the mass/volume-weighted particle size distribution, only samples containing volumetrically dominant sub-5 nm nanodiamonds (NDs) may be used for reliable characterization. However, conventional detonation nanodiamonds (DNDs) and top-down high-pressure high-temperature (TD_HPHT) NDs do not generally meet this criterium and so additional approaches and synthetic methods are needed.
In this work we show i) isolation of volumetrically-dominant sub-5 nm ND fractions from commercially available DNDs and TD_HPHT NDs by combination of ND size reduction followed by ultracentrifugation [1]; ii) bottom-up HPHT synthesis of sub-5 nm NDs (BU_HPHT NDs) from halogenated adamantanes at 8 GPa with excellent size control in the sub-5 nm region achieved by variation of the synthesis time and temperature [2]. Successful preparation of the sub-5 nm samples of three different ND kinds provides great opportunity not only to compare the typical spectral features of each ND kind but also to investigate size-dependent phenomena such as evolution of the Raman diamond peak parameters (position and full width at half maximum) down to 1.2 nm. Comparison of Raman spectra of DND and TD_HPHT NDs on the sub-5 nm scale reveals clear differences between the two types of NDs. We show that diamond core size, structural quality/defects, and temperature (in)stability caused by laser irradiation during the measurement are key features reflected in the particular NDs' Raman spectrum[1]. Raman spectra of the BU_HPHT NDs exhibit some additional unique features compared to conventional DNDs and TD_HPHT NDs. The most striking is nearly complete absence of sp^2-C related features in most of the investigated samples.
The size-dependent evolution of diamond peak parameters was investigated by multi-wavelength (442, 532, and 633 nm) Raman spectroscopy to identify and/or avoid any heating effect of the excitation laser on the diamond line position. Use of multiple wavelengths also enabled to study dispersion of Raman active bands. We show that down to 2.6 nm the diamond Raman line shift is only minor (2-3 cm^{-1}) which do not corroborate with the current phonon confinement models often applied to NDs. Only when the size decreases below 2 nm, larger shifts are observed (8-9 cm^{-1} for 1.4 nm sample).
Finally, we provide analysis of the first-time observed low-frequency (20−200 cm^{-1}) NDs related Raman scattering signals assigned to "breathing"-like acoustic modes as these signals exhibit clear size dependence. We show that in contrast to diamond Raman line parameters these features are more suitable for size analysis of sub-4 nm NDs as we evidenced a good match with the size values obtained from XRD data (Scherrer's formula)[3].

Controlled Synthesis of Sub-Five-Nanometer Diamond Particles Tengteng Lyu and Hao Yan; University of North Texas, United States

Diamond nanoparticles in the sub-five-nanometer size regime are crucial for several emerging technologies including subcellular imaging, quantum information processing, and drug delivery. State-of-the-art methods to produce nanodiamonds include mechanical grinding of bulk crystals, decomposition of hydrocarbon molecules, and detonation of explosives. However, no existing technique is capable of precise size control in the sub-five-nanometer regime.
Here we describe a method for controlled synthesis of nanodiamond with 2-5 nm diameter. The key innovation lies in the utilization of metal carbide nanoparticles as carbon sources. The reaction between these metal carbides with metal oxides under high-pressure-high-temperature conditions yields diamond nanoparticles with <5 nm diameter, uniform size, and high crystallinity. The size of the nanodiamond is precisely tuned by the nanostructured carbon precursor. Chemical doping of the precursor allows controlled incorporation of functional defects, enabling these nanodiamonds for key applications as bio-compatible high-resolution fluorescent markers, storage bits for quantum information processing, photon and electron sources as well as vehicles for targeted drug delivery. <!--![endif]---->

Multiplexed Sensing and Imaging Based on Complex Electronic Spin Manipulation of Nitrogen-Vacancy Centers in Diamond Junko Ishi-Hayase; Keio University, Japan

Nitrogen-vacancy (NV) centers in diamond are promising as highly-sensitive nanoscale quantum sensors for measuring several kinds of physical quantities such as magnetic field, electric field, temperature, pressure, etc[1]. It is because that spin-triplet electronic ground states of NV centers can be coherently manipulated using microwave (MW) field and optically initialized/readout with long coherence time at room temperature. Optically detected magnetic resonance (ODMR) has been typically used to demonstrate quantum sensing using NV centers. In this study, we propose and demonstrate multiplexed sensor using NV center ensemble in diamond for simultaneously measuring AC magnetic field and temperature.

One of the proposed multiplexed sensors is based on double or triple electron spin resonance transitions induced by simultaneously applying MW and radio-frequency (RF) fields[2-6]. By utilizing eigenstates under bias magnetic field perpendicular to the NV axis, all transitions between spin-triplet states

can be directly controlled by external MW and RF magnetic fields[4]. This is much different from the conventional quantum sensing under bias magnetic field parallel to the NV axis. In our method, we generate RF-dressed state or RF-doubly-dressed state by simultaneously irradiating continuous laser, MW and RF fields. The use of these dressed states enables us to implement MHz-range AC magnetic field sensing and temperature sensing using continuous-wave ODMR (CW-ODMR)[2,3,5,6]. the proposed method does not require a pulse sequence unlike conventional methods based on pulsed-ODMR; this greatly simplifies the procedure and apparatus needed for implementation. Moreover, the use of dressed states enables us to improve the sensitivity by suppressing the variances of strain and/or electric field[6].

Another of the proposed multiplexed sensors is based on simultaneous manipulation of electronic spins of NV centers with different axes by using MW pulses with different frequencies[7,8]. The simultaneous spin manipulation enables us to improve the sensitivity by synthesizing the signals and suppressing the noise from NV centers with different axes. Here, we demonstrate vector magnetic field sensing and temperature sensing by applying the proposed multi-frequency manipulation technique to spin echo and Ramsey interference measurements in an ensemble of NV centers with random orientations. We find that the sensitivity using the multi-frequency manipulation is better than that using the conventional single-frequency manipulation.

Bath-State-Dependent Quantum Phase on a Single NV Center Benjamin Soloway[1], Paul C. Jerger[1], Yuxin Wang[1], Mykyta Onizhuk[1], Michael Solomon[1,2], F. Joseph Heremans[1,2], Giulia Galli[1,1,2], Aash Clerk[1] and David Awschalom[1,2,1]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

The central spin model is important for developing qubits as sensors of environmental noise and protecting qubits from decoherence. In both noise spectroscopy and dynamical decoupling protocols, the central qubit is actively controlled. However, the qubit-bath interaction may enable changes in the qubit state to trigger changes in the bath, ultimately modifying the evolution of the qubit [1]. Here, we experimentally observe the self-interaction of the electron spin of the nitrogen vacancy (NV) center in diamond mediated by a bath of polarized ^{13}C nuclear spins. We are even able to detect the polarization of the bath using phase-resolved Hahn echo sequences. These techniques may assist in preparing high-fidelity memory states, improving nuclear spin hyperpolarization, and investigating the nature of environmental noise.

11:00 AM EQ07.05.03
Engineering Color Centers in Isotopically-Controlled Diamond Layers Christian Osterkamp[1], Priyadharshini Balasubramanian[1], Christoph Findler[1], Gerhard Wolff[1], Milos Nesladek[2] and Fedor Jelezko[1]; [1]Ulm University, Germany; [2]Hasselt University, Belgium

Nitrogen-vacancy (NV) centers in synthetic tailored diamond are promising and emerging platforms for quantum sensing technologies. The realization of such solid-state based quantum sensors is widely studied and requires reproducible manufacturing of NV centers with controlled spin properties, including the spin bath environment within the diamond crystal. A high nitrogen incorporation rate combined with the controllability of the NV axis alignment, makes <111> oriented diamond an interesting material for the creation of ensembles.
We engineer ^{15}NVs by nitrogen delta doping during a plasma enhanced chemical vapor deposition (PECVD) process and we are able to produce an isotopically controlled diamond environment by changing the ratio of $^{12}C/^{13}C$ atoms in the growth chamber. Moreover, since the presence of ^{15}NV hyperfine coupling, as well as the characteristic P1 bath spectrum from ^{15}N are observed, our growth facilities are capable of tuning a wide range of isotopic compounds within the diamond lattice.
Especially, shallow ensembles can be used for NV based magnetometry optimized for the detection of very small magnetic fields from outside of the diamond itself. Whereby the decoupling of the NV's electronic spins by driving the electronic spin bath and by using dynamical decoupling sequences results in an improved magnetic field sensitivity.

In summary, a non-invasive method is shown to rank NV ensembles regarding their suitability as ultra-sensitive magnetic field sensors. Imaging and electron spin resonance techniques are presented to determine operating figures and precisely define the optimal material for NV-driven diamond engineering. The functionality of the methods is manifested on examples of chemical vapor deposition synthesized diamond layers containing preferentially-aligned, isotopically controlled ^{15}NV center ensembles. Quantification of the limiting ^{15}N P1 spin bath, in an otherwise ^{12}C enriched environment, and the reduction of its influence by applying dynamical decoupling protocols, complete the suggested set of criteria for the analysis of NV ensemble with potential use as magnetometers.

High-Density NV Ensemble Produced by Electron Irradiation of Ultra High-Concentration Nitrogen-Doped CVD Diamond Kyosuke Hayasaka[1], Mayu Ueda[1], Kyotaro Kanehisa[1], Kazuki Otani[1], Yuki Ueda[1], Takashi Tanii[1], Taisuke Kageura[1,2], Shinobu Onoda[2], Shinpei Enomoto[3], Shozo Kono[3] and Hiroshi Kawarada[1,3]; [1]Waseda University, Japan; [2]National Institute of Quantum and Radiological Science and Technology, Japan; [3]Kagami Memorial Research Institute for Materials Science and Technology, Japan

Negatively charged nitrogen vacancy (NV) centers have potential applications in magnetic sensors and quantum communications [1]. In particular, the sensitivity of magnetic sensors scales with the square root of the quantum coherence time and the total number of NV centers [1]. Therefore, to improve magnetic sensitivity, it is desirable to increase the concentration of NVs while maintaining a long coherence time. Moreover, highly concentrated NV centers have recently emerged as a promising platform for investigating non-equilibrium quantum many-body systems, contributing to the observation of discrete-time crystals [2].
It is desirable to use diamond with a high concentration of nitrogen for the fabrication of high-concentration NV centers. Currently, nitrogen concentrations of at most 2×10^{20} [cm^{-3}] have been achieved in CVD diamond [3]. Furthermore, the higher the nitrogen concentration, the more atomic vacancies must be introduced. Electron irradiation with a single-ended accelerator [4] or TEM [5] is often used as a means of forming vacancies.
With TEM, the amount of electron irradiation per unit time can be adjusted by reducing the beam diameter. Therefore, it is possible to irradiate with a high dose of electron beams, which cannot be achieved with an accelerator. TEMs also have the advantage of being more easily accessible than accelerators. Therefore, we irradiated CVD diamonds containing the world's highest concentration of nitrogen ([N]=8×10^{20} [cm^{-3}]) prepared by the MPCVD method with electron beams using a TEM and investigated changes in NV density and spin properties in the irradiated area.
CVD synthesis was performed using a waveguide confined MPCVD system with quartz tube where plasma was confined within the waveguide, with a pressure of 110 [Torr], a microwave power 300 [W], and at a temperature of 850 [°C]. CO2, N2, and CH4 gases were used for homoepitaxial growth. The gas mixture condition was 2%, 8%, and 2%, respectively. The total gas flow rate was fixed at 200 [sccm]. HPHT synthetic (111)-oriented diamond substrate was used.
A 300-keV TEM (JEOL JEM-ARM300F) was used for electron beam irradiation because the minimum electron energy required for defect formation in (111) diamond is 220-keV [6]. After electron irradiation, vacuum annealing was performed at 1000°C for 2 hours. Next, a custom-made laser scanning confocal fluorescence microscope (CFM) was used to estimate the concentration of NV centers from the issue intensity. T^*_2 and T2 were also measured by Ramsey and Hahn-Echo measurements on the NV ensemble in the electron-irradiated region.
As a result, the volume density of the NV ensemble in the electron irradiated region increased with increasing electron dose from 10^{17} to 10^{20} [cm^{-2}]; at a dose of 1.0×10^{20} [cm^{-2}], the NV volume density reached 2×10^{17} [cm^{-3}]. In HPHT diamond([N]=3×10^{19} [cm^{-3}]), which was used as a comparison, the NV volume density was 4×10^{17} [cm^{-3}] after 1.0×10^{20} [cm^{-2}] electron doses. Since the NV volume density was on the same order of magnitude as that of HPHT diamond, the concentration of NV centers could be further improved by further irradiation with higher doses in the future. In addition, T^*_2 remained 50 ns and T_2 remained 0.5 μs despite such a high nitrogen concentration in the diamond.

Atmospheric-Pressure Flame Vapor Deposition of Nanocrystalline Diamonds over Large Areas Adrian Manjarrez[1], Kai Zhou[1], Changqiang Chen[1], Yan-Kai Tzeng[2] and Lili Cai[1]; [1]University of Illinois Urbana-Champaign, United States; [2]Stanford University, United States

Nanocrystalline diamonds (NCDs) are one of the many carbon allotropes that have attracted great attention for the advancement of many technologies, owing to their superior mechanical, thermal, and optical properties. Yet, their synthesis must be improved for availability at low costs and their widespread application. Here, we report the atmospheric-pressure flame vapor deposition (FVD) synthesis of NCD particles and thin films over an area of more than 28 cm2 using methane-hydrogen-air flat flames. Notably, the FVD method unlocks new conditions for diamond growth beyond the previously considered diamond-growth region of the C-H-O phase diagram. Additionally, we demonstrate that the FVD growth of NCDs can be facilely controlled by tuning the reactant gas composition, substrate material, seeding density, and external electric bias. Overall, with the low cost and simplicity for operation without the need of vacuum, this atmospheric-pressure FVD approach will offer new opportunities to facilitate the scaling-up of diamond synthesis.

2:15 PM EQ07.06.01
Bonding and Integration of CVD Diamond Components in Advanced Industrial Applications Ian Friel[1], Andrew Bennett[1], Julian Ellis[1], Firooz Faili[2], Teodoro Graziosi[1], Michael Pearson[1] and Daniel Twitchen[1]; [1]Element Six (UK) Ltd, United Kingdom; [2]Element Six Technologies US Corporation, United States

CVD diamond is a well-established and versatile engineering material which can be manufactured at scale to address a broad range of industrial and consumer sectors, such as defense, semiconductor test and manufacturing, high-end audio, and lab-grown jewelry. Typically, the CVD diamond component is integrated into a larger system to provide an engineering solution which exploits one or more of diamond's remarkable physical properties.

While the successful development of high-quality CVD diamond grades for various optical, electronic, thermal and quantum-sensing applications has been widely reported, the challenges inherent in integrating diamond are less well-understood. Here, many of diamond's properties, such as its chemical inertness, low thermal expansion coefficient, high stiffness and yield stress, as well as low toughness, present barriers to integration, which if not managed successfully can lead to poor adhesion of dielectric and metal coatings, or highly strained components and interface layers vulnerable to failure.

In this paper we discuss bonding and integration challenges and solutions in the context of state-of-the-art optical and thermal applications of CVD diamond, such as high-power Raman lasers, and heat spreaders for high power RF amplifiers.

2:30 PM EQ07.06.03
Strain Engineering of Diamond Microstructures by Trench Filling and Oxidation Keshab R. Sapkota, Andrew Mounce, Tzu-Ming Lu, George Wang

and Ting S. Luk; Sandia National Laboratories, United States

Diamond is considered as the “Mount Everest” of electronic, photonic, and quantum materials due to its outstanding properties, such as an ultrawide bandgap, ultrahigh thermal conductivity, ultrahigh dielectric breakdown strength, high carrier mobility, and hosts of quantum emitters. However, difficulty in doping due to deep dopant levels, indirect bandgap, and difficulty in controlling the color centers’ quantum levels have posed significant challenges to fully utilize diamond in electronic, photonic, and quantum applications. Based on recent theoretical predictions, the bandgap of diamond can be significantly tuned given enough strain. Additionally, it has been demonstrated that strain can manipulate the energy levels in color centers. Therefore, the ability to engineer strain in diamond can be a game changer for diamond based electronics, photonics and quantum applications. However, being the hardest material, diamond is notoriously difficult to strain. Here we present a novel, in-situ, and integrated approach to strain engineer diamond microstructure by growth and oxidation of material (e.g. Si, Al) filled in the micro-fabricated diamond trench. In this study, pairs of diamond fins are fabricated and the trench between fins is filled by poly-Si or Al. The oxidation of trench-filling material exerts stress on the diamond microstructures as a consequence of increased material volume and produces mechanical strain on the microstructures. We will present strain analysis on diamond microstructures as a function of trench dimension, oxidation temperature, and oxidizing materials as measured by electron microscopy and Raman spectroscopy.
Sandia National Laboratories is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Fluorescent Nanodiamond-Based Spin-Enhanced Lateral Flow Immunoassay for Detection of SARS-CoV-2 Nucleocapsid Protein and Spike Protein from Different Variants Neha Sharma, Wesley W. Hsiao and Wei-Hung Chiang; National Taiwan University of Science and Technology, Taiwan

Fluorescence Nanodiamonds (FND) have proved to be a promising candidate as biomarkers due to their great optical properties and high biocompatibility. Moreover, FNDs can be easily functionalized with biomolecules such as protein, enzymes. Furthermore, FND do not show photo-blinking, photobleaching and found to have a stable fluorescence and can be used as biomarkers in heterogenous environment due to their no cytotoxicity and biocompatibility. Recent outbreak of Covid-19 lead WHO to announce a pandemic. This disease has infected more than ~500 million people and caused ~6 million deaths. There are several methods to detect corona virus but most of them are required of long-time, expensive and larger laboratory instruments, highly skilled professionals, particular environmental conditions, low specificity and sensitivity. These drawback limits these methods to control that disease at global level. It is necessary to have fast, sensitive and lower cost rapid detection for preventing spread of disease at global level.
Here we report a simple and fast FND based Spin-Enhanced Lateral Flow Immunoassay (SELFIA) for the detection of SARS-CoV-2 virus. Two different antigen from Corona virus, Spike protein and Nucleocapsid protein were detected by SELFIA using FNDs as biomarkers. SELFIA is a homebuilt platform which incident green laser on sample LFIA strips in the presence of electromagnetic field. Antibody functionalized FNDs emit fluorescence when green laser incident on it. The fluorescence signal was detected to photomultiplier tube and amplified signal is received. We successfully detected Spike protein and Nucleocapsid Protein from corona virus from different mutations. This work offers a promising rapid method to detect SARS-CoV-2 with fast, highly sensitive and lower limit of detection (LoD).

3:30 PM EQ07.07.03
X-Ray Absorption Spectroscopy on Nanodiamonds in Water Arsène Chemin[1], Ronny Golnak[1], Jie Xiao[1], Andreas Weisser[1], Benjamin Kiendl[2], Anke Krueger[2,3] and Tristan Petit[1]; [1]Helmholtz-Zentrum Berlin for Materials and Energy GmbH, Germany; [2]Julius-Maximilians-Universität Würzburg, Germany; [3]Institut for Organic Chemistry, Germany

Easy production of solvated electrons from solar illumination would be a game changer for green chemistry and environmental research. The use of widely available synthetic diamonds to generate solvated electrons upon light irradiation in water has been proposed as a promising strategy to achieve CO2 or N2 reduction in liquid phase [1-2]. Free electrons can easily transfer to water because diamonds have a high energetic level of the conduction band and a negative electron affinity when its surface is hydrogenated. At first glance, the large band gap of diamonds (5.5 eV) should only enable excitation from deep UV light, limiting the electrons production using sun. However, CO2 photo(electro)chemical reduction with visible light has been previously reported [3]. Electron emission mechanisms from visible light radiation remains poorly understood but seems strongly related to the surface state of the diamonds and the interaction with water.
The surface chemistry of the diamonds in water as well as its functionalization, for example with Ru dye, plays a dramatic role on electron excitation and emission. It affects the interfacial properties such as electron affinity or the electron emission and solvation. X-ray absorption spectroscopy (XAS) can be used to characterize the surface states. XAS corresponds to the resonant excitation by X-rays from the core electrons into unoccupied electronic levels allowing a high chemical sensitivity. This provides knowledge on the chemical state of the surface atoms, the density of states and the photoelectron yield. While this characterisation is easily performed into vacuum, measurement in water is much more challenging due to the vacuum requirement for soft X-ray propagation.
In this work, we apply a new technique of XAS in liquid [4] to the characterization of the nanodiamonds film in interaction with water. The nanodiamonds are detonation nanodiamonds functionalized with Ru complex, which showed good photocatalytic properties. A similar method was previously applied to dispersed carbon dots [5]. Measurements were performed at BESSY II synchrotron in Berlin. We used a two electrodes liquid flow-cell with an ultra-thin membrane separating the liquid from the vacuum. The nanodiamonds are deposited on a gold-coated membrane used as working electrode. Here, we show that we can measure the absorption spectrum of nanodiamonds deposited on the membrane and of the water molecules in interaction with the nanodiamonds. The signature from both diamond core and of the functionalized molecules on the nanodiamond surface can be detected. By comparing this measurement to XAS in vacuum, we determine that the interaction with the liquid lead to strong modification of the surface states giving a new insight on possible pathways for the production of the solvated electrons in water.

Ultra High-Concentration Nitrogen-Doped CVD Diamond with Highest Crystallinity Mayu Ueda[1], Kyosuke Hayasaka[1], Kyotaro Kanehisa[1], Yasuhiro Takahashi[1], Chiyuki Wakabayashi[1], Taisuke Kageura[2] and Hiroshi Kawarada[1,3]; [1]Waseda University, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Kagami Memorial Research Institute for Materials Science and Technology, Japan

High impurity doping in diamond using microwave plasma chemical vapor deposition (MPCVD) has been actively investigated with many dopants such as boron, nitrogen, and phosphorus. In particular, high concentration doping as high as $2\times10^{22}cm^{-3}$ has been achieved for boron doping [1], whereas the highest concentration for nitrogen is only $2\times10^{20}cm^{-3}$ [2]. The fabrication of highly nitrogen-doped diamond is expected to realize highly sensitive magnetic sensing by NV centers and superconductivity theoretically predicted [3]. In general, increasing the proportion of supplied nitrogen gas degrades the film quality of diamond [4]. On the other hand, it has been reported that supplying carbon and oxygen at a ratio of 1:1 during deposition improves the film quality [5]. Diamonds doped with high concentrations of boron, which has a larger ionic radius than carbon, exhibit crystal expansion in vertical direction [1]. Up to now, there are no reports on crystal distortion in highly nitrogen doped diamonds where nitrogen, has a smaller ionic radius than carbon. In this study, we fabricated diamond and characterized the physical properties of the thin films by Reciprocal Space Mapping (RSM) using a XRD (Bruker D8 DISCOVER) and cross-sectional imaging using a TEM (JEOL JEM-2100F).
CVD synthesis was performed using a waveguide confined MPCVD system with quartz tube where plasma was confined within waveguide, with a pressure of 110Torr, a microwave power 300W and at a temperature of 850°C. CH_4, N_2, and CO_2 gases were used for homoepitaxial growth. The gas mixture conditions are [C,O]=1.2% (common value for C and O), [C,O]=1.5, 2.0%, and [C,O]=4.0% (common value for C and O). The total gas flow rate was fixed at 200 sccm, and samples were prepared by varying the ratio of gases. HPHT synthetic (111)-oriented diamond substrates were used.
As a result, the nitrogen concentration of [C,O]=4.0% was $8\times10^{20}cm^{-3}$ from SIMS measurements. It is the world's highest concentration of nitrogen existed in diamond. From the cross-sectional TEM images, it was confirmed that twinning defects were introduced into the epitaxial layer in [C,O]=1.5, 2.0%, and stacking defects were introduced into the epitaxial layer in [C,O]=1.2%.On the other hand, [C,O]=4.0% showed no twins or stacking faults, but dark spots which appeared to be nitrogen aggregation [6] in the epitaxial layer. The origin of these spots must be further investigated. In the Raman spectrum measurement (RENISHAW inVia Basis, 532nm), a peak at $1333cm^{-1}$, the Raman peak of diamond, was confirmed for all three samples. [C,O]=4.0% showed the FWHM of $8.6cm^{-1}$ at $1333cm^{-1}$. The FWHM is comparable to that of HPHT diamond with few defects. High quality nitrogen-doped diamond was produced despite of containing as much as $8\times10^{20}cm^{-3}$ nitrogen. The lattice expansion was calculated from RSM. [C,O]=1.2% exhibited 0.66% expansion in the horizontal direction and 0.20% shrinkage in the perpendicular direction. [C,O]=1.5, 2.0% exhibited 1.47% expansion in the horizontal direction and 0.50% shrinkage in the perpendicular direction. This anisotropic expansion and shrinkage is opposite to those of heavily boron doped samples [1] and is caused by high concentration of nitrogen above $5\times10^{20}cm^{-3}$. However, [C,O]=4.0% exhibited no crystal lattice expansion or shrinkage. The well-crystalline CVD diamond has been fabricated with the highest nitrogen concentration of $8\times10^{20}cm^{-3}$ by using [C,O]=4.0%. It is the most promising condition for high nitrogen incorporation with high quality CVD diamond equivalent to HPHT diamond and can be applied high sensitive NV magnetometry.

Chemical Mechanical Polishing Rate and Uniformity for Single-Crystalline Diamond Substrates S M Asaduzzaman[1], Aaron M. Hardy[2], Cristian J. Herrera-Rodriguez[1], Mark Tompkins[2] and Timothy A. Grotjohn[1,2]; [1]Michigan State University, United States; [2]Fraunhofer USA, Inc., Center Midwest, United States

Diamond has exceptional physical and chemical properties, including maximum hardness, thermal conductivity, and superior chemical erosion resistance. Chemical Vapor Deposition (CVD) diamonds are strong candidates for industrial use but can suffer from the non-uniform thickness and rough surfaces. The development of diamond applications in electronics can be greatly improved by precise polishing that produces minimal damage to diamond substrates. Among the numerous applications, polishing and planarizing operations are needed in the preparation of CVD diamonds for precision machining tools, electronic applications, optical windows, heat spreaders, and bonding of diamonds to other semiconductors. In terms of cost-effective processing and material surface finish, polishing is a crucial and limiting step for diamond applications. Polishing diamonds over the years has been accomplished in several ways. Chemical Mechanical Polishing (CMP) with strong oxidizing slurries to polish CVD diamond films is a promising approach [1-5].

We have studied the CMP process originally developed for the work described in [6] that put a GaAs membrane on a CMP polished diamond substrate/epi-layer. We have looked at quantifying the CMP polishing rate and the uniformity of the polishing across the diamond substrate. This study utilizes High-Pressure High-Temperature (HPHT) diamond samples with a 0-3° degree off-angle from the (001) surface orientation with dimensions of 3.5 x 3.5 mm^2

and larger. Since the applications of interest often have epi-layers of diamond grown by the CVD method, we studied the CMP process applied to CVD diamond grown on the HPHT substrates. To study the polishing rates, patterns are etched into the diamond surface so the CMP rate could be measured with the atomic force microscope (AFM) and surface profilometry techniques.

The CMP polishing equipment rotates the polishing wheel and sweeps/rotates the sample while using a self-leveling sample holder to maintain contact between the SCD surface and the grooved ceramic polishing wheel. The self-leveling approach helps achieve a repeatable, uniform, and proportionate material removal. With this approach, roughness can be reduced without too aggressively reducing the thickness or homogeneity of epitaxial layers. The oxidative CMP slurry mixture consists of potassium permanganate ($KMnO_4$) and boron carbide particles (1-3 μm) with phosphoric acid and DI water also in the slurry.

For determination of CMP removal rates and uniformity, CMP is performed for fixed time intervals with the surface profile of the previously etched structures on the diamond surface measured after each interval. The typical interval time between measurements was 60 minutes. Before and after each hour of CMP operation, microscopic checks, profilometer step scanning, and atomic force microscope (AFM) scans were performed. On the SCD substrate, measurements were performed at multiple locations. The typical CMP removal rates were 100-150 nm/hr. The surface profile scans, and AFM indicate that some material removal also occurs at the bottom of the etch structure as wide trenches and narrow trenches show different depths after CMP processing.

Following Polymer Degradation with Nanodiamond Magnetometry Runrun Li, Thea Vedelaar and Romana Schirhagl; University of Groningen, Netherlands

Degradable polymers have been widely used in the biomedical fields, including treatment of cancer, development of vaccines, manufacture of nanoparticles with increased plasma half-life, scaffolds for cell culture, and tissue regeneration or drug delivery. Their main advantages are their non-toxicity as well as great biocompatibility and biodegradability. Many kinds of polymers are used for various biochemical media in medical practice. Hence, it is important to precisely follow the degradation of polymers in real time. Common methods to evaluate polymer degradation encompass atomic force microscopy, gel permeation chromatography, nuclear magnetic resonance, and Raman spectroscopy. However, all of them have limitations, such as the requirement of large sample masses, interference from cellular biomolecules or organelles, and none of them allow for straightforward and time-efficient tracking of polymer degradation in real time with high precision. In this study, we made use of relaxometry or T1 measurements for the first time to track polymer degradation with nanoscale precision, both extracellular and intracellular. The method is a new technique based on fluorescent defects in nanodiamonds, which changetheir optical properties based on their magnetic surrounding. Since optical signals can be read out more sensitively than magnetic signals, this method enables unprecedented sensitivity down to the nanoscale. Here we investigated an exemplary polymer polylactic acid (PLA), whose degradation product, lactic acid, is eventually converted into H_2O and CO_2 through the citric acid cycle. For extracellular degradation, fluorescent nanodiamonds (FNDs) were incorporated into PLA films that were produced by spin-coating. Then, this thin film was immersed in a degradation medium, which contained Gd^{3+}. Gd^{3+} is a common contrast agent which causes a spin noise. When the film is degraded, Gd^{3+} can come closer to nanodiamonds and thus an increase in spin noise is detected. We found that T1 constants decreased gradually with the erosion of the film exposed to an alkaline condition. In addition, we accessed the mobility of nanodiamonds within the film and indicated the freedom of particles increased under the strong alkaline environment. We also compared T1 data with the conventional methods including quartz crystal microbalance, fourier-transform infrared spectroscopy and atomic force microscopy. The results were in good agreement with each other. For intracellular degradation, PLA conjugated with NH_2-DOTA-GA was linked to Gd^{3+} by chelate, and then FNDs were loaded to PLA-Gd to form nanoparticles (PLA-Gd-FNDs NPs) by the emulsion method. Afterwards, nanoparticles were taken up by the cells and degradation of PLA in the cells was detected in real time with our home-built T1 magnetometry. In that case we start with low T1 and the Gd^{3+} moves away from the nanodiamonds simultaneously with the PLA when nanoparticles are degraded intracellularly. Therefore, we find an increase in T1. At the same time, we could freely explore the movement of nanodiamonds loaded into PLA nanoparticles as a complement to the T1 results. Unlike traditional methods, T1 measurements provide localized detection with nanoscale resolution, and due to the stability and non-bleaching of nanodiamonds, this technique allows for long-term tracking. T1 and tracking have been used to follow the degradation of PLA in real-time, and we expect that they could be applied to other polymers as well.

EQ07.08.04
Analytical Solution of Electron-Spin Double Resonance Spectra in Diamond Under Strong RF Fields Derived by the Floquet Theory Takumi Mikawa[1,1], Yuichiro Matsuzaki[2,2], Ryusei Okaniwa[1,1], Yuta Nakano[3,3], Norio Tokuda[3,3], Hideyuki Watanabe[2] and Junko Ishi-Hayase[1,1]; [1]Keio University, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Kanazawa University, Japan

Detections of radio frequency (RF) magnetic fields with high sensitivity have been demanded in both pure and applied physics. A nitrogen-vacancy (NV) center in diamond has attracted much attention as a RF signal sensor with high sensitivity and high-spatial resolution because of its atomic size and long coherence time at room temperature. While many studies have proposed several methods to sense RF, electron-spin double resonance (ESDR) [1-2] enables to detect RF based on continuous-wave optically detected magnetic resonance (CW-ODMR). Due to its simple setup and sequence, the ESDR is suitable for wide-field sensing. However, previous studies [1-3] can explain the ESDR spectra only for the weak RF and cannot provide any analytical solutions for the characteristic phenomena under the strong RF. In this study, we theoretically and experimentally analyze the ESDR spectra for strong RF by adapting the double-unitary-transformation (DUT) approach [4] in the Floquet theory [5].
In the present of bias magnetic perpendicular to the NV axis, eigenstates of electronic spins of an NV center are represented by the bright state |B>, the dark state |D> and |ms = 0>. The resonant microwave (MW) magnetic can induce the transition from |0> to |B> or |D>, which results in the decrease of photoluminescence (PL) under a green laser excitation (CW-ODMR). The transition between |B>-|D> states can be induced by RF and its resonant frequency depends on the transverse strain and the transverse magnetic field. In the ESDR experiment, the PL intensities were measured by simultaneously irradiating continuous MW and RF with various frequencies. In Refs [1,2], the anti-crossings around |B>-|D> resonant frequency can be observed under

weak RF and well reproduced by the theoretical calculations assuming only rotating wave approximation (RWA). Under the strong RF, however, additional anti-crossings at different RF and MW frequencies appeared that cannot be reproduced using the previous theoretical approach [1,2]. Then, we introduce the Floquet theory treating the time-periodic Hamiltonian of the ESDR. According to the Floquet theory, the state of the NV center under driving RF forms a RF-dressed state by absorbing or emitting any RF-photons. For strong driving fields, we adapt the DUT approach in the Floquet theory to turn the strong driving term into many weak driving terms. Therefore, the analytical solutions of the DUT approach can reproduce the anti-crossings peculiar to strong RF. Moreover, we find that, the anti-crossings peculiar to strong RF are caused by the multi-photon transition where the MW induces the transition between dressed states generated by RF via |0>. In contrast, the anti-crossings under the weak RF [1,2] are caused by the one-photon transition between |B>-|D> states.
We use the DUT approach in the Floquet theory to analyze the ESDE and experimentally confirm that the analysis can reproduce the ESDR spectrum with the strong RF. Our result provides the insight into the applicability of Floquet theory for understanding physical properties of NV centers.

EQ07.08.05
Optical Properties of Silicon Vacancy (SiV) Centers in Nanodiamonds Fabricated by Detonation Process Yoshiki Saito[1], Yuto Makino[1,2], Yosuke Minowa[1] and Masaaki Ashida[1]; [1]Osaka University, Japan; [2]Daicel Corporation, Japan

Silicon vacancy (SiV) center-containing nanodiamonds (SiV-NDs) have attracted much attention as promising fluorescent probes due to their high biocompatibility and fluorescence properties. SiV centers in bulk diamond exhibit a sharp zero-phonon line (ZPL) with a linewidth of 5 nm in the biomaterial window (650-950nm) [1] at room temperature [2][3]. In addition, the SiV center emission has a large Debye-Waller factor (DWF), concentrating about 70% of the total emission in the ZPL [4]. This sharp photoluminescence is excellent for multicolor bioimaging and for distinguishing of autofluorescence. Recently, Daicel Corporation has demonstrated the synthesis of SiV-NDs by detonation process (SiV-DNDs) [5]. This method has the potential to pave the way for bioimaging applications because it can efficiently produce NDs with a single-digit nm size, which is extremely small compared to NDs produced by other methods. The small size allows non-invasive imaging. However, there is a concern that SiV centers in DNDs may show optical properties different from those of SiV centers in bulk diamond due to their extremely small size. For example, a nitrogen-vacancy (NV) center, another well-studied color center, in DNDs has been reported to show different optical properties from NVs in bulk diamond, such as the extinction of fluorescence caused by defects near the surface and inhomogeneous distribution of the ZPL due to energy level shifts depending on the position of the NV centers [6].
In the present study, we measured photoluminescence and photoluminescence excitation spectra (PLE) and conducted time-resolved photoluminescence measurements to investigate the optical properties of SiV centers in DNDs.
The optical properties were compared with those of typical SiV centers in bulk diamond; in the case of SiV centers in DNDs, the linewidth of ZPL is 14.4 nm at room temperature, which is wider than the line width of SiV centers in bulk diamond. Furthermore, the DWF of the SiV center in DNDs is 0.47, which is reduced to about 70% of that of the SiV center in bulk diamond. The luminescence lifetime of the SiV center in DNDs is 0.56 ns, which is about half of that of the SiV center in bulk diamond. PLE measurements confirmed SiV-DND emission under excitation wavelengths from 390 to 690 nm. PLE spectra is broad and more efficiently excited at longer wavelengths compared to SiV centers in bulk diamond.
We attribute these differences in optical properties to surface effects due to the very small particle size (~10 nm). The enhanced non-radiative transition probability and electron-phonon coupling resulting from the surface effects lead to homogeneous broadening of the ZPL and shorter fluorescence lifetime of the SiV centers in the DNDs. The rise in the low-energy side of the PLE spectrum is also considered to be the tail of the ZPL of the absorption spectrum. Moreover, surface effects cause fluctuations in the energy levels of the SiV centers in each DND. This fluctuation gives rise to the inhomogeneous broadening of the ZPL. However, we demonstrated that the photostability does not change, irrespective of the particle size. In summary, SiV-DNDs show a sharp photostable emission, a wide excitation wavelength range and a high excitation efficiency in the biomaterial window region, suggesting that they are promising fluorescent probes in the field of bioimaging.

Ultrafast Pump-Probe Dynamics of the Unknown 3237cm^{-1} Diamond Defect Absorption Feature Terng Junn Keat, Daniel J. Coxon, Vasilios G. Stavros, Mark E. Newton and James Lloyd-Hughes; University of Warwick, United Kingdom

The 3237 cm^{-1} absorption feature has often been observed in diamonds alongside the 3107 cm^{-1} feature which originates from the N_3VH defect. Despite the commonplace occurrence of both features, their relationship with each other has long eluded diamond researchers. Furthermore, the vibrational energy dynamics of the 3237 cm^{-1} are entirely unknown. Understanding this is vital in understanding the origins of this feature and its possible interactions with other diamond defects which are of significant interest. For example, the possibility of the 3237 cm^{-1} being a N-H bond vibration suggests that the defect responsible for this feature may act as a nitrogen sink. This is significant when trying to produce and/or characterize the famous NV^- defect, amongst others. Here, we present a thorough investigation on the infrared vibrational dynamics of the unknown 3237 cm^{-1} absorption feature and its relationship with the N_3VH defect. Fourier transformation infrared spectroscopy and ultrafast pump-probe measurements were conducted to establish whether the 3237 cm^{-1} also originated from the N_3VH defect, and if not, how the two defects are related. The vibrational energy states related to the 3237 cm^{-1} feature and their respective relaxation dynamics were also investigated. This, along with theoretical modelling of the unknown defect's energy potential via the Morse

potential model, further provided the dimensionless matrix element and the defect concentration calibration factor needed to quantify this defect from its infrared absorption spectrum.

EQ07.08.07
Sub-Bandgap Electron Emission from Diamond into Vacuum and Water Cesar Saucedo, Nathaniel F. Rieders and Robert J. Hamers; University of Wisconsin–Madison, United States

Diamond has the potential to enable novel photochemistry through the generation of solvated (hydrated) electrons. Hydrogen-terminated diamond surfaces are of particular interest as they exhibit negative electron affinity, allowing for efficient electron emission into vacuum. Due to diamond's large bandgap, photoelectron emission is typically achieved at short wavelengths (<225 nm), although emission using longer wavelengths is possible. Enhancing photoemission at longer wavelengths requires a better understanding of the photophysics involved in the sub-bandgap region. Understanding the energy distribution of emitted electrons and how this distribution depends on the energy of the photoexcitation source is critical for developing models of the sub-bandgap emission process. Our studies provide new insights into the mechanism and the role hydrogen and oxygen terminated surfaces have on the sub-bandgap electron emission into vacuum and water. We have modified a commercial photoelectron spectroscopy system to enable the use of sub-bandgap excitation energies. In addition, we performed photocurrent measurements with the same sub-bandgap excitation energies into water. Using various sub-band gap photon energies, we have measured the energy distribution of photoelectrons emitted from boron-doped (111) H-terminated and O-terminated diamond surfaces as well as emission into water. Initial observations demonstrate that sub-bandgap emission from both H- and O-terminated diamond substrates is possible. The efficiency of sub-bandgap excitation and distribution of emitted electron energies differs between surface terminations.

EQ07.08.08
Electron Emission from Nanodiamond Field Emitters Travis C. Wade[1], David Kerns[2], Glenn Hess[2], Keith Warren[3] and Jim Davidson[2]; [1]Evolve Diamonds LLC, United States; [2]International FemtoScience Inc., United States; [3]Spatial Microsystems, United States

Chemical vapor deposited (CVD) diamond is an attractive material for electron field emitters because of its low or negative electron affinity, excellent mechanical strength, and chemical inertness. Diamond's excellent mechanical strength and chemical stability contribute to excellent durability characteristics. The strong covalent sp3 bonds present in diamond have a stabilizing effect on the electron emission as compared to the weaker ionic bonds present in traditional metal cathodes. Nanocrystalline diamond, (grain size ~ 1 nm - 100 nm), possesses unique properties including deliberate and controlled amounts of sp2-carbon content and n-type electrical conductivity at room temperature.

The authors have demonstrated electron emission from widely spaced nanodiamond pyramidal tip arrays as well as lateral lithographically-patterned field emission arrays. Array tips have not been observed to be physically damaged by extended emission tests on the scales available to scanning electron microscopy (SEM). Methods developed by the authors permit analysis of diamond tip structure and provide a basis for optimization of field emitter composition and performance.

The authors are focused on developing new technologies, sensors and products for operation in extreme environments and applications (e.g., high and low temperature, pressure, radiation, etc.) where no other, or limited, capability currently exists.

EQ07.08.09
Incubation Effect upon FS-Laser Micromachining in CVD Diamond Cleber Mendonca, Lucas Nolasco and Filipe Couto; University of Sao Paulo, Brazil

Diamond is well known for its many remarkable mechanical, thermal, electric and optical properties. Among its unique features, it also presents interesting nonlinear optical effects, thus being a highly desired material for many photonic devices. Therefore, femtosecond laser micromachining can be used as a processing method for such devices due to its high micron/sub-micron resolution, which has been mostly exploited using fs-pulses at 800 nm. Although such a method has been intensively investigated, most experiments were performed by an fs-laser system centered at 800 nm. Thus, in this work, the incubation effect (damage threshold fluence as a function of the number of applied fs-pulses) is studied at 1030, 515, and 343 nm with 216 fs pulses using the zero damage method. By implementing the exponential defect model, the incubation parameter () was determined to be (0.14 ± 0.03) at 1030 nm (0.3 ± 0.1) at 515 nm, and (0.13 ± 0.04) at 343 nm, which indicates that at 515 nm, fewer fs-pulses are necessary to reach the minimum damage fluence value. In addition, a theoretical model of the electron density formed by a single fs-pulse, considering multiphoton excitation and avalanche ionization, was used to interpret the experimental result. Therefore, this work adds to the knowledge of fs-laser micromachining of CVD diamond from near IR to UV, improving such processing technique.

EQ07.08.10
Chemical Mechanical Polishing of Single Crystalline Diamond Epitaxial Layers for Electronics Applications Aaron M. Hardy[1], Cristian J. Herrera-Rodriguez[2], Matthias Muehle[1], Michael Becker[1], Edward Drown[1,2], Nina Baule[1], Mark Tompkins[1], Timothy A. Grotjohn[2] and John D. Albrecht[1,2]; [1]Fraunhofer USA Inc., Center Midwest, United States; [2]Michigan State University, United States

In order for single crystal diamond (SCD) to be practical as an electronic material for technical applications including solid state electronics, thin (<1 µm), precisely doped epitaxial SCD layers with very low (<1 nm) surface roughness are required. The roughness requirement is especially crucial for fabrication processes utilizing membrane transfer techniques. To meet roughness requirements, a post-growth chemical mechanical polishing (CMP) process may be employed. While the current body of literature gives valuable insight into the material removal mechanism, material removal rates (MRRs), subsurface damage, and resultant roughness[1–4], there is limited exploration of material removal uniformity or the need for post-growth smoothening of thin, epitaxially grown diamond layers for electronics applications.

To address this, we propose a self-leveling oxidative CMP process targeting repeatable, minimal, and uniform material removal. This process utilizes a ball-joint style self-leveling sample holder to keep the SCD surface in flat contact with a grooved ceramic polishing wheel under the conditions of wheel rotation, sample rotation, and sample sweeping. These innovations seek to meet roughness requirements without unnecessarily affecting the epitaxial layer thickness or uniformity.

In this study, an 8-hour oxidative CMP process was performed on two p^- epilayers grown on (100) SCDs cut to 3° off-angle. Five wear trenches were etched into each p^- epilayer after growth, and atomic force microscope (AFM) analysis of the trenches was used to evaluate material MRR and material removal uniformity. After CMP, the average roughness decreased from 3.83 nm and 1.57 nm to 0.20 nm and 0.16 nm for the two samples, respectively. The average MRRs for the two samples were found to be 41 nm/hr and 38 nm/hr as measured by mass loss, indicating a good degree of repeatability. Profilometer scans of the diagonals were used to further evaluate macroscale morphology and material removal uniformity.

In addition, we show how this CMP process has been deployed to smoothen p^- SCD device layers. The thickness of these layers ranged from 200 – 600 nm before polishing, exhibited typical roughness >2 nm, and displayed hillock formation. By using this process, the p^- SCD device layers were smoothened to roughness values typically <0.3 nm, and thinned to target thicknesses between 100 – 300 nm. Subsequently, these samples were used by collaborators for the fabrication of GaAs/diamond n-p diodes and AlGaAs/GaAs/diamond p-n-p heterojunction bipolar transistors (HBTs) by means of a semiconductor grafting membrane transfer process.[5]

An Electrochemical Sensor for Chemotherapeutic Agent Methotrexate Based on a Novel Graphitic Nano-Heterostructure Material Reham G. Elfarargy, Mahmoud A. Saleh and Nageh K. Allam; American University in Cairo, Egypt

A novel graphitic material was used to determine, using electrochemical voltammetry, whether methotrexate (MTX) is a chemotherapeutic and immunomodulator medication. The study shows an enhanced response compared to the previous ones. A graphite/CPE exhibits superior electrochemical oxidation and detection capabilities of MTX in biological platforms (plasma, urine) than bare Carbon Paste Electrodes. As part of the characterization of the synthesized graphitic material, several techniques were utilized, including X-ray powder diffraction (XRD), X-ray photoelectron spectroscopy (XPS), UV-visible absorption spectroscopy, scanning electron microscopy, Raman spectroscopy, cyclic voltammetry, square wave voltammetry, and electrochemical impedance spectroscopy. By using density functional theory (DFT), the electronic structure, adsorption energy, band gap, type of interaction, and stable configuration of the graphic material/CPE used were also investigated. For MTX concentrations in Britton Robinson Buffer (BRB) solution, urine, and plasma, the graphitic/CPE platform demonstrated linear response, with a higher recovery rate and a lower limit of detection (LOD) and limit of quantification (LOQ), compared with existing literature. Several studies using modified graphitic materials/CPE electrodes have shown promising results in terms of reproducibility, stability, and selectivity.

Study on the Growth of High-Quality Diamond Microparticles with Preselected Seeds and Their Practical Applications Tongtong Zhang[1], Madhav Gupta[1], Zhongqiang Wang[2], Lingzhi Wang[1], Jing Wang[3], Qi Wang[2], Lei Shao[3], Kwai Hei Li[4] and Zhiqin Chu[1]; [1]The University of Hong Kong, Hong Kong; [2]Peking University, China; [3]Computational Science Research Center, China; [4]Southern University of Science and Technology, China

The diamond materials have demonstrated copious applications in a wide range of areas due to their extraordinary features. Thus, various methods, e.g., chemical vapor deposition (CVD), have been developed to fabricate diamond materials with desired properties. However, the conventional CVD diamonds grown by detonation nanodiamonds (DNDs) seeds are unsuitable for most demanding applications that require diamonds with superior properties. Here, we propose to use our previously developed clean and rounded salt-assisted air-oxidized (SAAO) high-pressure high-temperature (HPHT) nanodiamonds (NDs)[1] as CVD seeds to grow high-quality diamond microparticles on the silicon substrate. The as-grown diamond microparticles are found to contain silicon-vacancy (SiV) centers with superior properties, i.e., significantly increased photoluminescence (PL) emission, narrow linewidth, etc., enabling a wide range of practical applications. For example, ultrasensitive all-optical thermometry measurements with an intrinsic noise floor of ~0.24 °C $Hz^{-1/2}$ are demonstrated by utilizing the SiV centers in the fabricated high-quality diamond microparticles.

At the same time, these chaotic diamond microparticles heterogeneously grown on silicon substrate also have great potential to be used as robust optical anti-counterfeiting labels. The location, size, and shape of each particle are random and unclonable due to the unpredictable CVD fabrication process. Notably, the robust and tunable signals of 1) SiV PL and 2) scattering from diamond microparticles are demonstrated to enable high-capacity optical encryption. Furthermore, this diamond-based anti-counterfeiting label shows extreme stability in various practical application scenarios, e.g., harsh chemical environments, high temperature, mechanical abrasion, and UV light irradiation.

Depth Dependence of the Radiative Lifetimes of Shallow Color Centers in Single-Crystalline Diamond Maryam Zahedian, Jietian Liu, Ricardo Vidrio, Shimon Kolkowitz and Jennifer Choy; University of Wisconsin–Madison, United States

Optically active defects in diamond are widely used as bright single-photon sources for quantum sensing, computing, and communication. For sensing applications, the measurement sensitivity and spatial resolution benefit from placing the spin defect in close proximity (within few to tens of nanometers) to the physical quantity being measured. Emission from shallow color centers is affected by the proximity of the emitters to the planar interface which alters their dielectric environment leading to changes in the emission rate and profile. Understanding the characteristics of shallow-color-center emission, including how the radiative lifetime is affected by proximity to the surface, is especially crucial for implementing near-field sensing measurements such as Förster resonance energy transfer and for designing photonic structures to control light-matter interactions with color centers. While it is well-known that the radiative power from an electric dipole decreases as the emitter approaches an interface with a higher-index dielectric, leading to an elongation in the radiative lifetime. For emitters in crystalline solids, modeling of this effect needs to consider the crystal orientation and direction of the surface cut, which can greatly impact the emission characteristics. In this paper, we provide a framework for analyzing the radiative lifetime of shallow (<100 nm) defects, in which optical transitions are derived from electric dipoles in a plane perpendicular to their spin axis. The radiative lifetime of electric dipoles is acquired by integrating their total radiative power where the lifetime of any electric dipole is inversely proportional to its radiative power. We present our calculations and preliminary experimental data for the depth-dependent radiative lifetime for Nitrogen Vacancy (NV) centers in (100)-cut diamond. Our experimental data agree with the calculations, confirming the lifetime elongation of emitters, close to the interface which proposes the feasibility of utilizing lifetime measurements as complementary technique for estimating the color center depth. Our calculations can be adapted for other vacancy defects in diamond and

have been extended to defects along any allowed orientation for diamond with (110) and (111) surface cuts.

EQ07.08.14
Nanostructured Plasmonic Diamond for Marine SERS Massimiliano Ramsay, Alexander C. Pakpour-tabrizi and Richard B. Jackman; Univ College London, United Kingdom

Surface-enhanced Raman scattering, or SERS, is an important optical sensing technique in which inelastic light scattering by molecules is greatly enhanced, enabling trace multi-component chemical detection. SERS typically involves metallic nanoparticles, Au or Ag, supported on a substrate such as Si, onto which the analyte of interest adsorbs. Enhancement arises from local fields generated by plasmon excitation in the NPs. However, SERS substrates degrade rapidly and are not suitable for re-use. Moreover, they are simply too fragile for use in environmentally challenging situations such as ocean analysis.
As a robust substrate for SERS, diamond has ideal optical properties displaying only a single intense peak at 1332cm-1 enabling the signal from many organic species to be detected with little interference. However, the reliance of van-der-Waals forces for NP adhesion to diamond offers little improvement. A solution is to include the NPs within diamond, sufficiently near the surface to retain their plasmonic enhancement of the SERS signal. Metallic NP plasmonics can be significantly affected by dielectric environment, shape and inter-particle interactions. Most methods for Au or Ag NP formation on diamond, lead to a range of NP sizes and separations whose inhomogeneous nature is then reflected in any layer created by overgrowth with diamond by CVD methods; these structures perform poorly as SERS substrates. Here, we have applied Nano-imprint Lithography (NIL) to direct the etching of ordered nano-holes into diamond substrates. Templated de-wetting of Silver films into diamond nano-holes was successfully demonstrated. Diamond was grown over these highly ordered nanoparticles arrays and SERS tests were carried out with sequential oxygen etches enabling the precise diamond over-layer thickness to be controlled. Using this approach exact control over NP size and spacing can be achieved. Excellent SERS performance results; the prospects for these robust diamond SERS substrates in challenging environments will be addressed.

Mechanical Properties of Pentadiamond—A Combined DFT and Reactive Molecular Dynamics Investigation Levi C. Felix[1], Raphael M. Tromer[1], Cristiano F. Woellner[2], Chandra Sekhar Tiwary[3] and Douglas S. Galvao[1]; [1]State University of Campinas, Brazil; [2]Federal University of Paraná, Brazil; [3]Indian Institute of Technology Kharagpur, Brazil

Recently, a new carbon allotrope called pentadiamond was proposed [1]. It consists of a network of pentagonal rings where both sp2 and sp3 hybridization are present. Recent works have shown that pentadiamond presents thermoelectric and optoelectronic [1,2] properties. 3D-printed pentadiamond structures [3] also exhibit the same topology-dependent mechanical behavior of the atomic model. In this work [4], we investigated the mechanical and electronic properties and the thermal stability of pentadiamond using DFT and fully atomistic reactive molecular dynamics (MD) simulations. The mechanical behavior, beyond the elastic regime, was investigated for three deformation modes: compression, tensile, and shear. Under compressive deformation, strong fluctuations in the atomic positions appear, which are responsible for the strain-softening at strains beyond the linear regime. These characterize its plastic flow. As expected, as we increase temperature, Young's modulus values decrease, with changes (up to 300 K) smaller than 10% (from 347.5 to 313.6 GPa). The fracture strain values present a broader variation, from ∼44% at 1K to ∼5% at 300K.

Detailed Atomic Structure Analyses of N-Doped NanoDiamonds Raul Arenal[1,2,3], Fredrik S. Hage[4], Quentin Ramasse[4] and Dieter Gruen[5]; [1]Instituto de Nanociencia y Materiales de Aragon (INMA), CSIC-U. Zaragoza, Spain; [2]Universidad de Zaragoza, Spain; [3]ARAID Foundation, Spain; [4]SuperSTEM Laboratory, United Kingdom; [5]Argonne National Laboratory, United States

Ultrananocrystalline diamond (UNCD) film is a crystalline diamond film consisting of 3-5 nm randomly oriented diamond crystallites surrounded by 0.2-0.3 nm wide grain. These films possess exemplary mechanical, electronic and optical properties [1,2]. Under normal process conditions, these UNCD films are highly electrically insulating, but they can become highly conducting when Ar is substituted in the synthesis gas with some N_2 [1, 5]. In this contribution, we have revisited, using aberration corrected microscopes and combining HR(S)TEM and EELS, the structure and local composition of these n-type UNCD films [3-5].

n-type UNCD films are composed of elongated diamond nanocrystals (called nanowires (NWs) [3]). The formation of these NWs is initiated when the N_2 content in the gas phase reaches about 10% in volume. From these studies, we concluded that the insulator-metal transition of these films is strongly correlated with the formation of these diamond NWs. Indeed, these NWs are enveloped by a sp^2-based carbon layer that seems to provide the conductive path for electrons [3-6]. Thus, here we will present the atomic structure studies and local EELS analyses developed on these complex films [5]. These results show where the nitrogen is located into these nanostructures and provide insights into their atomic configuration. These aspects provide very important information about the role played by nitrogen in the formation of such nano-objects.

In summary, these studies elucidate crucial questions concerning the local composition (atomic configuration) of these materials. This detailed knowledge is essential for better understanding the outstanding properties of such materials as well as for shedding light on their growth mechanism.

HPHT Growth of High-Quality Diffraction Grade Diamond Substrates for X-Ray Optics Ilya Ponomarev[1], Boris Feigelson[2], Jeffrey J. Derby[3], Scott S. Dossa[3], Marc Hainke[4], Christian Kranert[4] and Jochen Fredrich[4]; [1]Euclid Beamlabs LLC, United States; [2]U.S. Naval Research Laboratory, United States; [3]University of Minnesota, United States; [4]Fraunhofer IISB, Germany

Next-generation of synchrotron and Free-Electron Laser X-ray sources will increase the peak power by several orders of magnitude. In these conditions, X-ray intensity will become too severe for the existing materials. Large, single-crystal diamond is one of the few materials, if not the only one, suitable for high-power X-ray optical applications due to its unique combination of high thermal conductivity, low thermal expansion, and low X-ray absorptivity. We developed the modified High-Pressure High-Temperature (HPHT) temperature gradient growth technology that allows for growing the highest crystalline quality large diamond crystals, with dislocation density of less than 10 cm^{-2}. This near-equilibrium process is carried out under extreme conditions, where diamond single crystals are grown from a molten metal solvent (Fe, Ni, and Co and their alloys) under pressures in excess of 5 GPa and temperatures of 1,600 K and higher. Since there are no available diagnostics to monitor crystal growth in the HPHT cell directly, both indirect experimental growth monitoring and faithful models are needed to connect experimental outcomes to system design and process conditions. We present initial results from a collaboration that includes experimental growth carried out at the Euclid Beamlabs and two modeling efforts by the University of Minnesota and Fraunhofer. X-ray white beam topography of grown crystals is also discussed. This two-fold approach provides rigorous tools to both understand growth in this system and to perform subsequent optimization of growth conditions. In particular, we aim to more fully understand fundamental aspects of diamond nucleation and growth and identify process conditions that will achieve the highest crystalline quality in large diamond crystals.

EQ07.08.19
Steady State, Modulated and Transient Surface Photovoltage Spectroscopy of Diamond Thomas Dittrich[1], Steffen Fengler[2], Arsène Chemin[1], Peter Knittel[3], Igal Levine[1] and Tristan Petit[1]; [1]Helmholtz-Zentrum Berlin for Materials and Energie, Germany; [2]Helmholtz-Zentrum hereon GmbH, Germany; [3]Fraunhofer Institute for Applied Solid State Physics, Germany

Diamond is a promising material for applications in fields of electronics, optoelectronics, spintronics, energy conversion etc. For further development and deeper understanding, there is a need for highly sensitive and contactless characterization of electronic transitions and transport phenomena in single crystal and nanocrystalline diamond and at diamond interfaces. Light induced charge separation in space causes a surface photovoltage (SPV) on photoactive materials which can be studied with highly sensitive techniques such as steady state, modulated and transient SPV spectroscopy [1]. Recently, we developed a charge amplifier in combination with a perforated electrode that allows for complex SPV spectroscopy measurements on ultrawide bandgap semiconductors in dc (Kelvin probe), ac (modulated and transient) regimes at photon energies from near infrared to deep ultraviolet [2] [3] [4]. In this work, measurement principles of steady state, modulated and transient SPV spectroscopy will be explained, highlighting the high sensitivities of these techniques. Examples will be demonstrated for numerous transitions around and below the band gap of diamond which have been distinguished for differently terminated single crystal, polycrystalline and nanocrystalline diamond samples.

EQ07.08.20
Using Image Based Artificial Intelligence for *In Situ* Growth Prediction of Single Crystalline Diamond as a Tool to Improve SCD Wafer Dimensions and Growth Yield Matthias Muehle[1], Rohan Reddy[1], Arjun Srinivasan[1] and Elias Garratt[2]; [1]Fraunhofer USA, United States; [2]Michigan State University, United States

Single crystal diamond (SCD) is an attractive wide bandgap semiconductor material for a variety of applications ranging from advanced optics, solid state electronics to thermal management solutions. While lab-scale prototype demonstrations have demonstrated superior performance, utilizing diamond has been prohibitively expensive compared to more mature, commercialized semiconductor materials. This is attributed to the fact the SCD wafer size of suitable quality is smaller than 1 inch, and often as little as small as 3 mm x 3mm. For comparison, the commercially available wafer size for single crystalline Silicon Carbide is beyond 6 inches. A direct result is a lack of process scaling when processing individual diamond applications. The only way to overcome this is by controlling the size and quality of SCD wafers during chemical vapor deposition (CVD) growth to enable realization of wafers 2 inches in size and beyond either. This type of process control can be applied either for epitaxial layer outgrowth, or for tiled wafer growth. We are envisioning to address this challenge by developing an artificial intelligence (AI) based algorithm to predict SCD growth states (size and quality) through use of in-situ RGB images. Once established, this AI growth prediction can be incorporated as control system to increase SCD wafer size and quality, by adjusting process conditions before they achieve critical turnover points.

We are reporting on our efforts on AI algorithm development and validation. First, we installed a full-frame mirrorless interchangeable lens camera equipped with a macro lens to a CVD diamond reactor. Then a cumulative image-based AI pipeline consisting of three inter-connected thrusts was developed to model diamond growth. These are 1) Feature extraction pipeline, for extraction of geometrical features in the recorded imaged, 2) Defect detection pipeline, to extract macroscopic defect features in the recorded images, and 3) Frame prediction pipeline utilizing features, defects and reactor telemetry, to predict future image states 6, 8 and 12 hours into the future.

The objective for the feature extraction pipeline was to isolate and classify accurate pixel masks of geometric features like diamond, pocket holder and background, and their translation into geometrical shapes without the need of human-generated input. Our approach was enhanced to deliver results with high precision within the constraints of being limited to low-volume high-feature-complexity training dataset environments, given that data procurement, requiring physical SCD growth, is extremely time-consuming and expensive. Our best performing DL-based model achieved excellent accuracy metrics of >98% for the pocket holder, diamond top and diamond side features. Similarly, our DL-based defect detection pipeline achieved excellent accuracy metrics (>95%) for detecting center, polycrystalline and edge defects.

Prediction accuracies of ~99.9999% were obtained with minimal information loss between predicted and actual outputs. This constitutes a never-before obtained result of spatiotemporal (AI) prediction of diamond shape from in-situ obtained growth data obtained based on few inputs from data collected within an hour apart. This demonstrates the potential of these algorithms as a machine-intelligence-enabled solution for automated optimization and control of the diamond growth process.

EQ07.08.21
Quantum Diamond Magnetometer Sensitivity Optimized via Supervised Machine Learning Dane W. DeQuilettes, Eden Price and Danielle Braje; Massachusetts Institute of Technology, United States

Defect centers in diamond have the potential to revolutionize the fields of quantum sensing, computing, and communication with the capability to operate at room temperature. For example, defects such as NV (nitrogen-vacancy), SiV, and SnV have already established new performance benchmarks in magnetometers and quantum repeaters. Currently, many of these defects are introduced through destructive methods such as ion implantation where the introduction of unwanted defects leads to poor coherence properties and spectral wandering. Instead, plasma enhanced chemical vapor deposition (PE-CVD) offers an alternative route to achieve higher quality quantum properties from the bottom up, but the large PE-CVD growth parameter space makes it difficult to grow in desirable defects while avoiding formation of others. Here, we develop and apply a supervised machine learning approach with Shapley-based importance ranking and Bayesian optimization to determine the ideal growth parameters that lead to the highest NV^- defect yield and best magnetometer sensitivity. Using 15 processing conditions and >100 N-doped diamond samples as a training-test set, we reveal growth temperature and irradiation dose fraction (i.e. V/N_s) as key processing parameters. This work establishes a new methodology to optimize NV defects for magnetometry applications and a starting point for more sophisticated engineering of quantum defects for various quantum technologies.

Precise Current Monitoring over a Wide Dynamic Range for Electric Vehicle Batteries Using Diamond Quantum Sensors Yuji Hatano[1], Jaewon Shin[2], Junya Tanigawa[2], Yuta Shigenobu[1], Akimichi Nakazono[2], Takeharu Sekiguchi[1], Shinobu Onoda[3], Takeshi Ohshima[3], Takayuki Iwasaki[1] and Mutsuko Hatano[1,3]; [1]Tokyo Institute of Technology, Japan; [2]Yazaki Coprporation, Japan; [3]National Institutes for Quantum Science and Technology, Japan

Diamond quantum sensors with NV centers potentially have high sensitivity and a wide dynamic range. This feature is advantageous for EV battery monitoring applications. The peak value of EV battery current reaches ± several hundred amperes. So far, the accuracy of commercially available current sensors with a measurement range of ± several hundred amperes is about 1 A. On the other hand, the average battery current over the driving hours is about 10 A. Therefore, about a 10% margin is required in the remaining cruising mileage estimation. If the accuracy of the current sensor can be improved to 10 mA while maintaining a maximum range of ± several hundred amperes, the state of charge (SOC) of the EV battery can be accurately determined and the EV's cruising mileage can be extended by 10%.

In our prototype battery current monitor, a diamond sensor bonded to the end of an optical fiber was attached close to a copper busbar of 20 mm width and 8 mm thickness. The diamond sensor is a $2 \times 2 \times 1$ mm^3 type Ib (111) crystal treated by 3×10^{18} cm^{-2} EB irradiation and 1000°C annealing for 2 hours. The sensor contains 5-6 ppm NV- centers. A two-tone microwave is applied to the diamond sensor through a copper tape adhered to the sensor. The change in the fluorescence in response to the microwave frequency is the Optically Detected Magnetic Resonance (ODMR) spectrum.

The magnetic field is measured as the resonance frequency difference, that is, the difference between the low and high resonance frequencies in the ODMR. The (111) plane of the diamond sensor is placed perpendicular to the busbar surface as well as parallel to the current direction. The magnetic field at the diamond sensor position caused by the 10 mA busbar current is 170 nT. The sensitivity of 5 nT/√Hz enables the 10 mA detection in 1 kHz bandwidth. Three key points to ensure accuracy is as follows:

(1) Differential measurement
Differential measurement using a pair of diamond sensors placed above and below the busbar allows excluding external noise as common mode. Another purpose of the differential measurement is the elimination of the static magnetic field fluctuation caused by the temperature change. Two neodymium magnets are placed several centimeters apart from each other to provide about 20 mT static magnetic field at the diamond sensor so that the low and high resonance frequencies are separated even at the busbar current of ± several hundred amperes. Two diamond sensors are placed at the midpoint between these magnets, symmetrically positioned vertically across the busbar, so that the static magnetic fields applied to the two sensors are equal. This also eliminates the effect of the static magnetic field change due to the temperature change as common mode.

(2) Stable tracking of resonance frequency
The narrowness of the ODMR linewidth enables to follow the resonance frequency sharply by analog feedback from the photodiode output to the frequency modulation input of the microwave oscillator. On the other hand, the feedback is stable only within the linewidth. Therefore, the carrier frequency of the microwave oscillator should be intermittently adjusted so that the FM modulation amount be kept within the linewidth.

(3) Suppression of transverse magnetic field
To keep precise linearity between the resonance frequency difference and the busbar current, the transverse magnetic field applied to the [111] NV-axis by the busbar current should be minimized. For that purpose, the (111) plane should be carefully aligned perpendicular to the busbar surface as well as parallel to the current direction.

Relaxation Mechanisms of Single Dark Spins in Diamond Jonathan C. Marcks[1], Mykyta Onizhuk[1,1], Yuxin Wang[1], Nazar Delegan[2,2,1], Masaya Fukami[1], Maya Watts[1], F. J. Heremans[2,2], Aash Clerk[1], Giulia Galli[1,1,2] and David Awschalom[1,2,2]; [1]The University of Chicago, United States; [2]Argonne National Laboratory, United States

Decoherence of nitrogen vacancy (NV) centers limits sensitivity in magnetometry applications ranging from nanoscale NMR to navigation. A main source of decoherence arises from the substitutional nitrogen electron spin (P1 center) bath in the diamond lattice. Much effort has focused on decoupling NV and P1 spin interactions, but a full description of the underlying bath evolution remains incomplete. Here, we study interactions of a single P1 center with surrounding bath spins using a nearby NV center as a polarization source and probe. We present time-resolved measurements of the spin under external

laser and microwave excitation, revealing charge and spin dynamics at a single-P1 level. Alongside experiments we perform cluster correlation expansion (CCE) calculations to determine the structure of our spin bath, demonstrating characterization methods that account for local disorder.

9:00 AM EQ07.09.03
Manipulating Spins in Diamond with Magnetoelastic Films Nathaniel Beaver[1], Bin Luo[1], Seyed M. Abrishami[1], Isabel Martos-Repath[1], Piyush J. Shah[2], Derek A. Bas[2], Michael Page[2], Nian Sun[1] and Paul Stevenson[1]; [1]Northeastern University, United States; [2]U.S. Air Force, United States

Nitrogen Vacancy (NV) centers in diamond are extraordinarily sensitive magnetometers, capable of resolving picotesla fields. However, the large microwave fields required to control and manipulate the NV center can perturb the sensing target and are an obstacle to real-world deployment, motivating the development of new, efficient, control schemes. Using strain-generated magnetic fields in magnetoelastic (ME) films is a promising approach to addressing these challenges; highly localized magnetic fields can be efficiently generated, reducing power requirements and minimizing sample perturbation. However, the device requirements of NV center sensors are distinct from conventional applications of ME films, requiring new approaches to design and utilization.

In this talk, I will share recent results where coupled surface acoustic wave devices and ME films are used to drive spin transitions in the NV center. Our results highlight the strengths – and limitations – of these devices, revealing the interplay of efficient spin manipulation and increased noise from the magnetoelastic film, and enabling us to outline design principles for constructing hybrid NV center-ME film sensors.

Ab-Initio Theory of Spin-Lattice Relaxation for NV Center in Diamond Gergo Thiering[1,2], Matt Cambria[3], Shimon Kolkowitz[3], Ishita Kemeny[3], Ariel Norambuena[4], Yanfei Li[3], Aedan Gardill[3], Hossein Dinani[4], Vincenzo Lordi[5], Jerónimo Maze[6] and Adam Gali[1,2]; [1]Wigner Research Centre, Hungary; [2]Budapest University of Technology and Economics, Hungary; [3]University of Wisconsin-Madison, United States; [4]Universidad Mayor, Chile; [5]Lawrence Livermore National Laboratory, United States; [6]Pontificia Universidad Católica de Chile, Chile

Certain defects in diamond are promising candidates as building blocks for quantum information processing. In particular, the nitrogen-vacancy (NV) center in diamond has become one of the leading solid-state qubit contenders to its favorable properties. One of the most remarkable properties is its long spin coherence time: it can reach 1 ms at room temperature and can exceed seconds at cryogenic temperatures. In our present work, we will describe the spin-lattice interaction between S=1 electronic spin of NV center and the lattice phonons by means of density functional theory and experiments for a temperature range between 9 to 474 K in high-purity diamond samples. Spin-lattice relaxation is an intrinsic property of the host material and the defect that can be less obviously engineered like the coherence times by isotope engineering of the host material. As T_1 time is an ultimate limit for the spin coherence, deep insight about the spin-lattice relaxation processes is necessary for control of the NV center and understand this process for akin color centers in solids. Here, we review the first order and second order (Raman) spin-phonon relaxation processes acting between NV center's $|ms = 0\rangle \leftrightarrow |ms = +1\rangle \leftrightarrow |ms = -1\rangle$ spin states. To our best knowledge, only the ultralow temperature regime below 1 K has been discussed for NV center at ab-initio level, to date [1]. In this paper, we discuss the second order Raman transitions that dominate relaxation at high temperatures which is in stark contrast to the case of small molecules [2]. By invoking the ab-initio spin-phonon spectral functions, we propose a novel analytic model in which NV spin-phonon relaxation is characterized by interactions with two distinct groups of quasilocalized phonons which can be described as a double Orbach-process. In summary, we developed an ab-initio framework that can predict the spin-relaxation times and associated limit of coherence times for any spin-1 qubit center in diamond and related materials.

Diamond Particles Incorporated Fiber-Optic Probes for Biosensing Purposes Monika Janik[1,2], Mateusz Ficek[1], Maciej Glowacki[1], Mateusz Smietana[2] and Robert Bogdanowicz[1,2]; [1]Gdansk Univ of Technology, Poland; [2]Warsaw University of Technology, Poland

Integration of nanodiamonds with glass fibers is a powerful method of scaling diamond biosensing functionality. In this overview, we report on the volume incorporation approach for the integration of nanodiamond particles with optical fibers and coating with diamond particles to tailor optical sensing properties. The 750 nm and 140 nm diameter diamond particles were applied in those procedures. Manufactured optical fiber probes were analyzed using Raman mapping, SEM, optical and fluorescence spectra. SEM analysis reveals distinctly that the majority of the glass area is covered with single, separated diamond particles. Nanodiamond-doped fiber cross-section revealing a homogenous glass structure with incorporated sectionally nanodiamond particles. Diamond particles are tightly included in the glass structure with a mean adjacent distance of approx. 2.5 µm. Core-incorporated diamond particles allow to guide its fluorescence along the fiber is sensitive to the external environment. Diamonds deposited on the surface of optical-fiber probes tailor their transmittance and provide the interface for biosensing enhancing both optical and electrochemical responses. Following dedicated experimental work, doped diamond particles have the potential of extending the existing models with practical ways of optimizing signal coupling and readout to the guided modes in optical fiber-based biosensing probes.

Multifunctional Diamond Sensor for Deep Ocean Deployment Ralph Jennings-Moors and Richard B. Jackman; Univ College London, United Kingdom

Sequestration of CO2 in the planets oceans is one approach under consideration as humankind flights to tackle climate change. In this process CO2 would be pumped to depth greater than 3km where it liquefies and, as it is heavier than water would form permanent lakes on the ocean floor. The potential for CO2 storage this way is enormous. However, our oceans naturally contain CO2 at shallow depths and this has the effect of mild acidification of the marine environment - if the acidification is allowed to increase, severe adverse effects on marine life will result. Thus, there is a real need to monitor the pH of oceans over large areas and at many depths should CO2 sequestration technology become a reality. At present this involves the temporary deployment of large expensive equipment in limited regions of our seas. With the emergence of the internet-of-things (IoT) the concept of a permanently deployed more intelligent far-reaching network of ocean sensors has emerged - should such devices be sufficiently small and robust they could stay in position for years, occasionally rising to the surface to relay data bursts. Diamond is an ideal material for sensor fabrication that must survive in harsh environments and diamond pH sensors have been demonstrated by a number of groups. However, the real value for such devices lies in a multifunctional sensors within a robust housing with encased control electronics for remote operation. Moreover, most sensors demonstrated with diamond technology to date rely upon metal contacts on the sensor face that would readily corrode in the marine environment.

In this paper we show the design and realisation of a diamond sensor with housing suitable for high pressure deployment, where the ocean only sees a diamond face for the sensor. Real-time measurement of pH, dissolved oxygen, water resistivity and temperature are achieved. At the heart of this sensor technology lies conductive patterns of graphitic-like material within the diamond created by a laser direct write-process. The prospects for these devices will be discussed.

Nanocrystalline Diamond Nano-Mechanical Resonators Evan Thomas, Soumen Mandal, William Leigh and Oliver A. Williams; Cardiff University, United Kingdom

Nano-electro-mechanical systems (NEMS) incorporating miniature scale mechanical elements into electronic circuits are of interest in applications ranging from atomic resolution mass spectrometers[1] to single electron spin detectors[2]. For resonating structures, the frequency of operation is proportional to the acoustic velocity of the material from which they are fabricated, making diamond with its unrivalled value of 18000 m/s ideally suited for use in high frequency NEMS with minimal dissipation from scaling induced losses. While offering the benefits of diamond but in thin-film form, the use of nanocrystalline diamond (NCD) for smaller scale NEMS however is often prohibited by its considerable columnar growth induced roughness, complicating fabrication and resulting in significant surface associated dissipation[3]. In addition, the concentration of strain at the attachment points of typically used geometries is expected to radiate energy away from the device and lead to substantial loss that scales with frequency[4]. Through combining the use of chemical mechanical polished (CMP) stock with advanced geometries it is therefore expected that dissipation can be minimised in thin-film diamond based NEMS[5].

To this end, metallised doubly clamped and 'free-free' geometry resonators incorporating flexural supports were fabricated from intrinsic NCD films with and without CMP. The devices were then placed in a Quantum Design Physical Property Measurement System at cryogenic temperatures, and actuated magnetomotively through sweeping the frequency of an applied AC signal while in the presence of a static magnetic field[6,7]. Upon comparing the resulting resonances, a ~5-fold reduction in dissipation was observed upon switching from rough to polished films and the addition of 2nd mode flexural supports, highlighting the benefits of CMP and the use of anchor-loss minimising geometries.

3659 V 0.37 A/mm NO_2-Doped P-Channel Diamond MOSFETs Fabricated on Diamond Grown on Misoriented Sapphire Substrates Niloy C. Saha[1], Seong W. Kim[2], Koji Koyama[2], Toshiyuki Oishi[1] and Makoto Kasu[1]; [1]Saga University, Japan; [2]Adamant Namiki Precision Jewel Co., Ltd., Japan

Diamond is an ultra-wide-gap semiconductor for prospective high-power and high-frequency transistors, because it possesses high bandgap energy of 5.47 eV and a breakdown field of >10 MV/cm. A 1-inch-diameter diamond wafers were grown on (11-20) sapphire just substrate without cracking using the micro-needle technique [1]. Very recently, we have demonstrated a 2-inch-diameter (001) diamond wafer without cracking by using a misoriented (11-20) sapphire substrate. The diamond wafer showed the highest crystal quality; the lowest XRC FWHM of 98 arcsec and low dislocation density of $1\sim2 \times 10^7$ cm^{-2} [2]. In this study, we fabricated a NO_2-doped p-channel diamond MOSFETs on a high-quality misoriented diamond substrate, which showed the highest breakdown voltages of 3659 V among diamond FETs.
We used a (001) diamond as a substrate which was grown on a misoriented (11-20) sapphire substrate by 5° toward the [0001] c-direction. The H-terminated diamond substrate was exposed to 2% NO_2 gas diluted in N_2 to perform NO_2 p-type doing. After forming Au ohmic contact, 16-nm-thick Al_2O_3 bi-layer was deposited as a gate insulator layer, and Au gate was formed with a gate length (L_G) of 2 µm with gate-to-drain distance (L_{GD}) varied from 12 µm to 50 µm. Finally, the diamond p-channel was passivated with 16-nm-thick Al_2O_3 bi-layer.
The DC output characteristics of a MOSFET showed a maximum drain current of 372 mA/mm. The gate leakage current was $<10^{-4}$ mA/mm and an on/off ratio was determined as 10^7. The on-resistance was 98.3 Ωmm and transconductance was obtained as 81 mS/mm at V_{GS} of -3 V. The threshold voltage was 4.1 V indicative of normally-ON operation. The maximum field-effect mobility was estimated as 134 cm^2/Vs. The maximum off-state breakdown voltage reached 3659 V, which is the highest for diamond FETs.

1:45 PM EQ07.11.02
Normally-Off Operation in (001) Vertical Diamond MOSFET Using Oxidized Si Termination Diamond Channel Kosuke Ota, Yu Fu, Kento Narita, Chiyuki Wakabayashi, Atsushi Hiraiwa and Hiroshi Kawarada; Waseda University, Japan

The development of p-FETs corresponding to n-FETs is necessary to realize compact, high-power high-speed switching complementary inverters. To date, n-FETs using wide bandgap semiconductor materials such as GaN, SiC, and Ga_2O_3 have been studied extensively, but there are few reports on p-FETs. We have reported vertical diamond MOSFETs using 2-Dimensional Hole Gas(2DHG) which is induced independently of crystal orientation by hydrogen terminated diamond surface(C-H) and high-temperature ALD-Al_2O_3[1-4]. However, all conventional vertical diamond MOSFETs use C-H surface as channel and exhibit normally-on operation (+16 V ~ +30 V) with positively large threshold voltage, and normally-off operation has not been achieved[1-4]. Normally-off operation is essential for industrial power electronic application, and we have already demonstrated normally-off operation in lateral diamond FETs using oxidized Si terminated (C-Si-O) diamond as channel[5-7] which can be applied to vertical devices. In this study, we have fabricated (001) vertical diamond MOSFET with C-Si-O diamond channel and achieved the first normally-off operation(-10.2 V) in vertical diamond FETs.
Fabrication process is as follows. A total of 1.5 μm of nitrogen-doped layer was deposited on the (001) p^+ diamond substrate as current blocking layer by microwave plasma chemical vapor deposition(MPCVD), and trench with depth(W_T) of 3 μm was formed by inductively coupled plasma reactive ion etching(ICP-RIE). After trench formation, a 200 nm regrown undoped layer was deposited by MPCVD to induce 2DHG. Then, SiO_2 was deposited 300 nm as a mask by tetraethyl orthosilicate CVD, and the p++ layer([B]: 1×10^{21} cm^{-3}) was deposited by MPCVD after etching 300 nm of SiO2 and 40 nm of the Regrown layer in the p++ layer growth area by ICP-RIE. At this time, C-Si-O diamond channel was formed by SiO_2 and diamond reaction in reductive and high temperature atmosphere(~1223 K). After SiO_2 mask removal by HF and ICP-RIE, device isolation was performed by oxygen plasma. Then, the source electrode(Ti/Pt/Au) was formed, and 200 nm of Al_2O_3 was deposited as the gate insulator by high-temperature ALD method(450°C) using H_2O as the oxidant. Finally, drain electrode(Ti/Au) was formed on the backside of the substrate and gate electrode(Al) on the surface of the substrate to complete the device.
The lengths of source-source(L_{SS}), source-drain(L_{SD}), effective channel(L_{CH}), gate-drain(L_{GD}), trench width(W_T), and gate width(W_G) were 18 μm, 9.2 μm, 8.8 μm, 0.4 μm, 6 μm, and 25 μm, respectively. The maximum drain current density($I_{D,max}$) by the gate width was 8.05 mA/mm. The gate leakage current was less than 10^{-9} A at 300 K and on-off ratio was 10^7. The threshold voltage(V_{th}) was -10.2 V, achieving normally-off operation. For device with different dimensions (L_{SS}: 8 μm, L_{SD}: 9.2 μm, L_{CH}: 8.8 μm, W_T: 4 μm), $I_{D,max}$ was 102 mA/mm, R_{on} was 258 Ω mm, and V_{th} was -1.9 V, confirming normally-off operation. Compared to the threshold voltage of the conventional vertical C-H diamond MOSFET, the threshold voltage was shifted in the negative direction by more than 15 V. This large negative shift of the threshold voltage can be attributed to decrease upward band bending between diamond and Al_2O_3 due to increase the electron affinity of the C-Si-O interface (-0.25 eV)[8] compared to that of the C-H interface (-1.3 eV)[9].

2:00 PM EQ07.11.03
1.6K Operation of Diamond FETs with Superconducting Diamond Sources and Drains Targeting JoFET or SCFET Operation Chiyuki Wakabayashi[1], Yasuhiro Takahashi[1], Taisuke Kageura[1,2], Minoru Tachiki[3], Shuuichi Ooi[2], Shunichi Arisawa[2], Yoshihiko Takano[2] and Hiroshi Kawarada[1,4]; [1]Waseda University, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]National Institute for Materials Science, Japan; [4]The Kagami Memorial Research Institute for Materials Science and Technology, Japan

Superconducting currents are induced in the semiconductor channels of Josephson field-effect transistors (JoFETs) or Superconductor FETs (SCFETs) by the proximity effect from the superconductor. The carrier depletion or accumulation induced by the applied gate electric field control the critical currents of them. For example, JoFETs or SCFETs are realized by using Al contacts and Ge channels [1]. They can be applied for ultra-high speed and ultra-low power consumption operation of transistors. Furthermore, JoFETs can be used to call the Qubits of quantum computers in cryogenic environments. Boron-doped diamond exhibits superconductivity, with its superconducting transition temperature T_c of 10 K at its boron concentration of 1×10^{22} cm^{-3} [2] and a few types of Josephson junctions and superconducting quantum interference devices were realized [3][4]. Also, diamond is known as a wide-gap semiconductor. Therefore, it is possible to realize hybrid devices of superconductors and semiconductors with the same material.
We fabricated diamond FETs composed of 2DHG channels induced by hydrogen termination and ALD-Al_2O_3, and Superconducting diamond contacts which were homoepitaxially grown by microwave plasma chemical vapor deposition. The channel length L_{sd} were miniaturized down to 100 nm. The gate width W_g was 100 μm. The insulator Al_2O_3 was deposited by atomic layer deposition method with 10 nm at 573K. The Al gate electrode was deposited by Electron Beam vapor deposition with 100 nm. We evaluated low temperature operations of 2DHG diamond FETs down to 1.6 K with four terminal methods by applying a current instead of a voltage to examine the possibility of realization of JoFETs or SCFETs.
The *I-V* characteristics of the FET with L_{sd} = 100 nm and W_g = 100 μm were obtained at 1.6 K, 8 K and 12 K. We applied current I_{ds} = 10 μA, 100 μA respectively and applied gate voltage V_{gs} from -3.5 V to 1.0 V in 0.5 V increments. The drain current I_{ds} were modulated by applied gate voltage clearly. It is the first demonstration of diamond FET operated below 2K. The on-resistance R_{on} was 7.9 Ω·mm at 1.6 K at V_{gs} = -3.5 V. This value is about one-fourth of that at 12 K. That's because 1.6 K is well below the superconducting diamond T_c (~10 K) and the resistance of the superconducting diamond source and drain was disappeared. Also, it is possible that the proximity effect from superconducting diamond reduced the resistance of the semiconductor channel. Furthermore, we obtained *R-T* characteristics from 1.6 K to 12 K by applying bias current of 10 μA at V_{gs} = 0 V, -3.5 V respectively. When the gate voltage was not applied, the resistance drops around 10 K (~T_c) but increase remarkably as the temperature goes down from 10 K. This is because, the barrier of valence band maximum between boron-doped diamond and 2DHG diamond becomes prominent due to the lower temperature (1.6K). However, the increase of the resistance from 10 K down to 1.6 K was reduced by applying gate voltage since the carrier accumulation due to the applied gate voltage cause band bending and holes tunnel through the barrier. In this work, the superconducting current was not observed because the channel mobility at low temperature is decreased by ion scattering.
The 2DHG diamond FET with L_{sd} = 100 nm was operated in cryogenic environments down to 1.6 K. This result suggests that JoFET or SCFET operation would be possible by high mobility 2DHG diamond channel with further miniaturized structure.

2:15 PM EQ07.11.04
2DHG Diamond MOSFETs with Multi-Finger Structure for Gate Width Expansion and Improved RF Characteristics Akira Takahashi; Waseda univ, Japan

abstract
We have fabricated a high frequency 2DHG diamond MOSFET with air-bridge and multi-finger structure to increase the gate width. DC and RF performance of the double-finger devices and multi-finger devices were compared and investigated. As a result, the multi-finger devices did not degrade the current density due to the increase of gate width (W_{GT}).
1. Introduction
We fabricated 2DHG diamond MOSFET which W_G=1 mm using a multi-finger structure. High output power performance is critical for the RF amplifier applications. It is valid for high output to increase actual current by extending the gate width. The device with extended W_G may deteriorate output current because of self-heating, and influence characteristics of devices caused by increase of the gate resistance. In this work, 2DHG MOSFETs with multi-finger structure were fabricated on a diamond substrate, and its DC and RF characteristics were evaluated and compared with those of the double-finger structure.
2. Device information
Devices were fabricated on a (001) diamond substrate. After the boron-doped layer deposited, source and drain electrodes are deposited Ti/Pt/Au (20nm/20nm/90nm). After H-termination and isolation, deposited Al_2O_3 as gate insulator. After that, 100nm of Al was deposited as the gate. The gate length was fixed L_G=0.5µm and the source-drain length L_{SD} was fixed 4.0 µm. the gate-drain length L_{GD} defined as 2.5µm. The air-bridge over the gate fingers is made of Au (1µm) after resist application.
3. Result and Discussion
We compared DC characteristics of double-finger structure and multi-finger structure. The result of double-finger device with W_{GT}=25µm×2 at V_{GS}=-24V and V_{DS}=-40V, the maximum drain current density I_{Dmax} was 428mA/mm. The result of multi-finger device by air-bridge with W_{GT}=25µm×6 at V_{GS}=-24V and V_{DS}=-40V, the maximum drain current density I_{Dmax} was 433mA/mm. Since the drain current densities are almost the same in the double-finger and multi-finger devices the actual current value of multi-finger is almost three times higher than that of double-finger. In multi-finger, the current density is not degraded by gate resistance or heat, because W_{GU} (length of one finger) remains the same even when W_{GT} is increased.
The frequency at MSG and MAG convert, defined f_k, is decreased with increasing gate width. But it is confirmed that the rate of decreasing f_k with the multi-finger device is much smaller than that of double-finger device. Comparing the maximum oscillation frequency (f_{max}) with W_{GT}=1000µm, double-finger device indicates 4.8GHz and multi-finger device indicates 9.0 GHz. The reason why high f_{max} is obtained with multi-finger is that the gate resistance becomes smaller and the decrease in f_k is smaller, because the W_{GU} is maintained. These results indicate that the multi-finger structure, in which the gate length (W_{GT}) can be increased while keeping the length of one finger (W_{GU}) short, can suppress the decrease in f_{max} and improve the high-frequency performance.
3.Conclusion
In this work, we fabricated 2DHG diamond MOSFETs which W_{GT} = 1mm with multi-finger structure on (001) diamond substrate for RF application and evaluated DC and RF performance. It was also confirmed that the introduction of the multi-finger structure did not cause deterioration in current density as the gate width expanded in association with the increase of gate fingers. In the RF characteristics evaluation, it was found that the multi-finger structure has a smaller rate of decrease in f_k with an increase in gate width, and the maximum oscillation frequency is 9.0 GHz at W_{GT}＝100 µm×10 whereas 4.8 GHz at W_{GT}=500 µm×2. The multi-finger structure makes it possible to fabricate diamond devices in densely integrated structure with much smaller W_S (width of Source electrode between gate fingers). It improves high-frequency characteristics. Because of high thermal conductivity, the device integration is the advantage of diamond compared with GaN.

Detection of Solvated Electrons from Photoexcited Diamond Nathaniel F. Rieders, Cesar Saucedo and Robert J. Hamers; University of Wisconsin–Madison, United States

Diamond possesses the unique ability to act as a facile and robust electron emitter in both vacuum and non-vacuum environments. While emission into vacuum has been widely studied, much less is known about diamond electron emission into water. Direct detection of electrons photoemitted into water is challenging because of the short lifetime (hundreds of nanoseconds), small cross-section, and near proximity of the electrons to the liquid interface. We have been developing improved methods for detecting solvated electrons at solid-liquid interfaces using transient absorption spectroscopy. Our experiments using a 705 nm detection wavelength (near the maximum of solvated electron absorption) gives rise to intensity changes on the order of ~ 10^{-3} (0.1%), with lifetimes in agreement with expected values. In order to collect the complete solvated electron spectrum and enhance the specificity of detection, we have recently been developing a transient absorption system for complete spectroscopic analysis of solvated electrons produced via diamond photoemission. In this talk we will describe our efforts to detect solvated electrons from diamond into water, and efforts toward complete spectroscopic characterization of the transient absorption spectra. As time permits, we will also discuss the possibility of electron emission from other wide-bandgap materials.

3:45 PM EQ07.12.02
Transient Surface Photovoltage on B-Doped Single Crystal Diamonds—Charge Dynamics and Transfer Arsène Chemin[1], Peter Knittel[2], Philipp Reinke[2], Igal Levine[1], Thomas Dittrich[1] and Tristan Petit[1]; [1]Helmholtz-Zentrum Berlin for Materials and Energy GmbH, Germany; [2]Fraunhofer Institute for Applied Solid State Physics, Germany

Easy production of solvated electrons from solar illumination would be a game changer for green chemistry and environmental research. The use of widely available synthetic diamonds to generate solvated electrons upon light irradiation in water has been proposed as a promising strategy to achieve CO2 or N2 reduction in liquid phase [1-2]. Free electrons can be transferred to water because diamonds have a high energetic level of the conduction band and a negative electron affinity when its surface is hydrogenated. At first glance, the large band gap of diamonds (5.5 eV) should only enable excitation from

deep UV light, dramatically limiting the direct application of sunlight for photocatalysis with diamond. However, photogeneration via in-gap states is possible and CO2 photo(electro)chemical reduction with visible light has been previously reported [3].
In this work, we study separation of photogenerated charge carriers in differently terminated single crystal diamonds using transient surface photovoltage (SPV) spectroscopy under excitation over a wide spectral range below and above the bandgap. Transient SPV spectroscopy with a tunable laser is a contactless and highly sensitive technique probing electronic transitions from near infrared to deep ultraviolet in the time range from several ns to s [4]. It enables us to determine the excitation paths and charge transfer in diamond crystals depending on surface and bulk states. Namely, we determine the influence of the doping states and defects by comparing B-doped diamonds to reference intrinsic crystals and the influence of the surface states by comparing hydrogenated and hydroxylated surfaces. In complement, the surface states of the diamond crystals have been characterized by X-ray absorption spectroscopy performed at the synchrotron BESSY II in Berlin. The excitation of electrons in the diamond crystals with visible light can be related to doping states at low energy and surface state just below the bandgap. The possible emission of these charges from the diamond samples in air and in water have been characterized by photoemission and photocurent spectroscopies, respectively. While a wide range of excitation leads to charge separation in the diamond crystals, only the excitation related to surface state leads to electron emission.

Electron Emission from Negative Electron Affinity Surfaces of Planar-Type Diamond PIN Diodes Shoya Yamakawa[1,2], Hiromitsu Kato[2], Masahiko Ogura[2], Yukako Kato[2], Toshiharu Makino[2], Ryota Tsukamoto[1,2], Daisuke Takeuchi[2,1] and Ichiro Shoji[1]; [1]Chuo University, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Diamond is well-known as an ultimate material because of its superior properties and it is expected to be employed in next-generation power electronic devices. One of the unique properties of diamond is the electron emission from negative electron affinity (NEA) surfaces. A vacuum power switch using a vertical-type PIN diamond diode was reported, which was made use of electron emission from NEA surfaces obtained by hydrogen-termination, and switching at 10kV was demonstrated. [1] The vertical PIN diodes were fabricated on a p-type substrate and the mesa diodes were fabricated by ICP etching, since there is no n-type conductive substrate. Then in this study, we attempted to fabricate planer-type diodes on Ib(111) substrates using selective growth technique, which could avoid damage in the device caused by ICP etching. As a result, the planer-type PIN diodes fabricated successfully showed electron emission by turning on, and the highest electron emission efficiency was close to 1%, which was comparable to the vertical-type one. It means that the planer-type diodes have a potential of high electron emission efficiency as well as the vertical-type ones, even the body was fabricated only by thin-films. Since it is a planer-type, it is possible to apply not only for electron emitters, but also for quantum devices owing to its ease of observation from the top. In this paper, we will introduce such a high potential of the new planar diode-type electron emitters, with the discussion of electron emission mechanism.

Compressive Stress in Diamond Nanomembranes Paulius Pobedinskas[1,2] and Ken Haenen[1,2]; [1]Hasselt University, Belgium; [2]IMEC vzw, Belgium

Nanomembranes (NMs) are very thin (≤ 500 nm) and have very high aspect ratios of thickness to lateral dimension (≥ 10^4). This makes them extremely flexible due to the linear decrease of bending strain with thickness. At the extreme thinness, materials fold much easier.[1] When nanocrystalline diamond (NCD) thin films are grown on substrates, which have a higher thermal expansion coefficient than diamond, unavoidably, compressive stress is generated. When a NCD NM is released from such substrate a pattern of wrinkles and wrinklons evolves. The out-of-plane deformation is associated with the onset of an elastic instability, where the total energy is best minimized by the film bending rather than straining in-plane. These deformations strongly affect the electrical properties of B-doped NCD NMs.[2] Therefore, one cannot disregard the influence of wrinkles when dealing with any type of device that is based on NMs.

In this work, finite element simulations of compressive stress relaxation under gravity in a diamond NM as it is released from a supporting substrate are presented. As NCD consists of hard diamond grains and soft grain boundaries, the Young's modulus and Poisson's ratio are not expected to be the same as in bulk diamond.[3] To study the impact of elastic constants on wrinkling, calculations were made with different Young's moduli (E = 300, 600, 900, and 1200 GPa) and Poisson's ratios (ν = 0, 0.07, 0.14, and 0.21). The initial compressive stress of the NM was varied in the range from 0 Pa up to - 6 GPa. When a NCD thin film, which is 150 nm thick and has a compressive stress of up to -10^4 Pa, is released from the substrate as the NCD membrane, it relaxes without forming wrinkles. Symmetrical wrinkles form when the membrane relaxes from -10^5 Pa and higher compression. At absolute stresses larger than - 1 GPa the asymmetric wrinkling is dominant. The Young’s modulus and Poisson’s ratio does not have notable impact on the relaxed membrane shape as stress does. However, the Young’s modulus has higher impact on the relaxed membrane area and out-of-plane deformation range than Poisson’s ratio. The higher the Young’s modulus (or Poisson’s ratio), the smaller the area (and out-of-plane deformation range) of the nanomembrane is obtained after the compressive stress relaxation. Finally, the obtained results on wrinkling phenomena are explain through the system’s energy minimization.

An All-Optical Diamond Voltage Microscope Daniel McCloskey[1], Nikolai Dontschuk[1], Alastair Stacey[2], Charlie Pattinson[1], Athavan Nadarajah[1], Liam Hall[1], Lloyd Hollenberg[1], Steven Prawer[1] and David A. Simpson[1]; [1]University of Melbourne, Australia; [2]RMIT University, Australia

The development of fluorescent molecular sensors for imaging voltage changes in biological systems has revolutionized neuroscience, providing a tool to capture neuronal activity over large areas with sub-neuron resolution both *in vitro* and *in vivo* [1–3]. However, the poor photostability of molecular voltage sensors limits recording times to a few minutes [1–3], posing problems for longitudinal studies of network evolution and disease processes. These limitations have led to the uptake of lower-resolution extracellular recording techniques such as multi-electrode arrays (MEAs) for long term neurological research[4,5].

Here, we present an alternate platform for sensitive high resolution voltage imaging using fluorescent, charge-sensitive defects in a transparent diamond substrate [6]. The nitrogen vacancy (NV) defect in diamond possesses three optically distinguishable charge states known to be responsive to voltage changes in solution [7-9]. In this work, we will show that precise electrochemical control of the diamond surface termination, can effectively tune the ensemble charge state population to an optimal composition for voltage sensing consisting exclusively of the fluorescent neutral (NV0) and non-fluorescent positive (NV+) states. Using these charge state sensors, we establish an all-optical diamond voltage imaging microscope (DVIM) capable of real-time imaging of capacitive charge injection by a microelectrode in solution. Finally, we show that this sensing mechanism can be replicated and enhanced in an array of diamond nanopillars, possessing sub-millisecond fluorescence response times and sub-millivolt sensitivity suitable for a host of excitable cell imaging applications.

Formation of Nitrogen Vacancy Center in Diamond for Quantum Sensing Applications Tokuyuki Teraji; National Institute for Materials Science, Japan

Formation and control of electron spin of negatively charged nitrogen vacancy center (NV^-) in diamond is attracting much attention for next-generation quantum devices. For sensing applications, a relatively large amount of NV^- center is required to increase sensitivity. This corresponds to an increase of the total number of sensors. Typically, [NV^-] of 0.1−3ppm is desired to detect weak magnetic fields. The coherence time of the electron spin T_2 is another important factor for increasing sensitivity, and this value has been reported to be inversely proportional to the density of nitrogen concentration [1]. Considering these facts, we have optimized diamond growth condition for both chemical-vapor deposition (CVD) [2, 3] and high-pressure/high-temperature (HPHT) methods [4]. To prolong T_2, we applied ^{12}C isotopic enrichment and improved a crystalline quality of diamond. For obtaining higher [NV^-], first we improved controllability of nitrogen concentration in the doping range of 0.1−50ppm. Then, NV^- center is created in diamond crystals through electron beam irradiation and subsequent vacuum annealing. It is also important to elucidate the creation of point defects other than the NV^- center during NV^- center formation processes and to understand their effect on T_2, that is, on magnetic sensitivity. We performed electron paramagnetic resonance and photoluminescence measurements from this point of view [5].
In the CVD method, a free-standing diamond (001) single crystals were obtained by cutting the substrate after a growth of nitrogen-doped homoepitaxial diamond thick layer. The dimension of CVD single-crystal plates was typically $3\times3\times0.5mm^3$. In the case of HPHT crystals, after the bulk diamond crystals were grown, these crystals were cut parallel to the {111} crystal plane to obtain {111} single crystals. Typical size of the HPHT {111} single-crystal plates was $1.5\times1.5\times0.4mm^3$.

Isotopically Engineered Diamond for Quantum Technologies Fedor Jelezko; Ulm University, Germany

We will present a new solid-state architecture for a scalable quantum simulator that consists of strongly interacting nuclear spins formed by doping of diamond lattice with C^{13} isotope. Initialization and read-out of this quantum simulator is enabled by single nitrogen-vacancy centres implanted in diamond. The system can be employed to simulate a wide variety of strongly correlated spin models. We will also discuss the potential of isotopic engineering of diamond nanoparticles for ultrasensitive NMR and MRI.

Plasma CVD Engineering of Nitrogen-Vacancy Centers in (111) Single Crystal Diamond Hiromitsu Kato; National Institute of Advanced Industrial Science and Technology, Japan

Negatively charged nitrogen vacancy (NV-) centers will be high importance for a variety of quantum applications. Due to the long coherence time constant of NV- center even at room temperature, applications for quantum sensing, quantum information processing, and quantum register are very promising. Plasma-enhanced chemical vapor deposition (CVD) is one of the major approaches to introduce well-defined NV centers in diamond, as well as electron beam irradiation and ion implantation techniques. N-type Fermi control by phosphorus doping can offer charge-state stabilization of NV center, leading to longer coherent time at room temperature [1-3]. NV centers can be perfectly aligned along [111] axis by CVD growth on (111) surface [4,5]. Electrically excitation of NV defects and related readout with photo current, required to realize chip-scale magnetometers, have also been conducted by using diamond PIN junction diode structure [6-8]. All these achievements are based on our comprehensive progresses of CVD diamond growth, impurity doping, junction management, and device fabrication processes. Details will be discussed focusing on technical aspects peculiar to plasma CVD engineering of diamond NV centers.

Diamond Surface Nanostructures: Morphology Control, Formation Mechanism, and Applications Wenjun Zhang; City Univ of Hong Kong, China

The outstanding properties of diamond make it an excellent material for various applications. It is known that the potential applications of materials depend not only on their intrinsic properties, but also on the surface geometries in which they appear. The extreme properties of diamond, however, make it difficult to be structured to a desired geometry. This presentation will review the recent progress in the nano-/micro-structuring techniques of diamond films, in particular a simple and applicable method developed by us to nanostructure diamond (ranging from microcrystalline to nanocrystalline) surfaces using bias-assisted reactive ion etching (RIE) in hydrogen/argon plasmas. Various diamond nanocone/nanopillar/ nanowhisker (nanowire) arrays with high uniformity and tunable density have been achieved by using this method. The effects of initial film structure, surface roughness, and RIE conditions on the size, density, and geometry of nanostructures are revealed. Surface nanostructuring of diamond films is demonstrated to be an effective approach to extend and/or enhance the properties of diamond with respect to its bulk and film counterparts. Example applications of the diamond nanostructures in field electron emission electrode, in situ probing and drug delivery at the cell level, and electrocatalysis are also discussed.

10:00 PM EQ07.14.03
Synthesis and Characterization of Cubic BN / Diamond or Hexagon BN / Diamond Heterostructures Avani Patel[1], Jesse Brown[2], Saurabh Vishwakarma[1], David J. Smith[1] and Robert J. Nemanich[1]; [1]Arizona State University, United States; [2]Advent Diamond, United States

Boron nitride exists in various polymorphs, including sp3 bonded cubic (c-BN) or wurtzite (w-BN) and sp2 bonded hexagonal or turbostratic structures (h-BN or t-BN). The sp3 bonded c-BN or w-BN may be considered for high power electronics and the sp2 bonded h-BN or t-BN may have significant potential as a dielectric layer for surface passivation or as a gate insulator. For the power electronic applications, growth of c-BN or h-BN / diamond heterostructures with highly ordered interface and low interface defect density are essential. In this research, our goal is to form a BN / diamond heterostructure using a three-step approach 1) *in situ* plasma clean, 2) a nucleation step, and 3) an epitaxial growth step. The c-BN or h-BN layers are grown on boron-doped diamond substrates using electron cyclotron resonance plasma-enhanced chemical vapor deposition (ECR PECVD) with gas phase precursors of Ar, N2, BF3, H2 and He. The resulting c-BN or h-BN layers were characterized by *in-situ* X-ray photoelectron spectroscopy (XPS) and cross-sectional Transmission Electron Microscopy (XTEM). In-situ XPS results confirmed the presence of sp2 or sp3 BN near the top surface. The TEM measurements were used to observe the nucleation and morphology of the BN / diamond interface. The experimental results demonstrated that the nucleation and growth steps are optimized by controlling the ratio of hydrogen and fluorine at a higher deposition temperature (~ 850 °C). A comparative study of nucleation and growth of BN on (100) and (111) diamond substrates indicates that a reduced hydrogen flow rate in the initial nucleation stage and a higher substrate temperature in the growth stage promotes the growth of c-BN compared to the hexagonal or turbostratic phase of BN.

Frequency-Tunable AC Magnetometry by Using Electronic Spin Triple-Resonance of Nitrogen-Vacancy Center in Diamond Ryusei Okaniwa[1,1], Yuichiro Matsuzaki[2,2], Tatsuma Yamaguchi[1], Hideyuki Watanabe[2], Norikazu Mizuochi[3], Norio Tokuda[4,4], Yuta Nakano[4], Kensuke Kobayashi[5,5], Kento Sasaki[5] and Junko Ishi-Hayase[1,1]; [1]Keio University, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Kyoto University, Japan; [4]Kanazawa University, Japan; [5]The University of Tokyo, Japan

Nitrogen-vacancy (NV) center in diamond is expected to be a practical quantum sensor with high sensitivity and high spatial resolution due to the room-

temperature long spin coherence time and atomic-scale size [1]. Quantum sensing using NV centers is implemented by measuring spin-dependent photoluminescence (PL) and manipulating spin state by microwave (MW). Pulsed-optically detected magnetic resonance (pulsed-ODMR) is typically used for AC magnetometry[2,3]. Although achieving high sensitivity, it can be disadvantage to require sophisticated setup, rapid control and measurements, strong MW pulse irradiations and its calibration. Recently, our group proposed and demonstrated MHz-range AC magnetic field sensing using continuous-wave ODMR (CW-ODMR) which is simpler than pulsed-ODMR [4,5]. We utilized radio-frequency (RF)-dressed states of NV electronic spins by applying MW and RF magnetic fields (double resonance). However, it is difficult to change the frequency of detectable AC magnetic fields because of an intrinsic strain field in a diamond.

In this study, to avoid such potential drawback, we propose frequency-tunable AC magnetic field sensing by CW-ODMR based on electronic spin triple resonance. In this scheme, the MHz-range magnetic field (target RF) is applied to resonant transition between RF-dressed states generated by another RF field (control RF). Consequently, RF-doubly dressed states is generated and observed by CW-ODMR measurements to estimate the amplitude of target RF field. The target frequency is expected to be varied by controlling the RF-dressed states with changing the control RF field amplitude.

The NV center has spin-1 system described by eigenstates B, D, 0 under applying DC magnetic field perpendicular to the specific NV axis of it. When MW induces the transition from 0 to B(D), the PL intensity decrease (CW-ODMR). By measuring CW-ODMR spectrum with control RF field resonant to B-D transition (7.5 MHz), we observe four dips due to the splitting of B and D levels (RF-dressed states). As increasing the amplitude of control RF field, the splitting energy became larger. Furthermore, we applied the target RF field resonant to the lower transition between the RF-dressed states (5.4 MHz). Consequently, the energy levels of RF-dressed states were split into eight levels. This result demonstrates that RF-doubly dressed states were generated. By sweeping the frequency of target RF field, the anti-crossing structure was observed near the resonant frequency between the RF-dressed states. We found that the splitting energy of the anti-crossing spectra linearly increased as increasing the target RF amplitude. This result demonstrate that the amplitude of the target RF field can be estimated by measuring the splitting energy. Moreover, it is found that the detectable frequency of the target RF field can be tuned by changing the amplitude of the control RF. The obtained signal was larger than our previous work utilizing the RF-dressed states because the coherence time was extended by applying two different driving fields. This result shows that the sensitivity can be improved compared with that for the sensor based on the double resonance.

10:30 PM EQ07.14.05

Fabrication and Characterization of Femtosecond Laser Written Low Loss Depressed Cladding and Half-Ring Waveguides in Diamond Faik D. Ince[1], Yagiz Morova[1,1], Umut Yazlar[2] and Alphan Sennaroglu[1,1]; [1]Koç University, Turkey; [2]Appsilon B.V., Netherlands

We report on the fabrication and characterization of femtosecond (fs) laser written depressed cladding and half-ring waveguides in diamond. The propagation losses of 2.05 dB/cm for the depressed claddings and 1.2 dB/cm for the half rings are the lowest propagation losses reported to date for fs laser written waveguides in diamond. Such low loss values reveal the potential of diamond waveguides in efficient quantum sensing applications.

A polished single crystal CVD diamond was used in the experiments. The sample was positioned on a 3D translational stage and an amplified Ti^{3+}:Sapphire laser generating 120 fs pulses at 800 nm and at 1 kHz repetition rate was used during waveguide fabrication. Laser pulses were focused into the sample with a 40X objective. With 100 nJ of incident pulse energy and 0.4 mm/s scan speed, 6 waveguides were fabricated across the full length of the sample. Three of the waveguides had depressed circular cladding, whereas the rest had semi-circular, half-ring configuration. Fabrication depth of depressed cladding waveguides was determined as 100 µm. Core diameter (D) of the depressed claddings was kept constant as 60 µm and the number of written tracks (N) was set as N=36, 48 and 60. Half rings were fabricated directly below the crystal surface to create an interface between air and the waveguide core. Design parameters (D, N) of the three half-ring waveguides were set as (60 µm, 18), (90 µm, 28), and (120 µm, 36).

A He-Ne laser operating at 633 nm was utilized to characterize the waveguides. The laser beam was coupled to the waveguides with a converging lens and the guided beam exiting the waveguide was collimated with an aspheric lens (focal length f=6 mm). In order to reduce the mode mismatch between the focused beam and the waveguide core, converging lenses with focal lengths of f=4, 5 and 7.5 cm were used for half ring waveguides with D=60, 90 and 120 µm, respectively. For the depressed claddings, the optimum focal length for the converging lens was determined as f=7.5 cm.

By comparing the power transmission of the waveguide with the bulk transmission of the crystal, propagation loss was measured as 2.05, 3.04 and 3.99 dB/cm for the depressed cladding waveguides with N=36, 48 and 60, respectively. For the half rings, losses were found as 1.2, 1.8 and 6.1 dB/cm for the waveguides with D=60, 90 and 120 µm, respectively. The trend from the depressed claddings shows that an increase in N increases the propagation loss as well. This trend is expected since the fs laser written tracks introduce graphitic content to the track region, resulting in an increase in the loss of the waveguide due to the optical properties of graphite. We further examined the structure of the written tracks by using Raman microscopy and observed the G-band for graphite at 1575 cm^{-1}, which supports the mentioned trend. For the half rings, results indicate that as the core diameter increases, the propagation loss decreases. This trend is expected also, since increasing the core diameter also increases the size of the unmodified core region in relation to the modified graphitic region.

To summarize, the propagation loss of 2.05 dB/cm is the lowest loss reported to date for fs laser written depressed cladding waveguides in diamond. Results from the depressed cladding waveguide measurements showed that decreasing the number of written tracks reduces the loss. However, since reducing the number of tracks also decreases the refractive index contrast (Δn) and the ability of the waveguides to confine light, an optimum number of written tracks is needed for low-loss guiding. So, use of half-ring waveguides in diamond enables the confinement of light with reduced number of tracks, by taking advantage of the high Δn occuring at the air-waveguide interface. Switching to the half-ring waveguides resulted in propagation losses as low as 1.20 dB/cm, which is the lowest propagation loss reported to date for fs laser written waveguides in diamond.

Imaging Topological Order at the Picometer-Scale by Electron Ptychography David A. Muller; Cornell University, United States

Electron microscopy is often used to directly the image the atomic displacements in ferroelectrics, reaching a precision of a few picometers. As good as this is, it is still not sufficient to robustly measure many ferroic order parameters, including vorticity and higher order moments. Enabled by a new design of electron detector [1,2] that is capable of measuring the complete distribution of momentum transfers at every probe position, we construct a 4-dimensional phase space from which we solve the inverse multiple scattering problem and retrieve the underlying 3-dimensional potential of the sample. The lateral resolution of less than 20 pm is now limited not by the instrument, but by the thermal vibrations of the atoms themselves, and the precision is improved to well below 1 pm [3]. The resulting ptychographic reconstructions have allowed us to image the internal structures of both magnetic and ferroelectric vortices, skyrmions and merons, including their singular points that are critical for accurately describing the topological properties of these field textures.

11:00 AM *EQ08.01.02
Coupling of Ferroelectric Domain Walls with Liquid and Magnetic Interfaces Neus Domingo Marimon[1], Ch. Stefani[1], I. Spasojevic[1], V. Sireus[2], E. Menendez[2], J. Sort[2], Albert Verdaguer[2] and Gustau Catalan[1]; [1]Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC and BIST, Spain; [2]Universitat Autònoma de Barcelona, Spain

Ferroelectric domain walls strongly interact with its surroundings. In ferroelectrics thin films with exposed surfaces investigated by piezoresponse force microscopy (PFM), the main source of external screening charges is the atmosphere and the water neck, and therefore relative humidity (RH) plays a major role. In this context the speed as well as the creep-factor *m* describing the domain wall kinetics follow the behavior of water adsorption represented by the adsorption isotherm, indicating that the screening mechanism dominating the switching dynamics is the thickness and the structure of adsorbed water structure and its associated dielectric constant and ionic mobility.[1] On the other hand, the ferroelectrics can couple to other ferroic physical magnitudes in heterostructures such as FE/FM multilayers. In this context, the magnetic structure of magnetoelastic thin films can be manipulated by the tunable piezoelectric strain underneath: here I will show how in this case the dynamics of magnetic domain walls are dominated by the ferroelectric domain walls creating pinning sites that nucleate vortex like structures with predominant out of plane magnetic moments.[2]

High-Resolution Electric Field Mapping at Crystal Interfaces by Tilt-Scan Averaged DPC STEM Satoko Toyama[1], Takehito Seki[1,2], Bin Feng[1], Yuichi Ikuhara[1,3] and Naoya Shibata[1,3]; [1]The University of Tokyo, Japan; [2]JST PRESTO, Japan; [3]Japan Fine Ceramics Center, Japan

Local electromagnetic field distribution inside materials can be directly observed at high spatial resolution by using differential phase contrast (DPC) imaging in scanning transmission electron microscopy (STEM) [1]. In DPC STEM, momentum transfers of electrons due to electromagnetic fields are

detected by a segmented detector or pixelated detector placed on the bright field region. However, as for crystalline defects such as heterointerfaces, grain boundaries, etc., concomitant diffraction contrast seriously hinders the quantitative electromagnetic fields observation by DPC STEM.
In general, diffraction contrast dramatically varies with a slight change in beam tilt or sample tilt, whereas DPC contrast originates from electric fields and is insensitive to the slight tilt changes. Therefore, by averaging multiple DPC signals acquired with slightly different tilt conditions at the same sample position, the diffraction contrast can be suppressed (averaged) while reinforcing the electric field signals [2]. We have developed tilt-scan averaged DPC (tDPC) STEM system, which can average DPC signals obtained under multiple-beam tilt conditions and suppress diffraction contrast in real-time [3] [4]. tDPC STEM has been successfully applied to observe electric field and electron carriers in GaN-based semiconductor heterointerfaces [5], demonstrating the effectiveness of tDPC STEM.
In this study, we applied tDPC STEM for observing space charge layers in yttria-stabilized zirconia (YSZ) grain boundaries. tDPC STEM observation of YSZ Σ5[001]/(310) grain boundaries revealed that an electric field diverging from the grain boundary was distributed within 15 nm on both sides of the grain boundary. This result indicates the existence of positive charges at the grain boundary core accompanied by surrounding negative charges. On the other hand, little electric field fluctuation was observed at the Σ5[001]/(210) grain boundary. These results suggest that the electric field and the width of the space charge strongly depend on the local structures of the grain boundaries [6]. Details will be discussed in the presentation.

Quantitative 3D Imaging of Oxygen Defects in Multiferroic $(LuFeO_3)_9/(LuFe_2O_4)_1$ Superlattices Kasper Hunnestad[1], Hena Das[2], Constantinos Hatzoglou[1], Megan E. Holtz[3], Charles Brooks[3], Antonius van Helvoort[1], Darrell Schlom[3], Julia Mundy[4] and Dennis Meier[1]; [1]Norwegian University of Science and Technology, Norway; [2]Tokyo Institute of Technology, Japan; [3]Cornell University, United States; [4]Harvard University, United States

Oxide interfaces are a rich source for novel physical phenomena, ranging from interfacial superconductivity to unusual (multi-)ferroic effects. Over the last decade, significant progress has been made in both the understanding and engineering of oxide interfaces, propelled by the ongoing progress in the development of atomic-scale characterization techniques[1].
Here, we introduce atom probe tomography (APT) as versatile tool for studying oxide interfaces, investigating the 3D atomic-scale structure and chemical composition of $(LuFeO_3)_9/(LuFe_2O_4)_1$ superlattices. This system couples together ferroelectric and ferrimagnetic response, enabling a true multiferroic material with an intriguing display of charge redistribution at polar interfaces[2]. With our APT measurements we are able to reveal a subtle accumulation of charged oxygen vacancies at the $LuFe_2O_4$ layers which would typically go undetected with conventional microscopy approaches. We quantify the vacancy concentration and discuss their accumulation in relation to calculated defect formation energies, as well as their ability to stabilize an intriguing multiferroic domain structure. In general, this research establishes a new pathway for studying the interaction of interfaces and point defects in oxides, expanding related atomic-scale investigations into 3D with a new level of chemical accuracy.

Improper Ferroelectrics at the Ultrathin Limit Marta D. Rossell; Empa, Swiss Federal Laboratories for Material Science and Technology, Switzerland

Recently, improper ferroelectrics –materials in which electric polarization arises as a secondary effect of a leading order parameter– are receiving increasing attention. The family of hexagonal manganites (*h*-$RMnO_3$, R = rare earth) is a model system for improper ferroelectricity, where the electric polarization emerges as a byproduct of a primary lattice-trimerizing structural distortion, a combination of tilt and rotation of the MnO_5 bipyramids around the R^{3+} ion. The trimerization is described by a two-component order parameter **Q** consisting of the tilt amplitude Q and the angle φ of the MnO_5 bipyramids, but can also be related to the amplitude and phase of the corrugation of the R layer, which is easily visible and quantifiable by HAADF-STEM imaging [1]. However, while bulk *h*-RMnO bulk crystals have been intensively studied in the last decade, not as much of research at the atomic scale has been conducted on the improper ferroelectric behavior of technologically relevant ultrathin films.
Rather than the depolarizing field being the main challenge to achieving polar thin films, as in proper ferroelectrics, improper ferroelectricity in ultrathin films is determined by the thin-film specific behavior of its driving non-polar order parameter. In $YMnO_3$ thin films, substrate clamping and critical fluctuations of the order parameter lead to a lowering of the temperature of the phase transition, T_C^{film}. Thus, T_C^{film} decreases smoothly with $YMnO_3$ thickness and, inexplicably, at room temperature, the spontaneous polarization reaches zero for the two-unit-cell film [2].
Our current work focuses on the investigation of nanoscale confinement effects on the lattice trimerization of ultrathin $YMnO_3$ films. The structure and properties of the $YMnO_3$ films, with a special focus on the interfaces, are investigated by using a combination of quantitative (in-situ) HAADF-STEM and STEM-EELS, and density functional calculations. Our results advance the understanding of the evolution of improper ferroelectricity within the confinement of ultrathin films, which is essential for their successful implementation in nanoscale devices, such as ferroelectric tunnel junctions and resistive memories [3].

Dark-Field and Momentum-Resolved Electron Energy Loss Spectroscopy of Bi_2Se_3-Based Heterostructures for Spintronics Quentin Ramasse[1,2], Vlado Lazarov[3] and Demie Kepaptsoglou[1,3]; [1]SuperSTEM Laboratory, United Kingdom; [2]University of Leeds, United Kingdom; [3]University of York, United Kingdom

Engineering the structural or chemical architecture of functional materials at the nano or even atomic level enables emergent properties that rely on the interplay between fundamental properties of matter such as charge, spin and local atomic-scale chemistry. A striking illustration of the relevance of this strategy is provided by placing Bi_2Se_3, a topological insulator (TI) with topologically-protected helical two-dimensional surface states and one-dimensional bulk states associated with crystal defects, in close proximity with graphene. The strong spin-orbit interaction and proximity effects result in subtle and controllable electronic band structure changes at and near the interface, with exciting potential for spintronic applications. Here we probe at high energy resolution the interfaces in a system consisting of Bi_2Se_3 films grown by chemical vapor deposition on epitaxial graphene/SiC(0001), where the number of carbon layers can be carefully controlled to tune possible proximity effects between the film and the substrate. All experiments were carried out on a monochromated Nion UltraSTEM100 MC operated at 60kV, with a probe convergence semi-angle of 31mrad and a beam current of approximately 4pA (after monochromation to ~12meV resolution). Chemical mapping confirms the atomic-level chemistry of the layers, while the specific geometry of the sample offers opportunities for probing directly the spatial localization of electronic states within the graphene layers [1] and at the SiC/graphene and graphene/Bi_2Se_3 interfaces. Strikingly, the use of a dark-field EELS geometry, using e.g. a set of custom-developed annular apertures, reveals the emergence of locally resolved fine structure in the ultra-low loss region of the spectrum. In addition to a direct interrogation of the chemical bonds between the layers via their vibrational response, these observations are linked to the interplay between the various phonon modes and the Dirac plasmons in the TI layers, whose dispersion is mapped in momentum space with nm spatial sensitivity using a recently developed methodology for nanoscale momentum-resolved spectroscopy [2].

Real Space Topologies in Ferroelectric Superlattices Ramamoorthy Ramesh; University of California, Berkeley, United States

Complex topological configurations are a fertile playground to explore novel emergent phenomena and exotic phases in condensed-matter physics. I will describe the discovery of polar skyrmions in a lead-titanate layer confined by strontium-titanate layers by atomic-resolution scanning transmission electron microscopy (STEM). Phase-field modeling and second-principles calculations reveal that the polar skyrmions have a skyrmion number of +1 and resonant soft X-ray diffraction experiments show circular dichroism confirming chirality. Such nanometer-scale polar skyrmions exhibit a strong signature of negative permittivity at the surface of the skyrmion, which is furthermore highly tunable with an electric field. They are a new state of matter and electric analogs of magnetic skyrmions, and may be envisaged for potential applications in information technologies.

Predicting Phonon-Induced Spin Decoherence from First Principles—Colossal Spin Renormalization in Condensed Matter Jinsoo Park[1], Jin-Jian Zhou[2], Yao Luo[1] and Marco Bernardi[1]; [1]California Institute of Technology, United States; [2]Beijing Institute of Technology, China

Developing a microscopic understanding of spin decoherence is essential to advancing quantum technologies. Electron spin decoherence due to atomic vibrations (phonons) plays a special role as it sets an intrinsic limit to the performance of spin-based quantum devices. Two main sources of phonon-induced spin decoherence - the Elliott-Yafet (EY) and Dyakonov-Perel (DP) mechanisms - have distinct physical origins and theoretical treatments. Here we show a rigorous framework that unifies their modeling and enable accurate predictions of spin relaxation and precession in semiconductors [1]. We compute the phonon-dressed vertex of the spin-spin correlation function, with a treatment analogous to the calculation of the anomalous electron magnetic moment in QED [2]. We find that the vertex correction provides a giant renormalization of the electron spin dynamics in solids, greater by many orders of magnitude than the corresponding correction in vacuum. Our work demonstrates a general approach for quantitative analysis of spin decoherence in materials, advancing the quest for spin-based quantum technologies.

3:45 PM EQ.08.02.04
Molecular Beam Epitaxy Grown Tantalum Arsenide Weyl Semimetal Zuzanna W. Ogorzalek[1], Janusz Sadowski[1,2,3], Jaroslaw Domagala[3], Wiktoria Zajkowska[3], Slawomir Kret[3], Bartlomiej Seredynski[1], Rafal Bozek[1], Wojciech Pacuski[1] and Marta Gryglas-Borysiewicz[1]; [1]University of Warsaw, Poland; [2]Linnaeus University, Sweden; [3]Institute of Physics, Polish Academy of Sciences, Poland

Tantalum arsenide belongs to topological Weyl semimetals (WSM), with unusual electronic and magnetotransport properties. In WSM materials, the combination of distinct features of electronic structure and crystal lattice symmetry - either time reversal or inversion symmetry, leads to occurrence of so called Weyl nodes at the crossing points of two bands without spin degeneracy. The low energy excitations at the Weyl nodes behave as massless Weyl fermions with linear dispersion relations and opposite chiralities. In the band structure of TaAs 12 pairs of Weyl nodes have been identified in the distinct points of the Brillouin zone [1]; but so far TaAs has been obtained only in the form of bulk crystals [1-4]. We have grown TaAs by molecular beam epitaxy (MBE) on commonly used GaAs(001) substrates, in a III-V MBE system equipped with a valved cracker source for arsenic and e-beam source for Ta. TaAs crystallizes in a body-centred-tetragonal structure with the lattice parameters: a = b = 3.4348 Å; c = 11.641. Using in-situ reflection high energy electron diffraction (RHEED) we observe that in spite of a significant lattice mismatch to zinc-blende GaAs (with lattice parameter a=5.653Å) , TaAs grows on GaAs(001) in a fully 2-dimensional layer-by-layer mode, from the very first sub-monolayer deposition stage, with no initial 3-dimensional growth typical for epitaxy on the substrates with a high lattice mismatch. The orientation of TaAs is the same as that of the substrate, i.e. TaAs(001) planes are parallel to GaAs(001), but they are rotated by 45 degrees, hence the [110] in-plane direction of the GaAs substrate is parallel to the [010] one of TaAs. Such configuration decreases the lattice mismatch between TaAs and GaAs, but still it is as big as 19%. The twisting of TaAs(001) layers with respect to GaAs(001) substrate is observed in RHEED, and confirmed by X-ray diffraction and transmission electron microscopy (TEM) measurements. Even though no misfit dislocations are identified in TEM cross-sections visualizing the TaAs/GaAs interface, the TaAs surface morphology revealed by atomic force microscopy exhibits stripe-like structure with about 200 nm long and 20 nm thick planar columnar features parallel to GaAs[-110]. This hampers (so far) applicability of angle resolved photoemission spectroscopy (ARPES) to reveal topological properties typical to Weyl semimetals, such as bulk Dirac cones and surface Fermi arcs, due to much larger dimensions of UV-beam spot used in ARPES, but should not be an obstacle in much more local scanning tunneling spectroscopy measurements. The possibility of obtaining epitaxial layers of TaAs opens a way for integrating this WSM in heterostructures with other materials e.g. ferromagnets or superconductors, which enables investigations of proximity effects, impossible to explore using bulk TaAs crystals accessible so far.

Uncovering Chirality of Skyrmions in Polycrystalline B20 FeGe on Si Kayla Nguyen; University of Illinois at Urbana-Champaign, United States

Understanding chirality, the intrinsic handedness of a system, is important for future technologies using quantum magnetic materials. Of particular interest are magnetic skyrmions which are chiral and topologically protected, meaning that their spin textures can act as barriers from deformation in crystalline grains. However, most electron microscopy studies use Lorentz TEM or holography to investigate chirality of skyrmions in nearly perfect single crystals because Fresnel effects may cause signals from grain structures to be mistaken as magnetism when the two are comparable in size. In this work, we probe nanomagnetism of topological magnetic textures in sputtered thin film of B20 FeGe on Si to study the relationship between magnetic and crystal chirality. Using 4D-STEM, we find that the vorticity and helicity of these magnetic topological phases are coupled to the crystal chirality. Furthermore, our work shows that signals from magnetism can be disentangled from the crystalline effects for sub-micron grains, enabling a way to investigate topological magnetism in the presence of small polycrystalline grains. This methodology is important for spintronics and low-power magnetic memory technologies that rely on scalable techniques for large scale manufacturing of real devices.

4:30 PM EQ08.02.06
Atomic-Resolution Mapping of Metal-Insulator Phase Coexistence in Epitaxially Strained Ca_2RuO_4 Noah Schnitzer[1], Oleg Y. Gorobtsov[1], Ziming Shao[1], Jacob P. Ruf[1,2], Berit H. Goodge[1,3], Hari P. Nair[1], Darrell Schlom[1,3,4], Kyle M. Shen[1,3], Andrej Singer[1] and Lena F. Kourkoutis[1,3]; [1]Cornell University, United States; [2]Max Planck Institute for Chemical Physics of Solids, Germany; [3]Kavli Institute at Cornell for Nanoscale Science, United States; [4]Leibniz-Institut für Kristallzüchtung, Germany

Materials exhibiting metal-insulator transitions (MITs) have a variety of potential technological applications, but in many systems the mechanism of the transition and the coupling of electronic and lattice degrees of freedom are not fully understood. The Ruddlesden-Popper ruthenate Ca_2RuO_4 is a particularly interesting example due to the tunability of its MIT and strong lattice effects. Although both the metallic and insulating phases of Ca_2RuO_4 share the same Pbca symmetry, a structural transition is closely coupled to the electronic transition in which the insulating phase is distinguished by flattened octahedra [1]. The transition is highly sensitive to a variety of external stimuli including electric fields, with a threshold field of only 40 V/cm at room temperature [2], and epitaxial strain, which can tune the transition temperature over a broad range [3]. Notably, the current driven transition can result in extended stripe patterns of metallic and insulating phase coexistence, which are suggested to mediate the significant mismatch strain between the metallic and insulating phases [4, 5].

Here, a 40 nm thick Ca_2RuO_4 film epitaxially grown on $LaAlO_3$ is characterized through the MIT with scanning transmission electron microscopy (STEM). The compressive epitaxial strain stabilizes a uniform metallic phase at room temperature, but cryogenic STEM measurements reveal that upon cooling below ~230 K nanometer scale stripes emerge with modulated lattice parameters consistent with the insulating phase, forming a coherent extended nanostructure. Measurement of the nanostructure at atomic-resolution over hundreds of nanometers enables visualization of the complex mesoscale phase arrangement, as well as characterization of the atomic structure within the stripes and through the interfaces of the coexisting phases. In addition, nanoscale features such as defects, local strain gradients, and the substrate-film interface can be resolved and correlated with the nanostructure. Finally, taking advantage of recent instrumentation developments [6], the film is measured at atomic-resolution at intermediate temperatures between liquid nitrogen and room temperature, capturing the evolution of the nanostructure through repeated cycles of the MIT.

4:45 PM EQ08.02.07
Quantitative Surface-Magnetic Imaging by SEMPA to Measure the Dzyaloshinskii–Moriya Interaction and Investigate Three-Dimensional Magnetic Topologic Structures Robert Frömter[1], Mona Bhukta[1], Takaaki Dohi[1], Maria A. Syskaki[1], Fabian Kloodt-Twesten[2], Hans P. Oepen[2] and Mathias Klaeui[1]; [1]University of Mainz, Germany; [2]Hamburg University, Germany

Scanning electron microscopy with polarization analysis (SEMPA) is a versatile tool for high-resolution magnetic surface imaging. The capability of synchronous vector imaging is especially useful for accurately determining the in-plane angle of the local magnetization vector. Domain walls in ultrathin films with DMI and out-of-plane magnetization show a thickness-driven continuous transition from Néel to Bloch orientation, which is due to the 1/d reduction in DMI strength that is competing with the dipolar energy of the wall's magnetic charge. By measuring the DW angle and modeling the dipolar energy the DMI strength can be determined. We present examples for epitaxial, in-situ grown layers of Co/Pt(111) and Co/Ir(111) [1,2], where due to the absence of DMI in the ferromagnet/vacuum interface exactly the DMI of one epitaxially ordered interface can be measured. While UHV conditions are required in SEMPA, there is in fact no strict limitation to imaging in-situ prepared, uncapped magnetic layers. After covering an ex-situ sputtered sample with 1 nm of Pt imaging is still possible, however at reduced magnetic contrast [3]. This enables surface imaging of sputtered multilayer stacks with varied couplings that can host three-dimensional magnetic structures. Of special interest is this for imaging synthetic antiferromagnets [4], where due to the high surface sensitivity of less than one nanometer no contrast reduction from the AF coupled second layer occurs. The combination of high-resolution surface in-plane imaging with micromagnetic simulation and additional, less surface-sensitive microscopy methods allows for successful investigation of such structures. By tilting the sample or using additional techniques like MFM the out-of-plane component of the magnetization gets accessible and thus chiral objects like skyrmions or merons can be identified.

8:30 AM *EQ08.03.01
Atomic-Scale Visualizations of Topological Defects in Charge Order Superlattices Ismail El Baggari; Harvard University, United States

Charge order is the spontaneous formation of real space superstructures driven by electron-lattice coupling. Similar to other ordered structures such as crystals and magnetic lattices, charge order superlattices may exhibit a variety of defects with emergent properties. Here we use atomic-resolution scanning transmission electron microscopy (STEM) to visualize phase fluctuations and defects in charge order including dislocations, compression and shear deformations. These defects in the superlattice play a key role in nanoscale competition, incommensurate order, and long-range correlations. In particular, STEM shows how topological defects (dislocations) in the charge order lattice of a manganite destroy long-range ordering and host competing charge order instabilities. Non-equilibrium conditions can generate even more complex phase defect structures in charge order superlattices. In the case of 1T-TaS2 following ultarfast light excitation, we observe the formation of long-lived metastable charge order twins. Remarkably, these twins are delinetaed by a series of dislocations similar to low-angle grain boundaries. These atomic-resolution STEM visualizations show that charge order is a promising platform for realizing novel topological defects that are often intertwined with competing electronic instabilities.

9:00 AM *EQ08.03.02
Direct Electromagnetic Field Imaging by Atomic-Resolution Differential Phase Contrast STEM Naoya Shibata[1,2]; [1]The University of Tokyo, Japan; [2]Japan Fine Ceramics Center, Japan

Differential phase contrast imaging in aberration-corrected scanning transmission electron microscopy (DPC STEM) brings the possibility to probe the electromagnetic field distribution in materials and devices down to the atomic scale. Recently, it has been shown that intrinsic magnetic fields of an antiferromagnet can be visualized in real space by this technique. However, when applying this techniqe to crystal defects such as interfaces and dislocations, concomitant diffraction contrast has been a serious issue. We have developed a novel scanning system to supress diffraction contrast in DPC images, and quantitative electromagnetic field imaging at defect regions becomes possible. In this talk, serveal applications of DPC STEM to crystal interfaces will be reported.

9:30 AM *EQ08.03.03
Discoveries of "Hidden" Topologies Occurring Intrinsically Within a Multiferroic Matrix Lynette Keeney[1], Kalani Moore[2], Eoghan O'Connell[2], Sinead M. Griffin[3], Clive Downing[4], Louise Colfer[1], Michael Schmidt[1], Valeria Nicolosi[4], Ursel Bangart[2] and Michele Conroy[5,2]; [1]Tyndall National Institute, Ireland; [2]University of Limerick, Ireland; [3]Lawrence Berkeley National Laboratory, United States; [4]Trinity College Dublin, The University of Dublin, Ireland; [5]Imperial College London, United Kingdom

Single-phase multiferroics intertwine ferroelectric and ferromagnetic properties, providing novel ways to manipulate data and store information, as well as providing opportunities for exploring new chemistry and physics. In practice, due to the fundamental contra-indication between ferroelectricity (empty d^0 electronic structures) and ferromagnetism (occupied d^n electronic structures), single-phase multiferroics are exceedingly scarce. In recent years, we reported the design of such a novel room temperature magnetoelectric multiferroic material that could ideally be suited to future fabrication of revolutionary memory devices. To achieve this design, we took the approach of creating a new layered Aurivillius composition, $Bi_6Ti_xFe_yMn_zO_{18}$ (B6TFMO; x = 2.80 to 3.04; Y = 1.32 to 1.52; Z = 0.54 to 0.64), which combines differing types of *A*-site (Bi^{3+}) and *B*-site (Ti^{4+}, Fe^{3+}, $Mn^{3+/4+}$) cations, to drive both ferroelectricity and ferromagnetism within the same structural phase.
While this is a rare breakthrough on its own, in this presentation I will describe how we have lately uncovered remarkable polar topological structures close to regions where the B6TFMO layering is disrupted by naturally occurring structural defects. Here, the internal elastic strain and electrostatic energy gradients are altered to give rise to an inhomogeneous polarisation distribution of polar magnitude and polar rotation angle. Atomic resolution scanning transmission electron microscopy, in conjunction with polar displacement mapping, reveals nominally charged ferroelectric domain walls and non-trivial continuous rotations of ferroelectric polarisation into exotic polar vortex structures. These emergent topological structures hitherto lay "hidden", previously undiscovered within multiferroic B6TFMO, however they occur intrinsically, without the need for an artificial interface and in the absence of external strain engineering.
These distinctive types of 2*D* topologies are intriguing entities in matter, because they can offer spatially confined emergent functional properties, such as electrical conductivity within an otherwise insulating matrix. The internal characteristic length scales of these polar vortex domain walls (~5 nm) are much more compact than that of their magnetic counterparts (~10 to 100 nm), signifying potential to transcend the limits of classical data storage.

10:00 AM BREAK

10:30 AM EQ08.03.04
Revealing Fast Cu-Ion Motion in $CuInP_2S_6$ - $In_{4/3}P_2S_6$ Flakes Through the Ferroelectric to Paraelectric Phase Transition Marti Checa[1], Xin Jin[2,3], Sabine Neumayer[1], Ruben Millan-Solsona[4,5], Michael A. Susner[6], Michael McGuire[7], Andrew O'Hara[2], Gabriel Gomila[4,5], Peter Maksymovych[1], Sokrates Pantelides[2] and Liam Collins[1]; [1]Center for Nanophase Materials Sciences, Oak Ridge National Laboratory, United States; [2]Vanderbilt University, United States; [3]Institute of Physics & University of the Chinese Academy of Sciences, China; [4]Institut de Bioenginyeria de Catalunya (IBEC), The Barcelona Institute of Science and Technology (BIST), Spain; [5]Universitat de Barcelona, Spain; [6]Materials and Manufacturing Directorate, Air Force Research Laboratory, United States; [7]Materials Science and Technology Division, Oak Ridge National Laboratory, United States

Van der Waals layered materials exhibiting robust room temperature ferroelectricity offer a versatile platform for miniaturization of ferroelectric device technology. Within this class of 2D material systems, $CuInP_2S_6$ has received a significant degree of interest due to the revelation of ionically mediated polarization switching pathways, multistate ferroelectricity, ionic conduction, and complex interfacial chemistry. Moreover, it is possible to form stable self-assembled heterostructures of ferroelectric $CuInP_2S_6$ (CIPS) and non-ferroelectric (i.e., lacking Cu) $In_{4/3}P_2S_6$ (IPS), by controlling the targeted

composition and kinetics of synthesis. To date, the properties of CIPS/IPS interfaces naturally forming by in-plane epitaxy have received little attention. In this work, we use an advanced scanning probe microscopy approach to explore in detail the nanoscale variability of the AC ion-transport dependent functional properties (electromechanical, dielectric, and conductive) in CIPS-IPS flakes during the ferrielectric-paraelectric transition. First, we show evidence of a kHz ionically mediated electromechanical response of CIPS in the paraelectric phase (above TC). Second, we reveal the local dielectric constant and ionic conductivity changes across the CIPS-IPS heterostructure, by local in-situ imaging and explaining the dielectric peak of the ferroelectric phase transition with scanning probe microscopy. Finally, we find a temperature enhanced dielectric loss/ionic conductivity at the CIPS/IPS boundary that we propose is a result of enhanced Cu motion at the CIPS/IPS interface as supported by DFT calculations. Our results expose a new insight into polar properties of CIPS and open the possibility for tuning interfacial properties of the CIPS/IPS interface.

10:45 AM *EQ08.03.05
Synthesis of a Quantum Spin Liquid in the Thin-Film Form Julia Mundy[1], Johanna Nordlander[1], Margaret Anderson[1], Ismail El Baggari[2] and Charles Brooks[1]; [1]Harvard University, United States; [2]The Rowland Institute at Harvard University, United States

Magnetically frustrated materials offer a playground for realizing exotic magnetic ground states such as quantum spin ices and spin liquids. Synthesizing such quantum magnets in thin-film form allows further tuning of the magnetic ground state with dimensionality and epitaxial strain as well as the possibility to integrate these states with other functional materials. Here we use reactive oxide molecular beam epitaxy to synthesize thin films of hexagonal $TbInO_3$. This material is isostructural to the well-studied multiferroic material $YMnO_3$. Due to a lattice distortion accompanied by an improper ferroelectric polarization at high temperatures, the Tb^{3+} sublattice exhibits a stuffed honeycomb geometry which hosts frustrated magnetism. We study the interplay of ferroelectricity and the frustrated magnetic order in the thin film geometry.

11:15 AM *EQ08.03.06
Magnetoelectric Correlations in Inhomogeneous Multiferroics Manfred Fiebig; ETH Zürich, Switzerland

Magnetoelectric coupling phenomena in multiferroics were initially treated almost exclusively as bulk effects exhibited by homogeneous materials. In recent years, however, attention has moved to the inhomogeneous distributions of the multiferroic order down to the nanoscale. On the one hand, magnetoelectric phase control ultimately happens on the level of the mostly sub-micrometer-sized domains. On the other hand, domain walls, interfaces and thin films are nanoscale and/or topological objects that have been proving to be the source of intriguing magnetoelectric coupling effects. In my talk, I will therefore explore the fascinating world of magnetoelectric correlations in multiferroics that are inhomogeneous at the nanoscale and demonstrate their enormous potential for new types of correlations. Examples will include [1] a seemingly contradictory coexistence of strong local and forbidden global magnetoelectric coupling; [2] conversion of a multiferroic bulk state into a multiferroic domain wall in a non-multiferroic environment; [3] magnetoelectric transfer of an order parameter with a joking reference to teleportation.

SESSION EQ08.04: Theory of Higher Order Topological Structures

1:30 PM *EQ08.04.01
A Magnetoelectric Multipolar Taxonomy of Topologies Nicola Spaldin; ETH Zurich, Switzerland

We will show how many popular real-space electric or magnetic topologies can be classified in terms of their underlying magnetoelectric multipoles. The magnetoelectric multipoles form the next-order term, beyond the magnetic dipole, in the multipole expansion of a general magnetization density in a spatially varying magnetic field. They are known to occur in all linear magnetoelectric materials, where their simultaneous breaking of time-reversal and space-inversion symmetry is both responsible for the linear magnetoelectric effect, and contributes to the surface magnetization. Here we will describe other occurences of magnetoelectric multipoles that are relevant for real-space magnetic and electric topologies in materials. First, we will show that magnetic skyrmions can be classified in terms of magnetoelectric multipoles, allowing a straightforward determination of their textures via a magnetoelectric response measurement. Then we will show that conventional, non-magnetic ferroelectric materials contain hidden *reciprocal-space* magnetoelectric multipoles that should be detectable using magnetic measurements such as Compton scattering. Finally, we will discuss how the magnetoelectric multipoles manifest when topologically non-trivial real-space electric structures evolve in time.

Foundations of Topology in Ferroelectrics Igor Lukyanchuk; University of Picardie, France

During the past decade, it has been realized that various topological structures, arising in ferroelectrics may significantly contribute to their physical properties. Even the simplest topological formation, domain walls (DWs), bring new functional complexity and open a new avenue in the operating of ferroelectric devices at the nanoscale. Here we generalize topological consideration of the nanostructured ferroelectrics to small nanoparticles, nanodots, films, and nanorods and show that the topologically stable *knotting* of the polarization field lines and *topological chirality* results in a wealth of useful functionalities such as optical activity and THz vibrations of DWs.
Importantly, despite the seeming similarity, the origin of topological structures is very different in magnetic and ferroelectric systems. In magnetic systems, it is the local built-in Dzyaloshinskii Moriya interaction that induces the long-range chiral ordering of topological excitations. At variance, a distinct feature of ferroelectrics is that the topological excitations appear as a result of the spontaneous symmetry breaking due to an interplay of the confinement and depolarization effects where the topological excitations are generated by the long-range interaction of the depolarization charges, $\rho = -\mathrm{div}P$. Upon confinement the polarization field swirls to keep its divergenceless structure, the situation being similar to the incompressible liquid flow in the whirlpools or to the magnetohydrodynamic flow of the plasma interior of the stars. The topological classification scheme of these formations, unified by the constraint of the divergenceless of the vector field is by far more complex than that for the magnetic systems.
We demonstrate that the advanced 3D topological excitations, *vortices, skyrmions, and Hopfions*, characterized by the nontrivial *linking numbers* and *helicity* arise inside the nanostructured ferroelectrics and mimic the “topology of the Universe”. Our consideration is in-line with the ongoing paradigmatic shift in physics, marking the change from deriving properties of the matter out of the local structural symmetries to the global topological paradigm, which describes the fundamental properties of matter on the basis of their invariance under continuous transformations or perturbations.

Chiral Phase Transitions in Topological Phases at Oxide Superlattices Fernando Gómez-Ortiz[1], Pablo García-Fernández[1], Juan M. López[2], Piush Behera[3], Ramamoorthy Ramesh[3] and Javier Junquera[1]; [1]University of Cantabria, Spain; [2]Instituto de Física de Cantabria, University of Cantabria, Spain; [3]University of California, Berkeley, United States

Over the past few years, the existence of materials capable of showing non-trivial topological textures of the polarization pattern has attracted lots of attention triggered by the presumably higher density (due to their smaller sizes) and faster response (phonon frequencies typically range in the THz regime) than their magnetic counterparts making them good candidates for next generation electronic devices. In particular, structures arising in polar oxide nanostructures, due to the delicate interplay between elastic, electrostatic and gradient energies have emerged as a fertile playground to observe novel emergent phenomena and exotic dipole textures. Most studies were performed embedding a prototype ferroelectric ($PbTiO_3$) in superlattices with a prototype dielectric ($SrTiO_3$). Theoretical predictions together with an atomically precise synthesis and characterization of materials have lead to the observation of flux-closure [1], vortices [2], skyrmions [3] or merons [4] depending on the periodicity, mechanical and electrostatic boundary conditions. This delicate balance and multiminima potential energy surface suggest a very rich phase diagram with novel phase transitions [5-7] together with exotic physical responses such as negative capacitance [8] or chirality [9]. The involved typical sizes and the will of studying the dependence of the polar texture with external stimuli such as temperature or electric fields require the development of new modelling tools. In this respect, second-principles methods [10-11] are emerging as a valuable solution for such a problems.
In this talk, I shall describe the path of phase transitions occurring in the polar vortex chiral structures upon increasing temperature and characterize them with appropriate order parameters [12]. Although the overall polarization is zero throughout the process, the system suffers a first-order first transition from a chiral-crystal to a chiral-liquid of polarization vortices upon increasing temperature. Finally, a second order phase transition is found at higher temperatures where the mirror symmetry is restored and the system becomes a disordered achiral-liquid. Moreover, in the ordered polar vortex phase, under suitable mechanical (epitaxial strain) and electrostatic boundary conditions (built in potential), a deterministic and reversible control of chirality over mesoscale regions have been found under the application of homogeneous electric fields [13]. Second-principles simulations together with second-harmonic generation based circular-dichroism measurements have shown the existence of hysteresis between left- and right-handed chiral states under the application of such electric fields.

Instability of Dynamical Axion Mode Towards Finite-Momentum Jonathan Curtis, Ioannis Petrides and Prineha Narang; Harvard University, United States

The chiral anomaly is a striking signature of quantum effects which leads to violations of the continuity equation for a classically conserved current. In the case of a Weyl semimetal, this leads to a breakdown in the conservation of the chiral-charge current, which is conserved by the classical dynamics. In condensed matter systems this leads to a signature magnetoelectric response associated to anomaly due to the separation of the Weyl points in momentum space. In the presence of strong interactions however, a Weyl semimetal phase become unstable towards spontaneous symmetry breaking. If the chiral symmetry is spontaneously broken this then leads to a Goldstone mode which couples to the chiral anomaly leading to a dynamical magnetoelectric response -- a situation known as a dynamical axion insulator.

Here we consider a simple model of a charge-density wave in a Weyl semimetal and calculate the equations of motion for the Goldstone mode. Surprisingly, we find that the Goldstone mode appears to exhibit a negative phase stiffness, signalling instability of the mean-field towards finite momentum condensation. This is expected to lead to very strong fluctuations in the dynamical anomaly. We suggest a suitable long-wavelength theory which may govern the new axion dynamics in this system and comment on possible signatures.

Coexistence of Kondo Effect and Weyl Semimetallic States in Mn-Doped Mn_xVAl_3 Compounds Kwan-Young Lee and Jong-Soo Rhyee; Kyung Hee University, Korea (the Republic of)

Topological Dirac and Weyl semimetals are a 3-dimensional topological phase of matter, exhibit gapless energy bands with bulk band crossing that lead to the linear band dispersion. Degenerated Dirac bands are separated by breaking of topological symmetries, resulting in the formation of Weyl semimetal. The strong correlation effect in topological Weyl semimetal is a critical issue in condensed matter physics. Recently, one of the strong correlation effect, the Kondo effect, in Weyl semimetal was theoretically proposed but not yet realized experimental point of view. Here we suggest a coexistence of the Weyl semimetal and Kondo effect in disordered Mn-doped Mn_xVAl_3. Dilute magnetic element Mn-doping in type-II Dirac semimetal VAl_3 acts as a magnetic impurities that induces the tuning of its chemical potential so the Dirac points go closer to the Fermi energy and lifts its band degeneracy, leading to the Weyl semimetal topological phase transition. We observed the Kondo effect by several experimental points of view. Especially, the Kondo effect has confirmed by the electrical resistivity minimum at $T_K = 40$ K, and logarithmic increase of electrical resistivity, magnetic susceptibility, and specific heat divided by temperature with a significant Sommerfeld coefficient at low temperature. Furthermore, in order to confirm the topological phase transition from Dirac to Weyl semimetal, we affirm the experimental suggstion of Weyl semimetallic phase. One of the representative confirmation of the Weyl semimetal is the angle-resolved magnetoresistance, which has revealed the negative longitudinal magnetoresistance below Kondo temperature due to the chiral anomaly in Mn-doped Mn_xVAl_3. At low temperature below Kondo temperature ($T \leq T_K$), the exchange interaction by RKKY interaction in Mn_xVAl_3

breaks time-reversal symmetry even in Kondo screening, resulting in the topological phase transition from Dirac to Weyl semimetal. Also the angle-dependent planar Hall effect can manifests the nontrivial Berry phase of matter and the chiral anomaly which elucidates the same physical origin with negative longitudinal magnetoresistance. This research shows the coexistence of the Kondo effect and Weyl semimetallic state in experimental viewpoint as well as the temperature-induced topological phase transition.

How the Interplay of Spin-Orbit Coupling and Correlations Affects the Multipolar Order in Ba_2MgReO_6 Maximilian E. Merkel and Claude Ederer; ETH Zurich, Switzerland

Double perovskites with an open transition-metal 5d shell are interesting materials because they are influenced by the interaction of correlation and spin-orbit coupling effects, similar to Osmate and Iridate compounds.

Here, we present our study on Ba_2MgReO_6, an insulating double perovskite with a structural transition at 33 K and a Néel temperature of 18 K. In a previous study with density-functional theory (DFT)+U [1], the authors could correctly describe the two low-symmetry phases but not the cubic, paramagnetic phase above 33 K, which came out metallic.

Using DFT+dynamical mean-field theory (DMFT), we first show that we can obtain the cubic, insulating phase with a moderate Hubbard U, showing the importance of correlations in Ba_2MgReO_6, which are due to the narrow Re-t_{2g} bands.

We then look at how the interplay of Hubbard U and spin-orbit coupling can trigger a metal-insulator transition to better understand the physics at play here. Finally, we analyze whether charge quadrupoles or hexadecapoles couple more strongly to the phase transition from cubic to tetragonal at 33 K and compare them quantitatively to the DFT+U results.

Crystal Growth of Inter-Metallic Rhodium Compounds Nikola Subotic[1], Mochiku Takahashi[2], Yoshitaka Matsushita[2], Osamu Takeuchi[1], Hidemi Shigekawa[1], Takanari Kashiwagi[1] and Kazuo Kadowaki[1]; [1]University of Tsukuba, Japan; [2]National Institute for Materials Science, Japan

Our previous results on the $RhPb_2$ intermetallic compound [1] inspired us to search for new Rh compounds that may have topological and superconducting properties. Preliminary investigation of them in the ternary Au-Rh-Pb phase diagram has shown that $AuPb_4Rh_5$ exists newly [2]. Moreover, resistivity measurements of the grown crystals that had a chemical composition close to $AuPb_3Rh_3$ (EPMA results) have shown two superconducting transitions at 1.73 K and 2.8 K, which do not correspond to the transition temperatures of superconductors from the binary Au-Pb and Rh-Pb phase diagrams.

Further investigation of the ternary phase diagram yielded unexpected results. The EPMA measurements of grown crystals with an infrared mirror furnace similar to $RhPb_2$ [1] having the initial molar ratio of Au:Pb:Rh=1:4:1 showed that the crystals are Rh_2Pb_3, which seems not to exist to our knowledge or in the known binary Rh-Pb phase diagram [3]. This implies that the current understanding of the binary Rh-Pb phase diagram is incomplete.

During the $RhPb_2$ melting experiments[1], it was noted that Fe does react with the Rh-Pb alloy, indicating that some compounds might form. This inspired us to investigate further other phase diagrams as well. The melting experiments with a muffle furnace have shown that square-plate-like crystals can grow on the surface of the boule from the melt with an initial molar ratio of Au:Fe:Rh:Pb=2:2:1:4. Surprisingly, the EPMA measurements have shown that the grown crystals do not contain Au and Pb and it turns out finally to be FeRh. To our knowledge, this is the first time that single crystals of FeRh are grown from the melted flux of Au and Pb. The inter-metallic FeRh compound has been studied in the past intensively on peculiar ferromagnetic to antiferromagnetic transition, anomalous thermodynamical properties, crystal structural transformation, *etc*. near the stoichiometric 1:1 composition of Fe and Rh. However, the lack of a good single crystal has hindered understanding of these interesting properties of the RhFe intermetallic compound.The single crystal made by our method will
enaible us to uderstand more deeply the intruging RhFe intermetallic compound.

Characterization of Rare-Earth Titanate Pyrochlore Thin Films Synthesized by Molecular Beam Epitaxy Troy Powell, Margaret Anderson, Ari Turkiewicz, Nicole Taylor, Johanna Nordlander, Charles Brooks and Julia Mundy; Harvard University, United States

Pyrochlores are a class of metal oxide materials with the empirical formula $A_2B_2O_6O'$. Both the A^{3+} and B^{4+} sites are filled with select metal, metalloid, or lanthanide cations; the oxygen atoms coordinate roughly as a scalenohedron around the A site and as an octahedron around the B site[1]. These specific oxidations and coordinations create the environment for the non-symmetric distribution of electrons in the lattice. This non-symmetric distribution is partially responsible for the 'spin-ice' behaviors of some pyrochlores[2]. These metal cations also exhibit other unique magnetic properties including long-range ordered, spin-glass, and spin-liquid phases[3]. Here we synthesize thin films of pyrochlores using reactive-oxide molecular beam epitaxy. We study the structural and magnetic properties of rare-earth titanate pyrochlores thin films with a focus on oxidation and oxygen vacancies in these materials. Atomic-force microscopy (AFM) and x-ray diffraction (XRD) are used to verify the quality and identity of our grown films. We used SQUID magnetometry to characterize magnetic properties.

Doubled Quantum Spin Hall Effect in α-Antimonene Hsin Lin[1], Baokai Wang[2], Xiaoting Zhou[2], Yi-Chun Hung[3], Yen-Chuan Lin[3] and Arun Bansil[2]; [1]Academia Sinica, Taiwan; [2]Northeastern University, United States; [3]National Taiwan University, Taiwan

For a two-dimensional time-reversal symmetric system, the quantum spin Hall phase is assumed to be the same as the Z_2 topological insulator phase in the existing literature because the spin Chern number C_s and the Z_2 invariant yield the same topological classification. Here, by investigating the topological electronic structures of monolayer α-phase group V elements, we uncover the presence of a topological phase in α-Sb, which can be characterized by a spin Chern number C_s=2, even though it is Z_2 trivial. Our analysis shows that α-As and Sb share the same band representations at high-symmetry points (HSPs) and would thus both be classified as trivial insulators in terms of topological quantum chemistry (TQC) and symmetry indicators (SIs). However, we demonstrate the existence of a phase transition between α-As and Sb, which is induced by band inversions at two generic *k* points. In the absence of spin-orbit coupling (SOC), α-As is a trivial insulator, while α-Sb is a Dirac semimetal with four Dirac points (DPs) located away from the high-symmetry lines. Inclusion of the SOC gaps out the Dirac points and induces a nontrivial Berry curvature, endowing α-Sb a doubled quantum spin Hall insulator with a high spin Chern number of C_s=2. We further show that monolayer α-Sb exhibits either a gapless band structure or a gapless spin spectrum on its edges as expected from topological considerations.

EQ08.05.03
Electronic Structure Investigation of Magnetic Splitting and Gap Formation in Ferromagnetic Topological Insulator $(Cr_{0.35}Sb_{0.65})_2Te_3$ ChienWen Chuang[1,2], Y. Nakata[1], K. Hori[1], F. M. F. de Groot[3], F.-H. Chang[2], H.-J. Lin[2], C.-T. Chen[2], S. Gupta[1,1,1], F. Matsukura[1,1,1], S. Souma[1,1], T. Takahshi[1,1,1], T. Sato[1,1,1] and A. Chainani[2]; [1]Tohoku University, Japan; [2]National Synchrotron Radiation Research Center, Taiwan; [3]Utrecht University, Netherlands

We study the temperature (*T*) dependent electronic structure and magnetic properties of a high Curie temperature (T_c ~ 185 K) ferromagnetic topological insulator $(Cr_{0.35}Sb_{0.65})_2Te_3$ using Cr L-edge and Te M-edge x-ray absorption spectroscopy (XAS), x-ray magnetic circular dichroism (XMCD), and angle-resolved photoemission spectroscopy (ARPES). The *T*-dependent XAS and XMCD results show a systematic and spin-selective splitting of Cr 3*d* and Te 5*p* unoccupied density of states, resulting in a magnetic gap opening. The *T*-dependent XMCD signal and magnetic gap are consistent with bulk magnetization as well as mean-field theory. The full-multiplet charge-transfer cluster model calculations with a negative charge transfer energy show a good agreement with the experimental Cr L-edge XAS and XMCD spectra. The ARPES measurements show the Dirac-cone topological surface states (SS) below and above T_c, implying that the band inversion between the Sb and Te orbital is maintained even at high Cr doping level, and is consistent with a negative charge transfer energy. These results establish a direct link between Cr 3*d* dopant states and the Te 5*p* SS forming the magnetic gap in $(Cr_{0.35}Sb_{0.65})_2Te_3$.

Investigating Static and Dynamic Properties of Magnetic Hopfions with Advanced X-Ray Spectromicroscopies Peter Fischer[1,2]; [1]Lawrence Berkeley National Lab, United States; [2]University of California, Santa Cruz, United States

Topologically protected magnetic structures, such as skyrmions, are currently an intensely studied topic in the nanomagnetism community due to their scientific beauty and deep fundamental insight into nanoscale spin systems, but also with regard to potential future applications towards low-power, high-density and high-speed information technologies, which are required for the Internet-of-Things (IoT) and beyond [1-3].
Skyrmions are two dimensional chiral solitons where the magnetization smoothly covers a solid angle density of π radians coherently from the center of the spin texture to the opposite magnetization outside of the spin texture [4-5]. Recently, it has been realized, that expanding into the third dimension opens a door to explore highlycomplex topological magnetic structures that can only exist in 3D [6]. Among those 3D textures are magnetic Hopfions [7], which are three-dimensional knot-solitons with a topological class defined by its linking number. Theory has predicted that magnetic Hopfions can be stabilized, e.g., in chiral magnets. Those systems can host target skyrmions (TSks) which are seen as precursors to Hopfions [8-9].
Our recent research was able to stabilize magnetic Hopfions in tailored magnetic multilayers with a depth varying perpendicular anisotropy, and we confirmed the static properties of those Hopfion textures by a combination of two advanced x-ray spectromicroscopy techniques, specifically surface sensitive X-PEEM and bulk sensitive MTXM which allowed us to delineate Hopfions from TSks and torons [10].
In this presentation, we will discuss our recent experimental studies of the static character of magnetic Hopfions, using advanced X-ay microspectrosopy techniques, as well as results from micromagnetic simulations with high-performance computing (HPC), where we identified a field-driven transition from a Hopfion texture to a toron with distinct dynamics for each of the spin textures [11].

Controlled Ordering of Room-Temperature Magnetic Skyrmions in a Polar van der Waals Magnet Peter Meisenheimer[1], Hongrui Zhang[1], David Raftrey[2,3], Peter Fischer[2,3], Robert Birgeneau[1,2] and Ramamoorthy Ramesh[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]University of California, Santa Cruz, United States

Skyrmions are topologically-protected magnetic quasiparticles that are of great interest for their potential use in spintronic memory and logic. This is especially true in systems with native non-centrosymmetry, since the inherent Dzyaloshinskii-Moriya interaction can stabilize a robust topological phase at or near room temperature and zero field. Control and understanding of ensembles of skyrmions is important for realization of devices based on the technology. In particular, the order-disorder transition associated with the 2D lattice of magnetic skyrmions can have significant implications for transport and other dynamic functionality. Here, we investigate the condensation of the skyrmion phase in a polar, Van der Waals magnet. We then demonstrate that we are can engineer an ordered skyrmion crystal through structural confinement, demonstrating control over this order-disorder transition on scales relevant for device applications.

9:30 AM BREAK

Ultra-Reactive Domain Liquid Phase in $PbTiO_3/SrTiO_3$ Superlattices Hugo Aramberri[1], Mónica Graf[1] and Jorge Íñiguez[1,2]; [1]Luxembourg Institute of Science and Technology, Luxembourg; [2]University of Luxembourg, Luxembourg

$PbTiO_3/SrTiO_3$ superlattices display topological dipole textures in the ferroelectric layer that have recently been found to present excitations in sub-terahertz frequencies. Moreover, a previous work discovered an ultra-reactive phase in these materials in which the thermal activation can cause the domain walls to move spontaneously, resembling the behaviour of a liquid. In this work we employ second-principles models to map the phase diagram of these superlattices, which features three phases that can be deemed as a solid, a liquid and a gas phase. We also use molecular dynamics to study and characterize the dynamic response of these phases. Our findings indicate how the response of these materials can be optimized with respect to the design parameters of the superlattices (layer thicknesses, strain) and temperature. The tuneable sub-terahertz response of these systems makes them interesting candidates for applications in high-speed telecommunications.

10:15 AM EQ08.06.06
Microscopic Origin of Dirac Mass Gap Variation in the Intrinsic Magnetic Topological Insulator $MnBi_2Te_4$ Mengke Liu[1,2], Chao Lei[1], Hyunsue Kim[1], Yanxing Li[1], Lisa Frammolino[1], Jiaqiang Yan[3], Allan H. Macdonald[1] and Chih-Kang Shih[1]; [1]The University of Texas at Austin, United States; [2]Harvard University, United States; [3]Oak Ridge National Laboratory, United States

In intrinsic magnetic topological insulators, Dirac surface state gaps are prerequisites for quantum anomalous Hall and axion insulating states. Unambiguous experimental identification of these gaps has proved to be a challenge, however. Here we use molecular beam epitaxy to grow intrinsic $MnBi_2Te_4$ thin films. Using scanning tunneling microscopy/spectroscopy, we directly visualize the Dirac mass gap and its disappearance below and above the magnetic order temperature. We further reveal the interplay of Dirac mass gaps and local magnetic defects. We find that in high defect regions, the Dirac mass gap collapses. *Ab initio* and coupled Dirac cone model calculations provide insight into the microscopic origin of the correlation between defect density and spatial gap variations. This work provides unambiguous identification of the Dirac mass gap in $MnBi_2Te_4$, and by revealing the microscopic origin of its gap variation, establishes a material design principle for realizing exotic states in intrinsic magnetic topological insulators.

10:30 AM EQ08.06.08
Spin Texture of 1D Chains of Magnetic Atoms in a Novel Air-Stable 2D Magnet Eugene Park[1], Julian Klein[1], Zhigang Song[2], John P. Philbin[2], Aubrey Penn[1], Mads Weile[3], Baoming Wang[1], Prineha Narang[2] and Frances M. Ross[1]; [1]Massachusetts Institute of Technology, United States; [2]Harvard University, United States; [3]Technical University of Denmark, Denmark

Van der Waals 2D magnetic materials have emerged as a novel platform that offers unique optoelectronic, magnetic, and quantum properties.[1] Such low-dimensional spin systems have vast potential in applications such as spintronics and nanoscale magnetic devices. The ability to engineer the structure and defects with respect to magnetic, optical, and electronic properties is critical. For example, an optically active single defect may have potential as a quantum emitter interacting with and embedded in the novel magnetic environment. Air-stable 2D van der Waals magnets are relatively unexplored, making the study of such materials intriguing and helpful for both fundamental research and device design.

Here, we examine the structural properties of the 2D magnet $AgCrP_2S_6$, a compound that is similar to the family of $M_2P_2S_6$. Using scanning transmission electron microscopy (STEM), we measure structural parameters, identify the 1D chain structure of magnetic atoms, and visualize the alignment of the magnetic chains between layers with atomic resolution. We also explore the nature of defects and the possibility of controlling defect location using the STEM beam. We expect this crystal structure to offer a high opportunity for anisotropy of its magnetic properties as a 2D van der Waals magnet. By parameterizing a model spin Hamiltonian based on density functional theory calculations, we predict an unusual spin structure that develops from the chain arrangement of the magnetic atoms in this material. We discuss measurements to verify the modelled spin configuration using vibrating sample magnetometry and other techniques. Lastly, we compare the defects, atomic structure transformations, and spin texture with a more studied 2D magnet, $CrSBr$[2,3], to better understand the fundamental properties of defects and structures in these novel air-stable 2D magnetic materials as a basis for future control and application of magnetic and optical properties.

Emergence of Ferromagnetic Topological Surface State in FeSi and Nonlinear Dynamics of Magnetic Domains Naoya Kanazawa; The University of Tokyo, Japan

A chiral compound FeSi is a prototypical example of the strongly-correlated *d*-electron insulators. Its peculiar charge and spin dynamics, which cannot be explained by a simple mean-field picture of nonmagnetic insulators, have provoked many important physical concepts such as *d*-electron Kondo insulator and insulator-to-metal (reversed Mott) transition due to on-site strong Coulomb interaction.
Triggered by recent new insights into topological aspects of correlated insulators, FeSi is attracting renewed attention for its unusual properties. However, it remains highly nontrivial that compounds made of light (and usually common) elements, like FeSi, can bear topological characteristics. As evidenced by the recent numerous researches, the topological insulators necessarily contain heavy (and generally rare) elements with strong spin-orbit coupling (SOC) to protect their topological band structure.
In this study, we successfully demonstrate a novel surface state hosting metallic conduction and ferromagnetic order in FeSi thin film with nonmagnetic bulk state. We identify that the surface state is not categorized into the class of topological insulators but can be described by a central concept in the modern theory of electric polarization, i.e., Zak phase. Owing to the dipolar charge distribution of Zak-phase origin, the surface state produces the strong SOC properties despite the absence of heavy-metal elements. By taking advantage of the emergent SOC, we also realize various types of nonlinear electrical conductions such as unidirectional magnetoresistance and current-induced magnetization switching. These nonlinear responses are rooted in the non-equilibrium spin accumulation and the consequent dynamics of magnetic domains.
Our results shed light on compounds made of common elements and demonstrate rich phenomena related to magnetic-domain dynamics at the new type of topological polar surface.

Skyrmions in Spin-Orbitronics and Orbitronics—Novel Science and Applications in Memory and Non-Conventional Computing Mathias Klaeui; University of Mainz, Germany

Novel spintronic devices can play a role in the quest for GreenIT if they are stable and can transport and manipulate spin with low power. Devices have been proposed, where switching by energy-efficient approaches is used to manipulate topological spin structures [1,2].
Firstly, to obtain ultimate stability of states, topological spin structures that emerge due to the Dzyaloshinskii-Moriya interaction (DMI) at structurally asymmetric interfaces, such as chiral domain walls and skyrmions with enhanced topological protection can be used [3-5]. Here we will introduce these spin structures ad we have investigated in detail their dynamics and find that it is governed by the topology of the spin structure [3]. By designing the materials, we can even obtain a skyrmion lattice phase as the ground state [4]. Beyond 2D structures, we recently developed systems with chiral interlayer exchange interactions that lend themselves to the formation of chiral 3D structures [6].
Secondly, for ultimately efficient spin manipulation, we use spin-orbit torques, that can transfer more than 1hbar per electron by transferring not only spin but also orbital angular momentum. We combine ultimately stable skyrmions with spin orbit torques into a skyrmion racetrack memory device [4], where the real time imaging of the trajectories allows us to quantify the skyrmion Hall effect [5]. Recently, we determined the possible mechanisms that lead to a dependence of the skyrmion Hall effect on skyrmion velocity [7]. We furthermore use spin-orbit torque induced skyrmion dynamics for non-conventional stochastic computing applications, where we developed skyrmion reshuffler devices [8] based on skyrmion diffusion, which also reveals the origin of skyrmion pinning [8]. Such diffusion can furthermore be used for Token-based Brownian Computing and Reservoir Computing [9].
Beyond dynamics excited by spin-orbit torques the next step is to use orbital currents that generate orbital torques [10]. We have demonstrated that with an additional Cu/CuOx layer, the acting torques can be increased by more than a factor 10 [10]. This effect has been interpreted as resulting from an orbital Hall current that is converted to a spin current. Finally, an interfacial Orbital Rashba Edelstein Effect has been found, highlighting that the orbital analogues of both the spin Hall effect and the spin-based Rashba Edelstein or Inverse Spin Galvanic effect exist [11].

Topological Vortex Domains in Quantum Materials Sang Wook Cheong; Rutgers Univ, United States

Engineering of domains and domain boundaries is quintessential for technological exploitation of numerous functional materials. However, it has only recently realized that the configuration of these domains/domain boundaries can have non-trivial topology. We will discuss a new topological classification scheme of domain/domain boundary configurations with Ising-type or two-dimensional order parameters: $Z_m \times Z_n$ domains (*m* directional variants and *n* translational antiphases) and Z_l vortices (where *l* number of domains and that of domain boundaries merge). This classification, with the concept of topological protection and topological charge conservation, has been applied to a wide range of materials such as improper ferroelectric $R(Mn,Fe)O_3$, antipolar $In(Mn,Ga)O_3$, hybrid improper ferroelectric $(Ca,Sr)_3Ti_2O_7$, chiral & helical $Cr_{1/3}TaS_2$, antiferromagnetic $Nd_2SrFe_2O_7$ & a-Fe_2O_3,

antiferromagnetic & superconducting Sr_2VO_3FeAs, and CDW systems such as 2H-$TaSe_2$. We will also discuss the emergent physical properties of domain boundaries, distinct from those of domains. The presented topological consideration provides a basis in understanding the formation, kinetics, manipulation and property optimization of domains/domain boundaries in quantum materials.

4:00 PM EQ08.07.05
Low-Temperature Epitaxial Growth of Anti-Ferromagnetic MnTe at Bi_2Te_3 Oleg Maksimov[1], Katherine Hansen[1], Harish Bhandari[1], Bryan Rachmilowitz[2] and Ilija Zeljkovic[2]; [1]Radiation Monitoring Devices, United States; [2]Boston College, United States

There is significant scientific and technological interest in the epitaxial integration of ferromagnetic or antiferromagnetic materials with the topological insulators (TI). This allows the introduction of the ferromagnetic order into a topological insulator system and may lead to the development of novel spin electronic devices. It is anticipated that these heterostructures can be used as novel magnetoresistive random access memory (MRAM) devices with high charge-to-spin conversion efficiency. This implies that TI-based heterostructures can switch between 0 and 1 memory states much more efficiently, while consuming lower energy than the state-of-the-art magnetic tunneling junction-based heterostructures that use transition metals. The TI-based devices will be less susceptive to weak disorder and perturbations since writing process will occur via conventional writing field while electrical read out process will be topologically protected.
A key requirement for an operational heterojunction is a successful coupling of a TI with the magnetic material, which is facilitated by “atomically-clean” and abrupt junction interface. This should involve low-temperature deposition of the magnetic layer on the TI surface. This eliminates usage of the standard magnetic materials growth techniques, such as molecular beam epitaxy (MBE) and pulsed laser deposition, as they require the substrate temperatures greater than 300-350 ^{0}C, above what TIs can survive.
Here, we report on the innovative approach to grow a room-temperature antiferromagnetic semiconductor (MnTe) using atomic layer deposition (ALD) and to epitaxially integrate it with the topological insulator (Bi_2Te_3). MnTe films were deposited at <100> GaAs and <111> InP. While the MnTe at <100> GaAs were polycrystalline, epitaxial growth was achieved at closely lattice-matched <111> InP at temperatures as low as 120 ^{0}C. Bi_2Te_3 was grown by MBE at c-Al_2O_3, *ex-situ* transferred into the ALD system, and used as a template for MnTe growth. High-resolution X-ray diffraction studies demonstrated that epitaxial MnTe growth was achieved at 120 ^{0}C. Transmission electron microscopy showed that the MnTe / Bi_2Te_3 interface was atomically sharp. No amorphous and / or disordered regions were present at the interface within the imaged regions. Magnetotransport properties of the ALD-grown MnTe were also studied and will be reported here.
In summary, ALD was successfully used for the low-temperature epitaxial integration of MnTe antiferromagnetic semiconductor with the Bi_2Te_3 topological insulator. This opens the path for the realization of near-room temperature energy-efficient spintronic devices.

Surface Modalities of Stacked 2D Heterostructured Topological Materials David C. Bell and Austin Akey; Harvard University, United States

Topological materials present new challenges in terms of characterization, in particular how to minimize surface and sample damage while imaging and analyzing surfaces at the direct native level. Therefore, novel approaches are needed in order to corelate materials properties with surface topology. We have adapted LEEM multi-modal techniques such as Low Energy Electron Diffraction (LEEP), Photoemission Electron Microscopy (PEEM) and in-situ ARPES with high temperature annealing to study individual surface modalities. We have examined various topological materials in the form of bulk 2D heterostructures, specifically artificially constructed metasurfaces with unique order parameters (spin, lattice, localized charge and collective excitations (such as plasmons)).

It is possible to form, via controlled growth, systems with heterointerfaces in bulk materials. We will present the structure analysis of a novel synthesized material Ba6Nb11S28 along with key physical properties. This material naturally realizes vdW coupled heterointerfaces between transition metal dichalcogenide (TMD) monolayers (hexagonal NbS2, H-NbS2) and insulating spacers Ba3NbS5. TEM diffraction taken along the c-axis shows that the hexagonal spacer and TMD layers are commensurate. The electronic band structure can be understood as that resulting from superimposing a periodic potential defined by Ba3NbS5 onto monolayer H-NbS2. This is similar to the mechanism which yields flat bands and strongly correlated physics in twisted-bilayer graphene and TMD heterostructures. LEEM techniques and Low Voltage electron microscopy has been used to characterize grown materials with high resolution at low beam voltages to directly confirm structural layers, ordering and surface diffraction and relate them to metrics of possible topolgical material performance.

Spectroscopic Studies of the Topological Magnon Band Structure in a Skyrmion Lattice Markus Garst; Karlsruhe Institute of Technology, Germany

When magnons propagate across a non-collinear magnetic texture, they collect a Berry phase that can be interpreted as the flux of a synthetic orbital magnetic field. This Berry flux is related to the topological skyrmion density of the magnetic texture. For a topologically non-trivial skyrmion configuration, the magnon thus experiences a synthetic Lorentz force that bends the quasi-classical trajectories of the magnons. For a skyrmion lattice, the average synthetic field is finite such that the magnons are confined to cyclotron orbits of the corresponding magnon Landau levels. This is reflected in a magnon band structure with finite Chern numbers. Here, we report on a series of spectroscopic studies of this band structure using various techniques that allow to probe different regimes in energy-momentum space: magnetic resonance spectroscopy [1], spin-wave spectroscopy [2], inelastic neutron scattering

[3] and Brillouin light scattering [4,5]. These techniques have been applied to various cubic chiral magnets like MnSi, FeCoSi and Cu_2OSeO_3, that are well described by a universal effective continuum theory parametrized by a few parameters only. The combined data from all techniques are found to be in quantitative agreement with theory.

Topological Magnetic Structures and Their Dynamics Karin Everschor-Sitte; University of Duisburg-Essen, Germany

The current-induced dynamics of magnetic structures is quite complex. For example, magnetic skyrmions allow for 'banana kicks' in magnetism, i.e., not only a motion of the skyrmions along but also transverse to the current direction. This effect, which has become known as the skyrmion Hall effect [1,2,3], is often disruptive for device applications. In this talk, we will present possibilities of how to eliminate the skyrmion Hall effect [4,5]. As a particular example, we discuss helical phases which provide confined one-dimensional channels for high-speed skyrmion motion. We discuss how skyrmions can be generated in such helical backgrounds and analyze their stability [6].
Moreover, we will address the role played by topology in the physics of the skyrmion Hall effect. For example, it is widely believed that the skyrmion Hall effect, vanishes for overall topologically neutral structures such as (synthetic) antiferromagnetic skyrmions and skyrmioniums due to a compensation of Magnus forces. While this is true for spin-transfer torque-driven skyrmions, we show that this simple picture is generally false for spin-orbit torque-driven objects [7]. We find that the skyrmion Hall angle for spin-orbit torque-driven skyrmions is directly related to their helicity, which imposes an unexpected roadblock for developing faster and lower input racetrack memories based on spin-orbit torques.

Structural Chirality of Polar Skyrmions Probed by Resonant Elastic X-Ray Scattering Margaret McCarter[1], Kook Tae Kim[2], Vladimir Stoica[3,4], Sujit Das[5], Christoph Klewe[6], Elizabeth Donoway[1], David M. Burn[7], Padraic Shafer[6], Fanny Rodolakis[3], Stephen Lovesey[7], Gerrit van der Laan[7], Se Young Park[2], John Freeland[3], Dong Ryeol Lee[2] and Ramamoorthy Ramesh[1,1,6]; [1]University of California, Berkeley, United States; [2]Soongsil University, Korea (the Republic of); [3]Argonne National Laboratory, United States; [4]Pennsylvania State University, United States; [5]Indian Institute of Science, India; [6]Lawrence Berkeley National Laboratory, United States; [7]Harwell Science and Innovation Campus, United Kingdom

The emergence of real-space topological structures, such as ferroelectric and ferromagnetic skyrmions, is an increasingly popular area of research. As the sizes of these structures approch the nanometer-scale, new characterization techniques are required to map out complex polarization profiles in three dimensions. Resonant elastic x-ray scattering (REXS) is often used to study chirality in spin textures such as magnetic skyrmions and domain walls. However, the application of this technique to analagous electric polarization textures is less established. Here, we present a framework for analyzing REXS from an arrangement of charge quadrupole moments [1], which is applied to measurements on polar skyrmions that form in PbTiO3/SrTiO3 superlattices. By utilizing circularly polarized x-rays and extended reciprocal space scans, we gain insight into their three-dimensional chiral structure. Furthermore, we determine that both right- and left-handed polar skyrmions coexist, and their relative fraction can be extracted using REXS. This technique can be extended to study ordered electric and/or magnetic phases in similar systems. We discuss how this can be appied to complex structures that emerge in multiferroic $BiFeO_3/TbScO_3$ superlattices.

11:30 AM EQ08.10.03
Role of Polarization-Photon Coupling in Ultrafast Terahertz Excitation of Ferroelectrics Shihao Zhuang and Jiamian Hu; University of Wisconsin, Madison, United States

We investigate the role of polarization-photon coupling (specifically, the polarization-oscillation-induced radiation electric field) in the excitation of ferroelectric thin films by an ultrafast terahertz electric field pulse. Analytical formulas are developed to predict how the frequencies and relaxation time of three-dimensional soft mode phonons (intrinsic polarization oscillation) are modulated by the radiation electric field and epitaxial strain. Ultrafast terahertz-pulse-driven excitation of harmonic polarization oscillation in strained single-domain ferroelectric thin film is then simulated using a dynamical phase-field model that considers the coupled strain-polarization-photon dynamics. The frequencies and relaxation time extracted from such numerical simulations agree well with analytical predictions. In relatively thin films, it is predicted that the radiation electric field slightly reduces the frequencies but significantly shortens the relaxation time. These results demonstrate the necessity of considering polarization-photon coupling in understanding and predicting the response of ferroelectric materials to ultrafast pulses of terahertz and higher frequencies.

11:45 AM EQ08.10.04
Ultrafast Carrier Dynamics in Polycrystalline Low Cost Bi_2Se_3 Topological Insulator Valerio Campanari[1], Daniele Catone[1], Patrick O'Keeffe[1], Alessandra Paladini[1], Stefano Turchini[1], Faustino Martelli[1], Matteo Salvato[2], Nouha Loudaief[2], Elena Campagna[2] and Paola Castrucci[2]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]Università degli Studi di Roma Tor Vergata, Italy

Carrier dynamics in Bi_2Se_3 topological insulator thin films of different thickness were investigated by femtosecond transient absorption spectroscopy (FTAS) at 77K and room temperature, by using selected pump energies (from 2.5 eV down to 0.6 eV) and a wide spectrum probe (from 3.6 eV down to 0.9 eV). The fabrication process for growing Bi_2Se_3, that was recently developed[1], is quick, very inexpensive, easy to control and allows obtaining films of different thickness, endowed with topological properties, during the same procedure. In particular, ultra-thin films deposited on n-doped Si substrates with this method show good rectifying properties suitable for their use as photodetectors in the UV-Vis-IR range. The process consists of two consecutive procedures: first Bi_2Se_3 nanowires/nanobelts are deposited by standard catalyst-free vapor–solid deposition on different substrates positioned inside a quartz tube. Then, the Bi_2Se_3 stuck on the inner surface of the quartz tube is re-evaporated and deposited in the form of ultra-thin films on new substrates at a temperature below 100 °C.
FTAS measurements revealed several resolved bleaching signals that show different temporal dynamics. These spectral components can be attributed to the electron transitions at the various bulk or surface states present in the complex Bi_2Se_3 band structure and to plasmonic resonance of long-range strongly correlated electrons, as recently observed with ellipsometry in the same material.[2] We point out that the polycrystalline films used for this work show similar absorption spectra and carrier dynamics of epitaxial layers grown by MBE.[3,4]
Using a pump of low energy, but sufficient to give rise to interband transitions (e.g., 0.6 eV), we have observed absorption bleaching even at energies greater than that of the pump. By a careful study as a function of the pump fluence, we have been able to rule out any multiphotonic contribution to the absorption of the pump. The observation of absorption bleaching at energies larger than that of the pump is attributed to the depletion of the electron population in the bulk valence band (BVB) and/or in the lower Dirac surface states (SS1) that are involved in the interband transition permitted at 0.6 eV. Being the BVB and the SS1 also involved in high-energy transitions, that carrier depletion gives rise to a reduction of the absorption also at the higher energy resonances.
The wide experimental conditions used in our work allow a careful description of the transitions involved in the absorption spectrum and of the photoexcited carrier dynamics, thus providing novel and very useful insights into the properties that allow the fabrication of innovative, low-cost and wide-range photodetectors.

Investigation of the Hetero-Epitaxial Growth Behavior of the Ultrathin Dielectric Films with HfO_2/Al-Doped TiO_2 Bilayer Structure Dae Seon Kwon[1], Kun Hee Ye[1,2], In Soo Lee[1], Junil Lim[1], Haengha Seo[1], Tae Kyun Kim[1], Heewon Paik[1], Jonghoon Shin[1], Jung-Hae Choi[2] and Cheol Seong Hwang[1]; [1]Seoul National University, Korea (the Republic of); [2]Korea Institute of Science and Technology, Korea (the Republic of)

The locally hetero-epitaxial growth and interfacial properties of atomic layer deposited (ALD) Al-doped TiO_2 (ATO) and HfO_2 dielectric films were investigated with the HfO_2/ATO/Ru structure. The locally hetero-epitaxial growth of the ATO films on the Ru substrate could be divided into two stages: the first stage was highly affected by the Ru (and RuO_2) substrate and the second stage was by the ATO itself once the ATO fully covered the Ru substrate. The physicochemical properties of the films at each stage were investigated, supported by computational data, and local lattice-matched growth mechanisms were suggested. At a low thickness (<~4 nm) of the ATO film, the coherent structure of the rutile ATO with *in-situ* formed-rutile RuO_2 was more stable. However, at a higher thickness (>~4 nm), the incoherent structure of the rutile ATO was more stable, leading to the evolution of the new grains with random crystalline orientations. Subsequently, these structural differences in the rutile ATO highly affected the growth of the upper HfO_2 films. As a result, the evolution of the monoclinic phase of the HfO_2 film was suppressed on the ATO film with the appropriate thickness (~2.5 nm). Also, the surface morphology and the interfacial chemical bonding nature of the HfO_2/ATO films depended on the crystalline structure of the rutile ATO films. Finally, the electrical properties of the Pt/HfO_2/ATO/Ru structured capacitors were obtained. Minimum equivalent oxide thickness (EOT) and physical oxide thickness (POT) values were 0.61 nm and 4.28 nm, respectively, while still satisfying the specification of the dynamic random-access memory (DRAM) leakage current density (<10^{-7} A/cm^2 at a capacitor voltage of 0.8 V).

10:45 AM EQ09.01.03
Low Temperature Fabrication of 3D Integrated CMOS Devices by Via-Hole-Less Structure on Flexible Substrate Seongcheol Jang and Hyun-Suk Kim; Chungnam National University, Korea (the Republic of)

Complementary metal oxide semiconductor (CMOS) inverter is basic building blocks for complex integrated logic circuits, which require both p- and n-type thin film transistors (TFTs). Si-based CMOS shows good performance across n- and p- type transistors, however, Si require high temperature process that is not suitable for next generation flexible devices. Organic, Oxides, and metal chalcogenides are proposed for the high performance p-type TFTs, however, their fabrication process, physical nature, and electrical properties are not suitable for cutting-edge CMOS inverter. There are some reports that compose an inverter with only n-type TFTs, however, they suffer from low output swing, small input capacitance, large power dissipation and poor noise margin. To realize high performance CMOS inverter logic circuit, high performance p-type semiconductor with simple fabrication process is strongly required.
3-dimensional (3D) integration is an emerging technology that can offer minimized system, short interconnection, reducing packaging cost and integrate various devices. As Moore's Law reaches its limits, 3D integration technology becomes increasingly important. There are several 3D integration methods such as wire bonding and 3D through silicon via (TSV). Wire bonding is cheap and mature process, however, the process is only possible around die, low chip connection freedom, require interlayer, and suffer from RC delay. 3D-TSV shows the reduced footprint, improved Si efficiency, reduced RC delay and lower power consumption. However, 3D-TSV strongly limited to Si semiconductor and restricted on the use of other semiconductors. 3D via-hole-less is a novel multilevel integration system that is etchant-free, allows simultaneous metal interconnection, minimizes underlying device degradation and provides high substrate-compatibility.
In this work, we present the 3D integration of n-type ZnON and p-type Te TFTs through 3D via-hole less structure. ZnON is well known n-type materials which shows high field effect mobility. Tellurium (Te) is promise 2D p-type materials which can be fabricated via solution process or evaporation process with very low substrate temperature. Here, Te is deposited by room temperature sputtering system which is cost-effective and allow large area uniformity. To demonstrate the 3D via-hole-less structure, ZnON based n-type TFT and Te based p-type TFT were fabricated on the bottom floor and top floor, respectively. Alumina (Al_2O_3) was deposited by plasma enhanced atomic layer deposition (PEALD) using precursor of TMA and reactant of O_2 for the interlayer dielectric (ILD) and dielectric layer. Overall process temperature is under 200 ºC which is suitable for cheap flexible substrate. By using proposed etchant-free 3D via-hole-less structure, 3D stacked inverter was successfully fabricated, showing the high gain of ~ 20. Finally, flexible 3D via-hole-less CMOS inverter was fabricated on PI substrate.

Solution Combustion-Derived Hf0.5Zr0.5O2 Ferroelectrics for Negative Capacitance Field Effect Transistors Pavan Pujar, Hae Won Cho and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

Fabricating solution combustion-derived Hf0.5Zr0.5O2-ferroelectric films for negative capacitors is presented for the first time. The precursor used for the solution combustion reaction to form equimolar hafnia-based ferroelectric, i.e., Hf0.5Zr0.5O2 are designed to act as both combustible elements and cation sources - Hf and Zr. Jain's method, mainly used for calculating the stoichiometric quantities of precursors in propellant chemistry, has also been modified and applied in the present study. The assumption for this method that molecular oxygen does not take part in the reaction is not only refuted but also stoichiometric combustion in the presence of molecular oxygen is proposed. This reaction is followed by post-rapid thermal processing to crystallize the metastable, non-centrosymmetric orthorhombic phase. The thin-film stacks of ferroelectric and dielectric, Hf0.5Zr0.5O2/HfO2, are used to achieve small sub-thermionic swing magnitudes (forward sweep: 25.42 ± 8.05 mV dec−1, reverse sweep: 42.56 ± 4.87 mV dec−1) in 2-dimensional MoS2 negative capacitance field-effect transistors with a hysteresis of ≈40 mV at 1 nA that results in ultra-low-power operation.

11:15 AM EQ09.01.05

Toward Highly Pure Ferroelectric $Hf_{1-x}Zr_xO_2$ Thin Films by Tailoring the Strain in an Unstable Thermodynamic System Yu-Cheng Kao[1], Hao-Kai Peng[1], Kuo-An Wu[1], Yung-Hsien Wu[1] and Pin-Jiun Wu[2]; [1]National Tsing Hua University, Taiwan; [2]National Synchrotron Radiation Research Center, Taiwan

By utilizing the combined analyses of X-ray diffraction (XRD) and X-ray absorption spectroscopy (XAS), a systematic identification on the crystal phases of the polymorphic $Hf_{1-x}Zr_xO_2$ (HZO) thin films with various series of preparation conditions was presented. The results of the rigorous quantitative analysis show that the monoclinic phase (*m*-phase) and the tetragonal phase (*t*-phase) are mutually exclusive and a high fraction of orthorhombic phase (*o*-phase) up to 97% can be achieved under a specific process condition. Based on the observed correlation between the phase fraction and the in-plane strain, the strain-induced activation energy barrier was proposed to clarify the mechanism of kinetic phase transition process. The endurance test of the device, exhibiting that the wake-up degree (remnant polarization variation $\Delta P_r/P_{max}$) increases exponentially with increasing the content of tetragonal phase in the pristine state, indicating the transition from *t*- to *o*-phases as a possible mechanism of the wake-up effect. Our study presented herein points the way to efficiently optimize the strain towards highly pure orthorhombic HZO thin film through precisely controlling the process parameters, which is beneficial for the future development of ferroelectric devices.

SESSION EQ09.02: Ferroelectrics
Session Chairs: Yunseok Kim and Dennis Meier
Monday Afternoon, November 28, 2022
Sheraton, 2nd Floor, Back Bay D

1:30 PM *EQ09.02.01
The Third Dimension of Ferroelectric Domain Walls Dennis Meier; Norwegian University of Science and Technology, Norway

Ferroelectric domain walls are a paradigmatic example for the rich physics and application opportunities of topological defects. The research on ferroelectric domain walls has revolutionized the way we understand polar structures and triggered the development of conceptually new devices for nanotechnology.[1] Despite the immense research efforts, we have scratched only the tip of the iceberg. This is because the quasi-2D walls are embedded in 3D materials and, hence, inaccessible to standard nanoscale imaging techniques. From a theoretical point of view, it is clear that the walls within the bulk are not perfectly flat and just like in other 2D systems, such as graphene and transition-metal dichalcogenides, related corrugation phenomena are crucial for their electronic responses.
In my talk, I will discuss the importance of the 3D nanoscale structure for the emergent transport properties at ferroelectric domain walls. By combining tomographic microscopy techniques and finite element modelling, we revealed how electrical currents spread in the complex network of domain walls and topologically protected vortices in ferroelectric $ErMnO_3$.[2] The results demonstrate the impact of curvature effects on the electrical currents in domain wall networks, giving an additional degree of freedom for their control. In addition, I will introduce novel imaging approaches that allow for studying the interaction of domain walls with point defects in 3D with atomic scale resolution.[3] The results expand previous work on ferroelectric domain walls into the third dimension and reveal new opportunities for domain-wall based multi-level resistance control and unconventional computing.

Atomic-Scale Scanning of Domain Network in Ferroelectric HfO_2 Thin Films Kunwoo Park, Jihoon Kim, Sungsu Kang and Jungwon Park; Seoul National University, Korea (the Republic of)

Since the discovery of ferroelectric HfO_2 films in 2011, great attention has been drawn due to their nano-scale scalability, large polarization and coercive field, and compatibility with silicon-based engineering. The ferroelectricity of HfO_2-based thin films is commonly attributed to the polar non-centrosymmetric $Pca2_1$ orthorhombic phase (o-phase). The mechanism of o-phase stabilization remains unexplained, however, because the ferroelectric HfO_2 films are typically polycrystalline with nanometer-scale domains and those stabilizing effects are probably effective at the nanoscale. There are also additional questions regarding the size, structure, and distribution of ferroelectric domains, the structure of grain boundaries, and their relationship to the overall ferroelectric properties of the HfO_2 films.
Distinguishing different phases of HfO_2 is extremely difficult since the o-phase has nearly identical atomic structure to other phases. The position detection of oxygen atoms across a large region, which is required for ferroelectric domain mapping, is also exceptionally challenging due to their low Z-number. Therefore, the direct in-plane TEM study of the atomic structure of epitaxial HfO_2 films, with a capability to precisely resolve hafnium and oxygen over a wide area of the film, will be the ideal approach to resolve the above-mentioned questions.
In this work, we intensively studied free-standing ferroelectric Y:HfO_2 films with varying thicknesses from 1.5 to 11 nm. Crystallographic phases, their distribution, and local strain are analyzed according to the thickness using in-plane STEM analysis, which reveals that new high-symmetry and compressively strained polar phase stabilizing the ferroelectric phase is induced at the grain boundaries. Moreover, atomic-scale ferroelectric domain maps obtained through in-plane iDPC-STEM oxygen position mapping reveal a complex arrangement of ferroelectric domains, implying that non-polar regions and point defects in the vertical domain walls cause ferroelectricity weakening.

2:15 PM EQ09.02.03
Multilevel Polarization Switching in Ferroelectric Thin Films Martin F. Sarott[1], Marta D. Rossell[2], Manfred Fiebig[1] and Morgan Trassin[1]; [1]ETH Zürich, Switzerland; [2]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

The switchable bistable polarization in ferroelectrics allows for the binary control of optical, electronic, and catalytic properties that are essential for a wide range of applications. Going beyond the limitation of a binary remanent polarization and using that for evoking strongly non-linear material responses holds great promise for emerging spintronic and neuromorphic concepts. Here, we demonstrate that we can arbitrarily set the magnitude of the remanent ferroelectric polarization at the nanoscale in epitaxial $PbZr_{0.52}Ti_{0.48}O_3$ thin films with a single DC bias. By driving the ferroelectric system towards an instability near the PZT morphotropic phase boundary and controlling the resulting softness via epitaxial strain, we favor the formation of decoupled nanometric 180° domains that exhibit a broad coercive field distribution. Using in-situ optical second harmonic generation and X-ray diffraction, we investigate the emergence of the nanoscopic domain configuration. We then use piezoresponse force microscopy to demonstrate the possibility to locally and reversibly modulate the remanent polarization continuously between depolarized and saturated, while preserving the nanoscopic length scale of the domains. We highlight the direct technological relevance of nanoscale non-binary polarization switching, by showing first, the voltage-controlled tunability

of the nonlinear optical response in our films and second, the quasi-continuous tunability of the tunnel electroresistance in ferroelectric tunnel junctions.

2:30 PM EQ09.02.04
Z-Cut Barium Titanate Electro-Optic Modulators for Silicon Photonics Agham Posadas[1,2], Vincent Stenger[3], John DeFouw[3] and Alex Demkov[1,2]; [1]The University of Texas at Austin, United States; [2]La Luce Cristallina, United States; [3]SRICO, Inc., United States

$BaTiO_3$ (BTO) is a ferroelectric material that exhibits one of the largest Pockels coefficients among electro-optic (EO) materials, with a coefficient as high as 1300 pm/V in the bulk. In addition to the substantially larger Pockels coefficient compared to the alternative $LiNbO_3$, BTO is much easier to integrate with Si. Epitaxial BTO integrated on Si or Si-on-insulator (SOI) is a promising materials platform for building EO modulators based on the Pockels effect that can be used for fast, low-power optical switches, with applications ranging from sensors to novel forms of computing including neuromorphic and quantum computing.
.
The complex refractive index for sputter-grown epitaxial BTO films on SOI was characterized over visible and near-infrared wavelengths via variable angle spectroscopic ellipsometry. The resulting index value was 2.280 at 1550 nm. This result was in line with values reported for optical grade BTO films. A slab waveguide loss test was done using a Metricon 2010 prism coupler measurement system with optical loss attachment. Slab loss was measured to be in the range of 1.0 to 1.5 dB/cm for fundamental transverse electric and transverse magnetic modes at 1550 nm wavelength.

The electro-optic modulation was also measured in transmission geometry for a-oriented films, and in slot waveguide geometry for both a- and c-oriented films. The effective Pockels coefficient for the a-oriented films (combination of r_{42} and r_{13} Pockels tensor components) is measured to be 180 pm/V, while that for c-oriented films (r_{33}) is 110 pm/V. These yield V_{π}-L values of 0.42 and 0.3 V-cm, respectively, for the a- and c-oriented films. These results show that off-axis sputtered BTO films can yield electro-optic modulation similar to that of high-quality MBE-grown films and that the material would be suitable for implementation of low power, small footprint Mach-Zehnder interferometer (MZI)-type electro-optic modulators integrated on silicon.

We have fabricated Z-cut waveguide phase-shifters, with the ridge waveguide being etched directly in BTO and designed to support a TM mode signal. One issue with the more common TE mode devices is that fields applied along the X-direction of the crystal to access r_{42} experience an extremely high dielectric constant, typically over 1000. This high dielectric constant directly translates to decreased EO modulation efficiency. In contrast, fields applied along the Z-direction to access the r_{33} Pockels component experience a more typical dielectric constant less than 60. This reduction in dielectric loading can more than offset the reduction in EO coefficient. Another benefit to Z-cut films is that they are more readily poled along the surface normal direction to produce a uniform polarization across the wafer. We show that Z-cut modulators in BTO are suitable for making compact optical switches that can be used in high density optical networks.

2:45 PM EQ09.02.05
Exploring New Functionalities in Antiferroelectric $PbHfO_3$-Based Material Systems Megha Acharya[1], Ella Banyas[1], Handong Ling[1], Djamila Lou[1], Maya Ramesh[1], Abel Fernandez[1], Arvind Dasgupta[1], Yizhe Jiang[1], Brendan Hanrahan[2], Gabriel Velarde[1], Jeffrey Neaton[1], Mark Asta[1], Kristin A. Persson[1] and Lane W. Martin[1]; [1]UC Berkeley, United States; [2]US Army Research Laboratory, United States

Perovskite-based antiferroelectric (AFE) materials are getting renewed interest due to their unique polar order and to their interesting electric-field-induced AFE-to-ferroelectric (FE) phase transition which make them potential candidates for applications including capacitive energy storage, electromechanical actuation, electrocaloric cooling, low-loss microwave dielectrics, memory, *etc.* – most being crucial for low-power electronics. Such materials have been studied considerably less than their FE cousins and what limited work does exists primarily focuses on a few archetypal systems such as $PbZrO_3$ and its derived phases. Here, we focus on another candidate AFE system and its interesting properties, namely $PbHfO_3$.
In this presentation, we will begin by exploring the structural, chemical, and electrical properties of AFE $PbHfO_3$ as epitaxial thin films. The $PbHfO_3$ films exhibit characteristic double-hysteresis loops with a saturation polarization ≈53 μC cm^{-2} at 1.6 MV cm^{-1}. Using chemical modification at both the lead and hafnium sites, we are further able to explore two very different functionalities in the resultant $PbHfO_3$-based solid solutions, pointing to the versatility of this material system. First, in $Pb_{1-x}Sr_xHfO_3$ we observe a strong increase in the electric-breakdown strength and decrease in hysteretic loss, thus enhancing the capacitive energy storage density (U_r) and efficiency (η) with values as high as 77 ± 5 J cm^{-3} (U_r) and 97 ± 2% (η); well out-performing many known AFE materials.[1] From there, we explore the $PbHf_{1-x}Ti_xO_3$ system wherein titanium substitution results in the evolution of both the structure and (di)electrical properties. For all compositions studied herein, ferroelectric behavior was observed while the structure undergoes a rhombohedral-to-tetragonal phase transition with increasing titanium content. Further, intermediate $PbHf_{1-x}Ti_xO_3$ compositions (*i.e.*, x = 0.4-0.55) exhibited a mixed-phase (rhombohedral + monoclinic + tetragonal) structure akin to the morphotropic phase boundary (MPB) observed in the well-studied $PbZr_{1-x}Ti_xO_3$ system. Owing to the structural evolution, an enhancement in the dielectric response was observed in the intermediate compositions pointing to the presence of an MPB-like behavior therein. Further, we also measured the electromechanical response for all the chemistries revealing the piezoelectric displacement values to be on par with that of $PbZr_{0.52}Ti_{0.48}O_3$ films in the same geometry.[2]
Ultimately, from the current work, both $PbHfO_3$-based solid solutions can be viewed as viable alternatives to the prevalent $PbZrO_3$-based systems, offering comparable, if not better, performance while being relatively less reactive with silicon, thus, lowering the risks of forming detrimental interfacial phases. While each of these studies is one of just a few reports on synthesis and characterization of $PbHfO_3$-based solid solutions as epitaxial films, they can motivate future research efforts involving more detailed evaluation of mechanisms for polar behavior in AFE and their derived phases, a topic which is less well understood.

Highly Enhanced Ferroelectricity in HfO_2-Based Ferroelectric Thin Film by Light Ion Bombardment Yunseok Kim; Sungkyunkwan University, Korea (the Republic of)

Continuous advancement in nonvolatile and morphotropic beyond-Moore electronic devices requires integration of ferroelectric and semiconductor materials. The emergence of HfO_2-based ferroelectrics that are compatible with atomic-layer deposition has opened interesting and promising avenues of research. However, the origins of ferroelectricity and pathways to controlling it in HfO_2 are still mysterious. In this presentation, I will present how we are able to enhance ferroelectricity in these materials by local He ion bombardment and discuss the possible competing mechanisms for highly enhanced ferroelectricity. Our piezoresponse force microscopy results indicate that the amplitude of piezoresponse in the ion-bombarded region increased by approximately twofold compared with that in the pristine region and the scanning transmission electron microscopy results show that the large

enhancement of ferroelectricity by He ion bombardment can be caused by a homogeneous distribution of oxygen vacancies and a phase transition to the ferroelectric phase. These findings both reveal the origins of ferroelectricity in this system and open pathways for nanoengineered binary ferroelectrics.

4:00 PM EQ09.02.07
$BaTiO_3$ Nanostructures on Si Fabricated by Neon Ion Milling Olaniyan I. Ibukun[1,2], Sebastian Schmitt[1], Dong-Jik Kim[1], Jürgen Albert[1], Rama K. Vasudevan[3], Michael Zachman[3], Veeresh Deshpande[1] and Catherine Dubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany; [3]Oak Ridge National Laboratory, United States

Ferroelectric nanostructures are of great interest for fundamental studies on scaling effects of ferroelectricity and as building blocks for ferroelectric-based nanoscale devices for low power, high density integrated circuits. In this study, we investigate the ferroelectric properties of $BaTiO_3$ cylindrical nanostructures on Si. Epitaxial $BaTiO_3$ thin films were grown by molecular beam epitaxy on $SrTiO_3$-buffered Si (100) substrates Nanopillars with different lateral dimensions (from 200 - 500 nm) were then fabricated using focused neon ion milling in a Zeiss Orion Nanofab microscope[1]. The unpatterned thin films were first characterized using X-ray diffraction, Raman spectroscopy, and piezoresponse force microscopy (PFM) showing *c*- axis orientation and a ferroelectric behaviour. Ferroelectricity in the neon ion milled nanostructures was investigated using band excitation piezoresponse force microscopy (BE-PFM)[2] and contact Kelvin probe force microscopy (cKPFM)[3]. Their crystalline structure, strain state, and polarization were studied at a local scale by scanning/transmission electron microscopy (S/TEM). We find an imprint and a maximal switchable response in the nanostructures that are dependent on their lateral dimension. The information gained from S/TEM will be discussed, emphasizing the effect of the pillar lateral dimensions on the polarization state. Finally, the potential damage caused by the ions during milling will be evaluated.

Ferroelectricity and Resistive Switching in $BaTiO_3$ Thin Films with Liquid Electrolyte Top Contact for Bioelectronic Devices Maximilian T. Becker, Poppy Oldroyd, Nives Strkalj, Moritz Mueller, George G. Malliaras and Judith L. MacManus-Driscoll; University of Cambridge, United Kingdom

We investigate ferroelectric- and resistive switching behavior in epitaxial 18-nm-thick $BaTiO_3$ (BTO) films in a model electrolyte-ferroelectric-semiconductor (EFS) configuration for ferroelectric microelectrode applications [1] in bioelectronics. BTO films are grown by pulsed laser deposition (PLD) on semiconducting Nb-doped (0.5 wt%) $SrTiO_3$ (Nb:STO) single crystal substrates. The
ferroelectric properties of the bare BTO films are demonstrated by piezoresponse force microscopy (PFM) measurements. Cyclic voltammetry (CV) measurements in EFS configuration, with phosphate buffered saline (PBS) acting as liquid electrolyte top contact, reveal characteristic ferroelectric switching peaks in the bipolar current-voltage loop. The ferroelectric nature of the observed switching
peaks is confirmed by analyzing the current response of the EFS devices to unipolar voltage signals. Moreover, electrochemical impedance spectroscopy (EIS) measurements indicate bipolar resisitive switching behavior of the EFS devices, which is controlled by the remanent polarization state of the BTO layer. Our results represent a constitutive step towards the realization of neuroprosthetic implants and hybrid neurocomputational systems based on ferroelectric microelectrodes.

Enabling Ultra-Low-Voltage Switching in $BaTiO_3$ Yizhe Jiang[1,2], Eric Parsonnet[1], Alexander Qualls[1], Wenbo Zhao[1], Sandhya Susarla[2], David Pesquera[1,3], Arvind Dasgupta[1], Megha Acharya[1,2], Hongrui Zhang[1], Tanay Gosavi[4], Chia-ching Lin[4], Dmitri E. Nikonov[4], Hai Li[4], Ian A. Young[4], Ramamoorthy Ramesh[1,2,1] and Lane W. Martin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC and BIST, Spain; [4]Intel Corporation, United States

While Moore's law, first put forth in 1964, dictates and guides that the density of transistors per chip should double every two years, Dennard scaling, put forth in 1974, which states that the voltage and current should scale with the size of the MOSFET device (*i.e.*, decreasing 30% every year) while maintaining the same power consumption per area, is arguably more important for microelectronics today. Such scaling is, however, getting increasingly difficult each year, especially when devices approach the fundamental physical and quantum limits (*e.g.*, increased leakage current, Boltzmann tyranny, etc.). Since around 2003, we have failed to keep track with Dennard scaling and keeping up with Moore's law has increased in difficulty. Therefore, researchers have started looking for alternative beyond-CMOS approaches to computation, where new physical variables are used for memories and computing logic (or logic-in-memory approaches). Such novel devices rely on order parameters such as spin, polarization, or strain as a pathway to lower power and device metrics, such as operation voltages <100 mV, operation energies <10 aJ/bit, and switching delays <0.1 ns serving as effective marching orders to the community. In this spirit, ferroelectric materials, with their non-volatile polarization states and low read/write energies (*e.g.,* single-crystal $BaTiO_3$ exhibits switching fields ~1 kV cm^{-1} and energies ~0.1 J cm^{-3}, with a remanent polarization ~26 μC cm^{-2}), are exciting candidates for next-generation devices (*e.g.*, ferroelectric-RAMs, ferroelectric-FETs, negative-capacitance FETs, etc.). The performance of ferroelectric thin films, however, has traditionally been significantly worse than their bulk counterparts (*i.e.*, large coercive fields, reduced remanent polarization) thus making them unsuitable for real memories and logic devices.

Here, we will present a pathway to synthesize $BaTiO_3$ thin films with high-quality and nearly bulk-like properties, including small coercive fields < 10 kV cm^{-1}, small switching energies < 2 J cm^{-3} (*i.e.*, < 2 aJ/bit in a 10×10×10 nm^3 device) and relatively large remanent polarization > 10 μC cm^{-2}. By scaling down the thickness of the films even further, we have also achieved small coercive voltages < 100 mV; an important metric for real applications of these materials. During the process of reducing film thickness, depolarization fields are found to play an increasingly important role, destabilizing the polar order and causing a reduction in remanent polarization. The depolarization fields, however, also suppress the coercive field scaling in $BaTiO_3$ thin films, stopping it from increasing as the thickness of the film decreases (a trend described by the Janovec-Kay-Dunn scaling law). In our case, we observe essentially thickness-independent coercive field evolution for films < 150 nm in thickness. Switching-dynamic studies, combined with lateral size scaling, predict the possibility for sub-nanosecond switching time in devices as large as 10 μm^2 (*i.e.*, capacitor diameters ~3.5 μm). Attempts to integrate the $BaTiO_3$ thin films onto silicon substrates have also been made, showing ferroelectric switching characteristics similar to films grown on scandate substrates, demonstrating the potential of these materials for real applications. We will also discuss recent efforts to further reduce the lateral size of devices to the sub-micron and even hundreds of nanometer length scales and corresponding switching dynamics studies of these devices. In this size regime, different ferroelectric switching mechanisms could co-exist and give rise to different time limits for ferroelectric switching (*e.g.*, RC charging time of the ferroelectric capacitor,

intrinsic domain-growth limit, nucleus size limit, etc.). Moreover, as the lateral size gets smaller, sub-nanosecond switching times are expected. We will explore the ultimate speed limit for switching in these materials.

4:45 PM EQ09.02.10
From Chemical and Structural Considerations to New Stable Nitride Perovskites—A High Throughput Study Bastien F. Grosso[1], Daniel W. Davies[1], Bonan Zhu[1], Aron Walsh[2] and David O. Scanlon[1]; [1]University College London (UCL), United Kingdom; [2]Imperial College London, United Kingdom

Nitride perovskites, with ABN_3 formula, have the potential to start a new paradigm in semiconductor devices. In this talk, we present a high throughput study of (AB)-N_3 compositional space and show how candidate materials can be identified using simple chemical and structural considerations. We further thoroughly explore the potential energy surface of our candidate materials using symmetry elements and ab initio random structure searching (AIRSS) in order to identify a possible ground state structure. The outcome of our workflow is twofold. On the one hand, we provide new insights on the ground state structure of already identified candidate compositions and on the other hand we propose new thermodynamically stable, likely synthesizable, nitride perovskites.

SESSION EQ09.03: Integrated Ferroelectrics
Session Chairs: Athanasios Dimoulas and Susan Trolier-McKinstry
Tuesday Morning, November 29, 2022
Sheraton, 2nd Floor, Back Bay D

8:30 AM *EQ09.03.01
Hafnium-Based Ferroelectric Artificial Synapses on Silicon for Low Power In-Memory Computing Athanasios Dimoulas[1], Nikitas Siannas[1,2], Christina Zacharaki[1,2] and Polychronis Tsipas[1]; [1]NCSR Demokritos, Greece; [2]National and Kapodistrian University of Athens, Greece

The handling of a large number of inhomogeneous data requires artificial intelligence, energy efficiency and security which will all benefit from advancements in neuromorphic computing.
Ferroelectric multistate non-volatile memories based on Si-compatible Zr-doped Hafnia (HZO) [1] show promise for low power analog in-memory computing. They appear in different device "flavors" such as Ferroelectric Random Access Memory (FeRAM), Ferroelectric Field Effect Transistors (FeFET) [2] and Ferroelectric Tunnel Junctions (FTJ). The main focus in this presentation will be on FTJ-based devices which are resistive two terminal devices with non-destructive reading and excellent integration capability at the back-end of line of CMOS.
The work of ferroelectric HZO on Ge (100) substrates prepared by atomic oxygen deposition [3] in an MBE chamber will be presented first, covering performance and reliability characteristics (endurance and retention) [4]. When HZO thickness is scaled below 10nm, as necessary for FTJ devices, ferroelectric loop pinching and reduction of remanent polarization are observed which however recover after field cycling (“wake-up”). This behavior will be explained [5] in terms of depolarization fields in the framework of Landau-Devonshire theory.
Subsequently, it will be shown that MFS devices in the FTJ configuration with 5 nm HZO and SrTiO3 (STO) semiconductor bottom electrode behave as analog memristors with more than 16 intermediate non-volatile states (corresponding to 4-bit memory cell) which can be accessed by sequential identical or variable width/amplitude pulses. Devices are defined on bulk n-type Nb:STO (NSTO) and 20 nm thick epitaxial $SrTiO_{3-\delta}$ on Si (100) substrates deliberately prepared oxygen deficient by annealing in vacuum to induce n-type conductivity to the STO. It is found that the memristor devices on epi n-STO present a very good yield, robust ferroelectricity and excellent synaptic plasticity (potentiation and depression). The synaptic conductance weights G can be varied between max and min values in a dynamic range $G_{max}/G_{min} > 3$ showing potentiation and depression which emulate a biological synapse. The programming voltage is very low (~ 1-2 V) in full compatibility with voltage scaling trends in advanced CMOS, indicating that our devices are suitable for very low power memory operation. No retention loss was observed at room temperature for $>10^4$ sec.
Finally, future 3D integration schemes directly on Si with side wall FTJs will be discussed which result in very dense cross bar arrays as the main building block of low power analog in memory AI accelerators based on FTJs

Ferroelectric Diodes for Reconfigurable Compute-In-Memory Xiwen Liu, John Ting, Fiagbenu Fiagbenu, Jeffrey Zheng, Dixiong Wang, Pariasadat Musavigharavi, Eric A. Stach, Troy Olsson and Deep M. Jariwala; University of Pennsylvania, United States

The deluge of sensors and data generating devices has driven a paradigm shift in modern computing from arithmetic-logic centric to data centric processing. At a hardware level, this presents an urgent need to integrate dense, high-performance and low-power memory units with Si logic-processor units. However, data-heavy problems such as search and pattern matching also require paradigm changing innovations at the circuit and architecture level to enable compute in memory (CIM) operations. CIM architectures that combine data storage yet concurrently offer low-delay and small footprint are highly sought after but have not been realized. Here, we present Aluminum Scandium Nitride (AlScN) ferroelectric diode (FeD) memristor devices that allow for storage, search and neural network-based pattern recognition in a transistor-free architecture. Our devices can be directly integrated on top of Si processors in a scalable, back-end-of-line process. We leverage the field-programmability, non-volatility and non-linearity of FeDs to demonstrated circuit blocks that can support search operations in-situ memory with search delay times < 0.1 ns and a cell footprint < 0.12 μm 2 . In addition, we demonstrate matrix multiplication operations with 4-bit operation of the FeDs. Our results highlight FeDs as promising candidates for fast, efficient, and multifunctional CIM platforms.

Negative Capacitance Electronics—Manipulating Ultrathin Ferroelectricity in HfO_2-ZrO_2 on Silicon Suraj Cheema[1,1], Nirmaan Cheema[1], Shang-Lin Hsu[1] and Sayeef Salahuddin[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

The two-dimensional (2D) limit of ferroelectricity has extensive technological implications for the scaling of low power electronics. In particular, the negative capacitance (NC) effect in ferroelectrics has emerged to overcome fundamental computing energy limits [1]. However, advanced semiconductor technology integration requires NC stabilization at the ultrathin regime on silicon, posing significant materials challenges for conventional ferroelectrics.

To address this, we first established ultrathin ferroelectric order down to 1-nm and 5-Å thickness in doped HfO_2 [2,3] and conventionally antiferroelectric ZrO_2 [4], respectively, the same high-κ dielectrics used in today's advanced logic and memory technologies. These binary oxide films grown by atomic layer deposition on silicon boast ultrathin-enhanced polarization signatures [2-4] – in stark contrast to conventional perovskite oxide ferroelectrics – marking a breakthrough towards exploiting ferroic-based phenomena at ultra-scaled dimensions for electronics. Next, we leveraged the competing atomic-scale (anti)ferroelectric orders to design NC in sub-2-nm HfO_2-ZrO_2 superlattices [5] and 1-nm ZrO_2 [6], the gate oxide thicknesses required for today's state-of-the-art transistors and future 3D transistors, respectively. In contrast to previous NC reports, the microscopic origin of NC in these ultrathin films arises from mixed ferroelectric-antiferroelectric order. Furthermore, this work establishes the first demonstrations of capacitance enhancement – smoking-gun evidence of NC – in the technologically-relevant HfO_2–ZrO_2 system. This results in record-low equivalent oxide thicknesses, promising for ultralow-power transistor operation. Accordingly, this seamless materials swap – conventional high-κ dielectric HfO_2-ZrO_2 to (anti)ferroelectric HfO_2-ZrO_2 – demonstrates key performance benefits in NC transistors compared to established semiconductor foundry benchmarks [5,6].

Therefore, leveraging these materials breakthroughs at the 2D limit – ferroelectricity [2-4] and negative capacitance [5-6] – provides a realistic pathway towards energy-efficient electronics via integrated ferroelectrics. And from a thin film perspective, this approach to exploit 3D materials confined to the 2D limit – particularly within this simple binary oxide model system hosting unconventional and emergent ferroelectric size effects [2-4] – offers an atomic-scale approach to unlock previously hidden electronic phenomena [4-6].

New Materials for Three-Dimensional Ferroelectric Microelectronics Susan E. Trolier-McKinstry; The Pennsylvania State University, United States

Computing accounts for 5 – 15% of worldwide energy consumption. In the U.S., data centers alone consumed approximately 73 billion kWh in 2020. While recent efficiency gains in hardware have partially mitigated the rising energy consumption of computing, major gains are achievable in a paradigm shift to 3D computing systems, especially those that closely couple memory and logic. In the last decade, there have been major changes in the families of ferroelectric materials available for integration with CMOS electronics. This presentation will focus on new ferroelectrics with the wurtzite crystal structure, especially $Al_{1-x}B_xN$ and $Zn_{1-x}Mg_xO$, as materials that can be deposited at temperatures compatible with the back-end-of-the line (<400°C). Both sets of materials have large polarizations (75 – 125 μC/cm^2), with large, but strongly temperature-dependent coercive fields. The pseudo-activation energy for the coercive fields is on order 20 – 40 meV. As deposited, the films are (predominantly) unipolar. A wake-up process is therefore needed to nucleate new domain orientations; this process differs from the mechanisms for wake-up in perovskite or fluorite-based ferroelectrics.

10:30 AM EQ09.03.08
Ionic Bonds Control Ferroelectric Behavior in Wurtzite Nitrides Keisuke Yazawa[1,2], John Mangum[1], Prashun Gorai[2,1], Geoff L. Brennecka[2] and Andriy Zakutayev[1]; [1]National Renewable Energy Laboratory, United States; [2]Colorado School of Mines, United States

Ferroelectricity enables key integrated technologies from non-volatile memory to precision ultrasound. Wurtzite ferroelectric $Al_{1-x}Sc_xN$ has recently received significant attention because of its enhanced piezoelectric response [1], robust ferroelectricity [2] and Si process compatibility in addition to being the first known ferroelectric wurtzite. Since the discovery of the ferroelectricity of the material system, chemistry, stress, strain, and film thickness have been rigorously investigated to control ferroelectricity in this material system [2-5]. However, the origin and control of ferroelectricity in wurtzite materials is not yet fully understood. Understanding the root cause is important for coercive field engineering and new wurtzite ferroelectric material discovery to achieve low-power electronic applications such as non-volatile memories.

A part of hinderance for understanding the new wurtzite ferroelectric physics comes from the fact that the prior studies of ferroelectricity in $Al_{1-x}Sc_xN$ included explicit and implicit variables such as residual strain state, process parameters, target condition, chamber type, substrate type/treatment, etc. These variables convolute experimental effects, and the resulting data scatter can easily mask important but unrepresented factors such as microstructure and defects. Combinatorial techniques reduce uncontrolled process variables because a single film library can include all samples of interest and also offer significant advantages for rapid screening.

In this talk, we demonstrate that the local bond ionicity, rather than simply the change in tetrahedral distortion, is key to controlling the macroscopic ferroelectric response, according to our combinatorial film synthesis/characterization experiment and computational approach. Across the composition gradient in $Sc < 0.35$ range and 140 – 260 nm thickness in combinatorial thin films of $Al_{1-x}Sc_xN$, the pure wurtzite phase exhibits a similar *c/a* ratio regardless of the Sc content, due to elastic interaction with neighboring crystals. The coercive field and spontaneous polarization significantly decrease with increasing Sc content despite this invariant *c/a* ratio, due to the more ionic bonding nature of Sc-N relative to the more covalent Al-N bonds, supported by DFT calculations. Based on these insights, ionicity engineering is introduced as an approach to reduce coercive field of $Al_{1-x}Sc_xN$ for memory and other applications and to control ferroelectric properties in other wurtzite materials.

Novel Non-Perovskite Ferroelectric Oxides and Nitrides Jon-Paul Maria, John Hayden, Wanlin Zhu, Devin Goodling and Susan Trolier-McKinstry; Pennsylvania State University, United States

Ferroelectricity in wurtzite-based crystals was observed in 2019 and immediately introduced exciting opportunities to explore and discover new structure-property relationships in novel formulation spaces, and to investigate new integration and device implementations given new process compatibilities. The seminal discovery of ferroelectric $Al_{1-x}Sc_xN$ by University of Kiel reserchers initiated this excitement and was followed by comparable observations of polarization reversal in the structurally similar $Al_{1-x}B_xN$ and the $Zn_{1-x}Mg_xO$ systems. These observations lead one to speculate that ferroelectricity might be found much more broadly, even “everywhere”, by introducing the appropriate disorder.

In this presentation the structure-process-property relationships in the B-substituted AlN and Mg-substituted ZnO wurtzite systems will be demonstrated. The B-substituted materials exhibit square hysteresis loops with polarization values between 150 $\mu C/cm^2$ and 120 $\mu C/cm^2$ when boron concentrations range between 2% and 15% respectively. Coercive field values fall with additional boron, from 5.5MV/cm to about 5 MV/cm at B saturation. Bandgap values are approximately 5 eV or above in all cases. Material can be prepared between 100 °C and 350 °C with very little difference in electrical properties. W bottom and top electrodes are used in all cases. Capacitors can be prepared down to 50 nm thick before leakage current becomes problematic during low frequency hysteresis measurements.

Comparable results are found in the $Zn_{1-x}Mg_xO$ system. Between 25% and 35% Mg substitution, square hysteresis loops with remanent polarization values above 100 $\mu C/cm^2$ are readily achieved. Transmission measurements show bandgap values between 4.0 eV and 4.2 eV in this range. In comparison to AlBN, coercive field values for ZMO are as low as 1.7 MV/cm.

In addition to a discussion of properties and preferred synthesis routes, we will discuss the limitations to property engineering and scaling, and provide a complete update on observations/explorations in additional compositional and structural families. Finally, we will present our efforts to integrate these new ferroelectric crystals using "ground rules" that are consistent with the conventional semiconductor back end, addressing issues of temperature, chemical reactions, CMOS-accepted elements, and crystallographic texture.

11:00 AM EQ09.03.10
The Role of Disorder in Ferroelectric Aluminum Scandium Nitride Xiaoman Zhang[1], Andrew C. Meng[2,3] and Wen J. Meng[1]; [1]Louisiana State University, United States; [2]University of Pennsylvania, United States; [3]University of Missouri–Columbia, United States

Aluminum scandium nitride (AlScN) thin films have shown promise as a potential ferroelectric material for neuromorphic computing hardware applications. We report epitaxial growth of AlScN thin films on Si (111) at 800°C by ultra-high-vacuum reactive sputtering, with Sc compositions ranging from 0-39 at%. Structural characterization using x-ray diffraction and transmission electron microscopy shows the wurtzite to rocksalt structural transition occurring beyond 30 at% Sc. Sc incorporation into aluminum nitride (AlN) introduces two types of disorder. First, phase segregation at intermediate Sc compositions is observed, suggesting a miscibility gap in this alloy. Second, increasing width of nitride film diffraction features in the in-plane direction as the Sc composition increases suggests that disorder is directly related to Sc alloying. From these observations, we can define a disorder parameter and find that ferroelectricity in AlScN is correlated with an optimum level of disorder in the material.

SESSION EQ09.04: Low-Power CMOS
Session Chairs: Catherine Dubourdieu and Sasikanth Manipatruni

1:30 PM *EQ09.04.01
Quantum Materials Enabling Beyond CMOS Low Energy Compute John Plombon, Punyashloka Debashis, Dmitri E. Nikonov, Mahendra DC, Dominique Adams, Chia-ching Lin, Scott B. Clendenning, Marko Radosavljevic and Ian A. Young; Intel Corporation, United States

Since the proposal of the MESO logic device [1,2] by the Intel Corporation, the search for materials to realize energy efficient computing on the order of 1 aJ/bit has made much progress.

The importance of a highly energy efficient switch is detailed in the Semiconductor Research Corporation Decadal Plan for Semiconductors [3] which highlights that compute energy is a significant and growing percentage of the global energy production and is on an exponential growth path. The development of substantially lower energy switches is a key ingredient in building a sustainable compute ecosystem.

In the proof-of-concept MESO device [4], the magneto-electric (ME) material was $BiFeO_3$, the magnet was $Co_{0.9}Fe_{0.1}$, and the spin-orbit (SO) coupling material was Pt all deposited on $DyScO_3$ substrate. The ME material was deposited with pulsed laser deposition (PLD) and the magnet and SO material were deposited with magnetron sputtering (PVD). The ultimate MESO device will most likely be very different from the proof-of-concept device with some or all portions of the stack being deposited by other means meeting manufacturability requirements.

Two areas of disruption will be the substrate and the SO material. One path forward for a substrate compatible with a front-end of line integrated MESO device is epitaxial $SrTiO_3$ on Si. The path for material integration for back-end of line is wide open and new ideas are to be explored to enable epitaxial materials on amorphous substrates. The area of SO materials is a grand challenge for the research community with the goal of achieving nearly perfectly efficient spin-to-charge conversion in spin-orbit materials, topological insulators or other novel material systems.

The ME stack is within 4x of the goal of +/- 50mV switching voltage [5] but it has challenges of controlling built-in potentials that can easily exceed the switching voltage specification. Understanding, measuring, and controlling built-in potentials of the ME stack is another grand challenge for the research community that needs to be explored. The nano-magnet material will most likely move to a system that is more compatible with the ME complex oxides

and oxide ferromagnets.

Uniting the ME and SO parts of the MESO device will require manufacturable deposition processes that can scale to large substrates. This will require either innovations in the hardware for depositions techniques such as MBE and PLD, typically associated with epitaxial complex oxide film growth, or a transition to appropriately tuned versions of the more traditional high volume film growth techniques of atomic layer deposition (ALD), chemical vapor deposition (CVD) or (off-axis) physical vapor deposition (PVD). The relative merits and readiness of these film growth technologies for the manufacture of the MESO device will need to be explored.

With the need to drive for lower energy consumption for computing evident, this talk will explore the latest status of the MESO logic device as a path forward with a focus on the key role that quantum materials play in its realization.

Vertically-Integrated, Multivalued Logics from Heterojunction Transistors for Low Power and High-Efficiency Computing Hocheon Yoo; Gachon University, Korea (the Republic of)

Multivalued logic (MVL) circuits can significantly improve data processing efficiency based on additional logic states in new systems, potentially providing the development of high density information computing [1]. Multivalued logic circuits can be implemented by adopting a structure of heterojunction thin-film transistors (H-TR), where p- and n-type thin-film layers with a partial junction of each layer in contact with only one of the source and drain contact electrode. The above-described H-TR structure does not increase the number of transistors required to implement a multi-value logic operation, so that an additional state can be formed during circuit switching while maintaining the existing digital circuit structure. In this talk, I introduce recent efforts in our group to implement MVL by controlling negative differential transconductance (NDT). I also present our representative MLV development examples: (i) full swing ternary logics [2], (ii) asymmetric contact-based ternary logics [3], (iii) flexible ternary logics [3], and (iv) vertically-integrated ternary logics [4]. By presenting a comprehensive strategy for H-TRs-based MVL in various structures, this talk suggests that MVL is one of the emerging applications from new switching behaviors in transistors.

High Mobility InAs and InP Grown Directly on Amorphous Dielectrics at BEOL Compatible Temperatures Debarghya Sarkar[1,2] and Rehan Kapadia[2]; [1]Harvard University - Massachusetts General Hospital, United States; [2]University of Southern California, United States

A fundamental requirement to realize 3D integrated circuits is the ability to integrate single crystal semiconductor devices on the back-end of functional layers within a thermal budget of ~400 °C. Present state-of-the-art methods involve wafer bonding or epitaxial growth and transfer, since directly growing on amorphous materials by traditional epitaxial growth processes like MOCVD and MBE would give polycrystalline films with submicron-scale grains. To that end, a newly introduced and actively developing growth method called Templated Liquid Phase (TLP) has demonstrated the ability to achieve single crystal compound semiconductor mesas of areal dimension ~10um diameter on diverse amorphous substrates. While initial demonstrations of TLP growth were at temperatures around 500-600 °C, in this presentation we would discuss some of the recent material characteristics and device results achieved and insights obtained, for crystalline InP mesas grown on amorphous dielectrics at temperatures below 400 °C. The optoelectronic quality of InP is optimal when it is grown at 300 °C, a temperature which is low enough to enable back-end-of-line growth on fully fabricated Si complementary metal oxide semiconductor circuits. Excellent on/off ratios are demonstrated by nanosheet transistors fabricated using this low-temperature grown InP, with the fabrication process also entirely carried out at 300 °C or below. InAs grown by this method showed room temperature mobility of ~5800 cm^2/V-s, the highest mobility reported for any thin-film semiconductor material system directly grown on a nonepitaxial substrate, and which is close to reported values of epitaxially grown materials.

2:30 PM EQ09.04.04
Tuning Electrical Properties by High Electronegativity Dopant for Ambipolar Zinc Nitride Semiconductor Ji-Min Park[1], Kwun-Bum Chung[2] and Hyun-Suk Kim[1]; [1]Chungnam National University, Korea (the Republic of); [2]Dongguk University, Korea (the Republic of)

High-performance complementary metal–oxide–semiconductor (CMOS) integrated devices and circuits are widely used from memory devices to image sensors, logic devices, and switching and driving devices in displays. In the case of silicon-based CMOS, transfer printing technology is essential, which greatly increases the process cost. Therefore, it is necessary to develop NMOS and PMOS fabrication technologies capable of a direct deposition process on a substrate. On the other hand, high-density unipolar p-type and n-type (non-Si based) transistors are each individually fabricated with different semiconductor materials and integrated to form logic circuits. The separation process requirements of circuits further complicate the manufacturing process. In contrast, ambipolar transistors that can implement both p-type and n-type characteristics with a single material, are promising candidates for highly integrated CMOS circuits with effectively simplified designs.
So far, ambipolar semiconductor materials have been mainly reported based on copper nitride or organic/inorganic perovskite. However, copper nitride is not suitable for mass production and commercialization because high-temperature epitaxial growth is required during the deposition process. On the other hand, organic/inorganic perovskite has the advantage of being able to have both n-type and p-type properties as a single material. But, there is a problem that mobility is very low and unstable, so it is easily decomposed in the atmosphere. In order to overcome this limitation, it is necessary to develop a new ambipolar semiconductor material capable of large-scale deposition and excellent electrical properties.
Herein, the nitride-based semiconductor materials fabricated by the sputtering process at room temperature are proposed as the ambipolar semiconductor

material, which is advantageous for a large area and mass production. The fluorine (F) which has the high electronegativity can act as an acceptor when incorporated as an interstitial dopant in the Zn_3N_2 matrix. Therefore, both n- and p-type characteristics can be achieved through a single Zn_3N_2 material by controlling the amount of F during the sputtering deposition process. As a result, F-incorporated zinc nitride TFTs exhibited symmetric ambipolar properties with high field-effect mobility. Also, the CMOS-like inverters composed of two Zn_3N_2 ambipolar TFTs has been successfully implemented with excellent voltage gain characteristics. These characteristics offer the applicability to low-cost, large-area and high-efficiency CMOS circuits.

2:45 PM EQ09.04.05
Controlling Electrical Behavior Using a Magnetic Field in Early-Stage Memrectifiers Guinevere Strack[1], Jin Ho Kim[2], Alkim Akyurtlu[1] and Richard M. Osgood[2]; [1]University of Massachusetts Lowell, United States; [2]US Army Combat Capabilities Development Command Soldier Center, United States

Rectification is a nonlinear optical process through which power and energy can be harvested by subtracting photon energies. This process can be harnessed to enable lightweight power generating devices that could eventually replace or supplement finite power sources, such as batteries. Rectennas are antennas, with sub-wavelength dimensions that, at resonance, intensify the electric field when combined with metal–insulator–metal (MIM) barrier structures (diodes) that have nonlinear, asymmetric conductivity. Minimizing the external power required to drive or control device performance will increase the net power output of rectennas. Pulsing a magnetic switch requires very small amounts of input energy, compared to the amount of energy lost in CMOS-style capacitive memory (to leakage currents, currents required to change gate voltages, etc.).

This presentation will focus the fabrication and characterization of on an early stage ‘memrectifier’, comprised of ferromagnetic material. In this effort, we explored the magnetic reconfigurability of simple thin film devices, magnetic ‘memrectifiers’, which are nonlinear electrical devices that ‘remember’ a previous state or electrical behavior. Early stage memrectifiers were designed, fabricated, and electrically characterized in the presence of an applied magnetic field. The early-stage memrectifiers were comprised of several nanometric layers (Nb–Nb_2O_5–Co–Au). The ferromagnetic material, Co, was incorporated into the MIM diode to enable changes in electrical characteristics in the presence of a magnetic field. Niobium was deposited as the first metallic layer. The dissimilar metals, Nb and Co, were separated by the niobium oxide dielectric barrier layer, which was deposited in layers of varying thickness. The effect of the dielectric layer thickness, electrical characteristics, and magnetic reconfigurability were measured, and used to direct fabrication and design strategies.

Electrical characterization was carried out and J–V curves were obtained in the presence and absence of a magnetic field. The diode was subjected to three consecutive sweeps to test the repeatability of the electrical properties. On the fourth sweep, a magnet was placed next to the sample during the current–voltage sweep. The magnet was removed and then four more current–voltage sweeps were applied to the diode. The current density increased from 0.049 to 0.81 A cm^2, a 20-fold change. Control I–V curves obtained on gold films have revealed that the electrical characteristics are slightly changed in the presence of a magnetic field; however, the subsequent current-voltage sweeps revert to the initial electrical characteristics when the magnetic field is removed. Although this preliminary result is promising, additional experiments are needed before concluding that the change in electrical performance is indeed due to the magnetic field’s affecting the magnetic materials. In addition, the effect of the applied voltage and current in the presence of the magnetic field on the ‘remembered’ electrical state will be studied.

3:30 PM EQ09.05.02
Sub-10K Cold-Electron Injection to Silicon at Room Temperature Pushkar K. Gothe[1], Anthony Martinez[1], Ojas T. Bhayde[1], J. Tyler Gish[2], M. R. Tiscareno[1], Jiechao Jiang[1], Joseph Ngai[1], Efstathios Meletis[1], Mark C. Hersam[2] and Seong Jin Koh[1]; [1]The University of Texas at Arlington, United States; [2]Northwestern University, United States

The root cause of the excessive power consumption (or excessive heat dissipation) of modern large-scale integrated circuits is the intrinsic thermal excitation of electrons that follows the Fermi-Dirac distribution. The hot electrons at the Fermi-Dirac distribution tail overcomes the OFF-state energy barrier of transistors, leading to inadvertent large electron flows and thereby large OFF-state power consumption. Here we represent an approach in which thermally exited electrons are filtered by a quantum well (QW) state and only energy-filtered cold electrons are injected to semiconductor conduction band. We demonstrate that the energy filtering enables transport of extremely cold electrons, whose effective electron temperature can reach as low as 7 Kelvin at room temperature. The electron energy filtering structure was fabricated on a wafer scale using CMOS-compatible processes and materials. The energy filtering stack is composed of source metal (Cr), first tunneling barrier (0.5-1 nm Al_2O_3 or Si_3N_4), QW layer (1-5 nm SnO_2 or 2 nm Cr_2O_3), second tunneling barrier (1.5-2 nm SiO_2), and Si. Electrons are tunneled from the source to a QW state, and then energy-filtered cold electrons are tunneled from the QW state to Si conduction band. Room-temperature current-voltage (I-V) measurements showed extremely abrupt current jumps, which correspond to alignments of the QW levels with the conduction band edge of Si. Differential conductance (dI/dV) plots show narrow peaks, with their FWHMs (full widths at half maximum) only ~2 mV, corresponding to an effective electron temperature of 7 Kelvin at room temperature. This cold-electron injection demonstrated for a Si system has a potential to realize steep subthreshold swing of much less than 60 mV/decade at room temperature, leading to energy-efficient low-power transistors.

Growth of Topological Semimetal Cobalt Monosilicide for Scaled Back-End-of-Line Interconnects Yansong Li, Guanyu Zhou and Christopher Hinkle; University of Notre Dame, United States

The resistivity of conventional metal interconnects increases rapidly with decreasing size which causes high energy consumption with severe signal delay.

Electron scattering at surfaces and grain boundaries are found to be the main causes of this size effect. Topological semimetals, which can effectively suppress electron scattering at surfaces, are believed to be promising candidates to replace currently used conventional metals. CoSi, a topological semimetal with multifold fermions, possesses unique topologically protected surface states that are expected to decrease resistivity at scaled dimensions where surface transport dominates.
Here, we demonstrate the growth of CoSi thin films and single-crystal CoSi nanowires. CoSi thin film growth is achieved on c-plane sapphire and GaN substrates by MBE. Multiple characterization techniques including RHEED, HRXRD, and Raman microscopy are utilized for optimizing growth conditions and realizing single-phase CoSi thin film growth. CoSi nanowires are obtained by co-depositing Co and Si on HOPG substrates via MBE. By carefully controlling the Co flux and growth temperature, the CoSi nanowire dimensions and yield can be controlled and the single-crystal and single-phase nature of the CoSi nanowire are confirmed by TEM and EDX. We also demonstrate a new approach to transferring CoSi nanowires from the HOPG substrate to another carrier wafer by only introducing and freezing DI water. And four-probe devices were made on transferred nanowires via electron beam lithography for measuring the CoSi nanowire resistivity. We will discuss both the thin film and nanowire results, including the impact of in-plane texturing as well as the benefits of the nanowire synthesis. We will discuss resistivity vs. dimension and provide an outlook for using CoSi as scaled interconnects. This work was supported by IMPACT, a center in nCORE, a Semiconductor Research Corporation (SRC) program.

4:00 PM EQ09.05.04
Resistivity Scaling in CuTi and $CuAl_2$ Intermetallics for Narrow Interconnects Minghua Zhang and Daniel Gall; Rensselaer Polytechnic Institute, United States

The electrical resistivity ρ as a function of thickness d = 5.8-149/10.2-141 nm of epitaxial CuTi(001) and $CuAl_2$(001) layers is measured to quantify the resistivity size effect of these compound conductors and evaluate their promise as a replacement material for Cu in highly scaled interconnect lines in microelectronic devices. The layers are deposited by magnetron co-sputtering onto MgO(001) substrates and their epitaxy is confirmed by x-ray diffraction θ-2θ scans, ω rocking curves and φ-scans. The surface morphology is quantified by x-ray reflectivity and atomic force microscopy, and the composition measured by photoelectron spectroscopy and Rutherford backscattering. Data fitting of the measured ρ vs d yields room-temperature electron mean free paths λ = 12.5 and 15.6 nm for CuTi and $CuAl_2$, respectively, and bulk resistivities ρ_o = 19.2 ± 0.8 and 7.7 ± 0.4 μΩ cm. Air exposure causes surface oxidation and a resistivity increase for both intermetallic compounds which is attributed to a transition from partially specular to completely diffuse electron surface scattering. CuTi in direct contact with SiO_2 exhibits a 500 times longer failure time than Cu during room-temperature time-dependent dielectric breakdown (TDDB) tests using a 3 MV/cm bias. The overall analysis yields $\rho_o\lambda$ benchmark values of 24×10^{-16} and 12×10^{-16} Ωm^2, respectively, indicating that the evaluated compound conductors exhibit a conductivity advantage against Cu only if their higher cohesive energies and stability is exploited to achieve liner-free lines.

Amorphous Gallium Nitride by Low-Temperature MOCVD Growth for Back-End-Of-Line Transistors Tian Sun, Guanyu Zhou, Jaemin Shin and Christopher Hinkle; University of Notre Dame, United States

GaN is a promising material for BEOL access transistors due to its high electron mobility, large bandgap (for low leakage), and stability in a hydrogen environment (to minimize V_t variability). However, GaN is normally grown at temperatures (~1000 °C) much higher than the 450 °C typically considered BEOL-compatible. Due to the lack of thermal energy, metal-organic chemical vapor deposition (MOCVD) precursor decomposition is less efficient and adatom diffusion is insufficient, preventing the growth of high-quality GaN using typical growth strategies under BEOL constraints.

Amorphous GaN has been proposed as a promising material for electronic applications [1]. Here, we demonstrate the growth of amorphous GaN at BEOL compatible temperatures ≤ 450 °C by MOCVD with electrical properties starting to approach those necessary for access transistors. Through a detailed study of the growth conditions such as the V/III ratio of the precursors and low-temperature BEOL-compatible anneals, we were able to obtain amorphous GaN (as confirmed by XRD) with a 3.2 eV bandgap as measured by UV-Vis. Room temperature mobilities of 10-15 cm^2/V-s are demonstrated and initial transistors exhibit I_{on}/I_{off} ratios greater than 10^7 with subthreshold swings ~110 mV/decade. Crystalline GaN, grown using conventional two-step growth methods, shows a steep drop-off in mobility from the 350 cm^2/V-s when grown at 1000 °C down to 0 when grown at 450 °C. Our amorphous GaN grown at 450 °C has electrical properties that are comparable to crystalline GaN grown at ~750 °C. We will discuss the role of oxygen incorporation to suppress electron carrier concentrations and will provide detailed characterization of the films from XPS, Raman, TEM, XRD, EDX, and EXAFS.

SESSION EQ09.06: Magnetoelectrics and Multiferroics
Session Chairs: Manuel Bibes and Ramamoorthy Ramesh
Wednesday Morning, November 30, 2022
Sheraton, 2nd Floor, Back Bay D

8:15 AM *EQ09.06.01
Voltage and Current Controlled Nanomagnetism for Memory and Logic Ramamoorthy Ramesh; University of California, Berkeley, United States

Complex perovskite oxides exhibit a rich spectrum of functional responses, including magnetism, ferroelectricity, highly correlated electron behavior, superconductivity, etc. The basic materials physics of such materials provide the ideal playground for interdisciplinary scientific exploration with an eye towards real applications. Over the past decade the oxide community has been exploring the science of such materials as crystals and in thin film form by creating epitaxial heterostructures and nanostructures. Among the large number of materials systems, there exists a small set of materials which exhibit multiple order parameters; these are known as multiferroics, particularly, the coexistence of ferroelectricity and some form of ordered magnetism (typically antiferromagnetism). The scientific community has been able to demonstrate electric field control of both antiferromagnetism and ferromagnetism at room temperature. In parallel, there are some very intriguing new developments in SOT based manipulation of magnets. Particularly, the role of epitaxy and electronically perfect interfaces has been shown to significantly impact the spin-to-charge conversion (or vice versa). Under funding from the US. Department of Energy and the SRC-DARPA-JUMP funded ASCENT Center, current work is focused on ultralow energy (1 attoJoule/operation) electric

field manipulation of magnetism with both voltage and current, as the backbone for the next generation of ultralow power electronics. We are exploring many pathways to get to this goal. In this talk, I will describe our progress to date on this exciting possibility. The talk will conclude with a summary of where the future research is going.

8:45 AM EQ09.06.02
Magnetization Reversal in $BiFe_{0.9}Co_{0.1}O_3$ Thin Films 1- Spin Structure and Magnetization Reversal by Electric Field at Room Temperature in Co-Substituted Bismuth Ferrite Thin Film Kei Shigematsu[1,2], Keisuke Shimizu[1], Ryo Kawabe[1], Hajime Hojo[3], Haruki Shimizu[1], Marin Katsumata[1], Hajime Yamamoto[4], Ko Mibu[5] and Masaki Azuma[1,2]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan; [3]Department of Energy and Material Science, Kyushu University, Japan; [4]Tohoku University, Japan; [5]Nagoya Institute of Technology, Japan

Electric-field control of magnetism in multiferroic materials is a significant challenging issue on the development of novel low-energy-consuming nonvolatile memory devices. Perovskite bismuth ferrite $BiFeO_3$ is widely studied multiferroic material because of strong magnetoelectric coupling between the electrical polarization and antiferromagnetic magnetic ordering above room temperature, but $BiFeO_3$ does not show such spontaneous magnetization due to the presence of cycloidal spin modulation superimposed on G-type antiferromagnetism. Cobalt-substitution is one of the powerful ways to modify the electric and magnetic properties of $BiFeO_3$. Partial substitution of Co for Fe stabilizes the collinear phase with weak ferromagnetism preserving the *R*3*c* crystal structure. Neutron powder diffraction and Mössbauer spectroscopy measurements revealed a change in the spin structure from a cycloidal one at low temperature to a collinear one at room temperature. However, because the magnetic structure of $BiFeO_3$ is quite sensitive to lattice strain, the choice of single crystal substrate for thin film growth is of great importance.
Here we grew a single-phase ferromagnetic ferroelectric $BiFe_{0.9}Co_{0.1}O_3$ thin film grown on $GdScO_3$ substrate. The conversion electron Mössbauer spectroscopy on a nearly 100% ^{57}Fe-enriched thin film sample revealed the collinear spin structure, whereas the spectrum of the BFO thin film on the same substrate showed a cycloidal spin structure. The value of quadrupole shift was close to that of bulk BFCO (−0.20 mm/s) and that of (111)pc-oriented BFCO thin films (−0.217 mm/s), strongly suggesting that the spins are aligned perpendicular to the electric field gradient ($V_{zz} > 0$), which was along the polar axis. Further analysis of Mössbauer spectrum revealed that the possible directions of antiferromagnetic spin direction are limited to four, which is quite close to four of six 〈121〉 directions in the easy plane perpendicular to the polarization along the [111] direction. Each ferroelectric domain has four possible magnetization directions, all of which have an out-of-plane ferromagnetic component. The spontaneous magnetization is in four 〈110〉 directions, perpendicular to both antiferromagnetic spin direction and polarization. Magnetization reversal due to 71° ferroelectric switching is expected to occur if the octahedral rotation is accompanied by a change in the antiferromagnetic spin direction.
The correlation between the ferroelectric and ferromagnetic domains was investigated by performing piezoelectric force microscopy (PFM) and MFM on the as-grown BFCO thin film. Both PFM and MFM images exhibi A striped domain configuration with four polarization down domains can be seen, indicating the both ferroeectric and ferromagnetic domains are strongly coupled with each other. Magnetization reversal by polarization switching was demonstrated by tip bias of −7 V. In the area where pure out-of-plane 71° domain switching occurred, the magnetic domain structure was also preserved but the contrast of MFM phasel was reversed, indicating that the out-of-plane magnetization switched from downward to upward and vice versa in this area. This was the first direct observation of magnetization reversal by the electric field at room temperature. On the other hand, in the area where the striped domain structure is heavily modified, MFM image is also changed largely by the poling, though the contrast is correlated with the ferroelectric domain structure after the poling. These results indicate that an out-of-plane magnetization reversal can be achieved by 71° polarization switching without reconstruction of the ferroelectric domain.

9:00 AM EQ09.06.03
Magnetization Reversal in $BiFe_{0.9}Co_{0.1}O_3$ Thin Films 2 - Control of Ferroelectric and Ferromagnetic Domains by Trailing Fields Takuma Itoh[1], Marin Katsumata[1], Kei Shigematsu[1,2] and Masaki Azuma[1,2]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

$BiFeO_3$ (BFO) is the most widely investigated multiferroic material with a large electric polarization along the [111] of pseudocubic cell with a ferroelectric Curie temperature of 1103 K and an antiferromagnetic Néel temperature of 643 K. The presence of a cycloidal spin modulation prohibits the appearance of spontaneous magnetization. Partial Co substitution for Fe changes the spin structure to a collinear one with a spontaneous magnetization owing to the spin canting preserving the large electric polarization [1]. Therefore, $BiFe_{0.9}Co_{0.1}O_3$ (BFCO) is a multiferroic material with both a large electric polarization and a spontaneous magnetization at room temperature, which are perpendicular to each other. The magnetization reversal accompanying 71° polarization switching in a thin film has been observed at room temperature, which is expected to be utilized in ultra-low power consumption magnetic memory devices [2]. However, it is necessary to understand the behaviors of ferroelectric and magnetic domains during the polarization reversal process and deterministically control the polarization and magnetization direction.
In this study, the polarization of BFCO grown in (001) orientation was controlled in both out-of-plane and in-plane direction by utilizing the effective in-plane electric field, so-called trailing field, resulting from the scanning of the cantilever [3]. The polarization of the as-grown film was limited to four out-of-plane downward directions by self-poling effect. The cantilever was scanned with a bias voltage of −7 V for out-of-plane polarization switching, which resulted in a striped ferroelectric domain with two types of out-of-plane upward polarization affected by the trailing field. Then, the same surface location was scanned with the cantilever, the slow scan direction of which is opposite to the in-plane component of the polarization, with an increased tip bias (−10 V). This process corresponded to increasing an effective in-plane electric field without changing the direction of the out-of-plane electric field. After such in-plane electric field application, the ferroelectric domains were observed by piezoresponse force microscopy (PFM). It was found that all the polarizations were oriented in the direction of the trailing field while maintaining the striped domain. The magnetic domains were also observed by magnetic force microscopy (MFM) and was found to have a striped domain shape similar to that of the ferroelectric domain. From these results, we conclude that in-plane polarization can be controlled by using the trailing field. The magnitude of the electric trailing field generated by −10 V bias voltage was estimated to be about 40 kV/cm^{-1}. Normally, about 200 kV/cm^{-1} is required for in-plane polarization reversal of $BiFeO_3$ using planar electrodes, but in this trailing field, in-plane polarization reversal was achieved with only one-fifth of that voltage.
Consequently, we succeeded in changing the polarization direction to any desired direction by controlling three main factors: the sign and magnitude of the voltage between the cantilever and the bottom electrode, and the slow scan direction (the direction of electric trailing field). Magnetic domain imaging by MFM revealed that the ferroelectric and magnetic domains have similar shapes, suggesting a strong correlation between polarization and magnetism, indicating the magnetic domain can also be controlled by the trailing field. The above results suggest that the electric trailing field is a valuable tool to manipulate the ferroelectric and magnetic domains in multiferroic BFCO thin films.

9:15 AM EQ09.06.04
Exploring the Correlation Between the Spin-State Configuration and the Magnetic Order in Co-Substituted $BiFeO_3$ Koomok Lee[1], Kei Shigematsu[1,2], Das Hena[1] and Masaki Azuma[1,2]; [1]Tokyo Institute of Technology, Japan; [2]Kanagawa Institute of Industrial Science and Technology, Japan

$BiFeO_3$ is one of the most actively studied multiferroic materials that exhibits a robust ferroelectric order below ~ 1100 K and an antiferromagnetic (AFM) order below ~ 640 K. Numerous researches have been conducted to explore its potential in effecting electric field control of magnetic order for energy-efficient nonvolatile magnetic memory applications. The magnetic order in $BiFeO_3$ is complex in nature. Close competition between various magnetic interactions, such as isotropic symmetric exchange (SE), antisymmetric Dzyaloshinskii-Moriya (DM) interaction and single ion anisotropy (SIA), lead to the formation of magnetic orders like the (1) G-type AFM order and (2) long period cycloidal order (~62nm). By partial substitution of Co instead of Fe, its cycloidal order disappears, and a spin canted G-type AFM with saturation magnetization about $0.03\mu_B$/f.u. perpendicular to the electric polarization has been observed. Moreover, magnetization reversal by electric field was observed in $BiFe_{0.9}Co_{0.1}O_3$ thin film. Understanding the effect of Co substitution to magnetic order of $BiFeO_3$ could give us the guideline to enhance the weak spontaneous magnetization of this system which is critical for magnetic memory application.
In the present study, using density functional theory (DFT) calculations and by employing a constructed model spin Hamiltonian and Monte Carlo simulations, we have studied the stability of the canted G-type AFM as a function Co substitution level. Co^{3+} can exhibit various spin states, such as low spin (LS, S=0), intermediate spin (IS, S=1) and high spin (HS, S=2) states. This ambiguity pertaining to the electronic structure of substituted Co^{3+} further contributes to the complexities of the $BiFeO_3$ system. Our detailed investigations of various properties of $BiFeO_3$ system as functions of Hubbard U parameter and the concentration of Co^{3+} show that, the spin state of Co^{3+} ion strongly depends on the U value and the high spin state of Co^{3+} is relatively stable. The calculated volume reductions with increase of Co concentrations are in best agreement with the experimental observations corresponding to the mixing of HS and LS of Co. Finite temperature Monte Carlo results considering a wide range of magnetic parameters, lead to the identification of the factors that enhance the stability of the canted G-type AFM phase. We observe that the strong tendency of the HS Co^{3+} to orient in the $\{111\}_{pc}$ plane, which is perpendicular to the direction of the spontaneous polarization, enhances the stability of the canted G-type AFM phase and on the other hand the formation of the IS state contributes to the increase of the magnitude of net magnetization.
Our study indicates the existence of HS and LS Co in the system under investigation and suggests guidelines to enhance the multiferroic properties of $BiFeO_3$.

9:30 AM EQ09.06.05
Increasing Strain-Mediated Magnetoelectric Coupling in Nanocomposites with Residual Porosity Shreya K. Patel, Christopher Ty Karaba and Sarah Tolbert; University of California, Los Angeles, United States

This work examines the role of nanoscale structure in the control of magnetoelectric coupling in three-dimensional multiferroic composites. Three-dimensional composites allow for a much increased interfacial surface area between the magnetostrictive and piezoelectric components, which in turn can lead to a much enhanced magnetoelectric coupling over traditional planar stack composites. Here, we investigate a composite made up of a solution-processed mesoporous material with the pores filled by atomic layer deposition with the alternate material. Tuning the thickness of the ALD-deposited layer allows for control of final composite porosity. We have found that the strength of magnetoelectric coupling depends heavily on this residual porosity, with higher porosity leading to greater magnetoelectric response. In a composite of mesoporous cobalt ferrite (CFO) filled with only 25% bismuth ferrite (BFO), we have found that an applied voltage on the composite causes a decrease in the saturation magnetization of the composite to about 50% its unpoled value, while the sample filled 100% with BFO shows little change in saturation magnetization. High-resolution X-ray diffraction confirms that the residual porosity is necessary for strain transfer to occur from the piezoelectric to the magnetostrictive component, as the porosity allows for mechanical flexing throughout the film.

A Multiferroic Two-Dimensional Electron Gas Julien Bréhin[1], Yu Chen[2], Sara Varotto[1], Maria D'Antuono[2], Daniela Stornaiuolo[2], Cinthia Piamonteze[3], Marco Salluzzo[2] and Manuel Bibes[1]; [1]Unité Mixte de Physique CNRS/Thales, France; [2]CNR-SPIN, Italy; [3]PSI, Switzerland

Multiferroics are compounds in which at least two ferroic orders coexist – typically (anti)ferromagnetism and ferroelectricity – and whose investigation has been a major area of materials science during the last two decades. While magnetic order can arise in both insulating and metallic compounds, ferroelectricity is in principle only allowed in insulators, although ferroelectric metals were proposed over 60 years ago. Recently, several two-dimensional systems have been reported to behave as ferroelectric metals. Yet, their combination with magnetic order remains elusive. In this work, we show the coexistence of ferroelectricity and magnetism in a $SrTiO_3$-based two-dimensional electron gas (2DEG). Ti-$L_{3,2}$ edge X-ray linear dichroism data evidences a modulation of the Ti-O polar displacements depending on the ferroelectric polarization direction while transport data reveal a voltage-induced hysteresis of the sheet resistance, reminiscent of the ferroelectric polarization loop. The 2DEG displays anomalous Hall effect and magnetoresistance that can both be modulated and cycled by switching the remanent polarization, demonstrating a magnetoelectric coupling. Our findings provide new opportunities in quantum matter stemming from the interplay between ferroelectricity, ferromagnetism, metallicity and Rashba spin-orbit coupling.

In recent years, voltage and frequency scaling of CMOS technology has slowed down, accompanied by increasingly larger power requirements. To assure the continuity of Moore's Law, new beyond-CMOS logic devices need to be found. For this purpose, one of the leading options is the magneto-electric spin-orbit (MESO) logic device, where a combination of quantum materials and spin-based phenomena allows for energy-efficient logic and favourable device scaling [1, 2].

Here, based on the initial MESO proposal, we show voltage-based magnetization switching and reading at room temperature, in Pt/CoFe nanodevices fabricated on a multiferroic BiFeO3 layer [3, 4]. Switching is performed by application of a voltage pulse to the BiFeO3, which reverses its ferroelectric and antiferromagnetic state. Through interfacial exchange coupling, the CoFe magnetization is also reversed. Spin-to-charge conversion in the Pt/CoFe nanodevice is then used to probe the magnetization direction of the CoFe element. Additionally, we show PFM and MFM experiments where magnetization switching is imaged after each voltage pulsed applied. We discuss future strategies that need to be followed for the implementation of MESO-based logic circuits [4].

Investigation of Ferro- and Antiferromagnetic Memory Structures Using Scanning NV Magnetometry Peter Rickhaus[1], Umberto Celano[2], Liza zaper[3,1], Alexander Stark[1], Mathieu Munsch[1], Marco Nordmann[1], Hai Zhong[1], Martino Poggio[3], Christoph Adelmann[2], Paul van der Heide[2], Aurore Finco[4], Vincent Jacques[4], Vincent Garcia[5] and Patrick Maletinsky[3,1]; [1]Qnami AG, Switzerland; [2]imec, Belgium; [3]University of Basel, Switzerland; [4]Universite' de Montpellier, France; [5]CNRS Thales, France

To improve magnetic memories, significant efforts are made to reduce the size and spacing of magnetic bits. This implies that failures and defects can only be discovered with a non-invasive technique that can resolve small magnetic fields with high spatial resolution. Scanning NV magnetometry (SNVM) is the emerging quantum sensing technique that offers the required sensitivity.
We will demonstrate magnetic images of a few hot candidate materials for future magnetic memory devices.We will look at memory bits in antiferromagnetic chromia, antiferromagnetic cycloids in BiFeO3 [1], cobalt nanomagnets and ultra-scaled CoFeB nanowires [2]. We will reveal magnetic textures that are undetectable with standard characterization techniques. In this context, we will more broadly discuss the potential of SNVM as a powerful magnetic characterization tool.

11:15 AM EQ09.06.09
Giant Converse Magnetoelectric Effect in Co_2-Heusler Alloy/$Pb(Mg_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ Multiferroic Heterostructures Takamasa Usami[1], Shumpei Fujii[1], Yu Shiratsuchi[1,1,1], Amran M. Yatmeidhy[2], Shinya Yamada[1,1,1], Takeshi Kanashima[1], Ryoichi Nakatani[1,1,1], Yoshihiro Gohda[2,1] and Kohei Hamaya[1,1,1]; [1]Osaka University, Japan; [2]Tokyo Institute of Technology, Japan

The use of ferromagnetic/ferroelectric interfacial multiferroic heterostructures in spintronics devices is expected as a highly efficient method for controlling magnetization vectors by an electric-field (*E*) [1]. To incorporate the multiferroic heterostructure into the low-power consumption devices, a giant converse magnetoelectric (CME) effect is needed, where the CME coupling coefficient over 10^{-5} s/m is required. In this study, we report giant CME coupling coefficients over 10^{-5} s/m in the multiferroic heterostructures with ferromagnetic Co_2-Heusler alloys that are famous as spintronic materials having high spin polarization [2,3].
30-nm-thick Co_2-Heusler-alloy films (Co_2FeSi, $Co_2FeAl_{0.5}Si_{0.5}$, $Co_2Fe_{0.4}Mn_{0.6}Si$, and Co_2MnSi) were grown on (011)-oriented $Pb(Mg_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ (PMN-PT) substrates with inserting a 0.3-nm-thick Fe layer by molecular beam epitaxy at 300 °C. As a reference, ferromagnetic Fe_3Si (Fe_2FeSi) was also grown on PMN-PT(011). XRD measurements revealed that all the Heusler films are polycrystalline. In addition, we confirmed that the $L2_1$ or $D0_3$-ordered structures are included in Co_2FeSi, $Co_2Fe_{0.4}Mn_{0.6}Si$, and Fe_3Si films whereas only the $B2$-ordered structure is obtained in $Co_2FeAl_{0.5}Si_{0.5}$ and Co_2MnSi films.
The CME effect was characterized by in-plane magneto-optical Kerr-ellipticity measurements and conventional magnetization measurements at room temperature [3]. We found that all multiferroic heterostructures using Co_2-Heusler-alloy films show the 90° rotation of the magnetic easy axis by applying *E*. In addition, a giant CME coefficient over 10^{-5} s/m was obtained for all the Co_2-Heusler/PMN-PT(011) multiferroic heterostructures. For the Fe_3Si/PMN-PT(011), on the other hand, a small variation in the magnetic easy axis was seen. This study indicates that the presence of Co atoms in Heusler alloys is important to demonstrate the giant CME effect. We note that the use of Co_2-Heusler alloys is also useful to achieve high-performance spintronics devices.

11:30 AM EQ09.06.10
Voltage-Tunable Coupling to a Coplanar Waveguide Resonator Mediated by a Josephson Junction Field Effect Transistor—Part I William M. Strickland, Bassel Heiba Elfeky, Dylan Langone, Ido Levy and Javad Shabani; New York University, United States

Superconducting qubit circuits could benefit immensely from a low power and fast tunability mechanism. This tunability can mediate microwave photon storage for quantum memory, as well as dynamically control qubit-qubit coupling. However, many current implementations of a tunable coupler for superconducting qubits are based on Al-AlOx-Al Josephson tunnel junctions arranged in a loop controlled via an applied flux through the loop generated by a current on the order of a milliampere. As the system size scales up, the additional heat load will scale as the square of the number of flux lines. Low-power voltage-controlled Josephson junction field effect transistors (JJ-FET) fabricated on superconductor-semiconductor heterostructures have been utilized to make tunable qubits. We present a gate voltage tunable Josephson junction field effect transistor fabricated on an Al-InAs heterostructure embedded in a coplanar waveguide resonator.
We show how the properties of this device make it a viable option for a tunable coupler. We show measurements of the internal quality factor of the materials stack and find that the loss is dominated by the InAlAs buffer layer. By varying the inductance of the junction via a gate voltage tunable critical current, we find that the resonant frequency and external quality factor can be tuned. By completely suppressing the supercurrent flowing through the junction, the coupler can provide full isolation. Electromagnetic field simulations are utilized to understand and solve for the lowest frequency eigenmodes as a function of the Josephson inductance.
*This abstract is the first part of a two-part abstract. The second abstract will be presented by Bassel Heiba Elfeky.

11:45 AM EQ09.06.11
Voltage-Tunable Coupling to a Coplanar Waveguide Resonator Mediated by a Josephson Junction Field Effect Transistor—Part II Bassel Heiba Elfeky, William M. Strickland, Dylan Langone, Ido Levy and Javad Shabani; New York University, United States

Recent advances and innovation in material systems have provided promising solutions for efficient quantum information processing. Understanding how the properties of such materials affect the functionality and coherence of qubit systems is essential. For superconducting qubit platforms, low-power voltage-controlled Josephson junction field effect transistors (JJ-FET) fabricated on superconductor-semiconductor heterostructures have been utilized to make tunable qubits. Here we present a new voltage-controlled coupler system through coplanar waveguide (CPW) resonators.
Here, we show that a gate-tunable JJ-FET fabricated on an Al-InAs heterostructure embedded in a CPW resonator provides the tunability required to make a tunable coupler. By varying the inductance of the junction using a gate voltage which changes the critical current, properties of the resonator such as its

resonance frequency and external quality factor can be tuned. By completely suppressing the supercurrent flowing through the junction, the coupler can provide full isolation. Electromagnetic field simulations are utilized to understand the system's dynamics.
*This abstract is the second part of a two-part abstract. The first abstract will be presented by William M. Strickland.

Electrochemical Random Access Memory (ECRAM) for Neuromorphic Computing A. A. Talin; Sandia National Laboratories, United States

As we near the limits of conventional digital CMOS technology, new computing paradigms and architectures co-designed with novel materials and new devices are needed to drastically improve energy efficiency and meet the demands of new classes of data-intensive applications. Non-von Neumann computing using neuromorphic systems based on analog, 2-terminal resistive non-volatile memory elements has emerged as a promising approach, but its full potential has not been realized due to the lack of materials and devices with the appropriate attributes. To address this need, 3-terminal device concept based tuning electronic conductance in functional materials through solid-state electrochemical ion-insertion have emerged as a promising approach. These devices are now broadly known as electrochemical random-access memory (ECRAM). Unlike memristors, which require large write currents to drive phase transformations or filament growth, every electron transferred through the external circuit in ECRAM corresponds to the migration of ~1 ion used to store analogue information. Like *static* dopants in traditional semiconductors, electrochemically inserted ions increase or decrease the conductivity by locally perturbing a host's electronic structure; however, ECRAM changes the dopant concentration in a *dynamic* and *reversible* manner. The resulting change in conductance can span orders of magnitude, from *gradual* increments needed for analog elements, to *large, abrupt* changes for dynamically reconfigurable adaptive architectures. In my presentation, I will discuss the recent progress in ECRAM devices spanning organic, inorganic, and 2D materials, circuits, architectures and the rich portfolio of challenging, exciting fundamental science questions and how we can harness these to realize a new paradigm for low power neuromorphic computing.

Simulation of Switching Processes Inside Bilayer Valence Change Memory Cells by a Drift-Diffusion Model Nils Sommer[1], Stephan Menzel[1] and Rainer Waser[1,2]; [1]Peter Grünberg Institute 7, Germany; [2]Institute for Materials in Electrical Engineering 2, Germany

Valence change memory (VCM) cells are promising candidates for future nonvolatile storage devices [1]. VCM cells are characterized by their ability to switch between at least two stable resistance states by applying suitable bias voltages. A special structure of VCM cells are bilayer cells consisting of two semiconducting oxide layers, with one oxide serving as a tunnel barrier. Experiments show that a change in resistance of the cell can be caused by the exchange of oxygen between the two oxide layers [2-4]. However, the processes taking place are not yet well understood. We use a drift-diffusion model to simulate the movement of oxygen inside the semiconductor to gain a better understanding of the exchange process between the layers. We investigate the internal electric fields acting as a driving force on the oxygen, as well as the oxygen diffusion process that causes it to return to an equilibrium state. We show that an oxygen exchange deforms the shape of the tunnel barrier and by this changing the resistance of the cell. Further, we show that the change in resistance depends on the permittivity of the oxides.

Study of Resistive Switching in Polycrystalline $ErMnO_3$ Films Rong Wu[1,2], Sebastian Schmitt[1], Veeresh Deshpande[1], Florian Maudet[1] and Catherine Dubourdieu[1,2]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie, Germany; [2]Freie Universität Berlin, Germany

Rare-earth hexagonal manganites h-$R$$MnO_3$ (R=Y, Er, Ho to Lu) have been widely studied as multiferroic compounds. Recently, resistive switching behavior has been reported in polycrystalline hexagonal $YMnO_3$ thin films with promising applications for neuromorphic devices [1]. The particular interest in h-$RMnO_3$ compounds for memristive devices lies in the potential use of their peculiar ferroelectric domain pattern, and especially of their vortex lines where six-fold domains merge.
In this work, we report the evidence of resistive switching behavior in polycrystalline $ErMnO_3$ thin films. The films (~60 nm thickness) were prepared on Pt/Ti/SiO_2/Si substrates by room temperature RF sputtering and subsequent annealing at high temperature (700-900 °C). They were characterized at the macro and microscale by X-ray diffraction, scanning electron microscopy, and confocal Raman spectroscopy. Metal-$ErMnO_3$-metal devices were fabricated using Ti/Au top electrodes. The Au/Ti/$ErMnO_3$/Pt devices exhibit a bipolar resistive switching with a R_{OFF}/R_{ON} ratio larger than 10^4 and an ultra-low resistance of only 10 Ω in the low resistance state (R_{ON}), which may result in potential applications such as CMOS circuitry with low power consumption [2] and RF power switches [3]. We investigated the impact of electrical programming operations on the performances of the devices to improve their repeatability and endurance. Furthermore, we quantitatively studied the amount of hexagonal and orthorhombic crystalline phases by Raman spectroscopy and conductive atomic force microscopy and addressed the effect of their simultaneous presence on the resistive switching behavior of the films. We will discuss the properties of the different $ErMnO_3$ phases and the origin of the resistive switching mechanism in the stacks.

Advances in Spin-Transfer-Torque MRAM Daniel C. Worledge; IBM Research, United States

Spin-Transfer-Torque MRAM (STT-MRAM) is an emerging memory technology that possesses a unique combination of non-volatility, high endurance, and ease of integration using standard CMOS processing [1]. Initial applications include 1 Gb standalone memory for use as a write buffer in solid state drives, and embedded non-volatile memory for microcontroller units, as a replacement for embedded Flash. If the switching current can be reduced further, STT-MRAM could potentially be used as a replacement for SRAM in last-level-cache, providing significant system-level performance improvement due to higher density.

Materials innovation lies at the heart of MRAM research, particularly for the materials used in the magnetic tunnel junction, the device used to store, read, and write data. A magnetic tunnel junction consists of metallic magnetic free and reference layers sandwiched around a thin insulating tunnel barrier. This talk will first give an overview of STT-MRAM, including how it works and the application space, and will then review the materials innovations developed at IBM for reducing the switching current.

IBM has had a long history of research and development of STT-MRAM. Spin-transfer-torque switching was invented at IBM in 1996 by John Slonczewski [2], who also invented the magnetic tunnel junction [3] (which was also independently invented by Julliere [4]). High magnetoresistance using MgO tunnel barriers was first published by IBM and AIST in 2004 [5,6]. The development of perpendicularly magnetized STT-MRAM was first published by IBM and Tohoku University in 2010 [7,8]. Since then the IBM MRAM team has focused on reducing the switching current of STT-MRAM in order to enable last-level-cache applications. Key results include demonstrating reliable writing down to write-error-rates of less than 1e-11 [9], scaling down to 11 nm tunnel junctions switching in only 7.5 uA [10], and demonstrating fast reliable writing using 2 ns write pulses [11]. IBM and TDK jointly published the first demonstration of product-level yields in 2013, using an 8 Mb STT-MRAM product demonstrator [12]. Double magnetic tunnel junctions were developed to further reduce the switching current, by using two reference layers and two tunnel barriers, in order to provide torque to the free layer from both top and bottom interfaces [13]. Theory predicts that a factor of 10 reduction in switching current is possible, for perfect spin-polarization [14]. Most recently, a new device, called the double spin-torque magnetic tunnel junction was demonstrated to reduce the switching current in a similar manner, however without any penalty in the magnetoresistance, by using a low resistance non-magnetic spacer in place of the second tunnel barrier [15]. This exciting breakthrough opens up a path to using STT-MRAM as last-level-cache.

Topology for Energy Efficient Spintronics Claudia Felser; Max Planck Institute for Chemical Physics of Solids, Germany

Topology, a mathematical concept, recently became a hot and truly transdisciplinary topic in condensed matter physics, solid state chemistry and materials science. All 200 000 inorganic materials were recently classified into trivial and topological materials, such as topological insulators, Dirac, Weyl and nodal-line semimetals, and topological metals [1]. More than 25% of all materials host topological bands around the Fermi energy. Beyond the single particle picture, we have identified first antiferromagnetic topological materials [2]. Experimentally, we have realized ferromagnetic materials, examples are Co_2MnGa and $Co_3Sn_2S_2$. Surprisingly all crossings in the band structure of ferromagnets are Weyl nodes or nodal lines [3]. Mn_3Sn and $YbMnBi_2$ are examples of non collinear antiferromagnetic Weyl semimetals, which show giant values for the anomalous Hall and Nernst effect [4]. In the context of real space topology, skyrmions and antiskyrmions are a possible new direction for new data storage [5]. Our goal is to identify new quantum-materials for highly efficient spintronics, quantum computing and energy conversion.

Large Spin Hall Effects in a Model Epitaxial $BaPb_{1-x}Bi_xO_3$ / $La_{0.7}Sr_{0.3}MnO_3$ System Isaac Harris[1], Anthony Edgeton[2], Xiaoxi Huang[1], Reed Yalisove[1], George Fratian[1], Marcel Mazur[3], Lucas M. Caretta[1], Sandhya Susarla[1,4], Chang-Beom Eom[2], Dan Ralph[3] and Ramamoorthy Ramesh[1]; [1]University of California, Berkeley, United States; [2]University of Wisconsin–Madison, United States; [3]Cornell University, United States; [4]Lawrence Berkeley National Laboratory, United States

Spintronics is a promising field centered around next-generation devices that use electronic spin to store and manipulate information. Since there are no ohmic losses inherent in the transfer of spin – for example in magnons or pure spin currents – spintronic devices have the potential to be very energy efficient, and lots of efforts have been taken over the last few decades to apply spintronic principles to make 'beyond CMOS' devices. However, one of the major challenges in spintronics is to find material systems with efficient spin-to-charge conversion, and the lack of such model systems has kept practical, energy efficient spintronic applications from being realized. We propose a new pathway for discovering model systems with efficient spin-to-charge conversion in epitaxial oxide heterostructures. We present on one such system, $BaPb_{1-x}Bi_xO_3$ / $La_{0.7}Sr_{0.3}MnO_3$ (BPBO/LSMO), grown by pulsed laser deposition with excellent crystalline quality characterized by X-ray diffraction and TEM. Using spin-torque ferromagnetic resonance (STFMR) experiments, we measured a spin-orbit torque efficiency of 3 – over an order of magnitude greater than typical spin-orbit coupled metals. We confirm this measurement with samples grown and measured across 3 different labs, along with transverse STFMR and Second Harmonic experiments. We also find an enhancement of the spin-orbit torque efficiency for thinner layers of BPBO, indicating that the epitaxial interface plays an important role in the generation of spin-orbit torques. With a better understanding of the role of the interface in spin-orbit torque generation, and by exploring similar complex oxide systems, we hope to find a model epitaxial oxide heterostructure that can be used for energy efficient spintronic applications.

We acknowledge funding support from SRC-ASCENT for this project.

Current-Induced Switching in Spin-Filter Tunnel Devices Astha Khandelwal[1], Vinod Kumar[1], Yu-Hui Tang[2], Mark G. Blamire[3] and Bhagwati Prasad[1]; [1]Indian Institute of Science, India; [2]National Central University, Taiwan; [3]University of Cambridge, United Kingdom

The Internet of Things (IoT) devices needs to process a vast amount of data at high speed for smooth interfacing with other supplementary devices on the network. However, the current computational architecture is not efficient for this purpose. One of the potential solutions to tackle this issue is to use high-density nonvolatile memory (NVM). Magnetic random-access memory (MRAM) is one of the promising NVM technologies. The magnetic tunnel junction is the building block of the MRAM device. Intensive studies in the FM/B/FM MTJs, where a barrier (B) is separated by two ferromagnetic (FM) electrodes, have demonstrated that the relative orientation of two FM electrodes can be altered by either an external magnetic field or controlled by a spin-polarized current, i.e., the current-induced magnetization reversal via the spin-transfer (STT) or the field-like (FLST) components of the spin torque [1, 2]. The STT-MRAM technology has significant advantages over magnetic-field-switched MRAM, while the main challenge for implementing STT-MRAM is the requirement of high writing current for high-density and high-speed MRAM. Therefore, alternative writing and reading mechanisms for MTJs may provide a viable route towards switching energies per bit smaller compared with CMOS (~1 fJ). To achieve low-energy consumption in next-generation spintronics devices, much attention has shifted to the spin filter effect in ferromagnetic insulator europium chalcogenides [3] and perovskite oxides [4, 5]. So far, the spin-filter devices have been switched by the applied external magnetic field but to make a high-density memory solution, the current/voltage-induced switching would be required. Recently we have observed the current/voltage-dependent switching in $SmSrMnO_3$-based devices. The dI/dV vs. V of such spin filter device shows the large change in the dynamic conductance of the device at lower bias and low temperature (below T_c for the ferromagnetic insulator barrier layer). The underlying mechanism of such current dependent switching is not well understood. We have conducted detailed experiments to get a comprehensive understanding of the current-driven switching dynamics in spin-filter tunnel devices. The physical understanding and theoretical model for the experimental observations are being analyzed by both first-principles calculations and a tight-binding model with a self-developed JunPy+LLG package [6, 7]. The current-driven switching in spin-filter tunnel junctions can potentially be used for high-speed and high-endurance non-volatile memory devices for AI and IoT applications.

Energy-Efficient Time Series Data Processing Using HfO_2-Based 2Memristor-1Capacitor Integrated Temporal Kernel Sung Keun Shim, Yoonho Jang, Janguk Han, Jeong Woo Jeon and Cheol Seong Hwang; Seoul National University, Korea (the Republic of)

Recently, Reservoir Computing (RC), a temporal kernel-based computing method that processes input at the reservoir (a fixed recurrent network) and identifies it in the readout layer, has been studied due to its efficient but cost-effective learning in the machine learning field. Several attempts have been made to implement this reservoir functionality through a physical system using diffusive memristors that showed both nonlinearity and fading memory properties [1]. However, the time scale is fixed with the memristor's material properties in the previous studies, making it difficult to adjust the temporal properties of the kernel. In this study, nonvolatile W/HfO_2/TiN (WHT) memristor and TiN/ZrO_2/Al_2O_3/ZrO_2/TiN (TZAZT) capacitor-based temporal kernel with an integrated 2memristor-1capacitor (2M1C) structure is proposed to solve the issue with fixed time scale.

HfO_2-based memristor has been widely studied for various applications, including synaptic applications in neuromorphic hardwares. Especially, the WHT memristor in this study shows area-dependent electronic bipolar resistive switching behavior, which works as an analog switching device for the integrated temporal kernel. 2M1C kernel is composed of two serially connected memristors (M1, M2) and a capacitor (C1) which is connected in parallel with one of the memristors (M2). WHT memristor works as both a multi-level conductance device and a variable resistance that generates a broad range of RC delays along with C1. By modulating memristors and capacitors in the kernel circuits, time constants of the 2M1C temporal kernel can vary for 10^6 orders. This study analyzed how each element's characteristics affected the entire kernel properties.

The task of recognizing digit images in the MNIST database was conducted to verify the performance of the temporal kernel. 784 pixel data of MNIST images were binarized, chopped into n-bit pulse sequences, and fed to the kernel as an input signal. The kernel system can separate different pulse streams in terms of the number of pulses and intervals due to its unique delay dynamics through analog memristors. 2M1C kernel maps the processing results with two memristors (M1, M2; dual mapping), which projects the input signals into a higher-dimensional space. The high dimensionality significantly improves the kernel's separability, reducing the whole network's size needed for classification. Mackey-glass time series prediction test was applied to the 2M1C kernel for its data processing ability and showed excellent performance under the broad test conditions compared with previous studies [2,3].

2M1C temporal kernel shows that it can adapt to various tasks, and real-time data processing is possible under broad conditions by modulating M1, M2, and C1 values. The HfO_2-based nonvolatile memristor acts as an analog memory device as well as the dynamics-maker. The kernel machine took 200 ns of time and ~25pJ of energy to process one input pulse, substantially reducing time and energy compared with previous studies [3]. Tunable RC delay and dual mapping techniques further contribute to the kernel's energy-efficient and accurate processing ability.

High-Performance UV Photodetectors Using Oriented WO_3 Thin Films Grown at Low Temperature in Open Atmosphere Zhuotong Sun[1], Ming Xiao[1], Weiwei Li[2], Megan O. Hill[1], Rob Jagt[1], Louis-Vincent Delumeau[3], Kevin Musselman[3] and Judith L. MacManus-Driscoll[1]; [1]University of Cambridge, United Kingdom; [2]Nanjing University of Aeronautics and Astronautics, China; [3]University of Waterloo, Canada

Tungsten oxide (WO_3), an n-type semiconductor, has many potential applications, e.g. electrochromic devices, photodetectors, photocatalysts, supercapacitors, memristors, electrolyte-gated transistors, etc. In this work, we demonstrate ultraviolet (UV) responsivity in photodetector devices as an exemplar application of WO_3 thin films via a CMOS-compatible atmospheric pressure-spatial chemical vapour deposition (AP-SCVD) method. Films grown on Si at 320°C were conformal over cm^2, and their orientations were continuously tuned by controlling the deposition rate using unique parameters of AP-SCVD. Even though the films were grown in open atmosphere and did not undergo any further annealing, they showed high responsivity (10^{-3} A/W) in short response time (3.6 s), comparable to the performance of vacuum- or solution- grown films post-processed at temperatures of up to 600°C. More broadly, the films deposited by AP-SCVD have very strong potential for the wide-ranging applications of WO_3.

EQ09.09.03
Understanding the Correlations Between Structure, Electronic Properties and Oxygen Vacancy Migration in Samarium Nickelates Ranga Teja Pidathala, Devang Bhagat, Mirza Galib and Badri Narayanan; University of Louisville, United States

Ever growing advances in artificial intelligence for wide variety of applications ranging from driverless automobiles, unmanned aerial vehicles to healthcare, poses new challenges in developing strong, fast, and powerful data storage and computer processors. Strongly correlated electron materials like samarium nickelates with property of resistive switching can be potential candidate for brain like computing. The metal to insulation (MIT) or insulator to metal (IMT) transition in $SmNiO_3$ can be triggered by doping electrons in the d-orbital of Ni. In the current study, we have demonstrated that creating oxygen vacancies (OV) in well-defined order (square planar, pyramidal, tetrahedron) triggers the MIT or IMT transition based on its magnetic ordering (A-AFM, E-AFM, FM, G-AFM, S-AFM, T-AFM) in ground state. The structural changes caused due to OV's in $SmNiO_{3-\delta}$ changes the electronic properties of oxygen deficit samarium nickelates. We used climbing image nudge elastic band (CI-NEB) implemented in density functional theory (DFT) code to find the activation energies of OV migration with two different pathways, one in ab plane and other along c-axis and activation barriers are 1.15 eV and 0.95 eV respectively. We also studied the effect of different shapes and different concentration of OVs around the OV migration pathway. It is found that in each magnetic ordering, the barrier increases with increase in the shapes (pyramidal, square planar). It is also found that the S-AFM has the least and T-AFM has the highest activation energies, 1.25eV and 1.5 eV respectively. This study will further help us in understanding energy efficient way of triggering the MIT or IMT driven by OV transport in $SmNiO_{3-d}$ for designing the next generation electronics

EQ09.09.04
Effect of ZrO_2 Seed Layer in $Hf_{0.5}Zr_{0.5}O_2$ Ferroelectric Device Fabricated by PEALD Jina Song, MinJung Oh and Yoon Chang-Bun; Tech University of KOREA, Korea (the Republic of)

FeRAM (Ferroelectric Random Access Memory) is one of the next-generation memories and has a non-volatile characteristic through the electrical polarization of a ferroelectric. Therefore, research is being conducted as a memory to replace DRAM (Dynamic Random Access Memory), which has a problem of information volatility.
Among the HfO_2-based ferroelectrics, HfO_2 doped with Zr exhibits ferroelectricity in a wide composition range. The best ferroelectricity is measured when the doping concentration is about 50%. Recently, it has been reported that the ferroelectric properties of $Hf_xZr_{1-x}O_2$ (HZO) films are increased by forming a ZrO_2 seed layer.
In this research, an $Hf_{0.5}Zr_{0.5}O_2$ ferroelectric layer was formed using PE-ALD (Plasma Enhanced Atomic Layer Deposition). A metal-ferroelectric-metal (MFM) type capacitor was fabricated using TiN with a thickness of 50nm as the Top and Bottom electrodes. First, to analyze the characteristics of the HZO ferroelectric layer according to various lamination methods, the total number of ALD cycles was fixed at 120 cycles, and the HfO_2-ZrO_2 super cycles were set to 4 types: 5cycle-5cycle, 10cycle-10cycle, 20cycle-20cycle, and 60cycle-60cycle. After setting to, each super cycle was repeated 12, 6, 3, and 1 time to form a ferroelectric layer. Second, to investigate the characteristics according to the heat treatment temperature, the specimens in which the ferroelectric layer was deposited using PE-ALD were heat-treated at 450/550/650°C for 30 seconds in a N_2 atmosphere using RTA (Rapid Thermal Annealing). Finally, four types of MFM capacitors were fabricated without or with the Top/Bottom/Top and Bottom seed layers. Electrical characteristics were analyzed using Keithley 4200A-SCS, and the properties of endurance, I-E curve, and Hysteresis curve were compared. In addition, the crystallinity and component ratio of the ferroelectric thin films were analyzed through XRD, XPS, and TEM.

EQ09.09.05
Novel Phase Formation and Magnetism at the $Sb_2Te_3/Ni_{80}Fe_{20}$ Interface Alexandria Will-Cole[1], James L. Hart[2], Adrian Podpirka[3], Matthew Matzelle[1],

Nirjhar Bhattacharjee[1], Shreya K. Patel[4], Sarah Tolbert[4], Arun Bansil[1], Judy Cha[2], Don Heiman[1] and Nian Sun[1]; [1]Northeastern University, United States; [2]Cornell University, United States; [3]Johns Hopkins University Applied Physics Laboratory, United States; [4]University of California, Los Angeles, United States

Bilayer topological insulator/ferromagnet heterostructures are promising for spintronic memory applications due to their low switching energy and therefore power efficiency.[1] Topological insulators have been grown with molecular beam epitaxy (oriented, epitaxial films)[2,3] and RF magnetron sputtering (amorphous to crystalline oriented films)[4-6] and have demonstrated large spin-to-charge conversion efficiencies. However, the reactivity of topological insulators with ferromagnetic films is often overlooked in the spin-orbit-torque literature, even though there are reports that it is energetically favorable for topological insulators to react with metals and form interfacial layers.[7-11] Previously, we have investigated the interface of $Bi_2Te_3/Ni_{80}Fe_{20}$ and discovered that a novel topological antiferromagnetic phase forms at the bilayer interface due to selective Ni diffusion, which is possibly catalyzed by the topological surface states.[12] In our previous work the Bi_2Te_3 was grown via sputtering on thermal SiO_2/Si, and while it showed *c*-axis orientation, we suspect mosaicity to be present, which may limit the diffusion depth of the Ni into the Bi_2Te_3 film, thus limiting the thickness and uniformity of the interfacial antiferromagnetic phase. In our current work, we have grown Sb_2Te_3 with molecular beam epitaxy to ensure a highly ordered and epitaxial film, with the expectation that the diffusion depth of the Ni into the Sb_2Te_3 may be much deeper, providing a smaller gradient resulting in a more homogeneous antiferromagnetic interlayer. However, we find this interface to be highly complex with multiple phase formations, including a novel antiferromagnetic phase evident by the presence of large, negative exchange bias. We support our findings with temperature dependent magnetometry, high-angle annular dark-field scanning transmission electron microscopy, and theoretical calculations. Despite the complex nature of the $Sb_2Te_3/Ni_{80}Fe_{20}$ interface, we still observe significant enhancement of the Gilbert damping and reduction of effective in-plane magnetization, which is indicative of spin pumping in this heterostructure – Sb_2Te_3 is a spin sink due to its large spin-orbit-coupling.[13] This work highlights the role of interfacial chemistry in topological insulator/ferromagnet heterostructures.

Crystal Structure and Electric Properties of (100) $Ba(Zr_xTi_{1-x})O_3$ Thin Films on MgO Substrates by Pulse Laser Deposition Technique Ryo Takahashi[1], Yoshitaka Ehara[1], Yosuke Hamasaki[1], Shintaro Yasui[2], Shinnosuke Yasuoka[2], Hiroshi Funakubo[2], Shinya Sawai[1] and Ken Nishida[1]; [1]National Defense Academy, Japan; [2]Tokyo Institute of Technology, Japan

Microwave tunable devices are necessary components for next-generation communication applications. Ferrite, semiconductors, and ferroelectrics are typical tunable materials. Especially ferroelectric thin films have been studied for a long time because of their high dielectric constant and low power consumption. Moreover, microwave dielectric materials show advantages in terms of light weight, compactness, low loss, stability in temperature, and low cost in producing of communication devices. To date, $(Ba_{1-x}Sr_x)\ TiO_3$ [BST] has become one of the most popular ferroelectric materials studied and used as tunable microwave devices. However, its dielectric loss is still large, and the temperature dependence of the dielectric constant remains insufficient for applications. It is desirable to have not only high dielectric constant and tunability in a certain electric field range but also low dielectric loss. $Ba(Zr_xTi_{1-x})O_3$ [BZT] solid solutions are also tunable materials with potential use in devices for wireless communications, just above their Curie temperature in a paraelectric state. BZT is a possible alternative to BST in tunable microwave applications Zr^{4+} is chemically more stable than Ti^{4+} and maintains a low dielectric loss. Furthermore, BZT in the paraelectric phase has higher temperature stability than BST. Therefore, we focused on BZT thin films as a tunable ferroelectric material.
In this work, we fabricated BZT ($x = 0 \sim 1.0$) thin films with 500nm thick by pulse laser deposition [PLD] technique on MgO(100) and $(100)_cSrRuO_3//(100)BaZrO_3//(100)MgO$ substrates. It enables us to obtain preferential (100)-oriented BZT thin films. The structural properties of the films were characterized by x-ray diffraction [XRD] (MRD, PANalytical). Wavelength-dispersive x-ray fluorescence spectrometry [WDX] (PW2404, PANalytical) was carried out to investigate the composition and thickness of BZT thin films. All the XRD patterns showed only (001)/(100) diffraction peaks and no secondary phase. Reciprocal space mappings (RSMs) of BZT thin films showed that BZT thin films grew epitaxially on (100)MgO and $(100)_cSrRuO_3//(100)BaZrO_3//(100)MgO$ substrates. The electrical properties of the BZT thin films were measured by an impedance analyzer (4194A, Agilent). *P-E* hysteresis loops of BZT films become increasingly slim in shape with increasing Zr content because of the decrease in grain size. The dielectric constant dependence of electric field indicated that tunability is high in the region of $x = 0 \sim 0.5$ BZT thin films. The composition dependence of tetragonality, remanent polarization, and dielectric constant suggested that there may be a phase boundary between $x = 0.2$ and 0.3, and this tendency is similar to BZT ceramics. Therefore, our result suggests that BZT ($x = 0 \sim 0.5$) can be one of the significant candidates for microwave application which requires high tunability and low loss.

Stabilization of Various Polymorph in Multiferroic $ScFeO_3$ Film Yosuke Hamasaki[1], Shintaro Yasui[2], Tsukasa Katayama[3] and Mitsuru Itoh[2]; [1]National Defense Academy, Japan; [2]Tokyo Institute of Technology, Japan; [3]Hokkaido University, Japan

Polar iron oxides, which exhibit both ferroelectricity and (anti)ferromagnetism, are multiferroic materials, which promise potential application for a new type of memory device. Moreover, due to the strong magnetic interaction between Fe^{3+} cations, a higher magnetic order temperature in iron oxides is expected.
It is well known that a perovskite structure is thermodynamically stable in $Re^{3+}FeO_3$ (Re = Rare earth element). While hexagonal $ReFeO_3$ (h-$ReFeO_3$) with $YMnO_3$ -type structure which exhibits ferroelectricity and weak-ferromagnetism is metastable. $AlFeO_3$ and $GaFeO_3$ have a polar κ-Al_2O_3 structure which is a sesquioxide structure. When we consider crystal structures vs ionic radius of A^{3+} in $A^{3+}FeO_3$, $ScFeO_3$ is located at the cross point of various kinds of crystal structures.
Thin film fabrication techniques have contributed to the development of novel functional electronic materials and devices. Epitaxial films deposited on single crystal substrates suffering from interfacial strain due to a mismatch in the lattice constants between the film and the substrate allow stabilizing

metastable phases.
In this study, we attempted to stabilize various crystal structures in the film form by selecting the appropriate substrates or using a buffer layer and explored new polar iron oxides.
$ScFeO_3$ films were deposited on various substrates by pulsed laser deposition (PLD) technique. The crystal structure of films was characterized by X-ray diffraction (XRD) and scanning transmission electron microscope (STEM).
We stabilized five crystal structures: κ-Al_2O_3-, spinel-, corundum-, $YMnO_3$-, and bixbyite-type structures. XRD and HAADF-STEM were used to identify the phases. Four of the structures were obtained for the first time: κ-Al_2O_3-, spinel-, corundum-, and $YMnO_3$-type $ScFeO_3$. Since κ-Al_2O_3- and $YMnO_3$-type structures are polar, we investigated their ferroelectricity and magnetic properties.
The YMO-type $ScFeO_3$ film on a perovskite electrode showed a ferroelectric *P-E* hysteresis loop with Pr ~ 4.9 μC/cm^2. P_s of *h*-$ScFeO_3$ was simply calculated using the displacement of the Sc ion evaluated from the HAADF-STEM image. The obtained P_s was ~8.7 μC/cm^2, which is consistent with the observed value. HAADF-STEM observations also revealed that at the domain boundary, the Sc displacement pattern of up–center–down was found, indicating a nonpolar region due to its correspondence to the *P-3c* phase pattern, which was previously reported in an $ErFeO_3$ epitaxial film. In addition, the domain boundary was not straight compared with a proper ferroelectric perovskite. Magnetic measurements confirmed weak ferromagnetism with T_N = 195 K. The T_N value is the highest in hexagonal *Re*FeO_3 and *Re*MnO_3.
The κ-Al_2O_3- type $ScFeO_3$ film on a Nb doped $SrTiO_3$ substrate showed a ferroelectric *P-E* hysteresis loop with Pr ~ 4 μC/cm^2. Although the spontaneous polarization of ε-Fe_2O_3 calculated using Berry's phase is 21 μC cm^{-2}, the observed value is five times smaller than the theoretical value. This discrepancy can be correlated with the three in-plane domains. During polarization switching, because two close-packed oxygen layers shift in opposite directions along the *a*-axis (i.e., the in-plane direction in the ε-Fe_2O_3 film), this motion is suppressed by collision among the three in-plane domains. Magnetic measurements revealed the weak ferromagnetism with T_C ~ 295 K.

EQ09.09.09
Effect of Synthesis Condition on the Piezoelectric and Conductive Properties in $BaTiO_3$ Ceramics Eunjin Koh[1], Seunghun Kang[1], Choongseop Jeon[2], Seungyong Lee[2], Jinbok Shin[2], Jeongryeol Kim[2], Jungwon Lee[2], Donghoon Kim[1] and Yunseok Kim[1]; [1]Sungkyunkwan university, Korea (the Republic of); [2]Samsung Electro-Mechanics Co., Ltd, Korea (the Republic of)

Ferroelectric materials have been studied in various fields because of their unique properties, such as spontaneous polarization that can be switched by an electric field. In particular, barium titanate ($BaTiO_3$), which is a lead-free ferroelectric with a high dielectric constant, has been actively studied for applications in electronic devices, including energy storage applications and capacitor applications. Since electric devices have become miniaturized, the need to develop $BaTiO_3$ with smaller particle sizes and higher capacitance has been increasing. Although chemical modifications such as dopants, accomplished making $BaTiO_3$ smaller with high capacitance, there was a limitation in that macro-scale analysis techniques, which are not adequate for investigation of the nano-scale properties and mechanisms, have been mainly used. Consequently, to overcome this limitation, it is necessary to use a micro-scale characterization method to analyze the nano-sized particles. In this study, we employ piezoresponse force microscopy (PFM) and conductive atomic force microscopy (CAFM) to study $BaTiO_3$ ceramics according to the synthesis conditions of sintering temperatures, dopant species (Dy, Mn), and doping methods (oxide, poly). The investigation using PFM and CAFM reveals that the relative piezoresponse and leakage current depend on the sintering temperatures and dopant species. The uniformity of piezoresponse represents the dispersion of dopants which is different from doping methods. Furthermore, topography images revealed that particle size varied with the sintering temperatures, which is related to the dielectric constant. We explored the synthesis conditions that affect the piezoelectric properties and conductive properties of the $BaTiO_3$ ceramics using atomic force microscopy(AFM). Therefore, our findings can provide an understanding of the effect of the synthesis conditions on $BaTiO_3$ at a local level.

Invertible Boolean Logic Gates by Probabilistic Computing Based on the Cu_xTe_{1-x}/HfO_2/Pt Threshold Switch Jaehyun Kim, Kyung Seok Woo, Janguk Han and Cheol Seong Hwang; Seoul National University, Korea (the Republic of)

Complex optimization problems can be solved by sophisticated algorithms, burdening modern computers with significant circuit overhead and high computing power. A new concept called probabilistic computing, which uses "p-bits" operating at room temperature, was devised to handle this problem. The p-bit outputs fluctuate between 0 and 1 with time, which is similar to the behavior of binary stochastic neurons in the Boltzmann machine. Therefore, any stochastic element with tunable switching probability, such as magnetic tunnel junctions (MTJs), can be a potential candidate for building the p-bit hardware.[1,2]
In this study, p-bit hardware was built using the $Cu_{0.1}Te_{0.9}/HfO_2$/Pt (CTHP) threshold switch. The underlying switching mechanism of the CTHP memristor is based on ionic diffusion and drift of Cu ions, which form volatile conductive filament in the HfO_2 layer. The switching mode can be modulated by the concentration of Cu in the Cu_xTe_{1-x} electrode, which controls the injection of Cu ions into the oxide matrix.[3] The concentration of Cu was set to 0.1, where the device showed stable threshold switching behavior. The p-bit circuit was built with the CTHP device connected with a series resistor and a comparator to generate fluctuating random binary outputs with time. The random output of the circuit is mainly due to the variation of switching voltage, delay time, and relaxation time of the CTHP filamentary switching. The measured output voltage average shows a sigmoidal relationship with the input voltage, which is the main feature of the p-bits generating probabilistic outputs. Moreover, the circuit offers power, fabrication, and scalability advantages compared with the reported CMOS and MTJ-based p-bit hardware.
Using the CTHP p-bit characteristics, all 16 invertible Boolean logic gates were demonstrated by Python simulation, assuming the hardware architecture of the p-computing network. Aside from the conventional logic operations in the forward direction, an invertible logic gate can infer the inputs of the logic gate from the outputs. The p-bit outputs were generated following the sigmoidal circuit response considering the device variation. The energy functions and input functions determining the probability of the p-bit outputs were calculated in the field-programmable gate array (FPGA) and digital-to-analog converters (DACs). Moreover, the invertible operation of a half adder was confirmed, which shows the potential of the p-computing network to expand into the applications such as complex arithmetic logic units and integer factorization.

EQ09.09.12
Fabrication of Three-Dimensional Vertical Resistive Random Access Memory and Its Interference Phenomenon Induced by Lateral Charge Spreading Soo Kyeom Yong[1], Seung Soo Kim[1], Hae Jin Kim[2] and Cheol Seong Hwang[1]; [1]Seoul National University, Korea (the Republic of); [2]The University of Suwon, Korea (the Republic of)

The resistive switching random access memory (ReRAM) has been actively researched for decades as a memory that can store data by changing resistance. Due to its nonvolatile characteristics, ReRAM is being studied as a successor of the NAND Flash memory once it reaches the scaling or stackability limit.

The resistance change mechanism of ReRAM could be either an ionic switching mechanism in which a current path is formed and annihilated by the movement of metal ions or oxygen vacancies, or an electronic switching mechanism in which electrons are trapped or detrapped at the trap sites. Among them, electronic switching has the advantage of improving reliability because the electroforming step is unnecessary.
In this work, vertically-integrated ReRAMs (V-ReRAM) with three-word line (WL) stairs were fabricated using the HfO_2 as a resistive switching layer between Pt top and TiN bottom electrodes. After the memory holes with a diameter of ~1 μm were etched into the multi-layers composed of 50 nm-thick SiO_2 (interlayer dielectric) and 25 nm-thick TiN (word line) layers, the 10 nm-thick HfO_2 film was deposited by the atomic layer deposition. Finally, the Pt top electrode was deposited and patterned to complete the V-ReRAM structure. The V-ReRAM had a set voltage of ~6 V, and the ratio of LRS (lower resistance state) current to HRS (higher resistance state) current was > ~100. In addition, it showed self-rectifying characteristics allowing < 10 pA current up to -8 V in the negative voltage region, suppressing the sneak current issue.
The WLs of V-ReRAM share the resistive switching layer vertically deposited in the hole. Therefore, it could bear the lateral charge spreading problem, which deteriorates the data reliability. This problem was indeed confirmed, where the selected cell's HRS curve shifted toward the LRS curve when the adjacent cells were set to the LRS state. This phenomenon occurred because electrons stored in the adjacent LRS cells were diffused through the resistive switching layer to the selected cell, which causes HRS data retention problems.
The interlayer dielectric thickness was increased to solve this problem, but the improvement was only marginal. Therefore, the shallow trap density in the HfO_2 layer, which is the main factor of lateral charge loss, was decreased by plasma treatment. This method confirmed that charge loss in the nearby LRS cells could be minimized. However, the drift of the HRS curve toward the LRS in the selected cell was still observed, indicating unknown reliability issues.

EQ09.09.13
Improvements of Self-Aligned Multi Patterning Spacer Technology by PEALD Sn-Doped SiO_2 Suhyeon Park, Junyoung An, Heejun Yoon and Hyeongtag Jeon; Hanyang University, Korea (the Republic of)

Currently, EUV lithography begins to be adopted in a few patterning processes. But there is technical problem due to the low power of EUV light source and low hardness of EUV PR, self-aligned multi patterning (SAxP) have to be developed. SiO2 was chosen as a first spacer for self-aligned patterning. However, since SiO2 has low elastic modulus of 40GPa, spacer should be improved to prevent spacer collapse during further shrinkage of multi patterning. Therefore, SnO_2 is recently emerged as an alternative material. SnO2 has high modulus and good etch selectivity. But since there are problems of cost and etch issues, we have studied synthesis and characteristics of Sn-doped SiO2 as a spacer material.

Sn-doped SiO2 was mainly studied for optical applications using sol-gel or physical vaper deposition(PVD) such as sputtering. However, it is not a suitable for SAxP spacer deposition due to poor step coverage. Atomic layer deposition (ALD) is one of best method to solve above-mentioned problems. Due to self-limited ALD reaction, it has benefits such as excellent step coverage, uniformity, and thickness control. Also, Sn doping is easy to conduct through ALD super-cycles. Particularly, plasma enhanced ALD(PEALD) was utilized, which is driven by a high plasma energy, allowing low process temperatures to prevent thermal stress issue. As above, Sn-doped SiO2 has been deposited using PEALD.

In this study, we developed low-temperature Sn-doped SiO2 using BDEAS (Bis-Diethylamino Silane, $H_2Si[N(C_2H_5)_2]_2$), TDMA-Sn (Tetrakis(dimethylamido)tin(IV), $[(CH_3)_2N]_4Sn$) and O_2 reactant plasma as the Si, Sn precursor and reactant plasma. We studied about the effect of doping Sn in SiO2 film by varying the cycle ratio of SnO_2 and SiO_2 and their film properties were evaluated. The ratio of the SnO_2 and SiO_2 deposition cycle was varied from 15(SiO_2) : 1(SnO_2), 9:1, 6:1, 4:1 to 3:1. Auger electron spectroscopy (AES) was utilized to measure the atomic concentration. As the SnO_2 cycle ratio increase, the amount of Sn in the SiO_2 thin film increase. The X-ray photoelectron spectroscopy (XPS) showed that the greater amount of Sn in the SiO_2 thin film, the binding energy of Si2p and Sn3d shift toward lower, and more Si-O-Sn chemical bonding are formed, which increased the number of stiffer ionic bonds. Therefore, the Young's modulus measured by a nanoindenter increased from 39.9GPa at SiO_2 films to 90.9GPa at 3:1 film. However, the hardness results showed a different tendency showing decrease from 34GPa at 15:1 to 2.8GPa at 9:1 then increase to 7.9GPa at 3:1. This is because Sn is not well distributed in the SiO2 film due to the cyclic system of ALD and the low distribution energy of the low-temperature process, resulting in a bilayer structure of Sn-doped SiO2/SiO2/Sn-doped SiO2/SiO2 under the conditions of 15:1, 9:1 and 6:1. These results are compensated by X-ray reflectivity (XRR) and Time of Flight secondary ion mass spectrometer (TOF-SIMS) analysis. Moreover, the GPC of SiO_2 and SnO_2 is 1.45Å/cycle, 1.0 Å/cycle. The values of the Sn-doped SiO_2 films are in between value of pure SiO_2 and SnO_2.

EQ09.09.14
A Study on the Al Doping Effect of HfO2 Thin Films Using PEALD MinJung Oh, Jina Song and Yoon Chang-Bun; Tech University of Korea, Korea (the Republic of)

A memory semiconductor, a component that stores information, is an essential element in all electronic devices. There are many different types of memory semiconductors. Dynamic Random Access Memory (DRAM) and Flash Memory are widely used. Although DRAM has the advantage of processing data at high speed, it is a volatile memory that loses data when no power is supplied. Also, Flash memory has the advantages of being small, light, and robust against physical shocks, but the disadvantage is that the data processing speed is slow. They are reaching the limit of processing the lots of data generated by society.
Research on new memories to replace these devices is continuously being done. FeRAM (Ferroelectric Random Access Memory) is a next-generation memory with only the advantages of DRAM and Flash Memory. It can preserve data even when power is not supplied and process information quickly. This device is one of the representative non-volatile memories using ferroelectrics. It has a memory function by distinguishing '0' and '1' according to the polarization direction, and it can be used as a non-volatile memory by using the characteristic of maintaining polarization even when the voltage is cut off. It is known that the initial ferroelectricity occurs in perovskites such as SrTiO3, KTaO3, and CaTiO3. However, recently, HfO2 and ZrO2 thin films have emerged as new types of ferroelectric materials, and many studies have been conducted. Also, HfO2-based ferroelectric materials are being researched by doping various materials such as Zr, Si, Y, and Al. Among the many dopants, HfO2 exists in a high dielectric constant structure at high temperatures, so changing the crystal structure with a high dielectric constant at room temperature is crucial.
This study studied ferroelectricity by growing a tetragonal HfO2 thin film by doping with Al. In order to evaluate the non-volatile memory characteristics, a metal-ferroelectric-metal (MFM) structure was fabricated using an Al-doped HfO2 ferroelectric thin film. The Al:HfO2 thin film was fabricated using PE-ALD (Plasma Enhanced Atomic Layer Deposition), and the HfO2 thin film doped with 5-10 mol% Al was deposited by controlling the deposition ratio of HfO2 and Al2O3. TiN was deposited on the upper and lower electrodes to improve the ferroelectricity of HfO2 by sputtering. Annealing was performed between 500 and 700 degrees to generate crystallinity while removing organic matter. Transmission electron microscope (TEM) analysis was performed to confirm the structure of the thin film. In addition, X-ray photoelectron spectroscopy (XPS) was used to evaluate the Al:HfO2 doping concentration. The growth of the tetragonal phase according to the heat treatment temperature of Al:HfO2 was analyzed using XRD. To evaluate the electric properties of the thin film, the leakage current characteristics of Al doped HfO2 thin films were measured according to the applied voltage. In addition, Polarization (Pr) was measured to confirm the ferroelectric properties.

Physical Unclonable Function Devices Based on Randomness of Grain-Boundary Formation in Calcium Titanate Perovskite Layers Subin Lee and

Hocheon Yoo; Gachon University, Korea (the Republic of)

The stability of physical unclonable function (PUF) devices, regarded as the fingerprint of security applications, is the crucial point. Hence, we present a robust PUF device that maintains its randomness uninfluenced by ambient gases such as O_2 or H_2O. We synthesized calcium titanate (CTO) perovskite layers and controlled their grain boundary morphologies. The grain boundaries were formed differently by the annealing temperature, and as grain boundaries increased, the current value was distributed randomly. We also performed X-ray diffraction, X-ray photoelectron spectroscopy, scanning electron microscope, and UV-Visible spectrophotometer to investigate the CTO morphological change. The fabricated PUF devices which were annealed at 650 ºC and 800 ºC have different crystal structures, respectively. Through the mentioned comprehensive analysis, we observed that the CTO PUF devices annealed at 800 ºC provide increased grain boundaries compared to that of the same CTO annealed at 650 ºC. By measuring total 214 PUF devices, we also found that the current values were dispersed randomly at 800 ºC annealed device. Based on the CTO morphological control, the algorithm based on generative adversarial networks (GAN) is used and we evaluated the estimation component randomness and inter hamming distance. As a result, the less grain boundary device was analyzed to have the lop-sided statistics value which cannot operate on the security device. The randomness and inter-hamming distance were 4.16 % and 8 %, respectively. On the other hand, it is investigated that having lots of grain boundaries device has a random value which can form the Gaussian distribution. The randomness and inter-hamming distance were measured to 49.53 % and 46.55 % at 800 ºC annealed device. Therefore, we suggest the security device by the simple sol-gel process, having the random current value due to the control of grain boundaries.

EQ09.09.16

Pre-State-Dependent Ternary/Binary Logic Operation Obtained by Ink-jet Printed SWCNT/InO Heterojunction Transistors Somi Kim[1], Seoyeon Jung[2], Bongjun Kim[2] and Hocheon Yoo[1]; [1]Gachon University, Korea (the Republic of); [2]Sookmyung Women's University, Korea (the Republic of)

The conventional von Neumann architecture, in which memory and processor are separated, has limitations in processing speed, energy consumption, and integrated circuits for next-generation electronic products. To solve the bottleneck of the von Neumann architecture, it is desirable to develop a new logic driving operation technique that simultaneously satisfies logic and memory control operation. Here, we present a pre-state-dependent ternary/binary logic inverter using a single-walled carbon nanotube (SWCNT)/ indium oxide (InO) heterojunction anti-ambipolar field-effect transistor (FET), which is reliably formed by an ink-jet printing method. The suggested device has a logic-in-memory characteristic that allows it to operate in ternary or binary mode change depending on the previous state. To be specific, when the previous state is V_{DD} = 3 V, the output value at the intermediate input follows the same V_{DD} = 3 V, and when the previous state is G_{ND} = 0 V, the output value at the intermediate input is half V_{DD} = 1.5 V. The maximum DC gain peak of 11.42 V/V in the forward V_G sweep and 19.14 V/V in the reverse V_G sweep, respectively, demonstrated the functions of ternary and binary inverter operation. In the pulsed-measurement, this study also demonstrates the transient operation of the pre-state-dependent ternary/binary logic inverter circuit. Due to the hysteresis in the current-voltage curve of the InO FET used as the n-type FET and the negative transconductance (NTC) region of the anti-ambipolar FET, showing the binary behavior in the reverse bias while the ternary behavior in the forward bias. The device was manufactured by the ink-jet print method, which has multifarious advantages such as low cost, easy manufacturing process, ambient condition manufacturing, and large-area manufacturing.

Organic Charge Modulated Field–Effect Transistor-Based Pressure Sensor Operated by Electrospun Piezoelectric Polymer Taehoon Hwang, Jungyoon Seo and Hwasung Lee; Hanyang University, Korea (the Republic of)

Organic Field Effect Transistor (OFET) was a basic electronic device, and due to its high structure and signal amplification effect, it was receiving high attention for the development of pressure and chemical sensors and its application potential in the field of wearable electronics. However, in the case of an OFET-based sensor, since an active layer that could detect a signal is formed on top of the source/drain or gate electrode and works, the basic component of the device was damaged by external stimuli, and finally the stability of the unit device, There were issues with performance and reliability degradation. Organic Charge Modulated FET (OCMFET) had a characteristic where the voltage applied to the control gate was induced through an insulator and a operating voltage was applied to the floating gate, and depending on the voltage applied to the control gate, it was possible to control the carrier required to operate the element. Also, by configuring the sensing area in the extended floating gate, it could be applied as a sensor and operation of the element without damaging the components of the FET, so it was advantageous in terms of securing the stability of the element. In this study, an OCMFET was fabricated using Dinaphtho[2,3-b:2′,3′-f]thieno[3,2-b]-thiophene (DNTT) organic semiconductor and anodized AlOx dielectric, and pressure sensor was fabricated by applying electrospun PVDF-TrFE-elastomeric template with piezoelectric properties to floating gate. The PVDF-TrFE mat fabricated using electrospinning induced the alignment of b-crystals in the polymer by the applied voltage and the strong elongation force applied therewith, so it had high piezoelectric performance without the poling process. In addition, the template was fabricated by impregnating PDMS to impart elastomeric properties to PVDF-TrFE mat. The OCMFET-based pressure sensor developed through this study exhibits stable FET performance, so it can be applied to various wearable sensor fields such as human motion monitoring, biomedical, and artistic intelligence in the future.

Complementary Hybrid Superlattice Semiconductor with Multi-Channel Charge Transport and Mutual Stabilization Jongchan Kim and Myung M. Sung; Hanyang Univeristy, Korea (the Republic of)

We present an organic-inorganic hybrid superlattice as an example of near-perfect synergistic integration between organic and inorganic materials to achieve superior properties to those of individual components alone. The complementary hybrid superlattice is a multiple quantum well structure of 4-mercaptophenol organic monolayers and amorphous ZnO nanolayers. We observed multichannel formation in the hybrid superlattice, associated with a high-performance field effect transistor exhibiting excellent charge carrier mobility and steep subthreshold swing with band-like transport. In addition, mutual stabilizations between the organic monolayers and ZnO prevent the operation instability critical in exclusively organic and ZnO semiconductors.

EQ09.09.19

Effect of Biaxial Strain on the Electronic and Magnetic Properties of $CuFeS_2$ Roman Malyshev[1], Bjørnulf Brekke[1], Ingeborg-Helene Svenum[2,1], Sverre Magnus Selbach[1], Christoph Brüne[1], Arne Brataas[1] and Thomas Tybell[1]; [1]NTNU, Norway; [2]SINTEF Industry, Norway

Antiferromagnetic materials are robust in external magnetic fields. This, along with demonstrated high-frequency switching, enables the development of high-speed electronics. Here, magnetic semiconductors present an opportunity, as they enable doping and epitaxial strain to fine-tune their properties. $CuFeS_2$ is a thermoelectric, low-bandgap semiconductor and collinear antiferromagnet, with a Néel temperature above 800 K, making it a potential candidate for spin-based devices. Here, we investigate strain-engineering as a tool for controlling physical properties of $CuFeS_2$, and present a density functional theory (DFT) study on the effect of bi-axial strain on $CuFeS_2$. Neither tensile, nor compressive, bi-axial strain, +/- 5 %, alters the crystal structure or symmetry. However, the calculations show a small change in magnetic moments with strain, increasing under tensile and decreasing under compressive strain for Fe. For Cu atoms the magnetic moment increases for both tensile and compressive strain. The emergence of a small magnetic moment on the Cu atoms has previously been observed experimentally. The magnetic structure will be compared with changes in the band structure, density of state and the nature of the bands near the Fermi level in order to understand the effect of strain on the transport properties.

EQ09.09.20
The Effect of Molecular Additions to the Spin Transition and Conductivity of Spin-Crossover Molecules Thilini K. Ekanayaka[1], Yuchen Hu[2], Esha Mishra[1], Jared Paul Phillips[3], Saeed Yazdani[3], Alpha T. N'Diaye[4], Jian Zhang[5], Ruihua Cheng[3] and Peter A. Dowben[1]; [1]University of Nebraska Lincoln, United States; [2]University of Nebraska–Lincoln, United States; [3]Indiana University-Purdue University Indianapolis, United States; [4]Lawrence Berkeley National Laboratory, United States; [5]Lawrence Berkeley National LaboratoryMolecular Foundry, United States

With the increasing interest in organic molecular multiferroic electronic devices, for flexible non-volatile memory, manipulation of conductivity of various spin crossover (SCO) molecular materials has been gaining attention. Spin crossover (SCO) molecular materials are promising bi-stable magnetic materials and have been identified as an attractive candidate for memory devices. SCO molecules are transition metal based complexes which exhibit reversible spin transition between low spin (LS) and high spin (HS) states and can be fabricated into a voltage controlled device. The voltage control spin state switching of these SCO molecular thin film materials has been studied and the spin state switching by voltage leads to nonvolatile conductance change, when combined with an organic ferroelectric layer. But to make a competitive non-volatile memory device out of SCO and an organic ferroelectric, that can compete with silicon technology, there are several key criteria that need to be addressed. Building an SCO memory device with a low on-state resistance has proved to be a major challenge. The spin transition behavior of $[Fe\{H_2B(pz)_2\}_2(bipy)]$ spin crossover molecule has been well studied and has been used as a successful compoent of a non-volatile memory device, although the on-state resistance is high (approximately 10^3 Ohm.cm). With a molecular ferroelectric gate dielectric layer, molecular SCO $[Fe\{H_2B(pz)_2\}_2(bipy)]$ exhibited an on/off ratio of 4 to 5 and both isothermal switching and nonvolatility was demonstrated in the transistor device geometry. As an approach to increasing the conductivity, so as to increase the on/off ratio of the SCO molecular devices and make smaller devices practical, we have mixed TCNQ (7,7,8,8-tetracyanoquinodimethane) anions with the molecular SCO $[Fe\{H_2B(pz)_2\}_2(bipy)]$. When compared to the pure $[Fe\{H_2B(pz)_2\}_2(bipy)]$ molecular thin film SCO system, the conductivity is enhanced by mixing $[Fe\{H_2B(pz)_2\}_2(bipy)]$ with TCNQ. The spin transition of $[Fe\{H_2B(pz)_2\}_2(bipy)]$ is also perturbed by adding TCNQ. The transistor measurements taken for the $[Fe\{H_2B(pz)_2\}_2(bipy)]$ SCO + TCNQ, with and without a ferroelectric layer, shows large charge trapping the latter case.The system shows a low charge carrier mobility and higher drift carrier lifetime which is consistent with extensive charge trapping.

BiSb(012) Crystallinity and Strong Spin Orbit-Torque Enhancement Using Insertion Layers HanYin Poh, Calvin Ang and Wen Siang Lew; Nanyang Technological University, Singapore

Topological insulator is a promising candidate for spintronics applications as it has high charge-to-spin conversion due to its time-reversal symmetry and spin-momentum locking in the Dirac surface state. However, the surface state is vulnerable to disruption like exchange coupling to ferromagnet materials. Here, we demonstrate different insertion layer (Ti, Cu, Pt) at the Co/BiSb interface to promote the topological surface state of BiSb(012). The BiSb(012) surface state is in focus based on having 3 Dirac cone at the , which are ideal in obtaining high spin-orbit torque efficiency. The insertion layers induced large spin Hall angle of up to 10.4, that were otherwise negligible without any insertion layer. We further explore the spin-orbit torque efficiency with BiSb thicknesses ranging from 10 to 100 nm. Our results show a rapidly increasing spin-orbit torque efficiency with BiSb thickness that gradually saturates above 30nm. A clear correlation between the spin-orbit torque efficiency and the crystalline size of BiSb(012) was later verified via x-ray diffractometry. Thus, confirming the crystalline orientation of BiSb(012) being the crucial factor to achieve high spin orbit efficiency. Our work paves the way for the adaptation of topological insulators as the new class of spin source material for spintronics applications.

The Effect of Environment on Electronic Structure of Co Spin Crossover Molecules—An XPS, XAS and IPES Study Esha Mishra[1], Ping Wang[2], Thilini K. Ekanayaka[1], Kayleigh A. McElveen[3], Jared Paul Phillips[4], Mohammad Zaid Zaz[1], Saeed Yazdani[4], Alpha T. N'Diaye[5], Duy Le[6], Rebecca Y. Lai[3], Robert Streubel[1], Ruihua Cheng[4], Talat S. Rahman[6], Michael Shatruk[2] and Peter A. Dowben[1]; [1]University of Nebraska-Lincoln, United States; [2]Florida State University, United States; [3]University of Nebraska–Lincoln, United States; [4]Indiana University-Purdue University Indianapolis, United States; [5]Lawrence Berkeley National Laboratory, United States; [6]University of Central Florida, United States

Two valence tautomeric spin crossover cobalt complexes $[Co(SQ)(Cat)(4\text{-}CN\text{-}py)_2]$ and $[Co(SQ)(Cat)(3\text{-}tpp)_2]$ have been investigated with a combination of X-ray photoemission spectroscopy (XPS), X-ray absorption spectroscopy (XAS) and inverse photoemission Spectroscopy (IPES) with the aim of ascertaining the unoccupied molecular orbitals that contain both ligand and metal weight. The alignment of the spectroscopic core levels from XAS and IPES validates the existence of unoccupied metal ligand charge transfer state in these cobalt spin crossover systems. These studies demonstrated that the changes to the electronic structure of $[Co(SQ)(Cat)(4\text{-}CN\text{-}py)_2]$ and $[Co(SQ)(Cat)(3\text{-}tpp)_2]$, when an interface is created with either of polar organic molecule, poly-D-lysine or semi conducting polymer, polyaniline, is minimal. The metal-ligand unoccupied states have been identified and the states are largely insensitive to the polymer to spin crossover molecular interface, when the spin crossover complex is in the high spin state.

Spin-Polarized Flexoelectricity John D. Cavin and James M. Rondinelli; Northwestern University, United States

Flexoelectricity describes the coupling between electric polarization and a strain gradient. Because it is represented by an even parity rank-4 tensor, it is not prohibited by the presence of inversion symmetry in a crystal in the same way as piezoelectricity. First-principles methods for calculating flexoelectric tensor components have been developed that involve calculating electronic and lattice contributions using various charge-moment and force tensors.[1] In magnetic materials, these charge moments can be spin-polarized – that is, the densities of spin up and down electrons can respond differently to atomic displacement. Based on this principle, we developed a method for calculating spin-polarized flexoelectric tensor components. The existence of spin-polarization in the flexoelectric tensor could be used to create spin-polarized channels of surface charge. We apply our technique to several rock-salt materials with various magnetic orderings to calculate spin-polarized flexoelectric tensor components. We outline a method for experimental confirmation of our work by calculating effective spin-polarized flexoelectric coefficients for particular cases of beam-bending. This work predicts a novel method for developing spin-channels which may be of use in spintronics.

Charge Density Waves in Nano Alkali Molybdenum Oxide Bronzes Nick Russo, Yifeng Cao, Jun Cao, Xi Ling, Linda H. Doerrer and Kevin E. Smith; Boston University, United States

New computing paradigms require new materials exploiting novel phenomena. Another likely requirement is that the material be highly scalable and therefore nanosized. Here we present the preparation and characterization of nanoscale K0.3MoO3 an alkali molybdenum oxide and quasi 1D charge density wave (CDW) material. In bulk K0.3MoO3, CDWs are accompanied by many nonlinear electronic phenomena, such as hysteresis, nonlinear conductivity, and DC to AC conversion, as well as electrically controllable optical and IR properties. These novel phenomena may have some future potential application in computing.
We first present the synthesis of bulk powder K0.3MoO3 using redox mechanochemistry and thermal annealing under an inert atmosphere. From this bulk powder we then synthesize nanoscale K0.3MoO3 by additional mechanochemical ball milling and filtration and then deposit the product on Silicon wafers. We show that the crystal structure of the product is maintained while the average size is reduced with good distribution control using characterization by standards methods including x-ray diffraction and electron microscopy. We then comment on the change in the optical properties and CDW temperature as a function of size.

Propagation Properties of Spin Wave in Non-Magnetic Metal-Covered YIG Waveguide Takumi Koguchi[1,2], Kanta Mori[1], Pang Boey Lim[2], Mitsuteru Inoue[1], Kazushi Ishiyama[1] and Taichi Goto[1]; [1]Tohoku University, Japan; [2]Toyohashi University of Technology, Japan

Spin-wave devices attract many interests because of their low Joule heating and power consumption. These devices can be categorized into a novel spintronic application and have been studied widely recently. A yttrium iron garnet (YIG) is widely used as a waveguide for these devices because of its low damping constant, meaning a long propagation length. To fabricate the waveguide, many groups etch the YIG to change it into a rectangular parallelepiped. However, the demagnetization field in the etched YIG is non-uniform, and spin-wave propagation properties are degraded. The different internal magnetic field in the YIG waveguide shows different dispersion curve. Hence the preferred wavelength of the spin wave is also different. To improve the propagation properties, we propose to use a metal-covered YIG waveguide in this paper. The wavelength of the spin wave propagating in a YIG waveguide covered by the non-magnetic metal film is two times longer than that in a non-coated YIG waveguide [1]. Thus, the spin wave can be reflected at the boundary between the meal-coated YIG and non-coated YIG area, providing waveguide functions.
We prepared the YIG film epitaxially grown on gadolinium gallium garnet (GGG) substrate. The gold film was deposited onto the YIG film and formed into a waveguide shape using lithography. The <0.5 T magnetic field was applied to this composite perpendicular to the film plane. The forward volume spin wave was excited and detected using a coplanar waveguide connected to a vector network analyzer (VNA). The wavelength of the propagated spin wave was about 9 micrometers, close to previous reports. The spin-wave spectroscopy was obtained, showing the Kittel curve, and splitting peaks because of the wavelength selectivity of the antennas.
Furthermore, the width and length of the waveguide were varied, and spin-wave propagation properties were measured. These results indicated that the non-magnetic metal-covered YIG worked as a waveguide. We do not need to etch the YIG when we use this waveguide, increasing the uniformity of the internal magnetic field and magnetization in the YIG film and intensity of propagated spin wave compared with the previously etched YIG waveguide. Therefore, we demonstrated the usefulness of the non-magnetic metal-covered YIG waveguide.

Ferroelectric Phase Formation in $Hf_{0.5}Zr_{0.5}O_2$ Using Dual-Step PLD Growth Strategy for MoS_2 Negative Capacitance Field-Effect Transistors Uisik Jeong, Hae Won Cho, Pavan Pujar and Sunkook Kim; Sungkyunkwan University, Korea (the Republic of)

$Hf_{0.5}Zr_{0.5}O_2$ (HZO) is considered a prominent ferroelectric material at the thin film scale, which usually contain cubic(c), monoclinic(m), tetragonal(t) and orthorhombic(o) phases when crystallized. In particular, the asymmetric o-phase has its own ferroelectricity, but it is not easily obtained due to its metastable state. Comparative studies on the HZO grown on Si by pulse laser deposition (PLD) using 1) direct growth (high temperature deposition) and 2) dual step growth (Rapid thermal annealing (RTA) after RT deposition) strategies have been performed. Compared to other processes, PLD is easy to control the oxygen partial pressure, and high energy particles generated by the pulse laser can produce high quality thin film. Although many studies on ferroelectrics have been conducted with the ALD process, there has been no case of applying it to ultra-low power logic applications based on the PLD-HZO. We obtained a polycrystalline HZO by crystallization via direct deposition at a high temperature, whereas a pure o-phase without non ferroelectric m-phase is formed through RTA treatment after RT deposition with maximized ferroelectricity. By capacitance matching with a high-k dielectrics (HfO_2) on HZO grown on a Si, MoS_2 NCFET were driven with subthreshold swing of 20.42 and 26.16 mV/dec in the forward and reverse directions, respectively. By optimizing various parameters of the PLD process to obtain a ferroelectric HZO thin film, and to evaluate the device, it is expected to be a modeling study for the next generation low-power device research.

EQ09.09.27
Exploring the Limits of RKKY Coupling for Synthetic Antiferromagnets Amal El-Ghazaly and Karthik Srinivasan; Cornell University, United States

Synthetic antiferromagnets (SAFs), made from ferromagnet/non-magnetic metal/ferromagnet exchange-coupled heterostructures, represent a crucial component of magnetic tunnel junctions and giant magnetoresistance spin valves. Yet, beyond their usage for pinning the magnetization in these multilayer, ultra-thin-film stacks, the limits of their reach in thicker films and other applications have not been given much attention. The widespread practice is to grow SAFs with a non-magnetic metal spacer layer thickness optimized to achieve the first oscillatory peak for antiferromagnetic interlayer exchange coupling. However, recent work by Waring et al. suggests that when Ru is used as the metal spacer material, the second oscillatory antiferromagnetic exchange coupling peak may, in fact, achieve better antiferromagnetic anisotropy resulting from the fact that the slightly thicker Ru layer provides better uniformity of the grown material film [1]. This increased interlayer exchange coupling manifests itself as a narrower resonance peak with fewer damping losses in the SAF structure, thereby translating to more efficient, low-power operation. Delving deeper into this question of efficiency, the present research work explores the variation in magnetic anisotropy in $Co_{43}Fe_{43}B_{14}$/Ru/$Co_{43}Fe_{43}B_{14}$ exchange-coupled SAF trilayers. Thicknesses of both the non-magnetic and magnetic layers are experimentally varied to observe the change in RKKY coupling strength.

Varying the thickness of the Ru non-magnetic metal spacer between the two ferromagnetic layers produced the signature oscillatory behavior between ferromagnetic and antiferromagnetic interlayer exchange coupling. In the first set of experiments, Si substrate/SiO_2/CoFeB (5 nm)/R (t_{Ru})/CoFeB (5 nm)/Pt (5 nm) trilayer films were grown with a Ru spacer layer thickness varying between t_{Ru} = 0.25 to 3.0 nm, in increments of 0.125 nm steps. A single layer of CoFeB with thickness 10 nm (without a Ru spacer in the middle) was also deposited and used to calibrate the total magnetic moment expected from the SAF multilayer films. Upon inspection, the second antiferromagnetic RKKY peak appeared to correspond to the SAF trilayer with a Ru thickness, t_{Ru} = 1.875 nm, which was thicker than the 1.1 nm Ru thickness observed by Waring, et al. Nevertheless, by analyzing magnetization hysteresis behavior for each of the grown films, we demonstrate the gradual transitions between interlayer coupling configurations and strengths.

At the optimal antiferromagnetic interlayer coupling, t_{Ru} = 1.875 nm, the thickness of the ferromagnetic layers was also varied. For thinner ferromagnetic films, the exchange coupling across the Ru thickness is expected to have a strong effect throughout the entire magnetic thickness. However, as the

ferromagnetic layer thickness increases, the antiferromagnetic interlayer exchange coupling becomes less pronounced. This behavior is seen experimentally as the thickness of the ferromagnetic layer in the stack substrate/SiO_2/CoFeB (t_{FM})/Ru (1.875 nm)/CoFeB (t_{FM})/Pt (5 nm) is varied between t_{FM} = 2.5 nm to 25 nm in steps of 2.5 nm. As expected the antiferromagnetic exchange decreases as the thickness of the ferromagnetic layer it has to act upon increases, corresponding to an overall reduction in the anisotropy. Thus, this research illustrates that optimization of both the non-magnetic metal spacer and the ferromagnetic layer thicknesses can be used to achieve strongly-coupled and highly-efficient synthetic antiferromagnetic films for future low-power integrated systems.

Tunable Anomalous Hall Conductivity of Itinerant Ferromagnet CoS_2 Joonyoung Choi[1], Mi Kyung Kim[2], Wonshik Kyung[3,4], Changyoung Kim[3,4], Jin-Hong Park[5], Jun-Won Rhim[5], Se Young Park[6] and Younjung Jo[1]; [1]Kyungpook National University, Korea (the Republic of); [2]Yonsei University, Korea (the Republic of); [3]Institute for Basic Science, Korea (the Republic of); [4]Seoul National University, Korea (the Republic of); [5]Ajou University, Korea (the Republic of); [6]Soongsil University, Korea (the Republic of)

The electrical tunability of material is the most important property for the application of new technologies. Modification of anomalous Hall conductivity (AHC) is an example that is required for spin-torque devices or advanced magnetic sensors. In that case, cobalt disulfide (CoS_2) is a suitable material with the potential to increase its AHC a lot. CoS_2 is an itinerant ferromagnet and expected to be a magnetic topological material as it has turned out that there is small gapped Dirac-type dispersion at a little below the Fermi level as a Berry curvature (BC) source, originating AHC. The BC source is along the Γ-M direction in k-space and there are four of it in the first Brillouin zone possessing the same sign, resulting in a large contribution to AHC without canceling out each other. In this work, we measured the AHC of CoS_2, controlling the amplitude of AHC by Fe- (hole) and Ni- (electron) doping, respectively. Purely intrinsic origin and the largest value of AHC have been observed in $Co_{0.95}Fe_{0.05}S_2$. This result is well consistent with the AHC calculated by LDA+U methods in the energy scale.

Design Principles to Control Non-Bonding States for Highly Tribopositive Property Donghyeon Kang, Jihye Kim, SeongMin Kim and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

The development of tribopositive materials is highly required to realize durable and high-performance triboelectric generators. Here, we introduce a novel principle to control local dipoles for designing highly tribopositive materials and suggest nitrogen-based dimethylol urea (DMU), diazolidinyl urea and imidazolidinyl urea as promising tribopositive materials. A mechanism by which the nitrogen-based urea materials provide high tribopositive properties was investigated using negative local dipoles formed in the highest occupied molecular orbital composed of non-bonding electrons. Negative local dipole is formed by the electron accumulation around the high electronegative atoms, which attract electrons from bonded atoms and tend to donate their electrons to atoms in other materials, and thus negative local dipole induces the electron donating environment. In addition, we confirm the proposed design protocol by analyzing the charge transfer characteristics of DMU based on the dipole interaction through density functional theory (DFT) calculations, quantitatively.

Hexagonal MnTe - a Conducting Room Temperature Antiferromagnet Kacper P. Kluczyk[1], Katarzyna Gas[2], Michal Grzybowski[1], Michal A. Borysiewicz[3], Tomasz Fas[1], Jan Suffczynski[1], Pawel Skupinski[2], Krzysztof Grasza[2], Elzbieta Lusakowska[2], Andrzej Mycielski[2], Maciej Sawicki[2] and Marta Borysiewicz[1]; [1]University of Warsaw, Poland; [2]Polish Academy of Sciences, Poland; [3]Lukasiewicz Research Network - Institute of Microelectronics and Photonics, Poland

The idea of exploiting magnetic state of the antiferromagnets has become especially timely after groundbreaking demonstrations of current-induced control of Néel vector orientation in these materials [1-3]. Not only do these accomplishments motivate to search for new antiferromagnetic platforms, but also to reexamine some old, prototypic materials. One of such classical antiferromagnets is hexagonal MnTe, a semiconductor with a moderate bandgap (E_G ~1.3 eV) and the Néel temperature just above 300 K. This material in a form of thin films has been extensively studied recently pointing to the role of substrate on its electronic properties [4,5].

In this report we present results of studies of bulk hexagonal MnTe, a reference free standing system to its epilayer counterparts. The material is grown from the vapour phase via reaction of tellurium vapors with manganese powder at a temperature adjusted to reduce the formation of other crystallographic phases. A clear magnetic phase transition between the antiferromagnetic and paramagnetic states is observed at about 310 K, in agreement with the previous studies [4,6,7]. Although the samples are polycrystalline the individual grains have their hexagonal c-axis aligned in the same direction. This crystallographic composition is confirmed by observation of uniaxial magnetic anisotropy below the Néel temperature, whose temperature and magnetic field dependence are characteristic for a system with simple antiparallel spin structure within the *c*-plane but with the Néel vectors equally distributed among three possible orientations differing by 2p/3 [6]. Our findings makes highly unlikely the possibility of the existence of spin-flop processes reported earlier for epitaxial MnTe [4]. The samples are p-type with an activated character of the temperature dependence of the resistivity characterized by the activation energy of 10 meV. A clear anomalous Hall effect is observed with a pronounced hysteresis loop below the Néel temperature. This evokes questions about the origin of this effect in a magnetically compensated material. The possible origin of this effect will be discussed, referring to the novel concept of altermagnetism [8].

Realizing Topological Superconductivity in Ultrathin FeTeSe Films Shuolong Yang; The University of Chicago, United States

Topological superconductors are the material platforms to realize emergent quasiparticles called Majorana zero modes, which are the basic units for nonabelian statistics and topological quantum computation. Earlier material realizations of topological superconductors are semiconductor nanowires coated with low-temperature superconductors, which not only bear substantial manufacturing complications but also remain under debate in terms of the fundamental physics picture. Here we introduce our latest effort using molecular beam epitaxy to fabricate ultrathin $FeTe_xSe_{1-x}$ thin films on $SrTiO_3$ substrates, where the topological surface state is proximity-coupled to its own superconducting bulk. This leads to a robust topological superconducting state which is manifested in the observation of a superconducting Dirac surface state. By systematically varying the Te:Se ratio and the film thickness, we observe the Dirac surface state in ultrathin $FeTe_xSe_{1-x}$ films with $x > 0.7$ and thickness > 2 layers. As we thin down the $FeTe_xSe_{1-x}$ films, a drastic band structure evolution is identified due to the hybridization of the top and bottom Dirac surface states, which transforms the band structure quickly into a correlated insulating state in the monolayer limit. Our study not only marks the thinnest topological superconducting film ever fabricated so far, but also paves the road towards topological quantum devices based on ultrathin films.

Understanding the Transition from Metal to Hund's Insulator in CaFeO$_3$ Maximilian E. Merkel and Claude Ederer; ETH Zurich, Switzerland

Strongly correlated materials show great potential for energy-efficient transistors thanks to the sharp metal-insulator transition (MIT) that some of them exhibit. However, this MIT is almost always coupled to a structural distortion, which can lead to fatigue effects and limit the switching frequency. To better understand the different types of distortions, more fundamental knowledge about the complicated physics at work here is needed.

Recently, materials where strong correlations are caused by the Hund's interaction have attracted a lot of attention. In some cases, a dominant Hund's interaction can even lead to the emergence of a charge-disproportionated insulating (CDI) or "Hund's insulating" state, which can cause an MIT. One example is the perovskite transition-metal oxide CaFeO$_3$ (CFO) with a transition close to room temperature. This transition couples to a structural distortion that creates alternating large and small FeO$_6$ octahedra, leading to two inequivalent Fe sites with nominal Fe^{5+} and Fe^{3+} charge states.

We study CFO using density functional theory (DFT) and dynamical mean-field theory (DMFT). To characterize the CDI state, we first apply DMFT to a five-orbital Hubbard model applicable to CFO and demonstrate the emergence of the CDI phase [1]. We then investigate the energetics of the transition using fully self-consistent DFT+DMFT calculations, which show that both structural and electronic properties of the CDI state can be well described within DFT+DMFT.
Finally, we discuss the ligand-hole character of the charge disproportionation and analyze the role of the zero or even negative charge-transfer energy in CFO as well as its influence on the emergence of the MIT.

Tunable Perpendicular Magnetic Anisotropy in Amorphous Gd_xCo_{1-x} Alloys Karthik Srinivasan, Yulan Chen, Ludovico Cestarollo and Amal El-Ghazaly; Cornell University, United States

Amorphous magnetic alloys have been at the forefront in the development of magnetic random-access memory due to their favorable perpendicular magnetic anisotropies (PMA) and deterministic read/write mechanisms with magnetoresistance and spin-orbit torques. While amorphous ferromagnets are well researched, they are limited by low switching speeds (in ~ns) and constrained in their read/write energy-efficiency by the large angular momentum, which requires a large critical current for switching. Unlike ferromagnets, ferrimagnetically coupled systems offer faster switching dynamics due to their stiffer exchange interactions, minimal stray field due to their lower net saturation magnetization, and tunable anisotropy and net magnetization due to the existence of two counteracting sublattices. Here, we report on amorphous thin films of GdCo that have a ferrimagnetic order (antiparallel spin orientation) with bulk-like PMA and stoichiometries near its magnetic-compensation that coincide with lower total angular momentum compared to ferromagnets and the potential for much higher switching speeds on the order of tens of picoseconds. Sputter-deposited heterostructures of Ta(3 nm)/Pt(3 nm)/Gd_xCo_{1-x}(t)/Pt(5 nm) on Si/SiO_2(3 nm) substrates exhibit bulk-like PMA for Gd_xCo_{1-x} thicknesses of 5-12 nm and stoichiometries where x = 18-40%. A strong uniaxial anisotropy for out-of-plane magnetization with an anisotropy field (H_k) of 0.24 T was observed when the Gd:Co ratio was 35:65, which is near the composition that results in a magnetic compensation at room temperature. Interestingly, it was found that strong PMA in GdCo is possible only with a non-negligible amount of oxygen in the thin film. Oxygen flow rates were adjusted between 0-0.8 sccm during deposition and a maximum effective anisotropy energy density of 1 x 10^5 erg cc^{-1} was obtained for a metal cation to oxygen (R:O) ratio of 50:50, which corresponds to a flow rate of 0.5 sccm. Furthermore, X-ray photoelectron spectroscopy (XPS) revealed that with an increase in oxygen concentration, Co oxidizes preferentially over Gd, resulting in Co-deficient stoichiometries from lower sputter yields at higher oxygen flow rates. Strong PMA is observed in a stoichiometry of $Gd_{21}Co_{28}O_{51}$ with a Gd:Co ratio of 3:4 and an R:O ratio of 1:1, which suggests that the strong ferrimagnetic order likely arises through a superexchange-like coupling between the magnetic cations (R: Gd,Co) via the non-magnetic anion (O) in this amorphous alloy. With the single layer optimized, super-lattice heterostructures could be developed. Even greater PMA is achieved in a heterostructure with 10 repetitions of the $Gd_{35}Co_{65}$ alloy. These films exhibit an anisotropy field on the order of 11.6 kOe, which corresponds with switching speeds as low as 30 ps. The combination of ferrimagnetic ordering (lower total angular momentum) in amorphous GdCo (reduced thermal budget) and well-defined pathways for a strong PMA (low-energy magnetization switching due to the very short picosecond-range write pulses required) make these thin films a suitable choice for ultrafast energy-efficient memory devices.

Spin-Resolved Unoccupied States of $NiCo_2O_4$ Thin Films Arjun Subedi, Corbyn Mellinger, Xiaoshan Xu and Peter A. Dowben; University of Nebraska–Lincoln, United States

Theoretical calculations indicate that $NiCo_2O_4$ is a half-metal with fully spin polarized carriers [1], although realization of half metallicity is in fact very doubtful [2] especially at finite temperatures. It remains important, nonetheless, to ascertain whether $NiCo_2O_4$ is a high polarization material and whether the spin polarization has a projection in the plane of the thin film. We observed in-plane net spin polarized unoccupied states of $NiCo_2O_4$ near Fermi level

using spin-polarized inverse photoemission spectroscopy (SPIPES) which is an extremely surface sensitive technique. Although $NiCo_2O_4$ is thought to possess a perpendicular magnetic anisotropy, the presence of in-plane spin-resolved unoccupied states could indicate the influence of the surface on magnetic ordering.

Stimulation Rate-Dependent 1S1R Synapse with Short-Term Plasticity TiO_x-Based Exponential Selector Mun Yin Chee, Putu Andhita Dananjaya, Gerard Joseph Lim and Wen Siang Lew; Nanyang Technological University, Singapore

Short-term plasticity (STP) is an important synaptic characteristic in hardware-based artificial neural networks, as it is suitable for temporal information processing (TIP).[1–3] However, the STP feature is difficult to be demonstrated in a single non-volatile memory because it requires a certain degree of volatility. Generally, selector devices are implemented with a non-volatile resistive random-access memory (RRAM) in one selector-one RRAM (1S1R) configuration to suppress the sneak current in a crossbar array.[4,5] In this work, a TiO_x-based selector is introduced not only to suppress the sneak current but also to enable the TIP feature in the 1S1R synaptic device, which consists of a Pt/TiO_x/Pt exponential selector and a Pt/HfO_x/Ti RRAM device. Our measurements reveal that the exponential selector exhibits the STP characteristic, while the RRAM device enables the long-term memory capabilities of the synapse. With the corresponding 1S1R device, an on/off ratio of up to ~ 18 can be achieved under optimised reading conditions. Furthermore, 5000-cycle writing endurance was demonstrated with uniform switching. Moreover, the potentiation and depression synaptic characteristics are realised in the 1S1R device. Thereafter, we experimentally demonstrated the stimulation rate-dependent multilevel switching in the 1S1R device. 4 multilevel states were achieved in the 1S1R synapse using different frequencies of pulses at 100 000 Hz, 50 000 Hz and 100 Hz, demonstrating the TIP capability in the 1S1R device. This work therefore provides a reliable means of producing the TIP capability in a 1S1R device.

Metal-$Hf_{0.5}Zr_{0.5}O_2$-Al_2O_3-Metal Ferroelectric Tunnel Junction Stack Optimization for Enhanced ON/OFF Ratio Keerthana S. Nair[1,2], Marco Holzer[1,2], Catherine Dubourdieu[1,2] and Veeresh Deshpande[1]; [1]Helmholtz Zentrum Berlin, Germany; [2]Freie Universität Berlin, Germany

Hafnium dioxide-based ferroelectrics are enabling the integration of ferroelectric devices into CMOS technology due to their stable ferroelectric phase at nanometer thickness. The low-temperature crystallization (around 400°C) further allows $Hf_{0.5}Zr_{0.5}O_2$ (HZO) based devices to be integrated into the back-end-of-line of CMOS technology. Among the ferroelectric memory devices, ferroelectric tunnel junctions (FTJ) are well-suited for neuromorphic applications due to their ultra-low power consumption and potential to attain multiple resistance states through partial switching of domains from one polarization state to the other. The typical architecture of FTJ devices is metal-ferroelectric-metal, where the ferroelectric layer should be less than 5 nm in thickness and possess a high remnant polarization to achieve a high ON current. As stabilizing high polarization in sub-5 nm thick HZO layer is challenging, an alternate device stack consisting of Metal-Ferroelectric-Dielectric-Metal layers utilizing a thicker ferroelectric layer (~10-12 nm) has recently been demonstrated with a high ON/OFF ratio [1]. In this work, we study CMOS back-end compatible Metal-HZO-Al_2O_3-Metal FTJ with TiN and W metals. Different stacks, by changing the position of the metal electrode and the dielectric, are fabricated to find the optimum configuration for high ON/OFF ratio. It is observed that the ON/OFF ratio is highly dependent on the positioning of the W, TiN electrodes, and the Al_2O_3 dielectric. We will discuss the influence of processing sequence of the layers and the role of resultant interface charge trap density on the FTJ characteristics [2]. The impact of dielectric thickness on ON/OFF ratio will also be discussed. The optimized FTJ device is electrically programmed to demonstrate multiple resistance states through partial switching set and reset operations. The stability of the intermediate states will be discussed based on the endurance and retention characteristics.

Operando Direct Observation of Filament Formation in Resistive Switching Devices Enabled by a Phase Transformation Molecule Kunqi Hou, Wen Siang Lew and Wei Lin Leong; Nanyang Technological University, Singapore

Conductive filaments (CFs) play a critical role in the mechanism of resistive random-access memory (ReRAM) devices. However, in situ detection and visualization of the precise location of CFs are still key challenges. Herein, we demonstrate for the first time, the use of an organic π-conjugated molecule with phase transformation behavior for the positioning and visualizing of the CFs in the ReRAM devices. The π- conjugated molecule (called TT molecule)

has the capacity to transform its molecular shape between twisted and planner states under varying temperatures, which can be translated into corresponding adaptations in crystallization, aggregation behavior, and optical properties. Hence, based on localized Joule heating generated within filament regions, the π- conjugated molecule exhibited reversible optical transformation and thus reflecting the location of the underlying CF. Customized patterns of CFs were induced and observed by the π-conjugated molecule layer, which confirmed the hypothesis. Additionally, statistical studies on filaments distribution were conducted to study the effect of device sizes and bottom electrode heights, which serves to enhance the understanding of switching behavior and their variability at device level. Therefore, this phase transformation molecule and such approach have great potential in aiding the development of ReRAM technology.
Keywords: phase transformation, π-conjugated molecule, conductive filament, ReRAM, spatial filament mapping

Confined Conducting Filaments in Resistive Random Access Memory by Al_2O_3 Nanodome Shaped Arrays (NDSAs) via Glancing Angle Deposition Technology Toward Neuromorphic Computing Ying-Chun Shen and Yu-Lun Chueh; National Tsing Hua University, Taiwan

Resistive random access memory (RRAM) is vital to neuromorphic computing applications. However, filamentary RRAM cells are affected by transitions from abrupt switching to analog switching. In this study, we develop Al_2O_3 nanodome shaped arrays (NDSAs) by glancing angle deposition technology (GLAD) to geometrically confine the conducting filaments (CFs), for which conducting atomic force microscopy (C-AFM) was performed to analyze positions and dimensions of filaments. For the Pt/HfO_2/75 % Al_2O_3 NDSAs/TiN device, the dimension of the CFs can be restricted to 10-12 nm, whereas for the Pt/HfO_2/TiN device, the CFs were formed with the dimension of ~50 nm. The device first yielded multiple weak CFs that subsequently transformed into stronger and larger CFs when the coverage of Al_2O_3 NDSAs was reduced to 55 % while Pt/HfO_2/75 % Al_2O_3 NDSAs/TiN device exhibited synaptic features with more linear potentiation and depression, demonstrating the analog switching. The controllable coverages of Al_2O_3 NDSAs render the geometric design more promising as a memristor for future applications in neuromorphic computing.

Waterproof and Flexible Memristive Physically Unpredictable Functions for Highly Secured Neuromorphic Computing System Jungyeop Oh[1], Sungkyu Kim[2], Junhwan Choi[1], Sung Gap Im[1], Byung Chul Jang[3] and Sung-Yool Choi[1]; [1]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]Sejong University, Korea (the Republic of); [3]Kyungpook National University, Korea (the Republic of)

Recent advances in neuromorphic edge devices and Internet of Things (IoT) technologies have brought the unprecedented expansion of interconnected networks and devices, enabling artificial intelligence (AI) based services to the public. This AI service based on smart IoT devices is an attractive target for cybercriminals because it utilizes remotely connected networks to process large amounts of personal and security-related data. However, it is challenging for the software-based security system, which is subject to physical attack, to combat alone the threat of cybercriminals, therefore a built-in hardware-based security system is essential.
Here, we report that hardware-based security primitives implemented using a physically unclonable function (PUF) that exhibits the high entropy achieved via the random switching nature of a poly(1,3,5-trivinyl-1,3,5-trimethyl cyclotrisiloxane) (pV3D3)-based memristor. The excellent insulating property of pV3D3 induces the thermal dominating reset by localizing the Joule heat generated by the reset high current generated to the conductive filament and enhances the stochasticity of the tunneling distance for randomly ruptured Cu filaments. With high bandgap energy (E_g) (8.25 eV) and low-k (2.2) of the pV3D3, the pV3D3-PUFs exhibit near-ideal entropy, uniqueness, and uniformity as well as reconfigurability. Thanks to the outstanding chemical stability of pV3D3, pV3D3-PUFs show reliable operation under mechanical stress and the water immersion condition for IoT applications in outdoor environments. We demonstrate a 1kbit pV3D3 memristor crossbar array enabling the strong pV3D3-PUF via stochastic in-memory computing, inducing robustness to machine learning attacks of the multi-layer perceptron and the generative adversarial networks. Furthermore, the strong pV3D3-PUF passed the NIST randomness test and showed outstanding PUF performances compared to other emerging PUFs. Finally, we have proposed a protocol for highly secured smart IoT devices with pV3D3-PUF, which is expected to advance the era of hyperconnectivity.

Rational Design of Redoxed-Based Memristive Devices for Novel Computing Paradigm Regina Dittmann[1,2]; [1]Forschungszentrum Jülich, Germany; [2]RWTH Aachen University, Germany

Memristive devices have been a hot topic in nanoelectronics for the last two decades in both academia and industry. Originally proposed as digital (binary) non-volatile random access memories, research in this field was predominantly driven by the search for higher performance solid-state drive technologies (e.g., Flash replacement) or higher density memories (storage class memory). However, based on their large dynamic range in resistance with analog tunability along with complex switching dynamics, memristive devices enable revolutionary novel functions and computing paradigms. In this talk, we will present the current knowledge about the switching and failure mechanisms in different variants of redox-based memristive elements. In particular, we will show direct experimental evidence of the redox-processes gained by *in-operando* spectroscopy and microscopy. Using the quantitative numbers gained from these experiments as input for existing simulations offers a route to less empirical and more predictive models for memristive devices. Based on the microscopic understanding gained from *operando* spectroscopy and modelling, we will show approaches for rational design of material stacks with tailored properties for novel computing paradigm.

Forming-Free Interface-Type Memristors Aiping Chen; Los Alamos National Laboratory, United States

Memristors with excellent scalability have the potential to revolutionize not only the field of information storage but also neuromorphic computing. Conventional metal oxides have been widely used as resistive switching materials in memristors. Defects such as oxygen vacancy and interface play critical roles in filamentary-type resistive switching (RS) devices. In this talk, I will discuss the role of defects such as oxygen vacancy and cation deficiency, mosture, and interface on switching behavior in forming-free memristors.

2:15 PM EQ09.12.03

Effects of Cs Doping on Ion Transport in $MAPbI_3$ Hybrid Perovskite Memristors Matthew Flynn-Hepford[1], Arya Ahmadi[1], Holland Hysmith[1], Yongtao Liu[2], Mahshid Ahmadi[1], Anton V. Ievlev[2], Bobby Sumpter[2] and Olga Ovchinnikova[2]; [1]University of Tennessee- Knoxville, United States; [2]Oak Ridge National Laboratory, United States

Hybrid perovskite materials have drawn a lot of attention recently for solar energy applications, but the instability of these materials makes long term efficiency a major issue that needs to be addressed. The weak bonding in methylammonium lead iodide ($MAPbI_3$) that enables ion migration can be leveraged for memristivie applications where ion migration needs to be controlled rather than eliminated. We show that in modeled structures, cesium (Cs) doping the MA site (A-site) can enable stronger local bonding with the iodine (I) ions allowing for weak bonding ion conductivity channels that can help control ion migration under applied bias. Cs doped $MAPbI_3$ films were spin coated on glass/ITO substrates to act as an active layer for memristive devices. Local IV measurements were conducted using an AFM tip and a DC bias was applied to the tip in contact mode in order to induce ion migration. Kelvin probe force microscopy (KPFM) was used to probe the resulting variation in surface potential. The chemical origins of the surface potential variations were investigated using specially resolved time-of-flight scanning ion mass spectroscopy.

3:00 PM *EQ09.12.04
Schottky-to-Ohmic Switching in Ferroelectric Memristors Based on Semiconducting Hf0.93Y0.07O2 Thin Films Moritz Mueller, Maximilian T. Becker, Nives Strkalj and Judith L. MacManus-Driscoll; University of Cambridge, United Kingdom

We demonstrate resistive switching and memristive behavior in devices consisting of ultrathin (4.5 nm) semiconducting, epitaxial ferroelectric Hf0.93Y0.07O2 (YHO) films on La0.7Sr0.3MnO3 (LSMO)- buffered, Nb-doped SrTiO3 (Nb:STO) single crystal substrates with Au top electrodes. Unlike the tunneling-driven current-voltage characteristics of ferroelectric tunnel junctions (FTJs) which utilize ultrathin insulating (fully depleted) ferroelectric films, the semiconducting nature of our YHO films, i.e. the presence of free charge carriers introduced by Y doping, results in radically different currentvoltage characteristics. Current-voltage measurements reveal a polarization-modulated transition from Schottky-barrier-controlled charge transport to Ohmic conduction in the YHO devices, which results in a large on/off ratio of up to 540. Moreover, voltage pulse train measurements reveal a broad range of accessible resistance states, which indicates the memristive behavior of the devices. Our results represent an important step towards the development of future non-volatile memory and brain-inspired neuromorphic computing applications based on ultrathin semiconducting ferroelectric films

3:30 PM EQ09.12.05
Controlling Switching Stochasticity in Hybrid Memristors by Vapor-Phase Infiltration Chang-Yong Nam; Brookhaven National Laboratory, United States

Resistive random-access memory (RRAM) is promising for next-generation data storage and non-von Neumann computing hardware. However, tuning device switching characteristics and particularly, controlling their stochastic variation remain as critical challenges. Here, new organic-inorganic hybrid RRAM media are reported whose bipolar switching characteristics and stochasticity can be controlled by vapor-phase infiltration (VPI), an ex situ hybridization technique derived from atomic layer deposition. Hybrid RRAMs based on AlO_x-infiltrated SU-8 feature facile tunability of device switching voltages, off-state current, and on-off ratio by adjusting the amount of infiltrated AlO_x in the hybrid. Furthermore, a significant reduction in the stochastic, cycle-to-cycle variations of switching parameters is enabled by AlO_x infiltration, driven by the infiltration-induced changes in mechanical, dielectric, and chemical properties of organic medium and their influence on the dimension and formation characteristics of conductive filaments. Finally, multi-level analog switching potentially useful for neuromorphic applications are demonstrated, along with direct, one-step device patterning exploiting the negative-tone resist feature of SU-8. With the demonstrated control over switching characteristics and stochastic variation, combined with analog switching and one-step patterning capabilities, the results not only present a novel hybrid medium for RRAM applications but also showcase the utility of VPI for developing new, high-performance hybrid RRAM devices.

SESSION EQ09.13: Low Power Gated Electronic Devices

3:45 PM EQ09.13.01
3D-Stacked Organic Ternary Logic Circuits Utilize Nonvolatile Floating-Gate Memory Changhyeon Lee[1], Junhwan Choi[1], Chungryeol Lee[1], Seung Min Lee[1], Chang-Hyun Kim[2], Hocheon Yoo[2] and Sung Gap Im[1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Gachon University, Korea (the Republic of)

Nowadays, a large amount of information is generated in advanced electronic systems such as artificial intelligence (AI) and internet-of-things (IoT). Therefore, the method of increasing information processing density without increasing additional transistor have great attention. Multi-valued logic (MVL) circuits based on heterojunction transistor (HTR) are one solution. However, it is hard to satisfy all the important characteristics of T-inverters including 1) full-swing operation (in the sufficient input voltage (V_{IN}) range), 2) a well-defined intermediate logic state with the proper output voltage (V_{OUT} ~ half of the supply voltage ($V_{DD}/2$), logic "1") and 3) hysteresis-free, low-voltage operation.
Herein, Organic ternary logic inverter (T-inverter) with, a nonvolatile floating-gate (FG) flash memory is demonstrated. The T-inverter operation was controlled by the channel conductance control of the flash memory systematically. We adopt initiated chemical vapor deposition(iCVD) process, to fabricate vertically stacked 3-dimensional (3D) T-inverter. The vertical stacked structure allows increase the density per area. In the flash memory, ultrathin polymer dielectrics were utilized to obtain low-voltage operation. All process was done by in-situ patterning through shadow mask to achieve via-hole-less metal interconnection. Also, to electrically isolate the 1st layer flash memory and 2nd layer HTR, a 1 μm-thick interlayer dielectric (ILD) was deposited between the unit devices. For the polymer dielectric layers, poly(2-cyanoethyl acrylate-co-diethylene glycol divinyl ether) [p(CEA-co-DEGDVE)] (named pC1D1) was used as blocking dielectric layer (BDL) in this study. The pC1D1 has high dielectric constant, ($k > 6$) and superb insulating performance (breakdown field, $E_{break} > 3$ MV/cm). Poly(1,3,5-trivinyl-1,3,5-trimethyl cyclotrisiloxane) (pV3D3) was also employed as a tunneling dielectric layer (TDL) in the flash memory and also used as gate dielectric layer (GDL) in the HTR. The pV3D3 has low dielectric constant ($k < 2.3$) and provides a non-polar interface for the facilitated charge transport in the organic semiconductors. The programming/erasing voltage (V_{prg}/V_{ers}) was successfully reduced and the operating voltage was less than 5 V, which is low voltage compared to previous organic 3D logic circuits. Fabricated 3D T-inverter showed full-swing operation, ideal intermediate logic value (~$V_{DD}/2$), high DC gain exceeding 20 V/V as well as low-voltage operation (<5 V). Moreover, 3D T-inverter

showed excellent long-term stability (change of output voltage less than 3% after 10^4s). We believe the 3D T-inverter with flash memory developed in this study is expected to be one of the new platforms that can utilize in high-performance MVL circuits.

4:00 PM EQ09.13.02

Reduction of Operating Current by Device Size Miniaturization in Physical Reservoir Device Utilizing Electrochemical Reactions in Ionic liquid

Takuma Matsuo[1,2], Hisashi Shima[2], Masaharu Yonezawa[1,2], Yasuhisa Naitoh[2], Hiroyuki Akinaga[2], Toshiyuki Itoh[3], Toshiki Nokami[4], Masakazu Kobayashi[1,5] and Kentaro Kinoshita[1]; [1]Tokyo University of Science, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Toyota Physical and Chemical Research Institute, Japan; [4]Tottori University, Japan; [5]NAGASE & CO., LTD., Japan

Physical reservoir computing (PRC), which is a hardware implementation for a unique paradigm of recurrent neural network (RNN) called RC, attracts considerable attention because PRC is of great promise for advanced and low-power information processing (IP) [1]. PRC has a simple layer configuration: an input, reservoir, and output layers. Since the weight update in PRC is carried out only for the weights between the reservoir and output layers, the lower-power IP is strongly expected compared to the conventional RNN. Although various devices have previously been studied as a reservoir layer (i.e., physical reservoir device (PRD)), an appropriate choice of the physical dynamics in PRD is essential in view of the low-power device operation. Electrochemical reactions (ERs) at a liquid/electrode interface, which are known to exhibit the time-varying current response when voltage is applied, becomes a strong candidate because the electrochemical current reduction is expected by decreasing the electrode area [2]. Considering that liquid materials for PRD are required to withstand repeated voltage inputs, ionic liquids (ILs) are quite suitable because they are more resistant to the electrolysis than aqueous solutions. Besides, the ILs can dissolve various metal cations, which influence the electrochemical properties of PRD [3]. Herein, we report the device size dependence of operating current in IL-based PRD and demonstrate IP with the extremely small operating current of about 0.5 uA.
PRDs used in the present study had a square-shaped openings in the insulating SiO_2 layer on a pair of Pt input and output electrode patterns. The side length L of the square was 10, 100, and 300 um. By placing the IL droplet on those openings, the Pt/IL interfaces, which were the site of the ERs, were formed. As the IL material, a solvated IL, $Cu(Tf_2N)_2$:G3=1:1 (Cu-G3), was selected. The IP capability of the IL-based PRD was assessed based on the short-term memory (STM) task accuracy. In the present STM task evaluation, a binary data (0 and 1) stream $u(T)$ was input to the PRD as a triangular shaped voltage pulse (TVP) stream and $u(T\text{-}T_{delay})$, the input signal T_{delay} timestep before, was used as a training data at the timestep T. The sign of the TVP height for 1 and 0 was positive and negative, respectively. For updating the weights between the reservoir and output layers, the linear regression was used. The deposits on the Pt electrode formed during the device operation were investigated by X-ray photoelectron spectroscopy (XPS) after the washout of the IL droplet.
The output current from IL-based PRD showed L-dependent properties. Although the Faradaic current peak was observed in all the devices, the peak width became narrower for the smaller value of L. This result indicates that the ERs in IL-based PRD have a response time lag at the interface. Also, the output current decreased almost in proportional to the value of L^2, achieving about 0.5 uA for L = 10 um. The STM task accuracy slightly decreased with L probably due to the following two factors. One is the cycle-to-cycle variation in the net Pt/Cu-G3 interface area during the operation caused by the deposits on the Pt electrode, which causes the fluctuation in the electrochemical current values especially for smaller L. Another is presumably the cycle-to-cycle variation in the deposit compositional ratio. From the XPS results, it was found that Cu and some Cu compounds were formed on the Pt electrode depending on the applied voltage. The variation in compositional ratio for those materials reasonably causes the different output current even for the same input. Further operating power reduction by the device size miniaturization and IP performance boost in IL-based PRD are expected by realizing more repeatable and reliable ERs.

Operating Power Reduction and Information Processing Performance Improvement in Physical Reservoir Device Using Dehydrated Ionic Liquid

Masaharu Yonezawa[1,2], Hisashi Shima[2], Takuma Matsuo[1,2], Yasuhisa Naitoh[2], Hiroyuki Akinaga[2], Toshiyuki Itoh[3], Toshiki Nokami[4], Masakazu Kobayashi[1,5] and Kentaro Kinoshita[1]; [1]Tokyo University of Science, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Toyota Physical and Chemical Research Institute, Japan; [4]Tottori University, Japan; [5]NAGASE & CO., LTD, Japan

Edge computing is attracting considerable attention because the real-time secure and low-power information processing (IP) is expected. Especially for the IoT devices operated under the limited power-supply condition, the IP power reduction becomes crucial in addition to realizing higher performance. Therefore, a machine learning algorithm called reservoir computing (RC), which is a special type of the recurrent neural networks, is intensively investigated as a breakthrough to satisfy those requirements. The network structure of RC is quite simple, consisting of input, reservoir, and output layers. Because only the weights between the reservoir and output layers are updated in RC, the calculation cost reduction is expected. To implement RC by actual devices, physical reservoir devices (PRDs), in which actual physical phenomena plays a role of reservoir, are essential for edge computing and PRDs.
We have developed PRD using Faradaic currents (FCs) generated by the electrochemical reactions (ERs) in metal ion-doped ionic liquids (IL), which possess advantages such as a high design flexibility of material properties and an immunity to the electrolysis [1]. Because the FCs generated by ERs are much smaller than the operating currents of solid-state devices, IL-based PRD is suitable for low-power IP [2]. In this study, we focused on the water contained in IL. According to the previous report, about 10 mol% of water can be dissolved even in hydrophobic ILs such as [Bmim][Tf_2N] [3]. Also, it has been reported that the FC observed during the cyclic voltammetry for the dehydrated, low water content IL decreased below one-fourth of that for the high water content IL [4]. Therefore, further lowering of the operating power in the IL-based PRD is reasonably expected by reducing water content in IL. Herein, we evaluated the influence of water in IL on the operating power and IP performance of IL-based PRDs by comparing the electrical properties measured in the synthesized dry air (SDA) after vacuum dehydration and those measured in moisture-containing air (MCA).
The present PRD had a pair of input and output terminals made of a Pt thin film. To control the location of the ER, those terminals were covered by the insulating SiO_2 layer excepting the 100 μm x 100 μm sized square-shaped regions on each terminal. A droplet of 0.4 M Cu ion-doped [Bmim][Tf_2N] was placed between the terminals to form the Pt/IL interface inside the above-mentioned square-shaped regions. Time series data (TSD) consisting of "0" and "1" was input into the device as a triangular-shaped voltage pulse (TVP) stream, and the output current were measured. The signs of the TVP for "0" and "1" were defined to be negative and positive, respectively. TSDs consisting of alternately and randomly aligned “0” and “1” were used to investigate the basic electrical properties and the short-term memory (STM) characteristics of the PRD, respectively. In SDA, as expected, the peak current values during the device operation decreased below about one-fifth of those in MCA. Moreover, the memory capacity, which is a quantitative measure for the STM characteristics, increased by more than 40 %. The input-signal-dependence of output current waveforms became more prominent in SDA thanks to decrease in cycle-to-cycle current dispersion due to dehydration and consequently the memory capacity increased.
We successfully demonstrated both the IP power reduction and IP performance improvement of IL-based PRD in SDA. In addition, the difference in the output current waveforms between SDA and MCA suggests that the different ERs occur in the device depending on the water amount in IL. The ERs optimized for the IP task to be executed are crucial for improving the physical RC accuracy.

4:30 PM EQ09.13.04
Channelizing the Exemplary 'Lane Discipline' of Topological Insulators for Next-Generation Electronics Sagnik Banerjee[1], Koustav Jana[2], Anirban Basak[2] and Bhaskaran Muralidharan[2]; [1]Jadavpur University, India; [2]Indian Institute of Technology Bombay, India

Two-dimensional topological insulators (TIs), like monolayer group-IV and V Xenes with large intrinsic spin-orbit coupling, offer electrically tunable phase transitions due to their buckled lattice structure and present exciting prospects for futuristic low-power electronics. These materials possess robust conducting modes with enforced 'lane discipline' at their edges, which provide dissipationless channels for carrier transport and are unaffected even in the presence of scattering centers—the primary source of energy dissipation in modern semiconductor devices. These salient features make 2D topological insulators an excellent material choice for several interesting applications in low-power electronics. We discuss a couple of avenues, namely valleytronics and steep-subthreshold transistors, where 2D TIs have an immense potential to make significant contributions.
Firstly, we demonstrate an all-electrical valley filtering device that exploits the topological robustness of 2D TIs. Our device design draws inspiration from the previous proposals based on bilayer graphene in using the valley-polarized interface states appearing at the domain wall between topologically distinct phases. Spatially separating these interface states by the introduction of a large gap quantum spin Hall region in between the states added to their topological robustness and significantly boosted the valley filtering performance of our device. By adopting the scattering matrix formalism on a suitably designed device structure, valley-resolved transport calculations in the presence of non-magnetic short-range disorder have been done to gauge the valley filter performance in practical scenarios. Based on our numerical simulations, we also outline the role of SO coupling strength, device geometry, and other factors while designing an optimized valleytronic filter device with superior efficiency.
Next, we explore the emerging realm of topological transistors where one can achieve a subthreshold slope steeper than the thermionic Boltzmann's limit, which is indispensable for low-power device operation. Rashba spin-orbit interaction in 2D TIs enables a faster-than-linear response of the band movement to the applied field via the topological quantum field effect that can have encouraging implications in achieving sub-thermionic performance. Combining this with the prevailing advantage of dissipationless ON state conduction via robust, helical edge modes of the TI channel, makes topological quantum field-effect transistors an excellent device choice for ultra-low power electronics. However, realizing a working device design with the above merits requires a deep exploration of the topological quantum field-effect transition physics. Our numerical and analytical calculations highlighted the drawbacks in the subthreshold performance of a primitive design of the topological transistor. This led us to a partial solution to beat the thermionic limit by adopting a modified gating strategy. However, this strategy fails to preserve the dissipationless ON state performance due to bulk modes conduction. We then show that an out-of-plane antiferromagnetic exchange induced in the material via proximity coupling, effectuating transitions between the quantum spin-valley Hall and the spin quantum anomalous Hall phases, allows the ON state to remain topologically robust while surpassing the thermionic limit on the subthreshold performance. Further dephasing studies have been done on all the transistor designs mentioned above to gauge their performance in experimentally-relevant regimes. They reveal the robustness of the topological edge states under momentum relaxation scattering and the effect of varying degrees of momentum relaxation strengths on the subthreshold performances.
Our work thus provides a strong foundation for future investigations on harnessing topological phase transitions in two-dimensional topological insulators for next-generation low-power electronics.

SESSION EQ09.14: Piezoelectrics and Nanogenerators

A Novel PVDF-TrFE/KNN Composite Material for Low Power Flexible Electronics Devices Nitika Batra, Rajinder S. Deol, Henam S. Devi, Madhusudan Singh and Bhaskar Mitra; Indian Institute of Technology Delhi, India

Potassium sodium niobate (KNN) has emerged as a lead-free, environment friendly, and highly piezo-active substitute for lead-based piezoelectrics such as PZT [1]. However, it is difficult to deposit thick films of KNN (required for many IoT applications such as energy harvesting) with reasonable compositional control [2]. Additionally, thick piezoceramic films are brittle, and this is a major reliability concern in these devices. On the other hand, organic fluorinated polymeric piezoelectric materials such as PVDF, PVDF-TrFE etc., are flexible and compliant but have poor piezoelectric coefficients. Therefore composite materials combining the properties of ceramics, such as a high piezoelectric constant, and polymers, such as flexibility, are attractive. In this work a novel lead-free piezoelectric composite material consisting of sodium potassium niobate (KNN) sol in an organic piezoelectric polymer (PVDF-TrFE) has been developed. We have used KNN sol specifically to reduce the maximum temperature of the process. We investigated KNN sol addition in PVDF-TrFE polymer with material characterization as a function of KNN loading ratio. Piezoresponse force microscopy (PFM) results found the best composition material to have an electromechanical coupling coefficient of d33=107 pm/V (whereas PVDF-TrFE's d33 = 19 pm/V). The addition of KNN contributes toward higher film stiffness (Young's mod composite = 165.68 MPa and PVDF-TrFE = 161.8 MPa) and also increases surface roughness (23.90 nm for composite and 22.72 nm for PVDF-TrFE) and adhesion force (0.23nN for composite and 0.15nN for PVDF-TrFE) as measured using contact AFM. The current study demonstrated the applicability of this composite by fabricating a flexible energy harvesting device comprising of 2 µm film deposited by multiple spin coating at 2000 rpm on an Al-coated PET sheet, and a top metal film. After spin coating the layer was heated at 140º C in oven for 2 hours (which is the maximum tempertaure of whole process). The device generates an open circuit voltage of Voc=2.2V while an identical PVDF-TrFE-based device generates Voc=0.05V for the same loading. It is noteworthy that uniform, crack-free films were deposited using a low-temperature, low-thermal-budget method, which is typically a difficult task with piezoceramics, but it was accomplished easily the developed piezo composite.

Hierarchical Micro-Nano Patterned Modified PDMS Triboelectric Nanogenerator Enhanced by Carbon-Based Nanofillers Mina Shanbedi and Alamgir Karim; University of Houston, United States

Triboelectric nanogenerators (TENGs) have received recent interest in converting unconventional mechanical energy to electricity, particularly as a

sustainable form of energy generation from sources such as wind and friction. Energy conversion in TENGs is based on the triboelectrification and electrostatic induction effects. In this regard, Polydimethylsiloxane (PDMS) elastomer has been widely used as an excellent triboelectric active layer in TENG owing to its high electronegativity as ranked in the triboelectric series of different materials. The TENGs based on PDMS exhibit a relatively high energy conversion efficiency. However, its output electrical characteristics still need more development. Increasing the triboelectric polymer dielectric constant enhances the current density significantly by facilitating the charge transfer from the contact surface toward electrodes. Nanoparticles' presence enhances charge transfer in TENGs due to increasing the polymer matrix's dielectric constant when their concentration meets the percolation threshold. However, the TENGs' performance has not been investigated from the window of dielectric properties of polymer triboelectric active materials. The shape and sometimes the angle of nanoparticles also play a role in the outcome of the polymer's dielectric constant. This research investigates the effect of carbon-based nanoparticles on PDMS nanocomposite/aluminum TENG output, considering the aforementioned factors. The particles are chosen from various molecular shapes and dielectric constants, including carbon black (CB), carbon nanotube (CNT), graphene oxide (GO), and reduced graphene oxide (r-GO). On the other hand, one of the most practical approaches to enhancing the output performance of TENG is modifying the contact area between triboelectric active material layers. Patterning the surface and changing the shape and density of patterns on the surface is assumed to be an effective strategy for this purpose. The uniform and periodic nanoscale morphology of optical discs (CD and DVD) were replicated onto PDMS films. By changing the ratio of carbon black, the resolution of the CB/PDMS composite layer increases at 4 wt% and then decreases, which was explained according to the percolation theory of the conductive particles in the polymer matrix. The voltage and current output follow the same trend as the dielectric constant. The GO nanoparticle also shows the same behavior at the 1.5 wt%, which is the percolation threshold of GO in PDMS. However, the reduced graphene oxide aggregates faster because of not having the oxygen-containing chemical group and earlier percolation threshold. The procedure is followed by a sequential development of hierarchical low amplitude patterns made by etching treatment leading to perpendicular wrinkling from the DVD wrinkle lines. This method creates a hierarchical pattern as a superposition on the optical disc pattern. Our hierarchical topographic designed TENG led to a considerably higher current and voltage output. Due to having an efficient shape with higher roughness compared to the original CD and DVD patterns base and the flat PDMS surface. Here is a mathematical correction offered in the dielectric constant equations based on the PDMS nanocomposite dielectric properties investigation. The PDMS nanocomposite/Al TENG corresponding output for each filler is studied and compared with the dielectric properties of the nanocomposite. The mathematical correction is also reflected in TENG voltage and current equations.

Bulk Ferroelectric Metamaterial with Enhanced Piezoelectric and Biomimetic Mechanical Properties from Additive Manufacturing Jun Li; University of Wisconsin--Madison, United States

Three-dimensional (3D) ferroelectric materials are electromechanical building blocks for achieving human–machine interfacing, energy sustainability, and enhanced therapeutics. However, current natural or synthetic materials cannot offer both a high piezoelectric response and desired mechanical toughness at the same time to meet the practicality. Here, a lamellar ferroelectric metamaterial was created with a ceramic-like piezoelectric property and a bone-like fracture toughness through a low-voltage-assisted 3D printing technology. The one-step printed bulk structure, consisting of periodically intercalated soft ferroelectric and hard electrode layers, exhibited a significantly enhanced longitudinal piezoelectric charge coefficient (d_{33}) of over 150 pC N^{-1}, as well as a superior fracture resistance of ~5.5 MPa $m^{1/2}$, more than three times higher than conventional piezo-ceramics. The excellent printability together with the combination of both high piezoelectric and mechanical behaviors allowed us to create a bone-like structure with tunable anisotropic piezoelectricity and bone-comparable mechanical properties, showing a potential of manufacturing practical, high-performance, and smart biological systems.

Modulus-Tunable Triboelectric Nanogenerator for Maximization of In Vivo Ultrasound Transmission with Biocompatible 2-Hydroxyethyl Methacrylate Bosung Kim and Sang-Woo Kim; Sungkyunkwan University, Korea (the Republic of)

Ultrasound-driven triboelectric nanogenerator (TENG) is recently proposed as an energy solution technology for sustainable lifespan of the implantable medical devices (IMDs). While improving the ultrasound transmission to the TENG is urgent to achieve high energy generation, research on materials is hardly being conducted as an initial stage of current research. Here, a biocompatible 2-hydroxyethyl methacrylate (HEMA) is propsed as a both encapsulation and triboelectric layer for a modulus-tunable ultrasound-driven triboelectric nanogenerator (MU-TENG). As an acoustic impedance of HEMA can be modulated to be optimized for the surrounding environment with different contains of crosslinking concentrations, the ultrasound transmission to the MU-TENG can be increased 3.2 times compared to the case of titanium (Ti) packaging. Furthermore, the surface potential of HEMA can be highly increased by adding an ionic monomer, significantly enhancing the triboelectric output performance of the device. Consequently, we verified that the MU-TENG can generate sufficient energy to charge a 100 μF capacitor under in vivo condition at a rate of 23.9 μC/s, which is 3.7 times faster than the case with a Ti packaging. This strategy of using multi-functional HEMA for high-performance ultrasound-driven TENG could be promising energy solution technology for low-powered IMDs.

8:00 AM EQ09.15.01
Demonstration of Ferroelectric Properties in GaN Alloyed with Sc Masato Uehara[1], Ryoichi Mizutani[2], Shinnosuke Yasuoka[2], Takao Shimizu[3], Hiroshi Yamada[1], Morito Akiyama[1] and Hiroshi Funakubo[2]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Tokyo Institute of Technology, Japan; [3]National Institute for Materials Science, Japan

Traditionally, AlN does not exhibit ferroelectricity owing to its high barrier to polarization inversion. Recently, its ferroelectricity was demonstrated through an alloying with Sc [1, 2]. Its ferroelectricity in wurtzite nitride is a hot topic. The high remanent polarization (P_r) beyond 120 μC/cm^2 of $Sc_xAl_{1-x}N$ is attractive, but the high coercive field (E_c) value is a drawback. We experimentally succeeded in demonstrating the ferroelectricity in GaN by alloying with Sc. Considering that GaN is a mainstream semiconductor used in applications, such as power electronics and high-frequency devices, its ferroelectricity in $Sc_xGa_{1-x}N$ has received considerable attention.

The ferroelectricity of $Sc_xGa_{1-x}N$ (x = 0.35–0.44), was demonstrated in metal–ferroelectric–metal stack devices prepared by sputtering. The P_r value obtained from positive-up negative-down measurements was high, exceeding 120 μC/cm^2. The E_c of $Sc_{0.44}Ga_{0.56}N$ was approximately 3.6 MV/cm at 300 K, which reduced to 3 MV/cm at 473 K. Comparison with $Sc_xAl_{1-x}N$ revealed some important things. The P_r value was governed by the wurtzite u-parameter. On the other hand, the E_c values were governed by the Sc concentration rather than the u-parameter, regardless of the host material in $Sc_xGa_{1-x}N$ and $Sc_xAl_{1-x}N$. This indicates that the origin of the polarization inversion would be around Sc atoms. Moreover, the $P_r - E_c$ diagram shows that the E_c of $Sc_xGa_{1-x}N$ is lower with an equivalent P_r, compared with that of $Sc_xAl_{1-x}N$. The lower E_c of $Sc_xGa_{1-x}N$, which had an equivalent P_r value of ~120 μC/cm^2, was attractive. This was caused by the dependence of P_r on the u-parameter, dependence of E_c on the Sc concentration, and different u-parameters between $Sc_xGa_{1-x}N$ and $Sc_xAl_{1-x}N$.

8:05 AM EQ09.15.02
Controlling the Polarity of Scandium Aluminum Nitride (ScAlN) Piezoelectric Thin Films by Using Ge Addition Sri Ayu Anggraini, Masato Uehara, Kenji Hirata, Hiroshi Yamada and Morito Akiyama; National Institute of Advanced Industrial Science and Technology, Japan

A highly *c*-oriented wurtzite phased scandium aluminum nitride (ScAlN) piezoelectric thin film could exist in nature as aluminum/scandium (Al/Sc) or nitrogen (N) polar thin films. The utilization of multilayers piezoelectric thin films with different polarity can be advantageous for the performance of the device. For example, the performance of a solidly mounted resonator type bulk acoustic wave (SMR-BAW) can be enhanced by using a stack of N-polar and Al-polar piezoelectric thin films [1]. Since ScAlN-based resonators feature a significant improvement from aluminum nitride (AlN)-based resonators, wurtzite phased ScAlN has been extensively studied and has arose as the future material for many promising electronic applications including radio frequency (RF) filters [2-3]. Polarity control of ScAlN-based thin films is expected to bring further improvement in the performance of the current RF filter by enabling it to function at higher frequency range in 5G communication technology. In terms of polarity control, the addition of germanium (Ge) into AlN have been reported to capable of inversing the polarization direction of non-doped AlN from Al-polar to N-polar [1]. However, there are no report on addition of Ge to inverse the polarity of ScAlN. Therefore, in this study, we investigated of the effect of Ge addition on the polarization direction of ScAlN piezoelectric thin films.

The fabrication of the thin films were conducted by using radio frequency (RF) magnetron sputtering system. The concentration of Sc, Ge and Al was controlled by adjusting the power of cathodes during deposition process. In this study, we examine how co-addition of Sc and Ge into AlN on affect the polarity, the crystal structure, lattice parameters and surface state of each element in the thin films. Positive d_{33} value indicates that the thin film has Al/Sc-polarity while negative d_{33} value indicates that the thin film has N-polarity. All $Sc_xAl_{1-x}N$ thin films exhibited positive d_{33} values which indicate that the thin films have Al/Sc-polarity. Depending on the concentration and the ratio of Sc and Ge, co-addition of Sc and Ge into AlN resulted in thin films with negative d_{33} which suggested that the thin films have N-polarity. For example, $Sc_xGe_yAl_{1-x-y}N$ thin films with x = 0.3 and y = 0.05~0.14 exhibited N-polarity suggesting that co-addition of Sc and Ge into AlN yielded in thin films with inversed polarity. However, addition of Ge was found to unable to inverse the polarity of $Sc_{0.4}Al_{0.6}N$, since the resulting thin films exhibited Al-polarity. Based on these results, it can be inferred that Ge addition can be used not only to control the polarity of AlN but also the polarity of ScAlN, as long as the concentration of Sc is maintained to be less than 40 at.% and Ge concentration is also kept in a certain concentration range. Thus, both concentration and ratio of Sc and Ge are considered to be among the important parameters that control the polarization direction of the resulting thin films.

Study of Tunneling Switching Operation in Various Tunneling Barrier Materials Jeong Hee Shin; Korea Institute of Ceramic Engineering and Technology, Korea (the Republic of)

There has been increasing demand for electronic devices with ultra-high working frequency or speed to process big data quickly, especially in the fields of communications, the military, and aerospace as well as a high performance control process unit (CPU). However, traditional semiconductor switching devices cannot keep up with the demands of increased speed. Typical semiconductor switching devices are generally used a p-n junction and a Schottky barrier which perform a switching operation by combining electron and holes. A short channel length between source and drain is only solution to achieve high speed. It faces limit due to the resolution limit of the fabrication process and the short channel effect. Electron mobility was considered instead of physical dimension. Although high electron mobility transistor (HEMT), based on III-V group materials, is expected to increase the speed, its theoretical frequency limit is less than 1THz, even with several nanometer channel lengths. Thus, we have to solve the problem of switching speed through a new method.
Tunneling phenomenon is key mechanism as fast switching devices due to direct movement of electrons without hole-electron combination. Although tunneling mechanism can provide ultra-high working speeds (>THz), the very low switching ratio results in poor switching efficiency. Improving switching efficiency is highly motivated for high-speed efficient switching elements.
Our strategy is geometric electrode design to increase switching efficiency (On-off ratio). We have already demonstrated the effectiveness of geometric design. We also study various tunneling barriers to maximize it and the phenomenon (Tunneling transition between direct and Fowler-Nordhiem tunneling).

8:15 AM EQ09.15.04
High Performance Metal-Insulator-Metal $SrTiO_3$ Thin Film Capacitors Integrated on 300 mm Si Wafers for Advanced Technology Nodes Arnab Sen Gupta, Kaan Oguz, I-cheng Tung, Chia-ching Lin, Sou-chi Chang, Anandi Roy, Jason Peck, Brandon Holybee, Rob Jordan, Thomas Hoff, Sudarat Lee, Scott B. Clendenning, Ian A. Young, Uygar E. Avci and Matthew V. Metz; Intel Corporation, United States

Paraelectric Strontium titanate ($SrTiO_3$) perovskite thin films have recently gained attention in the semiconductor industry. This is due to their high dielectric constant of > 100 at room temperature, low dielectric loss and non-toxicity due to the absence of Lead[1,2]. Thin films of $SrTiO_3$ on various electrodes are being studied world-wide to demonstrate practical usage in the domain of Metal-insulator-metal (MIM) capacitors[3,4]. In this work we demonstrate a high performing two plate MIM capacitor utilizing the $SrTiO_3$ film integrated on a 300 mm Silicon (Si) wafer. Highly crystalline $SrTiO_3$ film was grown on crystalline Ruthenium (Ru) electrode using an advanced sputter technique. The complete stack is made of Ru/ $SrTiO_3$ / Ru thin films, where both the top and bottom Ru electrodes and a (200) oriented $SrTiO_3$ dielectric film were deposited utilizing back-end of line (BEOL) compatible conditions. Following the completion of the deposition step on the 300 mm Si wafer, the MIM capacitor was integrated in the fabrication facility using a state-of-the-

art integration flow. The resulting devices demonstrated a capacitance density of about 95 fF/um^2 with an average leakage of 2e^{-5} A/cm^2. This is a capacitance density boost of about 2.5 times compared to our previously reported MIM capacitor[5]. Furthermore, a record low equivalent oxide thickness (EOT) of about 0.4 nm has also been achieved with this MIM capacitor. The development of such a high performing capacitor together with the BEOL compatibility provides a significant advantage in lowering the voltage droop in a power delivery network without any significant area penalty in future technology nodes.

A Quantum Materials Path to Next-Generation Computing Sasikanth Manipatruni; Kepler, United States

Computing technology is the at the core of the information age forming the basis of all of millennium goals of United Nations. However, Computing is at a momentous point today as AI and big data drive massive demand for computational hardware, while historic Moore's law performance scaling is slowing down.

In this talk, I will outline a framework that combines the energy/dimension scaling (Moore's law), computer error rates (Shannon computing) and modern AI architectures (drawing mainly from Nature Physics 14, no. 4 (2018): 338) , https://www.nature.com/articles/s41567-018-0101-4).

A room-temperature quantum materials path to next-generation computing: Next, I describe a quantum and memory materials-centric approach to enable the computing for beyond the CMOS era. I will outline a number of pathways for computing devices that utilize quantum materials. I will generalize the search for the next computing device with a comprehensive list of quantum materials classes.

We will connect various required components of a computing system to the next generation materials. The materials and transductions are classified under switching, interconnects and detection and are tied to the required targets for materials performance. We also identify activity factor (i.e utilization of logic), memory BW wall (Turing wall) and thermal extraction as the near term limiting factors for computing. Finally, I describe potential ways to build generalized intelligence hardware overcoming interconnect, memory and compute bottlenecks.

A Spin-Orbit Torque Device Toward Energy-Efficient Neuronal Population Performance Chih-huang Lai[1], Po-Chuan Chen[1], Rudis Ismael Salinas[1], Chao-Yao Yang[2] and Sheng-Huai Chen[1]; [1]National Tsing Hua University, Taiwan; [2]National Yang Ming Chiao Tung University, Taiwan

Precise control over the intermediate states in a spin-orbit torque (SOT) device with multi-levels has been demonstrated a unique strategy toward high dense storage for an analog memory, which bridges the solid-state device and the neuromorphic computing into a newly developed research field in recent years. In this study, we demonstrate a SOT switching mechanism in the devices composed of Pd/Co/Ta trilayer featuring robust stabilization of intermediate magnetic states, which leads to precise controllability and superior stability of multi-levels. Magnetization reversal of Pd/Co/Ta devices by SOT takes place through the gradual nucleation of reversed domains with restricted domain wall (DW) motion due to DW precession over Walker breakdown, which guarantees stable magnetic multi-levels. Furthermore, we demonstrate that individual reversed magnetic domain can be regarded as a single neuron, and the whole device becomes an artificial neuron population (NP). Therefore, the period required for the magnetization reversal can represent the response time of NP. The DW velocity or nucleation rate in SOT devices thus can be corresponding to the interaction between neurons; accelerated DW motion (or nucleation), leading to faster reversal, can mimic the case that excited neurons would influence neighboring ones to quickly respond to stimulus together. We demonstrate that the relationship between stimulus strength and duration, commonly observed in biological NPs, can be achieved in the artificial NP, composed of a Pd/Co/Ta SOT device. Furthermore, we reveal the modification of the response time of artificial NP under the lowest energy consumption by tuning the DW velocity. Our work not only explores the fundamental physics of the SOT dynamics via both experimental imaging and theoretical micromagnetic simulation, but also demonstrates the potential neuromorphic application as a new branch of neuronal population. Our findings will open a revolutionary avenue for establishing biomimetic neurons toward the energy and time efficient neuromorphic technology.

A Correlated Polar Ferromagnetic Metal by Design Pu Yu; Tsinghua University, China

Polar metals with a combination of conflicting polarization and metallicity have garnered increased interests recently because of their promising functionalities. Adding ferromagnetism into this unique state would offer exciting opportunities to obtain exotic quantum states, analogous to magnetoelectric multiferroics with coupled polarization and magnetization. However, such an intrinsic ferromagnetic polar metal remains elusive, especially in strongly correlated electron systems. Here, we report the experimental realization of coexisting ferromagnetism, polarity, and metallicity in a new 3d transition metal oxide $Ca_3Co_3O_8$. Here, structural oxygen vacancies order to form a periodic stacking of oxygen tetrahedral monolayers alternating with octahedral bilayers. The magnetic metallic state is confined within the quasi-two-dimensional CoO_6 octahedra layers, while the broken inversion symmetry arises simultaneously from Co displacements, which is further enhanced by the onset of magnetism, indicating an intrinsic strong magnetoelectric coupling. This coupled response and dual absence of spatial-inversion and time-reversal symmetries produce an intrinsic magnetochiral anisotropy with exotic magnetic field-free nonreciprocal electrical resistivity. We also observe an extraordinarily robust topological Hall effect that persists over a broad temperature-field phase space arising from a Rashba-type spin-orbit coupling. Our work not only provides a rich platform to harvest the

fascinating coupling between polar and magnetic states, but also defines a novel design strategy to access a new class of oxide materials with rich properties through ordered oxygen vacancies.

10:00 PM EQ09.16.03
Emergent Magnetodielectric Materials for 5G Antenna Miniaturization—18H Hexaferrites Qifan Li[1], Yajie Chen[2] and Vincent Harris[3]; [1]University of Electronic Science and Technology of China, China; [2]Rogers Corporation, United States; [3]Northeastern University, United States

Antenna miniaturization technology based on traditional materials with high dielectric constant has the disadvantages of low efficiency, narrow bandwidth, and difficulty in impedance matching. Compared to high-permittivity dielectrics, magnetodielectric materials, which exhibit both relative permeability and permittivity greater than unity, can achieve competitive miniaturization performance and bandwidth enhancement due to their less capacitive nature and low electromagnetic energy concentration. The fifth generation (5G) communications call for high-performance magnetodielectric materials with high values of permeability and permittivity, low magnetic and dielectric losses, and high cutoff frequency over the sub-6 GHz frequency bands. Due to limited resonant frequencies and large natural resonance linewidth, conventional microwave ferrites and their composites, which are usually used over the frequency range from several hundred MHz to several GHz, do not meet these requirements.

Here, a unique type of hexagonal ferrites—Mg-Zn 18H hexaferrite ($Ba_5Mg_{2-x}Zn_xTi_3Fe_{12}O_{31}$), whose crystal structure can be interpreted as the structure of Y-type hexaferrites with intercalation of a three-layered hexagonal barium titanate block into the middle of the T-block, has been synthesized by a solid-state reaction route, and its microwave properties have been comprehensively investigated for the first time. Depending on the Zn content, the polycrystalline Mg-Zn 18H hexaferrite exhibits a saturation magnetization of 1–1.23 kG and a coercivity of 15–68 Oe. The small coercivity indicates the ease of domain wall motion through the lattice upon demagnetization and the great potential for low-loss applications. The permeability and permittivity spectra of the Mg-Zn 18H hexaferrite are extracted from the S-parameters measured with a vector network analyzer over 0.1–10 GHz. Narrow and strong magnetic resonant peaks up to 5 GHz are observed. The magnetic resonance shifts to lower frequencies and slightly broadens with increasing the Zn content. Fitted with the superposition of the domain wall resonance and gyromagnetic spin resonance, the Mg-Zn 18H hexaferrite shows an extremely low damping coefficient of 0.1–0.2, indicating concentrated magnetic loss within the narrow frequency range and implying a narrow ferrimagnetic resonance (FMR) linewidth. The FMR linewidth is confirmed to be 486-660 Oe by a resonant perturbation technique using a TE_{10} rectangular waveguide resonator at X band. Owing to this remarkably low damping coefficient compared to that of other microwave ferrites, which typically varies from 0.2 to 0.9, Mg-Zn 18H hexaferrite exhibits an excellent magnetic loss tangent as low as 0.06, as well as a small dielectric loss tangent less than 0.006. By modifying the atomic ratio of Zn:Mg in the formula, this low-loss property covers the entire S band from 2 to 4 GHz, representing the best magnetodielectric performance among the reported microwave ferrites for the S band applications. Moreover, the temperature dependence of the damping coefficient is 0.0004 K^{-1} over the range of 300–410 K, indicating an excellent thermal stability for the temperature variation of most communication applications.

For antenna miniaturization, depending on the Zn content, the miniaturization factor of the Mg-Zn 18H hexaferrite varies from 5.3 to 7.6. As an example, we demonstrate this capability for antenna size reduction by applying the Mg 18H hexaferrite to the substrate material of a 3.6-GHz patch antenna, which shows a miniaturization factor of ~5 and significant bandwidth improvement of ~50–110% over conventional dielectric substrates. These results imply the great potential of the 18H hexaferrites to be Co-free and low-cost alternatives to most microwave hexaferrites and reveal their great technological and commercial value for 5G communications.

10:15 PM EQ09.16.04
***Operando* XMCD and EXAFS Spectroscopies for Orbital Control by Reversible Strain at Co_2FeSi/PMN-PT Interface** Jun Okabayashi[1], Takamasa Usami[2], Yu Shiratsuchi[2], Ryoichi Nakatani[2] and Kohei Hamaya[2]; [1]The University of Tokyo, Japan; [2]Osaka University, Japan

Artificial ferromagnetic/ferroelectric multiferroic heterostructures have been widely investigated from both fundamental and technological aspects. The electric field (***E***) control of magnetism through the interfacial strain modulates the magnetic anisotropy in the magnetic layer. Controlling the magnetic anisotropy by the interfacial strain related to the orbital magnetic moments has a potential for future devices using both spins and orbitals. The relationship between strain and orbital magnetic moments has not been clarified because there were few tools to probe the changes of orbital magnetic moments. We have developed the ***E***-induced x-ray magnetic circular dichroism (EXMCD) technique in order to apply ***E*** to ferroelectric substrate $Pb(Mg_{1/3}Nb_{2/3})O_3$-$PbTiO_3$ (PMN-PT), which tunes the interfacial lattice constants of the Heusler alloy Co_2FeSi magnetic layer [1,2]. In this study, we discuss the microscopic origin of inverse magneto-striction effects or orbital-elastic effects concerning the orbital magnetic moments by using the EXMCD with the detection of element-specific local structural changes by extended x-ray absorption fine structure (EXAFS) analysis.

We prepared the samples of 10-nm-thick Co_2FeSi layer grown on single-crystal PMN-PT(011) substrates with thin Fe buffer layer insertion by molecular beam epitaxy at 300 °C. The ***E***-induced modulation of the in-plane magnetic properties was characterized by magneto-optical Kerr effect (MOKE) and XMCD, where the XMCD measurement was performed at BL-7A in the Photon Factory (KEK). The partial fluorescence yield mode was adopted to probe the signals more than 10 nm below the sample surfaces. To apply an ***E*** to the PMN-PT substrate along the [011] direction, a Au(100 nm)/Ti(3 nm) electrode was deposited on the backside of the PMN-PT substrate, where the Co_2FeSi film was utilized as a top electrode [3]. EXAFS during applying ***E*** for Fe and Co K-edges were also performed at BL-12C in KEK for the same samples.

The MOKE measurements revealed that the magnetic easy axis is along the PMN-PT [100] in-plane direction at $\boldsymbol{E} = 0$ when ***E*** is changed from +8 kV/cm to 0. By applying ***E*** of -8 kV/cm, the easy axis changes 90 deg. within the in-plane through the changes of lattice strain of 0.1 % order. The Fe and Co L_3-edge XMCD hysteresis curves also trace the same changes of magnetic anisotropy of 2.5×10^4 J/m^3, which corresponds to the changes of orbital magnetic moments (m_{orb}) of the order of 0.01 μ_B. The EXMCD spectra can detect the changes of m_{orb} by ***E*** for both Fe and Co *L*-edge XMCD, which suggests the relationship between the strain and the orbital moments. *Operando* EXAFS measurements also detect the change of nearest neighbor distance at Co site. These phenomena can be understood within the orbital moment anisotropy through the spin-orbit interaction which is controlled by applying ***E***. We found that EXMCD clarifies the origin of the reversible changes of magnetic anisotropy and links the relationship between macroscopic inverse magneto-striction effects and microscopic orbital moment anisotropy.

Thickness Scaling and Low Voltage Operation of Ferroelectric $(Al_{1-x}Sc_x)N$ Films Prepared by Sputtering Method Hiroshi Funakubo[1], Shinnosuke Yasuoka[1], Ryoichi Mizutani[1], Takahisa Shiraishi[2,1], Akinori Tateyama[1], Reika Ota[1], Kazuki Okamoto[1], Takao Shimizu[3,1], Masato Uehara[4], Hiroshi Yamada[4] and Morito Akiyama[4]; [1]Tokyo Institute of Technology, Japan; [2]Kumamoto University, Japan; [3]NIMS, Japan; [4]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Observation of ferroelectricity in $(Al_{1-x}Sc_x)N$ films by Fichtner *et al* in 2019 open the nonvolatile ferroelectric memory (FeRAMs) applications with low

power consumption [1]. Large remanent polarization (P_r) beyond 100 μC/cm^2 and easy orientation control toward the polar axis of these films enable us to apply not only conventional capacitor type memories, but also resistance-type memories using ferroelectric tunnel junction (FTJ). However, large coercive field (E_c), electric field for polarization switching, must be overcome for low power operation. We ascertained the ferroelectricity for the films down to 9 nm in thickness [2] and for the films deposited without heating [3]. In addition, we get the ferroelectricity for Sc-doped GaN films with lower E_c value than that of $(Al_{1-x}Sc_x)N$ films [4]. In this presentation, we tried to get the large P_r value even for thin films. In addition, we tried to analyze the determination factor of E_c by the analysis of the switching kinetics of $(Al_{1-x}Sc_x)N$ films.
Large P_r beyond 100 μC/cm^2 was obtained even for the 12 nm-thick $(Al_{0.78}Sc_{0.22})N$ films prepared under pure N_2 atmosphere [5, 6]. Leakage current density decreased comparing with the films prepared under Ar+N_2.
E_c value was found to be mainly determined by the crystal anisotropy of the deposited films as well as operation temperature and the frequency. Temperature dependency of E_c value was almost the same with those of conventional ferroelectric films including $Pb(Zr, Ti)O_3$ and HfO_2-based ferroelectrics, but its frequency dependency was relatively small. Polarization switching of $(Al_{1-x}Sc_x)N$ films followed Kolmogorov-Avrami-Ishibashi (KAI) model and its switching speed is faster than those of conventional ferroelectric films.
These results show that ferroelectric $(Al_{1-x}Sc_x)N$ nitrides is a promising candidate for memory applications.

7:00 AM EQ09.17.01
Fabrication of Thin-Film Transistor from Amorphous Oxide Semiconductors Kelsea Yarbrough, Makhes Behera, Sangram K. Pradhan and Messaoud Bahoura; Norfolk State University, United States

Thin-film transistors (TFTs) based on amorphous oxide semiconductor (AOS) are moving towards commercial world as a replacement for hydrogenated amorphous silicon (a:Si:H) TFTs in multiple flat-panel applications. AOS TFTs differ from the conventional complementary metal-oxide semiconductor (CMOS) electronic devices. Instead of using a bulk, crystalline semiconductor, AOS TFTs employ thin amorphous materials in which the channel layer is approximately few tens of nanometers. We have fabricated thin film transistor using a shadow mask technology. Shadow mask technology is a technique that allows a desired pattern to be transferrable onto a substrate. Shadow mask technology is similar to photolithography in patterning; however, it is more environmentally friendly, reusable, and cost effective. Shadow mask technology was used to deposit the active layer and the dielectric layer of our devices. The indium-free oxide-based channel material such as aluminum-doped zinc oxide (AZO) is the active material and can be deposited on glass substrate or silicon for TFT applications. High quality AZO thin films are grown using electron beam evaporation on p-type silicon and on glass for characterization purposes. The effect of Al content on zinc oxide crystal lattice are investigated using various characterization techniques. Atomic force microscopy provided thin film roughness, grain size, and surface morphology. X-ray diffraction provided crystal orientation for both dielectric and active layer deposition. Ultra-violet visible spectroscopy is used for transmission percentage and Keithley 4200 semiconductor characterization system provided dielectric performance and transistor characteristics including on/off ratio, mobility, and threshold voltage. We observed a dielectric capacitance as high as 698 pF and a minimum surface roughness of 0.176 nm. The lowest current density observed for dielectric performance is found to be in the magnitude of 10^{-8} A/ cm^2 and transistor saturation current exceeding 1.5 μA. This present work will provide valuable scientific input of AZO TFTs for the improvement of TFT devices.

This work is supported by the NSF-CREST Grant number HRD 1547771 and NSF-CREST Grant number HRD 1036494.

10:30 AM INTRODUCTORY REMARKS

11:00 AM *EQ10.01.02
Phase-Change Memory-Based Analog In-Memory Computing for AI Irem Boybat; IBM Research - Zurich, Switzerland

AI systems managed to reach and even exceed human performance in various cognitive tasks, ranging from image recognition to strategic games and to reasoning. AI models continue to grow in size, requiring us to re-think about how to architect computing systems. Analog in-memory computing is one non-Von Neumann approach, where computational tasks are performed in memory by exploiting the physical attributes of memory devices. This talk will focus on phase-change memory-based analog in-memory computing for accelerating deep learning inference and training. The limited analog computational precision will be discussed with particular attention to device non-idealities. Strategies to overcome these at device, circuit, architecture, and algorithmic levels will be reviewed. Analog in-memory computing-based system architectures tailored for various AI application domains, including low-power solutions, will be presented.

11:30 AM EQ10.01.03
Optimization of Interfacial PCM Layers to Enable High Resistance Doped PCM in Mushroom Cell Devices for Analog Computing Kevin W. Brew[1], Injo Ok[1], Ning Li[2], Timothy Philip[1], Benedikt Kersting[3], Shun Manita[4], William Lee[4], Iqbal Saraf[1], Juntao Li[1], James Demarest[1], Robert Bruce[2], Cheng-wei Cheng[2], Christian Lavoie[2], Takeshi Masuda[4], Takehito Jimbo[4], Nicole Saulnier[1], Matthew BrightSky[2] and Vijay Narayanan[2]; [1]IBM AI Hardware Center, United States; [2]IBM T.J. Watson Research Center, United States; [3]IBM Research Europe, Switzerland; [4]ULVAC, Inc., Japan

The use of mushroom cell PCM as an NVM memristive weight element for analog computing has been a focus of recent progress towards hardware designed for artificial intelligence. A major detriment of standard Ge-Sb-Te based materials (e.g. GST225) typically used in binary memories, is its relatively low resistance and a low crystallization temperature that leads to high power consumption when implemented in an array such as a neural network, and poor resistance-state retention, respectively. By doping PCM with insoluble non-conducting material to form a homogenous mixture (dPCM), the PCM grain sizes are confined, increasing the crystallization temperature, improving retention through increased crystallization temperature. The resistance of the dPCM is also significantly increased, decreasing programming current requirements. There is, however, a limit to the level of doping that can be used for dPCM as high amounts of dopant can create an inability for the device to SET to its crystalline state. In this work, we show how insertion of a thin, undoped or low-doped interfacial PCM layer between the confined bottom electrode heater (BEH) and the bulk dPCM allows for the use of higher doping and more resistive dPCMs to further reduce programming current requirements.

11:45 AM EQ10.01.04
Impact of PCM Noise on the Spiking Restricted Boltzmann Machine via On-Chip Trainable PCM Synapses Uicheol Shin[1], Masatoshi Ishii[2], Atsuya Okazaki[2], Megumi Ito[2], Rasch Malte[3], Wanki Kim[3], Akiyo Nomura[2], Suyeon Jang[1], Sung Min Lee[1], Wonseok Choi[1], Kohji Hosokawa[2], Matthew BrightSky[3], Seiji Munetoh[2] and SangBum Kim[1]; [1]Seoul National University, Korea (the Republic of); [2]IBM Research-Tokyo, Japan; [3]IBM T.J. Watson Research Center, United States

The spiking neural network (SNN) has been highlighted by its brain-like computing based on spike activities which could bring power-efficient performance, further suggested as the next generation of neural networks [1]. However, hardware implementation of SNN is still challenging as to be designed friendly for both hardware and algorithm, to process large amounts of spatiotemporal spike trains efficiently. In this work, we introduce our recent results [2] based on a fully functional chip with a sizable number of 1.4M synaptic phase-change memory (PCM) cells and all the Si CMOS circuits needed for the targeting algorithm, spiking restricted Boltzmann machine (RBM).
To implement the spiking RBM and its training algorithm, event-driven contrastive divergence (eCD) [3], synaptic crossbar unit cells are constructed with 6-transistor/2-PCM-resistor (6T2R) and peripheral stochastic leaky-integrate-and-fire (LIF) neuron circuits on fully silicon-integrated 90nm CMOS technology. A bidirectional, asynchronous, and parallel pulse-signaling scheme over an analog-weighted PCM synapse array is elaborately designed to be fitted with spike-timing-dependent plasticity local learning rule based on eCD. Since the RBM is a two-layer bidirectional neural network with a probabilistic-based algorithm, we elucidate the system basis with on-chip characterization results such as bidirectional LIF operations over various weighted PCM cells and sigmoid-like firing probability via random walk circuitry. A reasonable symmetricity between LIF and BLIF as well as the stochasticity from on-chip stochastic neuron circuits are shown, which are of critical importance to execute the spiking RBM. The densely integrated spiking RBM chip is configured with a field-programmable gate array (FPGA)-based evaluation system to efficiently transfer spike trains through on-chip scan chains to operate RBM algorithm phases. A fully hardware demonstration of pattern inference scored 93% on-chip training accuracy from 100 MNIST digit handwritten image samples. Furthermore, to clarify the generative performances of the spiking RBM chip, we experimentally demonstrated image reconstruction by inputting partial unperfect patterns. Simulation studies are also added to evaluate how well the impact of PCM-based intrinsic 1/*f* noise is suitable for the generative characteristic of spiking RBM. Thanks to well-fabricated units such as neuron circuits and synaptic cells operating asynchronously and parallelly, this work indicates the potential of power-efficient SNN processors by taking inherent advantage of spike sparseness.

1:30 PM *EQ10.02.01
The Metaheuristic Functionality based on Spontaneity of Memristor Devices for Neural Computing Hongsik Jeong; UNIST, Korea (the Republic of)

Memristor devices have been developed as emerging memory devices compensating for the weakness of conventional memory devices such as DRAM and Flash memory. Memristor devices also have been paid attention as synaptic devices for neural computing. The targeting characteristics of memristor devices as emerging memory devices and synaptic devices are very similar such as low power, non-volatility, high speed, etc. However, memristor devices have unique characteristics that conventional memory devices. Recently, some research has been performed to improve the computation ability by using unique characteristics of memristor devices different from those of existing memory devices as synaptic devices.
In this paper, the higher-level metaheuristic function beyond conventional neural computing will be discussed by using the unique characteristics of memristor-based synaptic devices. The metaheuristic algorithm based on the spontaneity of memristor devices makes neural computing more efficient without additional computing energy.

2:00 PM EQ10.02.02
Simulations of Volatile Memristors Based on Vanadium Dioxide—Linking Material Properties to the Dynamics of Neuromorphic Circuits Stefania Carapezzi, Gabriele Boschetto, Corentin Delacour and Aida Todri-Sanial; LIRMM, University of Montpellier, CNRS, France

Volatile memristors have been gathering a lot of attention as devices suitable for technological applications, such as neuromorphic devices and random number generators, to name a few. Their operating mechanism is a sharp and volatile resistivity variation, switching between high and low resistance states. A thorough understanding and modeling of this resistive switching are essential to fully exploiting volatile memristors. In this respect, multi-physics simulations are crucial. This is especially the case when dealing with devices fabricated with innovative materials, where both material growth and device processing are still to be completely controlled. Then, simulations allow to investigate the interplay between different material properties and/or device features that would be otherwise obscured due to the inherent variability of devices.
In this work, we show results of 3D technology computer-aided design (TCAD) electrothermal simulations of volatile memristors based on vanadium dioxide (VO_2). We avail of a dedicated TCAD approach [1], [2], developed to model the resistive switching of VO_2 volatile memristors as induced by the Joule effect. We combine the electrothermal device simulations with SPICE circuit simulations to simulate the dynamics of VO_2 oscillators. VO_2 oscillators have recently attracted a large interest [3] as the main elements for realization of systems of coupled oscillators, or oscillatory neural networks (ONNs), which are circuits whose dynamics resemble that of networks of neurons in the human brain [4]. By our mixed-mode TCAD-SPICE approach, we are able to link realistically VO_2 material properties to the behavior of the oscillator and the dynamics of simple ONN systems, thus being able to simulate realistically the working of ONN circuits as analogue computing engines. Our findings shed light on the coupled thermal and electrical behavior of VO_2 oscillator as well as the behavior of networks of VO_2 oscillators, providing some physical insights into the successful implementation of ONN technology.
Acknowledgments. Authors wish to thank Dr. S. Karg, IBM Research Europe, Zurich, Switzerland, for providing the experimental data used for calibrating the TCAD model and the valuable discussions about the experimental devices. Authors also wish to thank Dr. A. Nejim and Dr. A. Plews, of Silvaco Europe Ltd., Cambridgeshire, United Kingdom, for providing the customized version of PCM model [1] used to simulate the VO_2 material as well as for the useful discussions about the TCAD and mixed-mode simulations.

Polaron-Induced Metal-to-Insulator Transition in Vanadium Oxides from Density Functional Theory Calculations Jasleen Kaur, Chi Chen, Manas Likhit Holekevi Chandrappa and Shyue Ping Ong; University of California, San Diego, United States

Neuromorphic computing approaches have gained significant interest by researchers in the last decade to replace the existing von-Neumann architecture for faster, better, and more efficient machinery with ultra-low power consumption. Intending to emulate the human brain, phase-change memory devices have showcased many advantages to be used as an artificial synapse. V_3O_5, a member of vanadium Magnéli phases, is a Mott insulator known to exhibit temperature-dependent metal-insulator transition (MIT) at 428 K. In this study, we explore a new triggering mechanism to avoid temperature-induced MIT by forming polarons in the low temperature insulating V3O5 phase. We observe a decrease in the band gap from 0.63 eV to 0.47 eV in presence of free electron polaron and 0.51 eV for the system containing free hole polaron. The polaron migrations along different directions were compared using NEB calculations for systems containing free as well as bound polarons in the presence of oxygen vacancies. We find the polaron migration to be facile at low temperatures with the barrier ranging around 100 meV along different directions for both electron and hole polaron, achieving an increased conductivity in the insulating phase. Our studies suggest that this material can exhibit polaron-induced MIT at lower temperatures making it a more favorable candidate for nonvolatile memory in comparison to other vanadium oxides.

Optimization of Projected Phase Change Memory for Analog In-Memory Computing Inference Ning Li[1,2], Charles Mackin[3], An Chen[3], Kevin Brew[1], Timothy Philip[1], Andrew Simon[1], Iqbal Saraf[1], Geoffrey Burr[3], Malte J. Rasch[2], Abu Sebastian[4], Vijay Narayanan[2] and Nicole Saulnier[1]; [1]IBM Albany Nanotech, United States; [2]IBM T.J. Watson Research Center, United States; [3]IBM Almaden Research Center, United States; [4]IBM Research-Zurich, Switzerland

Phase change memory (PCM) is a promising candidate for non-von Neumann based analog in-memory computing – particularly for inference of previously-trained Deep Neural Networks. PCM with projection liner is designed for resistance drift mitigation. We show that PCM electrical properties-including resistance values, memory window, resistance drift, read noise, can be tuned systematically using the liner in the manufacturable mushroom PCM. We perform a systematic study of these electrical properties and their impact on the accuracy of several deep neural networks (DNN) using the analog AI simulation tool developed at IBM. We show that the DNN accuracy can be improved by the PCM with liner. We analyze the origin of the accuracy improvement and identify the design space for best performance.

We evaluate large neural networks with tens of millions of weights using the PCM with and without liner, and evaluate a variety of DNNs and test datasets at various times after programming, to study the network performance over time for chips using these PCMs. We evaluate PCM devices in various DNN types, including Recurrent Neural Networks (RNNs), Convolutional Neural Networks (CNNs), and Transformer-based networks. We also evaluate the devices using various weight mapping schemes, including a direct weight mapping scheme for one PCM per weight and an optimized weight mapping scheme using multiple PCMs per weight. We show that the accuracy enhancements from PCM with a projection liner are achieved for all these weight mapping schemes as well as for networks with different structure, complexity, type of nonlinear activation functions employed, etc. We also show that the accuracy is improved for both short term and long term after programming. The better long term accuracy of the liner devices is due to the lower drift coefficient and lower drift variability. The better initial accuracy is due to the reduced noise of the liner devices, despite a trade-off of a reduced memory window. We show that the liner device parameters need to be carefully chosen and identify a range of these parameters that enable the most improvement in network accuracy.

3:15 PM EQ10.02.07
Growing Smooth Polycrystalline VO2 Film on Silicon Platform for Neuromorphic Computing Olivier Maher[1,2], Roy Bernini[1], Nele Harnack[1], Bernd Gotsmann[1] and Siegfried Karg[1]; [1]IBM Research-Zurich, Switzerland; [2]ETH Zürich, Switzerland

Exploiting the phase transition of VO2 close to room temperature (68°C) enables many technologies such as optical switches, smart windows, and terahertz antennas. The insulator-metal transition associated with the crystalline phase-change also provides means to fabricate electronic switches and oscillators. Recently, electrically driven VO2 oscillators have been suggested for new AI-based computing paradigms including pattern recognition, solving optimization tasks, and NP-hard problems [1, 2]. A series of coupled VO2 devices exploiting self-oscillations induced through an electric current can be harnessed to build an oscillating neural network (ONN) [1, 3, 4]. Being able to process data locally with ONNs offers new power-efficient solutions to bypass the imbalance between the memory access speed and the computational time needed to process such heavy calculations [5, 4].
For the use of VO2 in industrial computing applications, CMOS-compatible circuits require high material quality concerning uniformity and surface roughness after depositing on a Silicon-compatible substrate such as Silicon oxide [6, 7]. Devices in planar and crossbar configurations have been fabricated to this end. The VO2 devices sit on a Si/SiO2 substrate ensuring CMOS compatibility. Fabrication of VO2 layers on non-crystalline substrates, however, tends to result in polycrystalline films with granular structure and considerable surface roughness [6]. This leads to undesired variability among electrical devices such as our oscillators that needs to be mitigated [7].
In this study, we show how to solve this issue by treating amorphous vanadium oxide films with an annealing step to recover smooth 50 nm-thick film in its crystalline VO2 form. The amorphous films are deposited by atomic layer deposition (ALD) using TEMAV (Tetrakis[ethylmethylamino] vanadium) and a water-based reaction. We studied different techniques to find a trade-off between crystallization and oxidation rate and phase. One annealing procedure consists of flashing the film with a high energy beam (FLA-50AS, Dresden Thin Film Technology) for 20 ms under oxygen atmosphere (200 mbar) with the sample preheated between 100°C and 310°C. As a reference, the ALD films were annealed by putting the sample in a low oxygen flow chamber (30-40 mTorr) for 10 minutes at a temperature of 520°C. The impact of the different annealing methods on the grain size, the surface roughness, the electric behavior, and the quality of the resulting VO2 film are studied through Raman Spectroscopy, Atomic Force Microscopy (AFM), and by measuring the resistance of the film at different temperatures. The nature of the underlying oxide layer and its effect on the quality of the VO2 is also studied to define which configuration leads to the best and most reproducible results.
Our network of VO2-based oscillators shows the promise of an attractive and scalable computing unit for hardware accelerators [3, 5], thanks to its MHz high-performance switching properties and CMOS compatibility.
This project has received funding from the EU's Horizon 2020 program under projects No 871501 (NeurONN) and No 861153 (MANIC). We thank the operations team of the Binnig and Rohrer Nanotechnology Center (BRNC) at IBM Research Europe - Zurich for their help and support.

3:30 PM EQ10.02.08
VO_2 Insulator-Metal Phase Change Based Neuromorphic Materials and Devices Haoming Yu, Sunbin Deng, Tae Joon Park, Qi Wang, Sandip Mondal and Shriram Ramanathan; Purdue University, United States

Vanadium dioxide (VO_2) undergoes a phase transition from insulating to metallic states through multiple stimulus, including heat, electric field etc. This inspires the use of VO_2 in artificial neurons to emulate the spiking behavior when the metal to insulator transition (MIT) of VO_2 occurs. Defects and non-stoichiometry profoundly affect the electrical properties such as threshold voltage and state retention. Recently, a few research articles have been presented showing the non-volatile synaptic behavior of VO_2 with oxygen vacancies, inspiring additional research in this direction. This proves the bi-functionality of VO_2. In this work, we will discuss properties of stochastic VO_2 neurons based on two connected VO_2 vertical devices. Two-step switching behavior in transient measurements is shown and is demonstrated to be due to the individual switching of the two devices. Furthermore, we show that the interaction of the two devices enables us to control the switching dynamics by locally controlling the temperature. Finally, we will present electrical characteristics of VO_2 films with intentional point defects such as hydrogen and oxygen vacancies to present a phase map of defect concentration, strain versus volatility and its relation to ground state resistance.

3:45 PM *EQ10.02.09
Optimized Weight Programming for Analog Memory-Based Deep Neural Networks Charles Mackin[1], Malte J. Rasch[1], An Chen[1], Jonathan Timcheck[2], Robert Bruce[1], Ning Li[1], Pritish Narayanan[1], Stefano Ambrogio[1], Manuel Le Gallo[1], S.R. Nandakumar[1], Andrea Fasoli[1], Jose Luquin[1], Alexander Friz[1], Abu Sebastian[1], Hsinyu Tsai[1] and Geoffrey Burr[1]; [1]IBM, United States; [2]Stanford University, United States

Analog memory-based deep neural networks provide energy-efficiency and per-area throughput gains relative to state-of-the-art digital counterparts such as graphics processing units. Recent advances focus largely on hardware-aware algorithmic training and improvements to circuits, architectures, and memory devices. Optimal translation of software-trained weights into analog hardware weights—given the plethora of complex memory non-idealities—represents an equally important task. We report a generalized computational framework that automates the crafting of complex weight programming strategies to minimize accuracy degradations during inference, particularly over time. The framework is agnostic to network structure and generalizes well across recurrent, convolutional, and transformer neural networks. As a highly flexible numerical heuristic, the approach accommodates arbitrary device-level complexity, making it potentially relevant for a variety of analog memories. Interestingly, this computational technique can optimize inference accuracy without the need to run inference simulations or evaluate large training, validation, or test datasets. By quantifying the limit of achievable inference accuracy, it also enables analog memory-based deep neural network accelerators to reach their full inference potential.

SESSION EQ10.03: Interfacial Phase Change Materials
Session Chairs: Valeria Bragaglia and Raffaella Calarco

8:30 AM *EQ10.03.01
Layered Chalcogenide Materials for Phase-Change Memory and Novel Applications Yuta Saito; National Institute of Advanced Industrial Science and Technology, Japan

Te-based chalcogenides are the key for the phase-change memory technology. The conventional phase-change memory relies on a reversible change between amorphous and polycrystalline phases. Recently, for the further improvement of memory performance, heterogeneously structured phase-change materials have been attracted attention. In fact, most conventional phase-change materials such as Sb_2Te_3 and $Ge_2Sb_2Te_5$ crystallize into a layered structure. Therefore, realization of reversible change between amorphous and highly oriented crystalline phases could have a potential to overcome conventional polycrystalline-based materials. In this talk, some examples of layered chalcogenides will be given with respect to fabrication, function, and novel applications.

9:00 AM EQ10.03.02
Finite Element Electro-Thermal Modeling of Interfacial Phase Change Memory Md Tashfiq Bin Kashem, Jake Scoggin, Ali Gokirmak and Helena Silva; University of Connecticut, United States

Phase change memory (PCM) is a high-speed non-volatile memory that utilizes the reversible and rapid transition between conductive crystalline phase and resistive amorphous phase of the phase change material to store information. One major bottleneck for PCM is the large power requirement to heat the active region above crystallization or melting temperature. To counteract this issue, a device engineering technique is to use thin film periodic structure of layers of two phase change materials known as superlattice or interfacial phase change memory (iPCM) [1,2]. The mechanisms behind the improved performance of iPCM are still under investigation, one experimental work indicates similar crystallization and melt-quench based amorphization of these devices as conventional PCM [2]. iPCM structures benefit from accelerated amorphization through increased number of material interfaces and reduced thermal conduction due to thermal boundary resistances (TBR). Moreover, because of difference in melting temperature, electrical conductivity and Seebeck coefficient of different materials constituting the superlattice, such layered structures may have the advantage of melting of only one of the alternating layers assisted by local heating or cooling due to Peltier effect at the interfaces. If the alternating layers are lattice matched, recrystallization (set) time is also expected to be much faster as crystallization can be achieved though templated growth at the interfaces.

In this work, we utilize our finite element phase change model [3-6] in COMSOL Multiphysics platform to perform electro-thermal simulations of reset and set operations on iPCM structures consisting of alternately stacked $Ge_2Sb_2Te_5$ (GST) and GeTe layers [7]. Electric current and heat transfer physics are employed together to account for Joule heating and thermoelectric effects (Thomson heat within a single material and Peltier heat at material interfaces) with temperature dependent Seebeck coefficients, thermal conductivities, electrical resistivities, heat capacities and TBR for each material / material pairs. Latent heat of crystallization and fusion are included in the amorphous-crystalline and solid-liquid transitions respectively [5], causing heat release at the crystal-amorphous boundaries during crystal growth and heat absorption at the grain boundaries during amorphization. High energy sites: grain boundaries and material interfaces are easier to melt, described as heterogeneous melting [6]. Updated current density function [8] and electrical conductivity model of GST [9] are incorporated in the simulation framework.

Our results on iPCM and conventional PCM structures of same dimensions and geometry (20 nm wide, 70 nm long pillar cells) show ~ 50% reduction in reset time and energy and more consistent set for iPCM. We explored the effect of the total number of layers and the thickness of each material in a period on the time and power requirements for memory operations. Increased number of layers improve speed and power efficiency. However, thinner layers may be less stable and more prone to mixing.

In-Based PCM Heterostructures—Electronic Properties at the Interface and Confinement of Thin Sb Layers Simone Prili[1], Flavia Righi Riva[1], Ernesto Placidi[2,1], Adriano Diaz Fattorini[3], Caroline Chèze[1], Marco Bertelli[3], Massimo Longo[3], Raffaella Calarco[3] and Fabrizio Arciprete[1]; [1]University of Rome Tor Vergata, Italy; [2]Sapienza University of Rome, Italy; [3]National Research Council-CNR, Italy

In the last years the widespread of internet and the consequent rise of the so called “Internet of Things” led to a significative increase of interconnection of people with each other and especially between objects that surround us. Among the “things” that have benefited the most out of such revolution, modern cars are by far one of the most representative examples: packed with sensors that monitor every aspect of the vehicle as well as the street environment, they constantly collect and analyzed large amounts of data in order to grant the safest and most comfortable driving experience. To achieve this goal, having a performing, embeddable and highly scalable device for the storage and processing of the information is paramount. Among possible different solution for this task, Phase change Random access memories (PCRAM) are by far one of the most promising candidates since they provide non-volatile device characterized by all the above-mentioned properties and can implement in-memory computing for optimization of AI algorithm.
However, current PCRAM benchmark active materials, $Ge_2Sb_2Te_5$ (GST 225) and other alloys lying on the $(GeTe)_m(Sb_2Te_3)_n$ pseudo-binary tie line, fail to meet the strict requirements for the implementation in a vehicle. In fact, despite their outstanding performances in devices working in ambient conditions, GST crystallization temperature is too low for the realization of memory devices for automotive applications, for which high stability at temperatures as high as 160°C is mandatory. To address this issue, In-based PCMs, characterized by inherently high crystallization temperature, could be solid candidates

for this goal. Our work focused on two alloys, In-Sb-Te (IST) and In-Ge-Te (IGT), both characterized by high transition temperature [1, 2], which we studied as single films and combined each other in a IST/IGT heterostructure. Amorphous samples were grown at room temperature by thermal evaporation of the constituting elements from ultrapure sources on Si(111)/SiO_x substrates by means of Knudsen cells in Ultra-High Vacuum conditions (UHV). Performing *in-situ* X-ray and Ultraviolet photoemission spectroscopy (XPS & UPS) we characterized the electronic properties, valence band (VB) and core levels, of the as-grown samples and managed to track composition variations across the IGT/IST interface. Valence band structures of the alloys will be discussed and compared with published density of states computed by *ab initio* molecular dynamics simulation based on DFT. Unexpectedly, the photoemission study of this heterostructure showed that no Sb diffuses through as-grown IGT, leading to the formation of sharp interface completely lacking antimony. This is particularly relevant especially because of the renewed interesting towards pure ultrathin Sb [3], a newfound promising PCM itself. In light of this, we have grown Sb/IGT heterostructures employing IGT as confinement material to study the crystallization of pure Sb and, by means of *ex-situ* X-ray diffraction, we characterized Sb/IGT heterostructures featuring Sb layers of different thicknesses to observe the effect of this parameter on the transition temperature.

Revelation of the Underlying Switching Mechanism Occurring in van der Waals GeTe/Sb_2Te_3 Superlattices Damien Terebenec[1], Nicolas Bernier[1], Vitomir Sever[1], Niccolo Castellani[1], Jessy Paterson[1], Francoise Hippert[2] and Pierre Noé[1]; [1]CEA, France; [2]LMGP, France

Phase-Change Memory (PCM) is widely recognized as the key emerging technology for the next-generation non-volatile memory. In PCM, the information is stored at the nanoscale in two distinct resistive states of a phase-change material: a polycrystalline state corresponding to the Low Resistance State (LRS), and an amorphous state for the High Resistance State (HRS named RESET). The main shortcoming of PCM is the high energy loss occurring within the memory cell, especially during the RESET operation requiring local melting of the phase-change material, followed by quenching of the liquid phase to the amorphous state. Therefore, reducing the heat loss that occurs during the RESET operation has become a tremendous challenge. A breakthrough in memory cell architecture has enabled a reduction in energy waste through improved thermal confinement within the memory cell.[1] Nevertheless, the architectural approach has reached a technological limit. In this context, materials engineering has become the main asset in order to improve PCMs, by seeking novel materials with undiscovered properties. For instance, GeTe/Sb_2Te_3 van der Waals superlattices (SLs) embedded in PCM have demonstrated outstanding performance. This is evidenced by a decrease in programming currents of the order of 40%, a better cycling endurance, as well as a higher transition speed than conventional $Ge_2Sb_2Te_5$ alloy located along the GeTe-Sb_2Te_3 pseudo-binary line.[2] This performance improvement has long been attributed to a novel mechanism of crystal-to-crystal resistive transition as opposed to the amorphous-to-crystal transition of conventional PCM. The change of electronic properties in GeTe/Sb_2Te_3 SLs has first been attributed to the result of coherent switching of Ge atomic planes at the interfaces with Sb_2Te_3 layers, leading to a change in the density of electronic states, hence the name "interfacial Phase Change Memory" (iPCM). However, the underlying switching mechanism occurring in the SL structure is still highly debated in the PCM community.
In this work, we study the memory performances of $[(GeTe)_2/(Sb_2Te_3)_X]_n$ SL with X=2, 4, and 8 nm, as well as the origin of the resistive switching occurring in SL PCM devices. GeTe/Sb_2Te_3 SLs were deposited by magnetron sputtering in a 200 mm cluster tool. They are obtained by a periodic stacking of nanometer-thick crystalline GeTe and Sb_2Te_3 layers oriented along the [001] axis normal to the substrate surface. In the literature, all models describing crystal-to-crystal resistive transition assume the existence of GeTe layers with pure Ge and Te planes within the SL structure. Nevertheless, we revealed by scanning transmission electron microscopy (STEM) that SLs exhibit an atomic structure consisting in stacking of Sb_2Te_3 quintuple layers, and different $Ge_xSb_yTe_z$ alloys ranging between 7 to 11 atomic planes.
Subsequently, SLs were integrated in phase-change memory (PCM) devices in a “wall structure”, with a polycrystalline GeTe alloy used as reference. $[(GeTe)_2/(Sb_2Te_3)_X]$n SL permits to significantly reduce the RESET current (>60%) in PCM compared to devices using conventional polycrystalline phase-change material. STEM imaging coupled with NanoBeam Electron diffraction of a $[(GeTe)_2/(Sb_2Te_3)_8]_4$ nm SL device previously switched in the HRS, unambiguously revealed the presence of an amorphous area above the heater. This result demonstrates that the resistive switching occurred through a melting-quenching process in SL, as in conventional PCM.[3] A thorough understanding of programming performance improvement offered by $[(GeTe)_2/(Sb_2Te_3)_X]_n$ SLs related to their atomic structure will be discussed.

Engineering Superlattice Materials and Interfaces for Improved Resistance Drift and Retention in Phase-Change Memory Xiangjin Wu, Asir Intisar Khan, Pranav Ramesh, Krishna Saraswat, H.S. Philip Wong and Eric Pop; Stanford University, United States

Phase change memory (PCM) is a promising candidate for data storage and neuromorphic computing. However, using traditional phase change materials like $Ge_2Sb_2Te_5$ (GST), PCM suffers from resistance drift resulting in undesired bit errors and inference accuracy degradation in compute-in-memory [1]. Recently, superlattice (SL) PCM with thin phase change layers has shown promise for low resistance drift [2-4]. However, the origin of low resistance drift and the role of the SL interfaces remain unexplored. At the same time, retention in such SL-PCM also demands attention to ensure its reliable operation.

Here, we uncover a correlation between resistance drift and SL interfaces in a GST based SL-PCM (Sb_2Te_3/GST) and simultaneously shed insight into its origin using temperature-dependent measurements. By controlling the number of SL interfaces, we obtain a low $\nu < 0.01$ and as low as ~0.002 measured for 10^5 seconds in 2 nm/1.8 nm Sb_2Te_3/GST SL-PCM. We also explore the retention in SL-PCM for the first time and demonstrate how the choice of SL layers can enable higher retention.

We fabricated SL-PCM devices with alternating Sb_2Te_3 and GST layers having different period thicknesses (1/number of interfaces). Measured resistance (R) vs. time shows >10× lower resistance drift in the SL-PCM device (ν <0.01) vs. GST-only control PCM ($\nu \approx 0.12$), both with ~110 nm BE diameter. However, for SL-PCMs the resistance drift increases with fewer SL interfaces (e.g., 4/1.8 nm/nm and 16/14.4 nm/nm SLs). This suggests that nano-confinement and van-der Waals gaps play an important role in reducing the resistance drift. We also find that intermixing and imperfections within SL layers increase the resistance drift.

To understand the origin of low ν in SL-PCM, we extracted conduction activation energy E_a from R vs. temperature (T) measurements, showing lower E_a in SL-PCM with more interfaces. We also find that 2/1.8 nm/nm SL-PCM displays a negligible change in both E_a and high resistance state after 85°C annealing. In contrast, both attributes show an increasing trend upon annealing for SL-PCM with fewer interfaces and for GST (no internal interfaces). This

suggests that less structural relaxation in SL-PCM with more interfaces reduces the resistance drift. The low $\nu < 0.01$ in our Sb_2Te_3/GST SL-PCM devices is maintained after extensive ($>10^6$) cycling, for various read stress and upon measurement at different read voltages, demonstrating robustness and reliability of the low resistance drift.

Next, we explore the retention of the resistance states in our SL-PCM devices. Our measurement shows that resistance states in Sb_2Te_3/GST SL-PCM devices retain up to a temperature annealing of 85°C for 1 hour. This relatively lower retention in these SL-PCM devices (vs. control GST) originates from the presence of low-retention Sb_2Te_3 layers within the SL. To address this, we replaced Sb_2Te_3 layers within the SL-PCM with $TiTe_2$ (higher melting *T* and higher stability) and $Ge_2Sb_2Te_5$ (GST) layers with $Ge_4Sb_6Te_7$ (a phase-change nanocomposite with higher crystallization *T*), thus conceptualizing $TiTe_2$/GST467 superlattice PCM. Our measurements of the $TiTe_2$/GST467 SL-PCM devices indeed confirm a significantly higher retention for the resistance states (145°C for 3 hours).

In summary, we uncover the role of interfaces within superlattice (SL) layers in achieving low the resistance drift of SL-PCM and explore the origin of such interface-controlled low resistance drift. By choosing optimized material layers within the SL, we further demonstrate SL-PCM with simultaneously high retention and low resistance drift, promising for multibit storage and neuromorphic computing using SL-PCM technology.

Thermodynamics and Kinetics of the Crystallization of Phase Change Materials from Complementary *In Situ* Microscopic Techniques Melissa K. Santala; Oregon State University, United States

Phase change materials (PCMs) are semi-conducting alloys with distinct optical and electrical properties in the amorphous and crystalline phases that make them useful for memory applications. In memory devices, amorphous bits are crystallized in nanoseconds by either laser or Joule heating, but the amorphous phase must also be stable against crystallization for long-term data retention. Crystal growth rates relevant to memory devices span orders of magnitude and fundamental questions regarding PCM crystallization mechanisms remain open, partly due to the difficulty in measuring crystallization kinetics in certain temperature regimes. This talk will cover the application of multiple imaging techniques used to directly quantify crystal growth rates in PCMs over a broad range of temperatures. The measurable growth rates from the different techniques span from ~10^{-9} to >10 m/s and the *in-situ* imaging techniques applied include optical microscopy, conventional transmission electron microscopy (TEM), and dynamic TEM, a photo-emission TEM technique with nanosecond-scale time resolution. The use of complementary *in situ* experimental techniques allow the crystal growth rates to be mapped over a large temperature range and can give insights into the crystallization kinetics of PCMs. Nanocalorimetry results using microfabricated devices designed to be using in a TEM holder will be described. These devices enable simultaneous collection of thermodynamic data along with TEM imaging of the crystal growth front. Challenges associated with integrating results from different microscopic techniques and the incorporation nanocalorimetry to probe the thermodynamics of crystallization with simultaneous TEM imaging will be discussed.

Space-Qualified Chalcogenide Materials Through ISS MISSE Exposure —From Property to Application Hyun Jung Kim[1], Kiumars Aryana[1], Cosmin-Constantin Popescu[2] and Juejun Hu[2]; [1]NASA Langley Research Center, United States; [2]Massachusetts Institute of Technology, United States

In March 2021, twenty-four samples of various phase change materials (PCMs - $Ge_2Sb_2Te_5$, $Ge_2Sb_2Se_4Te_1$, and Sb_2Se_3) along with metasurface optical components comprised of these PCMs, were delivered to the International Space Station (ISS) as part of the Materials International Space Station Experiment (MISSE-14) test campaign [1]. Although PCMs have previously been noted for their resilience to various forms of radiation [2], they had not been tested in a realistic space environment until this exposure campaign with joint NASA and MIT collaboration. During the six-month total open exposure time in low earth orbit (LEO), high-resolution cameras scanned and captured photographs of the samples to detect changes as a function of time along with on-orbit measured temperature, UV radiation, total atomic oxygen fluence, and total ionizing radiation doses. The samples were returned to NASA Langley Research Center in March 2022 for post-flight characterization. This duplicated the preflight characterization (i.e., material composition and crystallinity that limits switching speed, index contrast, loss, etc.) conducted before launch.

The space sector has witnessed tremendous growth within the past decade—not only from government agencies but also entrants from the private sector. Future growth in the capabilities of Earth observation, deep space, and planetary surface missions using miniaturized spacecraft platforms can only be sustained by innovations in the design of remote sensors and other sub-systems. Active metasurface optics with enhanced tunability and reconfigurability continues to redefine the boundaries of optical science [3]. The introduction of PCM technology and associated optical devices will help to accelerate the adoption of new architectures for reduced size, weight, power, and cost (SWaP-C) platforms in space.

Here we introduce results obtained from the MISSE-14 mission related to space qualification of PCM-based optic devices and constituent materials. We then discuss our recent work developing active integrated photonic devices and metasurface optics based on PCMs for space applications. This includes tunable and reconfigurable optical metasurface devices to support NASA space communication and LIDAR applications. PCMs are quickly becoming interesting photonics materials but questions related to mission suitability remain, particularly in regard to key properties like figures-of-merit (FOM, $\Delta n/\Delta k$), glass forming temperatures, and phase transition speeds. This talk will describe efforts to afford researchers the ability to have access to cost-effective data on exposure-induced changes to PCM fundamental physical and optical properties to assess their utility for space applications. The MISSE-14 sample exposure campaign allows a complete understanding of the limitations of the PCMs for various space-based electronic and optoelectronic applications.

Effect of Photoexcitation on Amorphized $Ge_2Sb_2Te_5$ Line Cells Stabilized by High-field Stress at Cryogenic Temperatures ABM Hasan Talukder, Raihan Khan, Md Tashfiq Bin Kashem, Faruk Dirisaglik, Helena Silva and Ali Gokirmak; University of Connecticut, United States

Phase change memory (PCM), one of the most promising non-volatile memory technologies, utilizes the large resistivity contrast between amorphous and crystalline phases of phase change materials like $Ge_2Sb_2Te_5$ (GST). PCM devices suffer from resistance drift which causes the amorphous resistance to increase over time, making it hard to implement multi-bit-per-cell operation. We have demonstrated that cell resistances can be stabilized within minutes by accelerating the drift with high-field stresses [2]. In this work, we have investigated the effect of photoexcitation on amorphized GST line cells stabilized by high-field stresses at cryogenic temperatures to understand the phenomena giving rise to resistance drift.
We amorphized GST line-cells at 80 K using 50 ns to 100 ns electrical pulses, stabilized the cells with several high-field voltage sweeps as we record the current, and observed the effect of photoexcitation at different temperatures up to 200 K. The contribution of photoexcited carriers, excited by a white LED, is clearly observed at 80 K in the low-field (< 20 MV/m) range. The photo-response increases with temperature up to ~150 K and remains constant beyond 150 K. The contribution of the photoexcited carriers become harder to observe for T > 250 K due to large number of thermally generated carriers. When the illumination is turned on and off periodically, electrical current flowing through the device shows sudden changes followed by very slow response (up to ~30 minutes at T = 150 K) [3]. The time scale for the slow changes suggests that the changes in the resistance are predominantly due to emptying and filling of charge traps, and not due to thermal perturbations induced on the cells due to exposure to light. The current through the device is insensitive to light but very sensitive to temperature in the high-field regime, and the high-field current does not change with periodic illumination, verifying that the observed response is not due to a thermal perturbation. These experimental results are used to determine the trap levels and the temperature dependence of band-gap of amorphous GST.

Comprehensive Review of Contacts to Phase Change Materials Suzanne Mohney and Kayla A. Cooley; The Pennsylvania State University, United States

Many devices, including memory and radio frequency switches, rely on the reversible transformation between amorphous and crystalline states of the phase change material. These devices require electrical contacts, and in many cases the contacts limit the overall device or circuit performance. In this presentation, we review the state-of-the-art on electrical contacts to the phase change materials GeTe, $Ge_2Sb_2Te_5$ (GST), $GeCu_2Te_3$, and $Ge_2Cr_2Te_6$. We address topics including contact resistivity, reactivity, thermal stability, and metal solubility. We especially emphasize contacts to GeTe due to our extensive work with this phase change material, and then we build upon our analysis of the metal-Ge-Te systems to include the metal-Sb-Te systems and finally to draw conclusions about contacts to GST.

2:00 PM EQ10.05.02
Simultaneous Thermodynamic and Kinetic Measurements of the Crystallization of an Ag-In-Sb-Te Phase Change Material Using Transmission Electron Microscopy and *In Situ* Nanocalorimetry Isak McGieson[1], Jim Ciston[2], Feng Yi[3], David LaVan[3] and Melissa K. Santala[1]; [1]Oregon State University, United States; [2]Lawrence Berkeley National Laboratory, United States; [3]National Institute of Standards and Technology, United States

An experimental platform using in-situ nanocalorimetry synchronized with high-frame-rate transmission electron microscopy (TEM) imaging has been developed and is being used to investigate the thermodynamics and kinetics of the crystallization of a phase change material (PCM) with a nominal composition of $Ag_3In_4Sb_{74}Te_{17}$ above its glass transition temperature. In-situ nanocalorimetry provides more accurate temperature measurements than other in-situ heating platforms as well as the high heating rates necessary to observe PCM crystallization above the glass transition temperature. High-frame-rate direct electron detectors capture the crystal growth in the milliseconds before impingement. The combined activation energy for nucleation and growth, the activation energy just for growth, and the enthalpy of crystallization are calculated from these measurements. Classical models for nucleation and growth are fit against these data using the temperature dependent viscosity as the free parameter. Models that predict the growth rate solely from calorimetry data are checked against the growth rate measurements.

2:15 PM EQ10.05.03

Optical Properties of Sb-Based Phase Change Materials Toward Visible and IR Photonic Applications Kotaro Makino[1], Yuta Saito[1], Shogo Hatayama[1] and Paul Fons[2,1]; [1]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [2]Keio University, Japan

Phase change materials including Ge-Sb-Te (GST) alloys exhibit a significant change in optical properties upon amorphous-crystalline phase change, and hence are promising for programable optical device applications in the visible and infrared wavelength range. The optical response of a material is governed by the complex index of refraction, namely the refractive index (real part) and the extinction coefficient (imaginary part). Recently, Sb_2S_3, Sb_2Se_3, and $Ge_2Sb_2Se_2Te_1$ were found to be good alternatives to GST due to their low extinction coefficients for the crystalline phases [1-3], although GST is still useful for some applications based on absorption change.
In this study, we performed first principles calculations to evaluate the optical constants of Sb-based phase change materials Sb_2Te_3, Sb_2S_3, and Sb_2Se_3. Our objective of the current study is to establish a standard computational procedure for further material development. By using Vienna Ab initio Simulation Package (VASP), we obtained complex index of refraction for both crystalline and amorphous phases. We also carried out ellipsometry measurements for sputter-deposited thin films (except for Sb_2Se_3) and found that use of a hybrid functional is crucial for accurate optical property simulations. Based on the simulation and experimental results, we found Sb_2S_3 is considered to be suitable for low-loss applications rely on refractive index change, while Sb_2Te_3 and GST is appropriate for control of absorption as previously reported.

The Significance of Antimony for Research on Phase Change Materials Martin Salinga; University of Münster - Institute of Materials Physics, Germany

For many years, phase change materials have been improved by mixing additional chemical species into alloys consisting of Ge, Sb and Te leading to rather complex compositions. A few years ago, in stark contrast to this common strategy, it was demonstrated that also pure Antimony can render phase change behaviour when spatially confined. Here, we discuss the role this product of maximal compositional simplification could play for research and applications.

3:30 PM EQ10.06.02
Low Temperature Wet-Chemical Synthesis of Sub-10 nm Sb Nanoparticles Enables the Stabilization of the Amorphous State Through Three-Dimensional Confinement Anne Frommelius[1,2], Konstantin Wirth[1,3], Thomas Taubner[1,3] and Ulrich Simon[1,2]; [1]RWTH Aachen University, Germany; [2]Institute of Inorganic Chemistry, Germany; [3]First Institute of Physics (IA), Germany

Non-volatility of the structural state together with fast switching times make phase change materials (PCM) extremely useful for data storage applications and showcase great potential for neuro-inspired computing.[1] The properties of PCM are commonly tuned by precisely changing stoichiometries or doping components, which may lead to phase segregation or degradation under operation.
By addressing these challenges, which arise from the compositional complexity of common PCM, Salinga *et al*. studied the threshold switching properties of monoelementary Sb thin films, which behaved similarly to commonly known PCM. The retention time of the amorphous state in 3 nm thin films was found to be approximately 50 hours at room temperature.[2]
In order to explore, whether the amorphous state of elementary Sb can further be stabilized by three-dimensional confinement, we focused our studies on the liquid phase synthesis of sub-10 nm Sb nanoparticles (Sb-NP) in amorphous state. This requires a synthesis route with extraordinary mild reaction conditions, i.e. reaction temperatures well below the crystallization temperature of Sb, which is enabled by a strong reducing agent.
The formation of a $BH_3{\times}THF$ complex allowed us to reduce Sb^{3+} at room temperature to finally yield ligand stabilized amorphous Sb-NP. Powder X-ray diffraction measurements (p-XRD) and transmission electron microscopy revealed sub-10 nm amorphous Sb-NP with long-term stability against crystallization of 7 weeks under ambient conditions. Additionally, the infrared response of amorphous and crystalline Sb-NP was compared using scattering type Scanning Nearfield Optical Microscopy (s-SNOM) and found to have reasonable differences, which allows us to distinguish between the amorphous and the crystalline state. Heating up the amorphous Sb-NP at temperatures above 100 °C led to crystallization which was verified by s-SNOM and p-XRD independently. These results give evidence that the metastable amorphous state of Sb can be further stabilized by our three-dimensional confinement approach.
Future ambitions on laser-induced switching will now focus on a statistical analysis of the phase stability and the implementation of the Sb-NP as PCM into an optically addressable prototype data storage device.

3:45 PM EQ10.06.03
Revealing the Crystallization Kinetic in Thin-Film Phase Change Material via 1,000,000 K/s Nanocalorimetry Jie Zhao[1], Jian Hui[1,2], Asir Intisar Khan[3], Zichao Ye[1], Xiangjin Wu[3], Tianxing Lai[2], Mikhail Efremov[4], Hong Wang[2], Eric Pop[3,3,3] and Leslie Allen[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]Shanghai Jiao Tong University, China; [3]Stanford University, United States; [4]College of Engineering, United States

Nanosecond switching speeds in phase-change memory (PCM) devices make its material-level kinetic investigation inaccessible for most calorimetric methods. Nanocalorimetry developed in our group provides quantitative insights into this “no man's land” with a scanning rate up to 1,000,000 K/s (two orders of magnitude higher than other calorimetric studies on PCM) and sample-size (10−40 nm thick) typical of PCM devices. Our preliminary calorimetric study[1] on 20 nm thick $Ge_2Sb_2Te_5$ (GST), with negligible thermal lag, reveals a single-step Arrhenius process dominated by the growth of

interfacial nuclei with an activation energy of 2.36 eV. Based on numerical simulation, crystallization growth velocity (CGV) is obtained consistent with that measured in PCM cells. This addresses a 10-year-debate originated from the unexpected non-Arrhenius kinetics measured by commercialized chip-based calorimetry, which reports CGV 10^3–10^5 higher than that of PCM cells. The viscosity of supercooled liquid GST, modeled from CGV, suggests a fragile-to-strong crossover at ~410 °C. Thermal properties of thin-film GST (melting, solidification, and specific heat) are also measured and agree with conventional calorimetry of bulk samples. The methodology developed in the preliminary work will also be applied to the fast kinetic investigation of other novel phase-change materials including, Ag–In–Sb–Te[2], $Ge_4Sb_6Te_7$ (high-temperature PCM) and superlattice Sb_2Te_3/GeTe[3-4].

Unravelling the Structure and Crystallization Mechanism of Amorphous Nanoparticle Phase-Change Materials Simon Wintersteller and Maksym Yarema; ETH Zürich, Switzerland

Chalcogenide-based phase change materials such as GeTe and Ge-Sb-Te are commonly used for phase-change memory (PCM) applications, where information is stored using a high contrast in the resistivity or refractive index of the amorphous '0' and crystalline '1' state. Data is written to the memory cell using electrical or optical pulses, which crystallize or amorphize the structure through induced Joule heating. As demand for faster memory and higher data density increases, PCM nanoparticles are well suited to act as the building blocks for future ultrasmall memory devices. To realize this and to optimize memory properties, the structure and switching mechanism of nanoscale PCM materials need to be well understood. To this affect we synthesize 5 nm GeTe nanoparticles, coat them in a ZnS shell isolating the effects of coalescence, and compare their structure and crystallization to sputtered 'bulk' GeTe.

The reversible phase transitions in PCM devices are extremely fast, strongly suggesting a close structural resemblance between the amorphous and crystalline phases. In contrast to this, the amorphous structure is generally assumed to consist of a highly random ordering of atoms, which is generally quite distant to the crystalline counterpart. This work uses ultrafast in-situ X-ray absorption spectroscopy (XAS) and theoretical calculations to study and quantify the amorphous structure of bulk and nanoscale GeTe. Through a series of high-temperature XAS measurements, we can slow down the nanosecond crystallization process and consequently provide a detailed crystallization mechanism, which is validated using molecular dynamic (MD) simulations. We argue that crystallization phase transition is diffusionless for Te atoms, while Ge atoms order via cleavage of Ge-Ge homopolar bonds forming Te-Ge-Te intermediate 'bridge' states. In parallel to experimental measurements, we developed a theoretical model of the amorphous structure, consisting of a disordered fcc-type Te sublattice and randomly arranged chains of Ge in tetrahedral coordination. This structure is relaxed using density functional theory (DFT) calculations and strongly matches our experimental data and previous literature on amorphous GeTe.

We apply our new knowledge about amorphous PCM materials to quantify differences between bulk and nanoscale GeTe. Finally, we extend our model to ternary X-Ge-Te systems and study composition effects on their phase-change properties. Our work provides a high-throughput pathway to model and optimize chalcogenide materials for PCM applications and to design scaling rules for sub-10 nm PCM devices.

Characterization of In2Se3 Crystalline Phase Changes as the Basis for Multilevel Phase Change Memory Nicholas D. Ignacio[1], Saban Hus[1,2] and Deji Akinwande[1]; [1]University of Texas at Austin, United States; [2]Oak Ridge National Laboratory, United States

Layered materials such as In2Se3 and MoTe2 have multiple crystal phases with differing electrical properties and can achieve reversible phase changes between them. Compared to transitions between amorphous and crystalline phase in conventional phase change memories (PCM), changes between crystalline phases are expected to have faster and low energy write operations for PCM even compared to interfacial PCM based Sb2Te3-GeTe superlattices due to the lower entropy of the crystalline-crystalline phase change. In2Se3 PCM have been demonstrated utilizing β and γ as the low and high resistance state respectively, however multilevel switching has not been extensively explored in part due to the stability of the crystalline phases at room temperature (RT).

In this work, we demonstrate the persistence of β phase In2Se3 in bulk phase at RT, previously only seen in single-crystal thin films and polycrystalline powders after annealing in an inert environment. Scanning tunneling microscopy (STM) is used to visualize the different phases as well as to measure the band gap with scanning tunneling spectroscopy (STS) after annealing at different temperatures and cooling to RT. After annealing α In2Se3 in UHV (<10^-10 mbar) at 300C for 1 hour, β was found as confirmed by the shift in band gap from 1.27 eV to 0.52 eV. We also report in-situ Raman spectroscopy taken during heating and cooling of monolayer and effective bulk films of In2Se3 in both inert atmosphere and in air. We show evidence that upon bulk In2Se3 cooling to RT after heating in an inert atmosphere a mixture α and β phases results as compared to annealing in air where β reverts to α upon cooling.

EQ10.07.02
Memristive Behavior of Li Intercalated $MoTe_2$ for Neuromorphic Computing Rifat Hasan Rupom[1], Eunho Lee[2], Pashupati R. Adhikari[1], Moonyoung Jung[2], Dongseok Suh[2] and Wonbong Choi[1]; [1]University of North Texas, United States; [2]Sungkyunkwan University, Korea (the Republic of)

Recently, memristor has emerged as an electronic neuromorphic device with an ability to control multiple resistance states by memorizing the history of

prior electrical input and mimicking the synapse for neuromorphic computing. Molybdenum ditelluride ($MoTe_2$) has attracted considerable interest among 2D transition metal dichalcogenides (TMDs) materials, because of its small band gap, tunable 1T′/2H phases, and favorable polycrystalline nature for ion migration. Herein, for the first time, we report lithium (Li) intercalated $MoTe_2$ neuromorphic device fabricated by a simple sputtering process exhibiting enhanced memristive behavior with varying Li ion concentration at different bias voltages**.** It is observed that $MoTe_2$ film effectively enhances the I_{on}/I_{off} and hysteresis current, which is attributed to high ion transport through the grain boundaries in polycrystalline $MoTe_2$. After ion-intercalation, I_{on}/I_{off} ratio was enhanced from 5 to $>10^3$ at lower sweep voltage with high retention and linearity conductance modulation for pulsative voltage. This work presents insights in making stable and large-scale $MoTe_2$ memristive device based on sputtered $MoTe_2$ and ion intercalation method. In this presentation, we will discuss the device performance and its mechanistic investigation.

Tunable, Reversible Glass–Crystal Transitions in Single & Binary Metal–Bis(acetamide) Glasses Mandy Liu[1], Adam H. Slavney[1], Songsheng Tao[2], Ryan McGillicuddy[1], Cassia Lee[1], Simon J. Billinge[2] and Jarad A. Mason[1]; [1]Harvard University, United States; [2]Columbia University, United States

With large electrical or optical contrast across a continuous transition between two phases encoding the logic states of "0" and "1", phase-change materials provide promises to address growing demand for data storage and processing. While glass–crystal transitions in chalcogenide alloys have long been studied for rewritable data storage and for neuro-inspired computing more recently, challenges remain with their high energy budget and limited structural diversity and tunability. Glassy phases of metal–organic frameworks offer great potential of using coordination chemistry and reticular synthesis to significantly reduce melting temperatures in comparison to chalcogenide glasses, as well as to predictively tune crystallization kinetics. Although recrystallization has rarely been observed in metal–organic glasses, here we report a novel series of two-dimensional networks $M(eba)_3[M'Cl_4]$ (eba = *N*,*N*′-ethylenebis(acetamide), M/M′ = Mn, Fe; M = Mn, Fe, Co, M′ = Zn) that undergo low-temperature melting (150–190 °C) and reversible glass–crystal transitions. Their glass transition temperatures (T_g) are well above 298 K, leading to very stable glasses under ambient conditions. This is attributed to the short polyethylene chain in the eba ligand, which restricts the conformational flexibility of the ligand in the melt and therefore reduces the entropy of fusion. The crystallization kinetics and glass stability of these compounds are readily tunable through the judicious selection of different metal cations and by liquid-phase blending to form binary glasses. This high tunability affords exciting opportunities of forming mixed glasses with precisely tuned glass stability and crystallization behavior tailored for a specific application. Notably, a large reflectivity contrast ratio of 3.7–4.8 for a glass–crystal transition is observed in a Co-containing binary glass, which is driven by changes to the coordination environment of Co centers during crystallization and vitrification. Beyond the $M(eba)_3[M'Cl_4]$ system, a binary metal–bis(acetamide) glass with longer polymethylene chain shows two distinct crystallization features, indicating the possibility of accessing multiple near-degenerate states with different optical properties by harnessing the compositional and structural diversity of metal–organic glasses. These results provide new insights into manipulating reversible glass–crystal transitions in metal–organic materials, which has implications for rewritable data storage at lower energy intensities and well-controlled continuous crystallizations for neuromorphic computing.

Spanning Femtoseconds to Seconds in the Photoinduced Response of Antimony Thin Films Sebastian Walfort[1], Daniel T. Yimam[2], Bart Kooi[2] and Martin Salinga[1]; [1]University of Muenster, Germany; [2]University of Groningen, Netherlands

The observable dynamics in electrical devices based on phase change materials span nanoseconds to decades. Any processes on timescales below nanoseconds are obscured by the limited time resolution of electronic circuits. Photonic circuits do not share this limitation [1]. Material dynamics on much shorter timescales are accessible, but must be understood in order to be exploitable in applications. This study investigates the photoinduced dynamics of the phase change material antimony in the time range from femtoseconds to seconds using optical pump-probe spectroscopy.

Certain aspects of the response of crystalline antimony to excitation with short laser pulses have been examined in the past [2]. The short-timescale response is characterized by the displacive excitation of a damped coherent phonon mode [3], the coupling of the hot electron system to the lattice initially leads to a non-thermal population of phonons [4], and in the long-timescale limit the optical contrast between an amorphous and the crystalline state exhibits a film thickness dependence [5]. However, there is no individual study that attempts to elucidate the photoinduced response of antimony in its entirety. Furthermore, the large parameter space of e.g. film thickness, pump fluence, or probe wavelength remains largely unexplored. Exploring, for instance, the role of the film thickness is expected to be especially important in antimony, where confinement below 10 nm already has been shown to influence a range of material properties such as the crystallization kinetics [6], phonon mode frequencies [5] or electronic structure [7]. Varying the thickness of the antimony film, its structural state through in-situ switching, the probing wavelength, pump fluence and base temperature, we measured the complete photoinduced response until its return to equilibrium. Comparison of the different processes across this broad parameter space is enabled by deriving a phenomenological model that can capture the entire response.

Investigation of Phase-Change Synapse Architectures by Integrating Electro-Thermal and Phase-Field Models Ho Thi Thu Trang and Kwon Yongwoo; Hongik University, Korea (the Republic of)

Phase-change memory is a promising technology for synapse application in neuromorphic computing because it is the most matured among the nonvolatile memory technologies. The PCM utilizes $Ge_2Sb_2Te_5$ (GST), a chalcogenide material, whose conductive crystalline and resistive amorphous phases correspond to data 0 and 1, respectively. The switching operation typically resembles heat treatment in material processing such as melt-and-quench for amorphization and annealing for crystallization via nucleation and growth. All the switching mechanisms are controlled by Joule-heating through electrical pulses. In this work, we constructed 3D PCM device simulation by integrating electrothermal and phase-field models in COMSOL Multiphysics. Two representative cell architectures are compared from the viewpoint of device performance and synapse application: one is self-heating wall (SHW), and the other is heater-based wall (HBW). Firstly, the device performance comparison including power consumption, on/off ratio, etc is conducted via recrystallization analysis by different falling-times in the range of 10ns and 100ns after reset operation. Secondly, the synapse characteristics are investigated, i.e., the conductance change data, which are obtained by applying a series of short and moderate current pulses for gradual crystallization after a reset pulse. From our simulations, we observe that the set operations by both melt-and-slow cooling and constant pulses (MSCP and CP) consume similar power. In a high-density memory array, the variability in devices is unavoidable. The MSCP with sufficient height can melt GST in all cells, which ensures

successful operation. On the other hand, the CP with a fixed height may fail to crystallize in some cells due the variability. Therefore, the MSCP may be more beneficial than the CP. In case of synapse characteristics, the SHW is superior to the HBW because it consumes less power and shows better linearity and graduality in the synaptic weight.

EQ10.07.06
Cryogenic Operation of Phase Change Memory Down to 4 K Sohui Yoon, Namwook Hur, Hongsik Jeong and Joonki Suh; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Understanding and realizing the memory operations of non-volatile memory cell under extreme conditions such as cryogenic environment is scientifically and technologically crucial. In this work, we demonstrate the cyrogenic operation of phase change memory (PCM) at 4 K and extensively investigate its SET/RESET programming characteristics over a wide range of temperatures. On the fundamental side, the temperature dependent behavior of phase transition and its dynamics of $Ge_2Sb_2Te_5$, a textbook example of phase change material, is monitored with the key device metrics including the voltage shift of RESET/SET operation and with varying input pulses (width, fall time, etc), respectively. It will certainly deepen our understanding on the crystallization mechanism toward a longstanding goal of low-power and high-speed PCM. On the applied side, we successfully fabricate PCM devices with a semi-confined cell geometry and demonstrate their reliable operations from room temperature to 4 K, supported by temperature-dependent resistance change. It will, therefore, be a promising option as the interface processing memory component for quantum computing often operated in the mK range.

EQ10.07.07
Three-Dimensional Phase Change Memory Architecture with Cylindrical Sidewall Electrodes Namwook Hur, Beomsung Park, Sohui Yoon, Sang-woo Park, Huimin Lee, Hongsik Jeong and Joonki Suh; Ulsan National Institute of Science and Technology, Korea (the Republic of)

Next-generation computing system beyond the von Neumann architecture requires the development of new hardware components, and memristive devices have been studied to meet such requirements. As a non-volatile memristor unit, phase-change memory (PCM) is highlighted with the proved nano-second level of fast operation speed and reliable device performances with simple fabrication process using conventional complementary metal-oxide semiconductor (CMOS) technology. Thus, it holds a high potential as non-volatile storage and neuromorphic memory devices, but it still requires device-level innovation for ultra-low operation energy and high-density memory cell arrays beyond the widely adopted 2-dimensional planar device configuration, known as mushroom type PCM. In this work, we propose a new three-dimensional (3D) memory architecture with cylindrical sidewall electrode contacts named heater-all-around phase-change memory (HAA-PCM). With the new design principle, it shows effectively low operation energy (~1 nJ) compared with the conventional PCM devices in the identical 0.18 μm node CMOS fabrication technology. Our 3D HAA-PCM architecture can be applicated to the next-generation artificial intelligence (AI) memory which requires ultra-low operation energy and high-density memory cell.

EQ10.07.08
Growth and Microstructure of GeTe-Sb_2Te_3 Heterostructures Deposited by Pulsed Laser Deposition Sonja Cremer[1], Lennart Voß[2], Nils Braun[1], Lorenz Kienle[2] and Andriy Lotnyk[1,3,4]; [1]Leibniz Institute of Surface Engineering (IOM), Germany; [2]University of Kiel, Germany; [3]The Research Institute of Advanced Technologies, China; [4]Harbin Engineering University, China

Characterized by non-volatility, scalability and fast operating speed Ge-Sb-Te based phase change alloys are well suited compounds for memory devices. Nevertheless, high power consumption and resistance drift turn out to be obstacles for big data application. Heterostructured phase change memory (HS-PCM) is shown to be a promising strategy to overcome these issues. However, underlying structure-property relationships are still highly debated. [1-3] As a first step for systematic performance improvement, we investigated how varying deposition parameters influence the microstructure of GeTe-Sb_2Te_3 heterostructured thin films.

The samples were grown at room temperature as non-periodic and periodic HS (npHS and pHS, respectively) using pulsed laser deposition (PLD). Advanced transmission electron microscopy combined with X-ray measurement techniques was applied for in-depth analysis of the microstructure.

For the npHS the system deposited using the highest laser fluence consists of alternating GeTe and Sb_2Te_3 layers. A small degree of interdiffusion of Ge into Sb_2Te_3 layers and vice versa is always present getting more pronounced with decreasing layer thickness. In contrast, the thin film grown using the lowest fluence is a single, completely intermixed layer with a composition close to $GeSb_2Te_4$. Revealing the deposition rate as a main influence factor for intermixing, the pHS consist of separated layers irrespective of the layer thickness.

GeTe layers within the HS are always amorphous whereas Sb_2Te_3 layers were found to grow nanocrystalline irrespective of laser fluence. As reported for fully crystalline Sb_2Te_3 [4], the nanocrystals are defective consisting of grain boundaries and bi-layer defects. Further characteristics are varying grain sizes and phases. Apart from the main {*00l*}-textured t-phase, c- and vacancy ordered (vo) phase are present. By electron beam exposure this structure transforms into the c-phase, similar as already reported for vo-$Ge_2Sb_2Te_5$ [5].

In conclusion, varying deposition parameters were found to mainly effect the intermixing in GeTe-Sb_2Te_3 heterostructured thin films. In contrast, irrespective of the deposition parameters and despite the room temperature deposition PLD grown HS are characterized by nanocrystalline Sb_2Te_3 layers. Considering the correlation of nanocrystallinity and improved operation efficiency reported for Sb_2Te_3-$GeSb_2Te_4$-HS in literature [6], this work provides insights into the relationship of deposition, structure, and properties of PLD grown GeTe-Sb_2Te_3-HS.

Phase Change Memory from Molecular Telluride Inks Florian Schenk, Darijan Boskovic, Till Zellweger, Alexandros Emboras and Maksym Yarema; ETH Zurich, Switzerland

Phase change memory (PCM) is an emerging data storage technology, where the information is stored by reversible switching of local bits between high-resistance amorphous and low-resistance crystalline phases of a material (logical “0” and “1”, respectively). The data is written by heating to the crystallization temperature (SET process). Vice versa, amorphization erases the data (RESET process).

Traditionally, phase-change material films are deposited via sputtering techniques, lithography, and lift-off. Solution-phase deposition of chalcogenides at ambient temperature and pressure provides a low-cost, scalable, and composition-flexible alternative. Additionally, thin film fabrication from the liquid phase gives access to new geometries of phase change memory devices (i.e., high-aspect ratio and multilayer arrays) and inexpensive high-throughput printing methods. One way to obtain such material inks is to dissolve bulk chalcogenides in an amine-thiol co-solvent. Annealing then forms compact crystalline thin films. This approach has shown its applicability for solar cells, thermoelectrics or resistive memory, but has not been researched for state-of-the-art telluride phase change applications yet.

Here, we synthesize a range of phase change memory material inks by dissolving bulk tellurides in an amine-thiol co-solvent formulation and subsequent purification steps. Deposition via spin-coating yields thin film telluride layers with tunable thickness, low surface roughness, and high crystallinity. We highlight the possibility to obtain stoichiometric binary materials (i.e., Sb_2Te_3, Sc_2Te_3 or Y_2Te_3) as well as composition-tunable ternary materials by admixing rare-earth telluride inks with antimony telluride. This yields homogenous doping in $M_xSb_{2-x}Te_3$ due to mixing on the molecular scale. We then demonstrate the benefits of ink formulations, e.g. deposition on patterned substrates like grooves and vias. Finally, we fabricate and test tailor-made prototype devices and quantify critical performance metrics such as I-V characteristics, switching behavior and speed, resistance contrast, power consumption, and cyclability of functional phase-change memory devices from molecular inks.

SESSION EQ10.08: PCM for Embedded Applications

8:30 AM *EQ10.08.01
Improving Crystallization Temperature by Ge-Incorporation in $Ge_xSb_yTe_z$ Phase Change Alloys and Heterostructures for Automotive Applications Raffaella Calarco[1], Adriano Diaz Fattorini[1], Marco Bertelli[1], Sara De Simone[1], Valentina Mussi[1], Francesco De Nicola[1], Massimo Longo[1], Giuseppe D'Arrigo[1], Inaki Garcia Lopez[1], Antonella Sciuto[1], Stefania M. Privitera[1], Massimo Borghi[2], Andrea Redaelli[2], Marie-Claire Cyrille[3] and Nguyet-Phuong Tran[3]; [1]Consiglio Nazionale delle Ricerce, Italy; [2]STMicroelectronics, Italy; [3]LETI, France

The interest in Phase Change Memory (PCM) devices with improved crystallization temperature is increasing for automotive applications, where devices must be able to operate reliably at high temperatures (> 160 °C) for at least ten years. Alloys like $Ge_2Sb_2Te_5$ (GST225) are already a standard to realize memory devices. However, one of the major disadvantages of GST225 single layers is the low crystallization temperature (T_c), which results in low thermal stability and limited data retention. An interesting option to increase T_c is to grow Ge-rich GST alloys. Here, several $Ge_xSb_2Te_5$ and $Ge_xSb_2Te_3$ layers were grown by RF-sputtering and their thermal stability was studied by X-ray diffraction (XRD) and Raman spectroscopy as a function of temperature. The compositional analysis was performed by X-ray fluorescence (XRF). The results showed that both T_c and Ge-segregation amount grow linearly with the Ge-content in the alloys. Among the different possibilities, our approach combines different phase change materials with opposite properties (Sb_2Te_3, $Ge_2Sb_2Te_5$ and $Ge_xSb_yTe_z$), also introducing a confinement Ge layer to realize interesting novel test devices. Therefore Sb_2Te_3/$Ge_2Sb_2Te_5$/Ge heterostructures with a total thickness of 110 nm were deposited by RF sputtering and their thermal stability was analyzed by X-ray diffraction and Raman spectra, evidencing a slower crystallization dynamic (by 50°C) than in $Ge_2Sb_2Te_5$. After optimization, the heterostructures were deposited onto proper single-cell vehicles prepared on Si(001) substrates and metal contacts were nanolithographically (EBL) defined. The subsequent technical analysis (I-V, R-V, R-cycles graphs for the SET/RESET states) showed that the cell has a programming current of 1.2 mA and an endurance of $2x10^5$ cycles.
This project has received funding from the European Union's Horizon 2020 research and innovation program under Grant Agreement No. 824957 (“BeforeHand:” Boosting Performance of Phase Change Devices by Hetero and Nanostructure Material Design).

9:00 AM EQ10.08.02
Atomistic Simulations of the Decomposition Pathways of Ge-Rich GeSbTe Alloys for Phase Change Embedded Memories Omar Abou El Kheir and Marco Bernasconi; University of Milano-Bicocca, Italy

The prototypical $Ge_2Sb_2Te_5$ phase change compound displays a crystallization temperature too low for embedded phase change memories of interest for applications in the automotive sector. Ge-rich GeSbTe (GST) alloys are emerging as promising materials for embedded memories thanks to the higher thermal stability of their amorphous phase. Upon crystallization Ge-rich GST alloys undergo a phase separation into Ge and a less Ge-rich GST alloy. This phase separation enhances the crystallization temperature, but it also gives rise to some drawbacks such as a high cell-to-cell variability and a drift of the electrical resistance with time in the set state. The details of the decomposition process are, however, largely unknown. In this work, we report on high-throughput calculations based on Density Functional Theory on the decomposition pathways of Ge-rich GST alloys. We first calculated the formation free energy of GST alloys in the central region of Ge-Sb-Te ternary phase diagram and their distance from the convex hull. These data allowed us to estimate the decomposition propensity of Ge-rich GST alloys which suggested a possible strategy to minimize phase separation by still keeping a high crystallization temperature.

9:15 AM *EQ10.08.03
Ge-Rich Phase Change Heterostructures for Automotive Applications Marie-Claire Cyrille; CEA-Leti, University Grenoble Alpes, France

Phase change memory (PCM) is a mature technology, versatile enough to fulfill the requirements of automotive, Storage Class and neuromorphic applications. Automotive applications have the most stringent specifications as they require high data retention in a large temperature range and soldering

reflow compatibility. Thanks to their ability to sustain high crystallization temperatures, Ge-rich GeSbTe alloys have proven their ability to meet those constraints and have been successfully introduced in advanced CMOS technology nodes such as 28nm FDSOI and 18nm FDSOI. However Ge-rich GeSbTe materials can exhibit phase segregation upon crystallization which induce variability and can prove detrimental to PCM arrays reliability. We have developed Ge-rich GeSbTe heterostructures and multilayers tailored to automotive requirements with the specific goal of delaying phase segregation in order to improve set and reset state resistance variability while maintaining good data retention.

Molecular Beam Epitaxy of Ge-Rich GeSbTe Alloys for Automotive Applications Stefano Cecchi[1,2]; [1]University of Milano-Bicocca, Italy; [2]Paul-Drude-Institute, Germany

Chalcogenide phase change materials (PCM) have been identified as promising candidates for the development of storage class memories,[1] as well as brain-inspired computing.[2] GeSbTe (GST) alloys along the GeTe-Sb_2Te_3 pseudo-binary line are employed as the active material in non-volatile solid-state memories.[3] Among $(GeTe)_m(Sb_2Te_3)_n$ compounds, $Ge_2Sb_2Te_5$ (GST225) is so far the best performing material for PCM memory devices.
For embedded devices requiring a higher crystallization temperature, e.g. for automotive applications, the use of GST225 is prevented. The tailoring of the crystallization properties of GST by engineering the alloy composition is therefore fundamental. In this framework, GST alloys with Ge-rich composition have shown increased crystallization temperatures proportional to the excess of Ge.[4]
Molecular beam epitaxy (MBE) allows the design of GST alloys with high structural quality, tuning phase, composition and vacancy ordering.[5] Moreover, it enables the fabrication of superstructures such as multilayers and superlattices with unique control of structural and electrical properties.[6,7]
The presentation will focus on the investigation of GST with Ge-rich composition grown by MBE. Recent results on the crystallization properties of Ge-rich GST films deposited amorphous will be shown.[8] Strategies to fabricate high-quality epitaxial films with GeTe-rich composition will be discussed next, aimed at controlling the alloy composition between GST225 and GeTe. The characterization of structural, vibrational and ferroelectric properties as function of composition, supported by density functional theory calculations, will be presented.

Interplay Between Electronic and Structural Properties of Epitaxial and Amorphous Ge-Rich GST Alloys and Heterostructures Flavia Righi Riva[1], Caroline Chèze[1], Giulia Di Bella[2], Ernesto Placidi[2], Simone Prili[1], Adriano Diaz Fattorini[3], Stefano Cecchi[4], Massimo Longo[3], Raffaella Calarco[3], Omar Abou El Kheir[5], Marco Bernasconi[5] and Fabrizio Arciprete[1]; [1]University of Rome Tor Vergata, Italy; [2]Sapienza University of Rome, Italy; [3]CNR Institute for Microelectronics and Microsystems-IMM, Italy; [4]Paul-Drude-Institut für Festkörperelektronik, Germany; [5]University of Milano-Bicocca, Italy

The impressive amount of data and information generated by modern electronic systems still requires large numbers of fast, cheap, and power-efficient embedded non-volatile memories and processing devices. Modern cars represent an important example of modern electronic system where sensors monitor every aspect of the vehicle as well as the street environment, resulting in a huge amount of collected and analyzed data. In this context, Phase change materials (PCM) based on chalcogenide alloys are a valid technology for the realization of non-volatile memories and are currently attracting much interest also as suitable materials for in-memory computing applications, where a reproducible set of multilevel resistance values is required [1]. Among the PCM most technologically relevant, the ternary $(GeTe)_m(Sb_2Te_3)_n$ alloys (GST) are the most widely used, commonly in the composition $Ge_2Sb_2Te_2$ (GST 225). Due to its great performances in terms of crystallization speed GST225 is in fact the prototype alloy chosen for most practical uses. However, in view of neuromorphic applications aiming at the emulation of synaptic behavior, improved material properties such as wide programming windows, low resistance drift and, particularly for automotive applications, high crystallization temperature T_x are still mandatory. For this reason, thermally stable PCM have been recently investigated [2], among which Ge-rich Ge-Sb-Te alloys (GGST) were found to be promising candidates for the realization of non-volatile memories working at high temperatures. Furthermore, the combination of different PCM is a valid strategy to tailor the material properties for the realization of embedded devices with optimized performances. Here, we present a photoemission study of amorphous GGST-based bilayer heterostructures grown by Physical Vapor Deposition (PVD), and epitaxial GGST samples grown by Molecular Beam Epitaxy (MBE). Sb_2Te_3/GGST and GST225/GGST heterostructures are obtained by successive partial depositions of amorphous GGST of increasing thickness by co-evaporation in ultra-high vacuum of the constitutive elements from solid source Knudsen cells. The evolution of the electronic properties of the heterostructures are studied *in-situ* during the interface formation by a combination of X-ray and Ultraviolet photoemission spectroscopies (XPS and UPS) and *ex-situ* X-ray diffraction (XRD) and Raman spectroscopy. Information on composition and intermixing of the alloys across the heterostructures and the final stable composition of thick GGST layers are obtained and discussed. Valence bands measured by UPS are compared to the theoretical density of states calculated by DFT. Also, the effects of thermal annealing at increasing temperatures are discussed with particular focus on the role of the interface on the crystallization of the GGST second layer.
Molecular Beam Epitaxial GGST alloys along the pseudo-binary line are also characterized by XPS and UPS and compared to a standard GST225 sample. Results are interpreted based on the current structural models of trigonal GST and their evolution after subsequent annealing steps is discussed.

Innovative $GeSe_{1-x}Te_x$ Alloys—An Opportunity for Embedded Phase-Change Memory Applications Martina Tomelleri[1,2], Anthony Albanese[2], Chiara Sabbione[2], Niccolo Castellani[2], Valentina Giordano[3], Daniel Benoit[1], Francoise Hippert[4] and Pierre Noé[2]; [1]STMicroelectronics, France; [2]CEA-LETI, France; [3]ILM, UMR 5306 Univ. Lyon 1-CNRS, France; [4]Univ. Grenoble Alpes, CNRS, France

The unique portfolio of properties of chalcogenide phase-change materials (PCMs), such as Ge-Sb-Te and GeTe, has created and continue to provide exceptional opportunities in resistive memory technologies and data storage [1]. Despite their well-established performances, PCM memory still faces a

number of challenges for a large-scale commercialization. In the case of embedded applications such as for automotive market, the thermal stability of the amorphous (a-) phase must be high enough to avoid unwanted crystallization and thus ensure the code integrity and the endurance of the device at high temperature for long time (industrial criteria of 150°C for 10 years) [2]. Until now, no PCM based on a defined and homogenous compound has been able to meet this challenge. The most common approach has been to use chalcogenide Ge-Sb-Te alloys that are highly enriched in Ge with respect to alloys lying on the well-known GeTe-Sb_2Te_3 pseudo-binary line. The crystallization is slowed down by the required out-diffusion of the Ge excess from the PCM crystalline phase. However, while such an approach has contributed to strongly increase the crystallization temperature (T_x) and thus the data retention, the required huge Ge phase segregation upon crystallization is very difficult to master. Therefore, this could hinder the programming of the memory cells leading to a degradation of reliability in device fabrication process [3].
In the present work, we propose the innovative $GeSe_{1-x}Te_x$ alloys, belonging to the GeTe-GeSe pseudo-binary line, as a homogenous material capable to overcome this technological limit [4]. $GeSe_{1-x}Te_x$ thin films with various composition were obtained using magnetron co-sputtering of pure GeSe and GeTe targets in 200/300 mm industrial microelectronic tools. By means of resistance measurements (Four-point probe) as function of temperature, we followed the crystallization of $GeSe_{1-x}Te_x$ thin films and we observed a significant improvement of thermal performances with decreasing x, reaching very high T_x hence leading to unprecedented high thermal stability of the a-phase. In addition, the resistivity contrast between a- and c-phases is extremely large, except for GeSe, reaching about 8 order of magnitude for the lowest Te content. X-ray diffraction has been performed on c-$GeSe_{1-x}Te_x$ films (annealed at 430°C) and a rhombohedral phase isostructural to GeTe has been observed for the entire x range, apart from the c-GeSe that shows an orthorhombic structure. Based on this result, we could exclude the presence of any detrimental phase segregation, confirming the homogeneity of the alloy after crystallization and the complete solubility of selenium in the GeTe phase. Moreover, the presence of the rhombohedral c-structure in $GeSe_{1-x}Te_x$ thin films is beneficial since it promotes the formation of a unique bonding mechanism recently called “metavalent” bonding (MVB), which is responsible for the uncommonly high property contrast between a- and c-phases of PCMs [5]. The combination of high thermal stability and wide resistivity contrast in a homogenous alloy, represent an important breakthrough for embedded resistive memory technology, making Se-rich $GeSe_{1-x}Te_x$ thin films especially attractive for automotive PCM applications requiring high data retention.

PCM Applications—An Historical Review to Look to the Future Paolo Fantini; Micron Technology Inc., Italy

A historical review of the PCM technology from its first proof of concept up to the most recent achievements of the research will be provided. A parallel historical glance to the product development is also proposed as background to lead the discussion on the opportunities that PCM can bring in the actual scenario of memory eco-system. Against the dream of PCM as universal memory, this paper offers guidelines for PCM applications in the widespread scenario separating the Short-time memory (like DRAM, short both for latency and retention) and the Long-time memory (like NAND, long both for latency and retention), thus contributing to the heterogeneous memory eco-system. In particular, Author will reserve a more extensive discussion for PCM in the Storage Class Memory arena and in the neuromorphic and in-memory computing applications.
The SCM arena represents the ideal realm for the PCM technology from the side of performances like speed and endurance, but a 3-D structure integration must be considered to reduce the cost of PCM devices. To this aim, a cross-point stacked solution combining a PCM with an Ovonic threshold switching as selector has been proposed. In a longer-term perspective, more compact cell design, resembling the 3D vertical NAND of today, should be considered. The primary benefit of such a design is the cell being defined in a single lithographic step, thus reducing the cost. A technological challenge to enable the foundation of this kind of Vertical 3D architectures lies in the ability to deposit conformal and composition-controlled chalcogenide films via ALD technique.
PCMs are also strongly considered as electronic analogue of biological synapses able to implement the Spike-Time-Dependent-Plasticity (STDP) mimicking the synapse functionality. PCM can emulate the biological behavior of synapses and it offers multiple advantages such as scalability, reliability, endurance, multiple programming resistance levels giving them a suitable candidate for implementing large-scale synaptic systems.
PCM technology can also play a relevant role in overcoming the performance limits of the von Neumann architecture, based on a strict separation between the computation unit and memory, where data and instructions for the processing unit use the same data bus, leading to the so-called von Neumann bottleneck.
It will be shown as dense Non-Volatile Memory (NVM) crossbar arrays to few nanometer dimensions is a promising path to build computing systems able to overcome the von-Neumann bottleneck, performing the computation on the memory elements, as the human brain efficiently does, thus avoiding the redundant load-and-store operations. There are still many open challenges to make it a reality, like the improvement of the cell endurance with programming cycling, but definitively, PCM can contribute to mimic what biology figures out: doing the compute in memory. The astounding progress through the Moore’s scaling law made possible demonstrations of truly remarkable tasks of artificial intelligence (AI), but at the expense of an energy consumption that is orders of magnitude higher than the one of the human brain.

SESSION EQ10.09: Nanophotonics with PCM

New Platforms for Reconfigurable Nanophotonics Enabled by Nonvolatile Phase-Change Materials Sajjad Abdollahramezani and Ali Adibi; Georgia Institute of Technology, United States

Phase-change materials with very large change in their optical properties upon transition between amorphous and crystalline phases are promising candidates to miniaturize the fundamental reconfigurable nanophotonic and metaphotonic building blocks like phase shifters, delay lines, tunable nanoantennas, and reconfigurable spatial light modulators that are essential for a large range of applications including communication, quantum photonics, computing, imaging, and ranging.

This talk is focused on the unique features of nonvolatile phase-change materials for enabling new classes of reconfigurable nanophotonic and metaphotonic devices with subwavelength feature sizes through forming new hybrid material platforms by their integration with dielectric, plasmonic, and more conventional CMOS-compatible integrated nanophotonic materials (e.g., silicon and silicon nitride). The fundamental properties of such devices and their ability for dynamic wavefront engineering as a major functionality for enabling state-of-the-art applications like switching, structural color, and

ranging will be discussed. Practical issues like speed, minimum feature size, power consumption, and agility of such hybrid reconfigurable platforms will be covered, and a list of potential areas of improvement to enable state-of-the-art applications will be presented.

2:15 PM EQ10.09.03
Optical Properties of Innovative $GeSe_{1-x}Te_x$ Phase-Change Material Thin Films for On-Chip Active Components, Non-Linear and Brain-Like Computing Applications Anthony Albanese[1,2], Martina Tomelleri[1], Jean-Baptiste Dory[1], Christophe Licitra[1], Benoît Charbonnier[1], Jean-Baptiste Jager[3], Aurélien Coillet[2], Benoît Cluzel[2] and Pierre Noé[1]; [1]CEA-LETI, France; [2]ICB, France; [3]CEA-IRIG, France

In this work, the linear and nonlinear optical properties of innovative $GeSe_{1-x}Te_x$ thin films in amorphous as-deposited state as well as after crystallization by annealing are studied. These alloys, obtained by industrial magnetron co-sputtering of GeSe and GeTe targets, belong to the GeSe-GeTe pseudo-binary line lying between the covalent GeSe compound and the "metavalently" bonded GeTe phase-change material (PCM). They are considered as very promising candidates for high temperature non-volatile resistive memory [1], emerging all-optical neuromorphic circuits and IR photonic applications. In fact, they exhibit fast and reversible phase transformations between amorphous and crystalline states with unprecedented large contrast of electronic and optical properties, a very high thermal stability of the amorphous phase compared to other PCMs [1] as well as a high transparency in the NIR-MIR range in both states. By modifying the Te content of the $GeSe_{1-x}Te_x$ thin films, one can tailor their linear and non-linear optical properties for a wide range of innovative optical and photonic applications.
To compare candidate PCMs and evaluate the impact of their optical losses on the performances of optical switch applications, a figure-of-merit was introduced as $FOM=\Delta n/\Delta k$, where $\Delta n=n_{cr}-n_{am}$ and $\Delta k=k_{cr}-k_{am}$, with n and k refractive index and extinction coefficient of the amorphous (am-) and crystalline (cr-) phase, respectively. Ideally, PCMs with large Δn and small Δk are desired. In this work, the best FOM at 1.55 µm wavelength is found for $GeSe_{0.4}Te_{0.6}$, for which FOM = 13, almost 6 times higher than that of GST-225 reference material with a low FOM of 2.3 at 1.55 µm. Moreover, all the studied compositions showed very high FOM values compared to the most promising composition previously proposed in the literature ($Ge_2Sb_2Se_4Te_1$ alloy with a FOM value of 4.2 [2]). Besides, the high transparency window in the IR, coupled with large optical non-linearities observed in chalcogenide glasses, also offers opportunities for the development of innovative near- and mid-infrared (NIR-MIR) components such as super-continuum (SC) laser sources, optical sensors for gas spectroscopy, IR microlens arrays and all-optical integrated circuits. The non-linear refractive indices n_2 of the am-films were obtained by using the Sheik-Bahae model. The latter is an analytical approach that estimates the n_2 indices using the values of the linear refractive index n and the optical band gap energy E_g^{04}. Outstanding n_2 values are obtained for all $GeSe_{1-x}Te_x$ am-films in the NIR-MIR range. These values are two to three orders of magnitude higher than that found in SiN_x thin films, considered nowadays as the reference material for on-chip non-linear NIR photonic applications.
To summarize, the study of the optical properties of $GeSe_{1-x}Te_x$ thin films shows that these new exciting PCM compounds offer promising FOM ($\Delta n/\Delta k$) for purpose of optical switch applications requiring high refractive index contrast upon crystallization with limited optical losses, in particular at 1.55 µm. Besides, the amorphous films exhibit a good thermal stability up to crystallization occurring above 300 °C [1], as well as high non-linear refractive index offering promising opportunities for on chip non-linear NIR-MIR devices.

High-Performance Reconfigurable Infrared Metasurfaces with Phase-Change Materials Kyung-Ah Son, Jeong-Sun Moon, Ryan Quarfoth, Hwa-Chang Seo, Chuong Dao, Elias Flores, Hanseung Lee and David Chow; HRL Laboratories, United States

Optical metastructures and metasurfaces are emerging with properties that could support the development of flat optics with aberration correction, ultrathin focusing lenses, resonant absorbers, polarimeters without moving parts, phase shifters, and holograms. Optical metasurfaces consisting of subwavelength optical resonators or antennas can provide control over the phase, amplitude, and polarization of incoming light, beyond what classical refractive and diffractive optical components can offer. Currently, there is growing interest in reconfigurable or tunable metasurfaces, which can add additional functionality enabling multi-functional dynamic optical components. Phase change materials (PCMs) have been recently explored for reconfigurable optical devices such as spatial light modulators [1,2] and metasurfaces [3,4], where the PCM-based reconfigurable resonant absorber concept has been demonstrated with an optical reflectance contrast of 40% - 75% in the Near-Infrared spectral range.
In this talk, we will present large-scale reconfigurable infrared metasurfaces consisting of greater than 30 million pixelated optical antennas integrated with PCM mesa structures over a 1cm x 1cm area, where the metasurfaces demonstrate 99% resonant absorption and state-of-the-art optical reflectance contrast at off-resonant wavelengths.

Phase Change Materials for Reconfigurable Nanophotonic Applications Qian Wang; Institute of Materials Research and Engineeing, ASTAR, Singapore

Nanophotonics has garnered intensive interests owing to its unique capabilities on unprecedented manipulation of light in the subwavelength regime for high speed and large bandwidth information transmission and computation. However, to rival electronics in terms of integratability and reprogrammability, nanophotonics must evolve into the next generation miniaturized and reconfigurable platforms with tunable properties on demand. Chalcogenide phase-change materials (PCMs), which retain the 'memory' of sub-threshold excitations and enable multiple-step gradual phase transition, have been identified as a promising platform for tunable and reconfigurable nanophotonic frameworks for ubiquitous functionalities from imaging and communication to sensing. In our work, we explore the multi-level optical phase transition of chalcogenide phase change material, Germanium-antimony-tellurium (GST), induced by femtosecond laser pulses. The pixilated phase change of GST in sub-micro marks results in a dramatic change in optical properties from amorphous to crystalline states. Various applications are demonstrated including high density data storage, re-writable flat photonics metamaterial, reconfigurable phase change photomask, and multi-step tuning of third harmonic generation. It is believed that the such reconfigurable mechanism of phase change materials will advance photonics in the next-generation light-related applications e.g. all-optical neuromorphic computing, adaptive optics, imaging/display, and engineering, etc.

***Ab Initio* Calculations of the Electronic Properties of the Metastable β'-MnTe Phase for Terahertz Optical Switching Applications** Paul Fons[1], Hiroyuki Tsuda[1], Toshiharu Saiki[1], Kotaro Makino[2], Yuta Saito[2], Shogo Hatayama[2], Yuji Sutou[3], Yi Shuang[3] and Mihyeon Kim[3]; [1]Keio University, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan; [3]Tohoku University, Japan

α-MnTe, the stable room temperature phase of MnTe, crystallizes in the NiAs hexagonal structure with space group P63/mmm (194). It is a p-type antiferromagnetic semiconductor with a bandgap of about 1.4-1.5 eV. The α-MnTe is known to transform in ambient conditions into the wide (2.7 eV) bandgap p-type β-MnTe semiconducting phase at approximately 1000°C. The β-MnTe phase assumes the Wurtzite structure with space group P6(3)mc (186) while at the same time experiencing a large (20%) decease in density. The use of MnTe as a phase-change material has been recently reported in the form of an electrical device structure that exhibits bistable behavior and upon Joule heating switches between α-MnTe and a metastable phase β'-MnTe with a negligible change in density with a concomitant 10^3 increase in resistivity.[1] The temperature coefficient of resistivity suggests that the β' phase is semiconducting while TEM measurements indicate that the structure is Wurtzite with the same space group as the β-MnTe. Based upon TEM measurements, it was proposed that the transition from the α and β' phases is displacive in nature, but little is known about the electronic properties of the beta phase.
Recently some of the current authors have explored the use of another phase-change material $Ge_2Sb_2Te_5$ (GST) in optical switching applications in the infrared region. GST, however, suffers from a large extinction coefficient as well as a small contrast in refractive index outside of the infrared region. The use of MnTe as a material for optical interferometric switching offers the possibility of extending optical switching into the terahertz region, however, little is known about the optical and vibrational properties of the different phases of MnTe and in particular the β'-MnTe phase. We have investigated the optical and electrical properties of the α, β, and β'-phases of MnTe using ab-initio calculations with the plane wave code Vasp. We have carried out GGA+U calculations on the different phases using Hubbard U values determined by a self-consistent procedure to determine the equation of state of each phase as well as the dielectric properties of each phase. The calculated bandgap of the β'- was confirmed to be approximately three times that of the α-MnTe phase similar to that experiment trend between the α and β-phases. In addition, the calculated results indicate a small extinction coefficient and a large contrast in refractive index between the α, and β'-phases suggesting that MnTe may be an excellent candidate as a material for terahertz switching applications. Details of the dielectric constants, infrared absorption, equation of state, and other electronic properties will be reported.

Atom Probe Tomography—A Probe for Bond Breaking Experiments Oana Cojocaru-Miredin; RWTH Aachen University, Germany

Laser-assisted field evaporation is studied in a large number of compounds, including amorphous and crystalline phase change materials employing atom probe tomography. This study reveals significant differences in field evaporation between amorphous and crystalline phase change materials. High probabilities for multiple events with more than a single ion detected per laser pulse are only found for crystalline phase change materials. On the contrary, amorphous phase change materials as well as other covalently bonded compounds and metals possess much lower probabilities for multiple events. The origin of this stringent difference between crystalline and amorphous phase change materials has been investigated in this work. In fact, here we demonstrate that the field penetration depth is considerably higher for crystalline phase change materials with metavalent bonding than for amorphous phase change materials with covalent bonding or for metals with metallic bonding. These findings further consolidate the concept of metavalent bonding as being responsible for the outstanding physical properties and unusual bond-breaking behavior in atom probe tomography.

8:45 AM *EQ10.10.03
Ge-Rich GeSbTe Alloys—Material Properties and Devices Stefania M. Privitera; Consiglio Nazionale delle Ricerche, Italy

Enrichment of GeSbTe alloys with germanium has been proposed as a valid approach to increase the crystallization temperature and therefore to address high temperature applications of non-volatile phase change memories, such as embedded or automotive. Despite the achievement of higher crystallization temperature, Ge-rich GeSbTe alloys commonly suffer of segregation of pure Ge, with the formation of less Ge-rich compositions that may adversely affect the device cyclability and endurance. With the aim to find some possible routes to limit the Ge segregation, starting from the compositions along the GeTe-Sb_2Te_3 pseudo-binary line, we investigate several GeSbTe alloys enriched with low or high amount of Ge. The temperature dependence of the electrical properties of the amorphous alloys and the formation of the crystalline phases have been investigated in thin films by in situ electrical measurements and ex-situ structural analysis, determining the formed phases. The segregation and decomposition processes have been also discussed on the basis of density functional theory calculations, identifying the compositions which are expected to be less prone to decompose with Ge segregation. Single cell memory devices with the most promising material have been manufactured and tested. The characterization of the devices confirm the expected material performance. After a forming process, the device operates between two distinct logic states (SET and RESET) with one order of magnitude of resistance contrast, and can be reversible switched for up to 10^6 cycles. Upon annealing for 1 h, the one order of magnitude resistance contrast is preserved up to 240°C, and the complete crystallization of the RESET state is not observed even for annealing at temperature up to 280°C.

Identifying the Defect States in Chalcogenide Glass for Ovonic Threshold Switching Selector Meng Xu, Rongchuan Gu, Xiangshui Miao and Ming Xu; Huazhong University of Science & Technology, China

The recent development of 3D semiconductor integration technology demands a key component, the ovonic threshold switching (OTS) selector, to suppress the current leakage in the high-density memory chips. Yet, the unsatisfactory performance of existing OTS materials becomes the bottleneck of the industrial advancement. Due to the heavy first-principles computation on disordered systems, a universal theory to explain the origin of mid-gap states (MGS), which are the key feature leading to the OTS behavior, is still lacking. To avoid the formidable computational tasks, we adopt machine learning method to understand and predict MGS in typical OTS materials. We build hundreds of chalcogenide glass models and collect major structural features from both short-range order (SRO) and medium-range order (MRO) of the amorphous cells. After training the artificial neural network using these features, the accuracy has reached ~95% when it recognizes MGS in new glass. By analyzing the synaptic weights of the input structural features, we discover that the bonding and coordination environments from SRO and particularly MRO are closely related to MGS. The trained model could be used in many other OTS chalcogenides after minor modification. The intelligent machine learning allows us to understand the OTS mechanism from vast amount of structural data without heavy computational tasks, providing a new strategy to design functional amorphous materials from first principles.

9:30 AM EQ10.10.05
Combinatorial Exploration of New Phase-Change Memory Materials for Neuromorphic Computing Applications Heshan Yu[1], Asir Intisar Khan[2], Changming Wu[3], Huairuo Zhang[4], Albert Davydov[4], Apurva Mehta[5], Mo Li[3], A. Gilad Kusne[4], Eric Pop[2] and Ichiro Takeuchi[1]; [1]University of Maryland, United States; [2]Stanford University, United States; [3]University of Washington, United States; [4]National Institute of Standards and Technology, United States; [5]Stanford Synchrotron Radiation Lightsource, United States

Neuromorphic computing, one of the non-von Neumann computing architectures, is recently developed to overcome the bottleneck of the data transfer between the processing and memory units in von Neuman computing architecture. As one of the most promising candidates for developing a neuromorphic architecture, phase-change memory materials (PCMs) in both photonic and electronic devices show fast non-volatile multi-level switching between the amorphous and crystalline states, but still have some shortcomings in meeting the demands of the neuromorphic computing, e.g., resistance drift, energy consumption, etc. With the assistance of machine learning, in particular, the closed-loop autonomous systems which can greatly accelerate screening materials for multiple properties, we have systematically performed combinatorial exploration targeting several fundamental properties across a broad composition range of M-Sb-Te ternary systems, where M is a transition metal. The composition spread libraries are fabricated on Si wafers by the co-sputtering method, and their composition ranges are measured by wavelength dispersive spectroscopy. To identify optimized compositions, X-ray diffraction measurements (synchrotron diffraction), Raman spectroscopy, resistance and optical property mapping are carried out. Some compositions are identified to show enhanced properties, e.g., $Ge_4Sb_6Te_7$ (GST467) [1], $Ti_{0.3}SbTe_2$, etc. Compared to the widely-used $Ge_2Sb_2Te_5$ (GST225), these identified compositions show higher phase-change temperatures and lower melting point temperatures. The electrical devices fabricated using these phase-change memory compositions show clear multi-level switching with low resistance drift and low quenching energy. To determine the microstructure of the identified PCMs, scanning transmission electron microscope (STEM) measurements are carried out. They have revealed that $TiTe_2$ nanoprecipitates have grown homogenously inside the Ti-Sb-Te matrix for $Ti_{0.3}SbTe_2$ and the SbTe nanoprecipitates have grown epitaxially with the GST matrix for GST467. We believe the nanocomposite configurations are playing the role of precursors which facilitate phase transformation processes. The results here suggest that these compositions can be promising for neuromorphic devices. This work is funded by an ONR MURI (Award No. N00014-17-1-2661) and the Center for Innovative Materials for Accelerated Compute Technologies (IMPACT), one of the centers in nCORE, a Semiconductor Research Corporation (SRC) program.

All-Dielectric Metagratings with Phase-Change Materials for Non-Volatile Reconfigurable Photonics in the MWIR to LWIR Nikolaos L. Tsitsas[1] and Stavroula Foteinopoulou[2]; [1]Aristoteleio Panepistemio Thessalonikes, Greece; [2]University of New Mexico, United States

Non-volatile phase-change materials (PCMs) have opened up a multitude of possibilities in reconfigurable photonics, receiving a growing attention recently partially driven also by the relevance of these platforms to quantum and neuromorphic computing applications. The vast majority of these works focus around telecommunication wavelengths and incorporate GST, a material well known from the electronics industry used for re-writable optical data storage (CD-RW, DVD-RW). GST however can be reconfigured efficiently only at very small thicknesses of about 100 nm which limits transferring its use to MWIR and LWIR applications. Also the rather high optical loss in the crystalline phase of GST limits the range of high performing photonic designs for reconfigurable functionalities.

In this talk, we propose a new PCM-based platform functional in the MWIR to LWIR spectral range that leverages the fully dielectric properties and amorphous phase stability of a new PCM,- belonging to a family of Ge-Sb-Se-Te (GSST) alloys [1]-, together with the strong beam re-direction capabilities of all-dielectric periodic metagratings [2]. We discuss the key underlying mechanisms and design principles of such platform that lead to reconfigurable beam splitting and beam steering. We believe these results are highly relevant in many infrared applications such as infrared components for integrated photonics, long-range lidar, etc.

Crystallization Simulations of Amorphous Ge-Sb-Te Alloys Wei Zhang; Xi'an Jiaotong University, China

Ge–Sb–Te (GST) alloys are leading phase-change materials for non-volatile memory and neuro-inspired computing.[1] Upon fast crystallization, these

materials form rocksalt-like phases with large structural and vacancy disorder, leading to an insulating phase at low temperature. Here, a comprehensive description of crystallization, structural disorder, and electronic properties of $GeSb_2Te_4$ based on realistic, quantum-mechanically based (ab initio) computer simulations with system sizes of more than 1000 atoms is provided.[2] It is shown how an analysis of the crystallization mechanism based on the smooth overlap of atomic positions (SOAP) kernel reveals the evolution of both geometrical and chemical order. The connection between structural and electronic properties of the disordered, as-crystallized models, which are relevant to the transport properties of GST,[3] is then studied. Furthermore, it is shown how antisite defects and extended Sb-rich motifs can lead to Anderson localization in the conduction band. Beyond memory applications, these findings are therefore more generally relevant to disordered rocksalt-like chalcogenides that exhibit self-doping, since they can explain the origin of Anderson insulating behavior in both *p*- and *n*-doped chalcogenide materials. Single-Element Switch Min Zhu; Shanghai Institute of Micro-Systems and Information Technology, China

Nonvolatile phase-change memory has been successfully commercialized, but further density scaling below 10 nanometers requires compositionally and structurally homogeneous materials for both the memory cell and the associated vertically stacked two-terminal access switch. The selector switches are mostly amorphous chalcogenide Ovonic threshold switches (OTSs), operating with a nonlinear current response above a threshold voltage in the amorphous state. However, they currently suffer from the chemical complexity introduced by the quaternary or even more diverse chalcogenide compositions used. We present a single-element tellurium (Te) volatile switch with a large (≥11 MA/cm^2) drive current density, ~10^3 ON/OFF current ratio, and faster than 20 nanosecond switching speed (Figure 1). The low OFF current arises from the existence of a ~0.95 eV Schottky barrier at the Te-electrode interface, whereas a transient, voltage pulse-induced crystal-liquid melting transition of the pure Te leads to a high ON current. Our discovery of a single-element electrical switch may help realize denser memory chips [1, 2].
Key words: Te, single-element, switch, Ovonic threshold switches, phase change memory

Low-Entropy Phase Transition in Indium Selenide for Integrated Photonic Memory Tiantian Li[1,2], Yong Wang[2], Wei Li[2,3], Anderson Janotti[2], Stephanie Law[2] and Tingyi Gu[2]; [1]Xi'an University of Posts and Telecommunications, China; [2]University of Delaware, United States; [3]Los Alamos National Laboratory, United States

Optical phase change materials have emerged as key active components in logic and memory units for optical signal processing and storage. Antimony (Sb) based chalcogenides and chalcogenide alloys have been widely adopted in all-optical and optoelectronic memory technologies, including $Ge_2Sb_2Te_5$, $Ge_2Sb_2Se_4Te_1$, Sb_2Se_3, and Sb_2S_3, where the amorphous-to-recrystallization transitions emerge as an energy and speed bottleneck for these O-PCM memories. Distinguished atomic rearrangements in polymorphic layered chalcogenide materials have attracted great attention across multiple disciplines. The lattice constant dependent free energy between crystalline states across at the critical excitation level where the phase transition takes place. The low entropic crystalline-crystalline phase transitions potentially can revolutionize the power efficiency and data throughput in optical memristive devices. The research on crystalline-crystalline structural transitions for electronic memories has been limited to a few publications, and the phase transition pathways remain controversial. In this work, we focus on the transition between two layered crystalline states (α and β) of In_2Se_3, which have the same underlying rhombohedral crystal system.
Temperature-dependent in-situ high energy x-ray diffraction and derived pair distribution functions reveal that the structural phase transitions between these two layered structures are achieved through 'inter-layer shear glide' and In-Se bond rearrangement. Differential scanning calorimetry measured reversible phase transition temperatures is around 220ºC, compared to the melting temperature beyond 600ºC in Sb-based O-PCM. The optical transparency at telecommunication wavelength is predicted by first-principal density functional theory calculations. The 0.81eV fundamental bandgap difference between the two states promises sufficient contrast of their refractive index and conductivity, according to Moss's rule and Kramers–Kronig relations. The measured complex refractive index spectra in molecular beam epitaxial grown continuous thin films confirm the optical bandgaps of both states are beyond 1eV. On the device level, nonvolatile all-optical switching is demonstrated in MBE-grown In_2Se_3-silicon microring resonators with infrared light excited photo-thermal effect. The covered length of the transferred α-state flake on the silicon single-mode waveguide is around 1.5 μm. Transition into β-state was achieved at the exposure energy of 0.25 nJ. The resonance wavelength red-shifted 100 pm. The extinction ratio increased from 4.45dB to 6.27dB. With the linear coupled-mode-theory fitting of those transmission spectra, the extracted intrinsic quality factors were switched between 4,800 (α-state) and 7,500 (β-state), and the coupling quality factor was kept around 5,000. When the exposure energy increased to around 0.56 nJ, the resonance peak shifted back, and the extinction ratio decreased to the original value. The transistor arrays defined on the thin film measure thermally excited resistivity switching from 10^6 to 10^0 Ω cm. The polymorphic O-PCM's optical transparency at telecommunication and low entropic switching may break the power and speed bottleneck for integrated photonic in-memory computing systems.

Mexican-Hat Potential Energy Surface in Two-Dimensional III_2-VI_3 Materials and the Role of Entropy Barrier in Their Ultrafast Reversible Ferroelectric Phase Change Yu-Ting Huang, Nian-Ke Chen and Xian-Bin Li; Jilin University, China

Because of the spontaneous-aligned electric dipole, which can be switched reversibly by an external electric field, ferroelectric materials have been utilized for applications in nonvolatile memories and neuromorphic computing. However, the miniaturization of conventional ABO_3 ferroelectrics is hindered by the depolarization field. Recently, a new kind of two-dimensional (2D) van der Waals layered material, In_2Se_3, has emerged as a potential solution for low-dimensional ferroelectrics due to its intrinsic ferroelectric polarization at the nanoscale, even down to the limit of a monolayer. At present, the atomic structure and ferroelectricity of the α phase have been firmly identified. However, the study of the paraelectric β phase is still lacking and even its atomic structure is controversial, which limits the speed of the ferroelectric phase transition. Here, using first-principles calculations and molecular dynamics studies, a unique Mexican-hat potential energy surface (PES) is identified for the family of 2D III_2-VI_3 materials for the first time.[1] Taking In_2Se_3 as an example, the PES results in an unexpected pseudo-centrosymmetric (paraelectric) β phase where the presumed centrosymmetry is in fact broken at every moment, which resolves the current structural controversy between theory and experiment. We further show that while the α-to-β (ferroelectric-to-paraelectric) phase transition is fast and coherent, assisted by an in-plane shear phonon mode. However, a random distribution of the Se atoms in the trough of the Mexican-hat PES sets up a sizable effective entropy barrier to slow down the β-to-α transition considerably, which will be the origin of the speed limitation of current In_2Se_3-based ferroelectric devices. If one orders the β phase (due to the formation of in-plane ferroelectric domains), the reverse transition can take place within tens of picoseconds in the presence of a perpendicular electric field. This study unfolds new physics in 2D III_2-VI_3

materials with important technological implications. Not only it unifies theory with experiment, but also it points to new directions for achieving ultrafast reversable ferroelectric phase change, whereby improving the performance of existing ferroelectric devices, such as memory and neural computing hardware, especially in terms of their integrated storage density and speed.

Atomic Imaging of Layered Structure Phase-Change Materials Jiangjing Wang and Wei Zhang; Xi'an Jiaotong University, China

Fast and reversible phase transitions in chalcogenide phase-change materials (PCMs), in particular, Ge-Sb-Te (GST) compounds, are not only of fundamental interests but also make PCMs based random access memory a leading candidate for nonvolatile memory, and neuromorphic computing devices. Disorder plays an essential role in shaping the transport properties of GST. Recently, increasing efforts have been undertaken to investigate disorder in the layer-structured GST compounds. In this work, we focus on hexagonal GST. We thoroughly characterized the structural and chemical features of the major defects in hexagonal GST at atomic scale through chemi-scanning transmission electron microscopy (STEM) experiments, including the stacking faults, the in-plane and out-plane twin-like structure, and a unique bilayer structure. By combining nanoscale density functional theory (DFT) modelling and simulations, we clarified the underlying reasons of the abundance of these defects and their effects on the electronic and transport properties of hexagonal GST.

Plethora of Many-Body Ground States in Magic Angle Twisted Bilayer Graphene Dmitri ^. Efetov; LMU Munich and Institut de Ciencies Fotoniques, Germany

Twist-angle engineering of 2D materials has led to the recent discoveries of novel many-body ground states in moiré systems such as correlated insulators, unconventional superconductivity, strange metals, orbital magnetism and topologically nontrivial phases. These systems are clean and tuneable, where all phases can coexist in a single device, which opens up enormous possibilities to address key questions about the nature of correlation induced superconductivity and topology, and allows to create entirely novel quantum phases with enhanced interactions. In this talk we will introduce some of the main concepts underlying these systems, concentrating on magic angle twisted bilayer graphene (MATBG) and show how symmetry-broken states emerge at all integer electron fillings [1]. We further will discuss recent experiments including screened interactions [2], Chern insulators [4], magnetic Josephson junctions [4], quantum criticality [5], re-entrant correlated insulators at high magnetic fields [6] and discuss some of the avenues for novel quantum sensing applications [7].

Correlated Electronic States in TMD Moire Superlattices Probed by Microwave Impedance Microscopy Yongtao Cui; University of California Riverside, United States

Moire superlatttices formed by angle-aligned multilayer stacks of 2D materials have recently become a rich platform to discover novel electronic states, such as superconductivity, correlated insulators, and magnetism. In this talk, I will talk about our recent work on the study of correlated states in moire superlattices of semiconducting transitional metal dichalcogenides monolayers. We employ scanning microwave impedance microscopy to probe the local conductivity of these moire superlattices. We find that correlated insulating states can appear when the moire superlattice is partially filled with carriers at simple fractional fillings. When additional layers are introduced in the moire structure, we find that the correlated states can be manipulated in various ways. By applying an electric field, the carriers can be driven to populate in two different layers yet still form insulating states, which can be interpretted as an excitonic insulator.

9:30 AM *NM01.01.03
Electronic Control of Magnetism in Magnetic Chern Insulators Charles Tschirhart[1], Evgeny Redekop[1], Lizhong Li[2], Tingxin Li[3], Shengwei Jiang[3], Kenji Watanabe[4], Takashi Taniguchi[4], Martin Huber[5], Kin Fai Mak[2] and Jie Shan[2]; [1]UCSB, United States; [2]Cornell University, United States; [3]Shanghai Jiao Tong University, China; [4]National Institute for Materials Science, Japan; [5]University of Colorado Denver, United States

A variety of intrinsic magnetic Chern insulators have been discovered in moiré superlattice systems, including in both graphene and transition metal dichalcogenide heterostructures. Unlike in previously discovered magnetic Chern insulators, fabricated by adding magnetic dopants to thin films of topological insulators, these systems have magnetism supported entirely by electronic interactions intrinsic to the topological bands. This fact helps limit disorder in these systems by removing the need for magnetic dopants, but it also intimately ties the magnetic order to electronic properties of the system, and thus facilitates electronic control of magnetism. I will discuss electronic switching of magnetization in Chern insulators through two different mechanisms: topological contributions to magnetization and intrinsic spin-orbit torques. I will explain how these mechanisms work in practice in twisted monolayer/bilayer graphene and in AB-WSe2/MoTe2 using transport measurements and magnetic imaging performed with our nanoSQUID microscope.

Experimental Investigation of Non-Trivial Band Topology and Quantum Geometry in van der Waals Materials Chun Ning (Jeanie) Lau; The Ohio State University, United States

The interplay between quantum confinement, non-trivial band topology, symmetries and electronic interactions gives rise to a rich variety of correlated phenomena and topological phases in van der Waals heterostructures. Here I will present our recent works on this topic, focusing on tunable transport of charges and Cooper pairs in quasi-1D topological insulators, emergent magnetism in rhomohedral-stacked few-layer graphene, and strongly renormalized band velocity and experimental evidence for strong-coupled superconductivity that is enabled by quantum geometry in twisted bilayer graphene.

11:00 AM *NM01.01.05
Diverse Nature of Excitonic States in Transition Metal Dichalcogenide Moiré Superlattices Mit H. Naik[1,2]; [1]University of California at Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Recent experimental measurements have demonstrated signatures of novel exciton states in moiré superlattices of bilayer transition metal dichalcogenides. However, the microscopic nature and origin of these moiré excitons was not well understood, and previous studies relied often on empirically fit models that did not fully account for the electron and hole degrees of freedom of the exciton. We performed state-of-the-art first-principles *GW*-Bethe Salpeter equation calculations and discovered a rich diversity of excitonic states in large-area transition metal dichalcogenide moiré superlattices. These studies, which involve thousands of atoms in the reconstructed moiré unit-cell, are made possible by a novel computational approach we developed, the pristine unit-cell matrix projection (PUMP) method [1]. In rotationally aligned WSe_2/WS_2 moiré superlattice, we find some excitons of a modulated Wannier character and others of a previously unidentified intralayer charge-transfer character [1]. In 57.7° twisted bilayer WS_2, we discover layer-hybridized excitons with in-plane charge transfer character. These characteristics originate from the strong modulation of electron wavefunctions due to atomic reconstructions of the moiré superlattice. Due to the weaker binding and larger spatial extent of the in-plane charge-transfer excitons, they can be strongly modulated by external electrical field, doping charges, and substrate screening. Experimental reflection contrast [1], electron energy loss spectroscopy [2] and scanning tunneling spectroscopy confirm these predictions.

11:30 AM *NM01.01.06
Moiré Effects Approaching and Within the Bulk Graphitic Limit Matthew Yankowitz; University of Washington, United States

Moiré quantum materials have recently emerged as highly tunable platforms for the study of strongly correlated and topological states of matter. Although first realized in twisted bilayer graphene, a wealth of new physics has recently been discovered in other twisted multilayer graphene structures. Here, I will discuss an array of moiré-driven effects that emerge in the family of twisted *M*+*N* graphene multilayers, defined as structures created by stacking and slightly rotating *M*-layer and *N*-layer Bernal-stacked graphene sheets. We observe spontaneous isospin symmetry breaking and signatures of non-trivial topology in a wide variety of these structures (e.g., t1+2, t2+2, t1+3, t2+3, etc). Although the precise details vary across platforms, we find an apparent universality of the overall correlated phase diagram resulting from the similar flat moiré bands of these different structures. We further discover entirely new types of moiré reconstruction effects upon entering the bulk graphitic limit, in which the total number of graphene layers exceeds ~10 (e.g., t1+10). The surface moiré potential can strongly modify the transport properties of the entire bulk graphite sheet, indicating the dominant role of the band hybridization at the moiré interface. Our work points toward a general understanding of strongly correlated and topological states, as well as moiré band reconstruction, in multilayer graphitic systems with a single rotated interface.

SESSION NM01.02: Imaging and Tailoring Moire Superlattices

1:30 PM *NM01.02.01
The Quantum Twisting Microscope Shahal Ilani; Weizmann Institute of Science, Israel

In this talk I will present a fundamentally new type of scanning probe microscope, the Quantum Twisting Microscope (QTM), capable of performing local quantum interference measurements at a twistable interface between two quantum materials. Its working principle is based on a unique tip, made of an atomically-thin two-dimensional material. This tip allows electrons to coherently tunnel into a sample at many locations at once, with quantum interference between these tunneling events, making it a scanning electronic interferometer. With an extra twist degree of freedom, our microscope becomes a momentum-resolving local probe, providing powerful new ways to study the energy dispersions of interacting electrons. I will present various experiments performed with this microscope, demonstrating quantum interference at room temperature, probing the conductance of in-situ twisting interfaces, and imaging local energy dispersions in a variety of quantum materials.

2:00 PM *NM01.02.02
Quantitatively Mapping Relaxation in Moiré Superlattices Using Interferometric 4D-STEM Daniel K. Bediako; University of California, Berkeley, United States

It is now well established that changing the relative orientation and/or lattice constant mismatch between vertically-stacked single atomic layers modulates emergent physicochemical behavior through the formation of moiré superlattices. However, the band structures and emergent physics of moiré materials are highly sensitive to spontaneous structural deformations, namely lattice relaxation (or “atomic reconstruction”) and resulting intrinsic strain fields, in addition to extrinsic/incidental heterostrain. While it is widely accepted that lattice reconstruction universally occurs in moiré superlattices with small twist angles, direct experimental information regarding the mechanics of the relaxation process and the manifestation of intralayer strain remains limited. This knowledge gap presents critical impediments for generating accurate models that would allow the rational design and interpretation of the electronic/optical/photonic behavior in these systems. To address this challenge, we have developed Bragg interferometry, an imaging methodology that translates intensity information from scanning transmission electron microscopy diffraction data into quantitative measurements of intralayer deformations in encapsulated moiré superlattices. This talk will cover insights into measurements of lattice relaxation in twisted bilayer and trilayer graphene, as well as moiré superlattices of transition metal dichalcogenides. The results of this work serve to deepen our understanding of fundamental structure–property relationships in moiré superlattices and provide a framework for leveraging structural distortions and strain as additional tuning knobs for modifying the unique (opto)electronic behavior of these structures.

2:30 PM NM01.02.03
Tailoring Moiré Wavelength in van der Waals Heterostructures via Interfacial Heterostrain from Thin-Film Stress Capping Layers Mohammad A. Hossain[1], Yue Zhang[1], Kelly Hwang[1], Paolo Ferrari[1], Edmund Han[1], Priti Kharel[1], Tara Pena[2], Joe Maduzia[1], Stephen M. Wu[2], Pinshane Y. Huang[1] and Arend M. van der Zande[1]; [1]University of Illinois at Urbana-Champaign, United States; [2]University of Rochester, United States

Due to their high deformability, two-dimensional (2D) materials are ideal candidates for using strain engineering to manipulate the electronic structure and material properties. One system ripe for strain engineering is the moiré superlattice created by stacking nearly commensurate 2D layers. Moiré systems show diverse physics, which are extremely sensitive to the structure and size of the moiré superlattice such as “magic angle” superconductivity in bilayer graphene or strongly bound interlayer excitons in reconstructed transition metal dichalcogenide heterostructure superlattices. Most studies use interlayer twist to generate the moiré superlattice. However, generating an interlayer heterostrain has been proposed as a more flexible tool for inducing the moiré superlattice by modulating the relative lattice constant between the layers. Developing new strategies to induce and tailor heterostrains will open up new dimensions of materials design in moiré superlattices.

An enormous opportunity comes by borrowing techniques developed for strain engineering in the semiconductor industry to apply strain to 2D materials by depositing thin film stress capping layers i.e., MgO, MgF_2, etc. [1]. These approaches apply the strain from the top down, suggesting the enticing possibility for controlled heterostrain in 2D heterostructures.

Here, we investigate strain transfer across the van der Waals interface in twisted MoS_2-WSe_2 heterostructures. We deposited MgO through a shadow mask onto a MoS_2-WSe_2 heterostructure, to generate a patterned array of squares with regions covered and not covered by the stressor. We used Raman spectroscopy to measure the E^1_{2g} and A_{1g} peak positions between stressed and unstressed regions on the heterostructure and deconvolved the applied strain and doping effects in the MoS_2 layer by extracting the relative shift in both peaks. To quantify the heterostrain between the constituent layers, we deposited the stressor on two opposite stacking configurations: MoS_2(top)-WSe_2(bottom) and WSe_2(top)-MoS_2(bottom). At the center of a square with 30 nm thick MgO, when MoS_2 is the top layer, the applied tensile strain reaches up to 0.8%. In contrast, when MoS_2 is the bottom layer, tensile strain is limited to less than 0.2%, demonstrating that strain transfer to the bottom layer is minimal due to slip at the 2D interface. The magnitude of the applied strain scales with the thickness of the stressor layer, showing the ability to tailor the heterostrain in 2D heterostructures by more than 0.6%/layer.

To understand how quickly the interlayer heterostrain equilibrates away from the localized stressor layer, we performed hyperspectral Raman mapping and generated spatial maps of the local strain and doping. We found that for the top layer, there is a sharp drop in strain at the edge of the stressor, but some strain extends significantly beyond the edge, taking up to 12 μm to reach equilibrium generating an in-plane heterostrain gradient of ~0.06% strain/μm. This indicates that the low friction at van der Waals interfaces allow heterostrains to propagate for long distances.

Heterostrains show strong potential for tailoring the moiré superlattice wavelength: a 1% strain in an aligned bilayer is equivalent to a 0.6 degree twist, while 1% strain can modify the moiré wavelength in 1° twisted bilayer by more 10%. This is the regime where much of the most interesting physics and interfacial mechanics occurs. We will explore the potential for using dark field electron microscopy or scan probe techniques to directly measure modifications to the moiré wavelength induced by heterostrain.

Taken together, heterostrains via stress capping layers show many new opportunities for spatially patterned or anisotropic moiré superlattices.

Scanning Tunneling Microscopy of Twisted 2D Semiconductors Adina Luican-Mayer; University of Ottawa, Canada

In this talk we discuss scanning tunneling microscopy studies of ferroelectric domains at symmetry-broken interfaces of marginally twisted WS_2 films. The analysis of the ferroelectric domain network can give detailed information about the deformations in the assembled layers and we demonstrate that one can achieve full control over the conditions for the redistribution of polarization across the domain network.
We discuss two characteristic regimes of domain evolutions: approximately equilateral triangular stacking order domains featuring partial dislocation at the domain boundary, and elongated triangular domain in which the primary domain walls merge, achieving perfect screw dislocation. The domain geometry was found to be well described by a simple string-like model, allowing for parameter-free prediction of domain wall shapes and lengths in the elongated triangle regime.

Local Spectroscopy of Gate-Tunable Correlated Chern Insulating State in Twisted Monolayer-Bilayer Graphene Tiancong Zhu[1,2]; [1]University of California, Berkeley, United States; [2]Lawrence Berkeley National Laboratory, United States

Twisting and stacking two-dimensional van der Waals materials provides a versatile platform for investigating emergent quantum phases of matter driven by strong correlation and non-trivial topology. One example is twisted monolayer-bilayer graphene (tMBLG), where correlated Chern insulating states with electrically switchable magnetic order have been recently demonstrated in transport measurements. I will discuss scanning tunneling microscopy (STM) measurements where high spatial resolution provides new insight into the interplay between correlation, topology, and local structural distortion in determining the electronic and magnetic properties of tMBLG. Our STM spectroscopy (STS) provides evidence for the formation of interaction-driven energy gaps at both ½- and ¾- filling of a moiré mini-band in tMBLG. Magnetic-field-dependent STS measurements further indicate a non-zero total Chern number of $C_{tot} = \pm 2$ for the ¾-filled correlated insulating state. In certain regions of the sample, we find that the sign of C_{tot} can be reversed via electrostatic gating in a finite magnetic field, consistent with the electrically switchable magnetic order reported in previous transport studies. This electrical reversibility, however, is not universal and depends strongly on the local hetero-strain (relative strain between the monolayer and bilayer graphene) in tMBLG. The electrical switching of magnetic order appears to result from a competition between the orbital magnetization of filled bulk bands and chiral edge states that is highly sensitive to strain-induced distortion of the moiré superlattice. Our finding illustrates the critical role of local environmental factors in shaping correlation and topology in twisted two-dimensional systems.

Transport of Confined One-Dimensional Excitons at Monolayer Lateral Heterojunctions Libai Huang; Purdue University, United States

Atomically precise lateral heterojunctions based on transition metal dichalcogenides provide a new platform for confining excitons in one-dimensional (1D). Here, we present the transport of 1D interfacial excitons in a type II WSe_2-$WS_{1.16}Se_{0.84}$ lateral heterostructure using ultrafast microscopy with ~ 200 fs temporal resolution and nanoscale spatial resolution. Our measurements revealed highly mobile 1D interface exciton at room temperature. Strong repulsive exciton-exciton interactions led to enhanced exciton transport along 1D interface than 2D interlayer excitons in conventional transition metal dichalcogenides heterobilayers. These results highlight that atomically thin lateral heterojunctions can be designed as novel “highways” for excitons.

The moiré superlattices of 2D semiconductors exhibit many novel physics phenomena, including moiré excitons and correlated insulating states. While extensive studies have been conducted to investigate the properties of the moiré superlattices between monolayer TMDCs, the effect of the layer degree of freedom on moiré excitons and correlated insulating states remains uninvestigated. In the first part of this work, we demonstrate layer-modulated moiré excitons and correlated insulating states in WSe_2/WS_2 moiré superlattices. We investigate reflectance contrast spectra of WS_2/WSe_2 moiré heterostructures with varying WSe_2 layer number. The layer degree of freedom strongly modifies the resonant energies of the moiré excitons. In addition, the 1L/2L and 1L/3L WS_2/WSe_2 show an extra excitonic peak close to the original WSe_2 A-exciton resonance, a result of the interfacial nature of the moiré coupling. The carrier density to reach each correlated insulating state is the same for 1L/1L, 1L/2L and 1L/3L WS_2/WSe_2, indicating the moiré flat band is isolated from the trivial valence bands from the additional WSe_2 layers.
Based on the above result, we further show that the valence bands of the 1st and the 2nd WSe_2 layer in 1L/2L WS_2/WSe_2 can be tuned to overlap by applying an electric field. Holes can partially populate the 2nd WSe_2 layer at a total filling of one hole per moiré supercell, which is evidenced by the emergence of exciton-polarons from the 2nd WSe_2 layer. The abrupt changes of peak positions and intensities of moiré excitons suggest that the system is in an insulating state at n=-1. From particle-hole transformation, electron-like carriers reside in the moiré flat band of the 1st WSe_2 layer and are bound with holes in the 2nd WSe_2 layer due to strong Coulomb interaction, forming an excitonic insulator phase. Our result demonstrates a new moiré system for the study of correlated many-body physics in two dimensions.

Low-Frequency Raman Study in Precisely Controlled Interlayer Twist Angle Using Etchant-Free Thin-Film Transfer Manpreet Boora[1], Yu-Chuan Lin[2], Chen Chen[2], Joan M. Redwing[2] and Jae Yong Suh[1]; [1]Michigan Technological University, United States; [2]The Pennsylvania State University, United States

Two-dimensional transition metal dichalcogenides (TMDs) have attracted great attention because of their scalability and tunability of optical bandgaps depending on the number of stacked layers. Twisted TMDs have gained even more interest because of the additional degree of freedom arising from the twist angle, which provides a controllable playground for studying phonon-phonon couplings, twist angle-dependent interlayer excitons, and charge transfer dynamics. A monolayer of TMDs has a stoichiometry of MX_2 where M is a transition metal (M = W or Mo) sandwiched between two layers of chalcogen atoms (X = S, Se). For twisted bilayer graphene, the magic angle is 1.1°, and the flat band appears only for a narrow range of twist angles (1.1°± 0.1°). For TMDs, however, there exists a wider range of twist angles, spanning from 4° to 5°. Moreover, long-wavelength Moiré superlattices arise either from a difference in the lattice constant or a twist angle between two stacked layers. These Moiré patterns in twisted TMD bilayers have emerged as a highly tunable platform for studying strongly correlated electron physics.
Our research focuses on the precise control of the interlayer twist angle with a clean and large interfacing area. For making stacked bilayer homo and heterostructures, the individual monolayer used in our research is epitaxially grown coalesced films using the growth method of Metalorganic Chemical Vapor Deposition (MOCVD) on a 2'' sapphire substrate. The highlight of our work firstly lies in making controlled twisted bilayer high-quality large-area samples (9 by 9 mm^2). The degree of twist angle is controlled using a special transfer stage to stack WS_2 bilayers with a range of twist angles from 0°,1°, 2 °, 3°, 5°, 7°, 9°, 10°, 15°, 20° to 30°. The significance of our work includes creativity in stacking these large area bilayers using an etchant-free transfer method. As the monolayer is grown on a sapphire substrate and only the second layer is transferred, it makes the interface between the two layers cleanest which is very important to study the interlayer excitons and phonons. AFM images support the claim of high quality of transferred films as there are no pores or cracks in the films which usually arises in other transfer techniques like wet transfer methods. Our work makes a significant contribution to understanding phonon interactions using Raman spectroscopy for twisted bilayer structures. Low-frequency Raman modes are studied using 488 nm (ultra-frequency laser) excitation to map the dependence of inter-layer breathing and shear modes showing up in the range of -50 cm^{-1} to 50 cm^{-1} wavenumbers. For small twist angles (2°,3°, and °5) moiré phonons start appearing and then disappears in case of large twist angle. Our works report the first-time mapping of low-frequency Raman modes (-100 cm^{-1} to 100 cm^{-1}) and high-frequency Raman modes using resonant laser 532 nm and non-resonant laser 488 nm excitation source for WS_2 twisted bilayers. We will also discuss the results of temperature-dependent photoluminescence and optical absorption showing the evolution of interlayer coupling in twisted TMDs.

Optical Sensing of Semiconducting Moiré Superlattices Chenhao Jin; UC Santa Barbara, United States

Moiré superlattices formed between two-dimensional (2D) materials provide new opportunities to engineer novel quantum phenomena, as exemplified by the intriguing observations in twisted bilayer graphene (tBLG). Semiconducting transition metal dichalcogenides (TMDCs) represent another distinct class of moiré system, where the low-energy physics is largely captured by a single-band Hubbard model. In this talk, I will discuss our efforts to study semiconducting moiré superlattices with optical spectroscopies. Taking advantage of the strong light-matter interaction in 2D semiconductors, we access various correlated phases with high sensitivity optical probe. The imaging capability further allows us to look into their spatial variations in wide field.

SESSION NM01.04: Synthesis and Mechanical Properties

New 2D with Atomically Thin Crystals Jiwoong Park; University of Chicago, United States

2D van der Waals (vdW) crystals provide a powerful materials platform for studying two dimensional (2D) electron transport. In this talk, I will start with the large-scale processes for generating 2D crystalline semiconductor films and superlattices that could be used to fabricate atomically thin integrated circuits. Then we will discuss new directions, where we use these 2D materials to realize non-electronic 2D transport phenomena, for example, observed

from phonons, photons, and mass. These new approaches could empower the development of 2D phononics, 2D photonics, and 2D mechanics.

2:00 PM NM01.04.02
In-Plane Thermal Conductivity of Twisted 2D Materials Sorren Warkander[1], Zhuowa Wu[2], AKM Newaz[2] and Junqiao Wu[1,3]; [1]University of California, Berkeley, United States; [2]San Francisco State University, United States; [3]Lawrence Berkeley National Laboratory, United States

The physics of moiré heterostructures and the opportunity to tune the properties of 2D materials via the twist degree of freedom has seen substantial interest in recent years. However, thermal properties, especially in-plane thermal conductivities, have seen minimal study. The large moiré supercell present for 2D materials stacked at small twist angles and the resultant zone folding may lead to reduced in-plane thermal conductivity; shifts in low-energy phonon modes due to twisting may also impact thermal properties. Molecular dynamics simulations for both graphene and molybdenum disulfide predict reduced in-plane thermal transport in twisted structures. For MoS_2 and for graphene at relatively large twist angles, greater suppression is seen for larger moiré supercells; in graphene at small angles a partial recovery of the thermal conductivity has been predicted, implying the existence of a critical twist angle at which thermal conductivity is minimized. Despite these interesting results, experimental work on twisted bilayer systems has been very limited.

We have recently developed a new technique, transducerless time domain reflectance (tTDR), that allows the use of a standard time domain thermoreflectance (TDTR) setup to measure the thermal properties of semiconductors without the requirement of the metal transducer layer typically used in TDTR measurements. This enables the measurement of ultra-thin materials where a transducer layer would thermally short the sample. In this work, we use tTDR measurements to study the in-plane thermal conductivity of suspended 2D materials, seeking to understand the properties of native few-layer samples and twisted bilayer moiré heterostructures.

Modulation of Moiré Superlattice and van der Waals Interaction in Stacked 2D Layers Gwan-Hyong Lee; Seoul National University, Korea (the Republic of)

Van der Waals (vdW) heterostructures have attracted widespread attention because of their intrinsic interfacial properties and a large degree of freedom in designing heterointerfaces. It has been demonstrated that moiré superlattice in stacked 2D layers induces unprecedented properties of vdW heterostructures, such as moiré exciton, confined quantum transport, and superlattice reconstructions. In this talk, I will introduce how to modulate moiré superlattice and vdW interaction at the heterointerface of different 2D materials. I will show atomic reconstruction of the twisted transition metal dichalcogenide (TMD) layers into full commensurate phase by using encapsulation annealing with hexagonal boron nitride (hBN). The full commensurate phase of two TMD layers showed strong enhancement of photoluminescence from interlayer exciton, which indicates that the momentum coordinates of two different TMD layers are well aligned after encapsulation annealing. I will also show the abnormal in-plane anisotropic conductivity of MoO_3/graphene heterostructure that has an elongated superlattice due to a large mismatch of lattices and crystal structures. The periodic potential of MoO_3 single crystal deposited on the graphene induces a distortion of the graphene band structure near Fermi level of graphene, leading to electrical anisotropy in the graphene. Our work shows novel strategies to modulate moiré superlattice and vdW interaction in stacked 2D layers.

3:45 PM *NM01.04.05
Strain Engineering 2D Moiré Superlattices Stephen M. Wu; University of Rochester, United States

Strain engineering in electronics has been widely utilized over the last 20 years to enhance carrier mobility in most standard Si-based CMOS fabrication processes. These process-induced strain engineering techniques, engineered from the nanofabrication process itself, are simple, reliable, applied device-to-device, and highly scalable down to the nanometer scale. Here, we talk about how process-induced strain engineering translates to the world of 2D materials, and how this may be applied to twisted bilayer van der Waals heterostructures to deterministically engineer moiré superlattice structure. Using the deposition of high-stress thin films [1-3], we show a high level of control over layer-by-layer strain in magnitude, directionality, uniaxiality/biaxiality, and tension/compression in 2D heterostructures. This is a damage-free process, that is reliable to low temperatures (at least 4 K), highly time stable (at least 14 mos.), and can be used up to the strain soliton creation limit, typically 2% in most transition metal dichalcogenide (TMDC) systems. We show this technique can be used on high-angle twisted bilayers, as well as low-angle twisted bilayers where reconstruction effects dominate. Optical spectroscopy combined with real space moiré visualization will be used to show the effects before and after strain engineering is applied. Discussion about how these strain engineering techniques may be used to tame uncontrolled strains in 2D moiré heterostructures will also be addressed.

Universal Torsional Periodic Lattice Distortion in Twisted 2D Materials Suk Hyun Sung[1], Yin Min Goh[1], Hyobin Yoo[2], Rebecca Engelke[3], Hongchao Xie[1], Zidong Li[1], Andrew Ye[4], Parag B. Deotare[1], Andrew J. Mannix[5], Jiwoong Park[4], Liuyan Zhao[1], Philip Kim[3] and Robert Hovden[1]; [1]University of Michigan, United States; [2]Sogang University, Korea (the Republic of); [3]Harvard University, United States; [4]The University of Chicago, United States; [5]Stanford University, United States

At low twist angles, moiré heterostructures periodically restructure and spontaneously break symmetry to form complex superstructures [1,2,3]. Periodic restructuring of twisted 2D materials is a direct consequence of competition between interlayer van der Waals registry energy and intralayer elastic energy cost. Here, we use a torsional periodic lattice distortion (PLD) model [4] to concisely describe the relaxed superstructure and electron diffraction patterns across a variety of twisted 2D materials. The moiré of twisted bilayer graphene (TBG) periodically unwinds energetically favorable AB/BA stacked regions to increase AB/BA area, and unfavorable AA stacked regions are further twisted to decrease their area. We use a torsional PLD model to describe the in-plane distortion of twisted 2D materials. The torsional PLD ($\mathbf{\Delta}_N$) is made-up of three non-orthogonal, transverse distortion waves of equal amplitudes and harmonics thereof.

Torsional PLDs in twisted 2D materials are a universal phenomenon at low twist angles and not limited to TBG [2,3,5,6]. We found evidence of torsional PLD existing in four distinct twisted 2D systems: a) low twist angle TBG, b) 4-layer (4L) of WS_2, c) twisted double bilayer CrI_3 and d) twisted $WS_2/MoSe_2$ heterostructure. Quantum mechanical multislice simulation [7] of electron diffraction patterns with torsional PLDs applied show good agreement with the experimental diffraction patterns. Notably, for near magic-angle TBG, single-harmonic torsional PLD ($\mathbf{\Delta}_1$) matches quantitatively with the experimental SAED patterns [4].

A torsional PLD model reduces the complexity of low-twist angle moiré crystals to a single order parameter across a variety of 2D materials ranging from

graphene, metal dichalcogenides, metal trihalides homostructures to heterostructures of 2D materials.

Calculation of Mechanical and Thermal Properties of MoS_2 Using Surface Acoustic Waves Anikeya Aditya[1], Nitish Baradwaj[1], Ankit Mishra[1], Kenichi Nomura[1], Aiichiro Nakano[1], Priya Vashishta[1], Rajiv Kalia[1], Kory Burns[2] and Assel Aitkaliyeva[2]; [1]University of Southern California, United States; [2]University of Florida, United States

Surface acoustic waves (SAWs) propagate along the surface of materials or at the interface between a solid-air, solid-liquid, solid-solid, and solid-vacuum. SAW's energy is confined to the surface (within the depth of one wavelength) and propagates in the two-dimensional (2D) interface region. SAW's velocity depends on the elastic property of the material. Hence SAWs can be used to determine mechanical properties like Young's modulus, and thermal properties like thermal conductivity and diffusivity in 2D materials. In this work, we use the SAWs originating on the MoS2 monolayer and bilayer to calculate their thermal conductivity and Young's modulus. We also examine the effect of defects like nanopores on SAW propagation and material properties. We investigate how the relative twist in a bilayer and the resulting moire pattern affect the SAW propagation and related properties.

Valley-Layertronics in Moiré Superlattices Wang Yao; University of Hong Kong, China

Long wavelength moiré pattern in van der Waals stacked 2D materials has provided a powerful tool towards designer quantum materials that can extend the exotic properties of the building blocks. For band edge carriers located at the Brillouin zone corners (valleys), the interlayer coupling features sensitive dependence on the atomic registry between the constituting layers. In twisted TMDs homobilayers, such coupling in the moiré pattern manifests itself as a location-dependent Zeeman field acting on the active layer pseudospin. Berry curvature arising from such layer pseudospin texture corresponds to a pseudo-magnetic field that realizes fluxed superlattices tunable by twist angle, strain and interlayer bias [1,2], underlying the quantum spin Hall effect in low energy mini-bands. Ultrafast dynamic modulation of the layer pseudospin texture by bias pulse or Terahertz field further introduces pseudo-electric field for spin/valley manipulation [3]. In moiré patterns distorted by non-uniform strains, the interplay of moiré interlayer coupling and strain together leads to non-Abelian Berry phase effects [4]. I will also discuss other manifestations of the moire modulated layer hybridization on carrier topological transport.

The work was supported by Research Grant Council of HKSAR (17306819, AoE/P-701/20, HKU SRFS2122-7S05), and the Croucher Foundation.

How Much Can We Control the SWNT Atomic Structure During the Floating Catalyst Chemical Vapor Deposition (FC-CVD) Synthesis? Esko Kauppinen; Aalto University, Finland

Floating-catalyst CVD (FC-CVD) is a highly promising technique for the scalable synthesis of single-walled carbon nanotubes (SWNTs). We have been studying FC-CVD systems with several carbon precursor molecules, including CO, C_2H_4, CH_4, ethanol, methanol, isopropanol, and toluene, using mainly iron catalyst nanoparticles, either generated in-situ via ferrocene vapor thermal decomposition or pre-made via the spark discharge aerosol generator. We have determined the SWNT atomic structure i.e. (n,m) distributions directly via the electron diffraction of individual tubes supported by the optical absorption spectroscopy studies. Using ferrocene as the catalyst precursor, CO as the carbon source and CO_2 as the growth promoter, we show that the SWNT (n,m) distribution and the related thin film color can be directly tuned by adjusting the CO_2 concentration. Also, the fraction of metallic tubes can be tuned via adding carbon dioxide. We will present results on the synthesis of mainly semiconducting tubes from ethanol via adding methanol, and also from isopropanol as the carbon source when using nitrogen carrier gas with minor fraction of hydrogen as the carrier gas. The chiral angle distributions from both CO and ethanol are biased towards the armchair side, while those from hydrocarbons are rather flat. The higher the synthesis temperature the broader are the (n,m) distributions when using ferrocene based catalysts. Finally, we will present mechanistic studies addressing the activity of the catalysts on both ferrocene as well as spark generated based systems.

11:00 AM *NM02.01.02
Synthesis of Carbon Nanotube with High Crystallinity and High Aspect Ratio with New Catalyst Precursors Using Deep-Injection Floating Catalyst Chemical Vapor Deposition Seung Min Kim[1], Ji Hong Park[1,2] and Suryun Oh[1,3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [3]Gwangju Institute of Science and Technology, Korea (the Republic of)

A floating catalyst chemical vapor deposition (FCCVD) can be a method to continuously synthesize carbon nanotubes (CNTs) with high crystallinity, because CNT synthesis is usually performed at relatively high temperature. Since CNT synthesis by FCCVD occurs in a vapor phase, the gas flow pattern inside the reactor turns out to critically affect the synthesis of CNTs. Based on the understanding of gas flow pattern, a deep-injection FCCVD (DI-FCCVD) technique is developed. In this technique, all reactants are injected directly and rapidly into high-temperature reaction zone through thin alumina tube; this process leads to simultaneous thermal decomposition of well-mixed catalyst precursors and formation of uniformly-sized catalyst particles, and thus synthesis of CNTs with high aspect ratio (AR > 17000) and high crystallinity (I_G/I_D > 60) at relatively high production rate (> 6 mg/min). Using DI-FCCVD technique, the effects of new catalyst precursors on CNT synthesis are investigated. Different catalyst precursors have varying thermal decomposition temperatures and catalyst particles with smaller sizes are expected to be formed using a catalyst precursor with high thermal decomposition temperature. Therefore, CNTs with higher aspect ratio from smaller-sized catalysts could be synthesized using catalyst precursors with high decomposition temperature. Four catalyst precursors (ferrocene, acetyl-ferrocene, ferrocene-carboxaldehyde and methyl-ferrocene) are selected according to their electron donating and withdrawing properties of functional groups on ferrocene. The electron donating functional groups activate the ferrocene and help the precursors to decompose at the lower temperature. On the contrary, the electron withdrawing functional groups deactivate the ferrocene and make the precursor decompose at higher temperature. Thermal decomposition behavior of catalyst precursors and subsequent formation of catalyst particles are observed in real time by utilizing *in-situ* transmission electron microscopy (TEM) with increasing the temperature. When we use catalyst precursors with low decomposition temperature (ferrocene and methyl-ferrocene), by changing the sulfur concentration, the catalyst sizes and the properties of synthesized CNTs (productivity, purity, and diameter) are also changing. On the other hand, in the case of catalyst precursors with high decomposition temperature (acetyl-ferrocene and ferrocene-carboxaldehyde), sulfur concentration less critically affects CNT synthesis. CNTs using acetyl-ferrocene are continuously synthesized to have very low impurity (~ 3 wt% of Fe) and very high aspect ratio (AR > 20000) at reasonable production rate. This study can provide new insights towards how to control CNT synthesis using the configuration of the reactor and the characteristics of various catalyst precursors.

11:30 AM *NM02.01.03
Ultra-Long Carbon Nanotube Forest via *In Situ* Supplements of Iron and Aluminum Vapor Sources Hisashi Sugime; Kindai University, Japan

Growth of carbon nanotube (CNT) forests in large scale is one of the main challenges to utilize the attractive properties of CNTs in variety of applications. To date, several groups have reported the growth of centimeter-scale CNT forests, and the maximum length that has been reached is ~2 cm using an iron-gadolinium (Fe-Gd) catalyst on an aluminum oxide (Al_2O_3) support [1]. Nevertheless, with the conventional approaches, there seemed to exist a ceiling preventing growth that went beyond ~2 cm. Therefore, it is necessary to realize a method that achieves longer CNT forests while alleviating the growth termination which is mainly caused by the structural change of the catalyst nanoparticles [2].

In this work, a carbon nanotube forest with a length of 14 cm grew with an average growth rate of 1.5 μm s^{-1} and a growth lifetime of 26 h [3]. Several key factors to realize this unprecedented long growth such as catalyst conditions, growth conditions in chemical vapor deposition, and reactor system were clarified. It was found that the combination of the catalyst system of iron/gadolinium/aluminum oxide ($Fe/Gd/Al_2O_x$) [4] and the in situ supplements of Fe and Al vapor sources at very low concentration was crucially important. A cold-gas system, where only the substrate is heated while keeping the gas at room temperature, was employed to suppress unnecessary reactions and depositions [5]. The long carbon nanotube forest enabled macroscopic measurements of the tensile and electrical properties of the carbon nanotube wires, and it gave several important insights for industrial applications of the carbon nanotubes in the future.

Pixelated Carbon Nanotube Forest Darian Smalley[1,1], Masahiro Ishigami[1,1] and Robert Peale[1,2]; [1]University of Central Florida, United States; [2]Truventic, United States

Carbon nanotube forests (CNTFs) were grown on a patterned substrate to form square pixelated arrays. Two-level full factorial optimization first determined the best conditions for synthesis by chemical vapor deposition, catalyzed by Fe nanoparticles deposited on oxidized silicon substrates. Varied parameters included growth temperature, growth time, and acetylene-to-hydrogen gas flow rate ratio. Argon was used as a carrier gas. Reactive ion etching of the substrate in oxygen plasma dramatically improved forest growth rates. Uniform square 7x7 pixel arrays were produced by contact photolithography and lift-off of the deposited Fe. Each pixel was subdivided into square islands separated by gaps with different island and gap dimensions, ranging from 4 to 50 microns and 1 to 10 microns, respectively. Uniform CNTF heights were grown with controllable values from 15 to 2500 microns. The results demonstrate the fabrication of thermally and electrically isolated vertically aligned CNTF islands, which have applications to batteries, sensors, infrared absorbers, and IR or electron emitters.

1:45 PM NM02.02.02
Proof of Concepts About Pulling Out Carbon Nanotube Sheets and Yarns—A Molecular Dynamics Study Luís F. Thomazini and Alexandre F. Fonseca; State University of Campinas, Brazil

Although growing carbon nanotube (CNT) forests is well-known today, growing so-called *drawable* CNT forests, i.e., vertically aligned CNT forests that allow for direct pulling out CNT fibers, sheets or yarns, requires certain conditions. There are three main theoretical hypotheses for the mechanism of conversion of vertically oriented bundles of CNTs into longitudinally oriented CNT fibers during pulling out process. The simplest model [1] considers that the vertically aligned CNT bundles interact only by van der Waals forces. By arguing that van der Waals alone is not able to explain why the CNT bundle being pulled out does not simply detach from the rest of the CNT forest, a second model [2] proposes that something else connects the main vertically aligned CNT bundles in drawable forests. It proposes that individual CNTs or small bundles of CNTs connect the main vertically aligned large CNT bundles, also by van der Waals forces. These connections, during the pulling out of one CNT large bundle, move and get accumulated at the opposite extremity of the forest. This accumulation of connections would, then, transfer the pull-out force on the first CNT bundle to the next, thus keeping the process running continuously. The third model [3] also predicts the existence of connections that get around and entwine one or more large CNT bundles. During the pulling out of the first CNT bundle, the connection strengthens the contact with the neighboring vertically aligned CNT bundle and pulls it out. As the three models might hold true for different structures of CNT forests, using tools of classical molecular dynamics (MD) simulations, we decided to investigate the validity of their main features: van der Waals forces, movement of interconnections, transfer of the pulling-out force from the first to the second large CNT bundle and pulling out of the next bundle. Although the size of real CNT forests prohibits their full atomistic simulation, we designed local structural models that are, at the same time, large enough to test and prove the concept of each feature from the pulling out models, and small enough to be atomistically simulated. We show that the concepts behind the pulling out mechanisms of the last two models hold true, so they are really important in the role of converting vertically aligned CNT forests to longitudinal CNT fibers, sheets and yarns. This work was supported by São Paulo Research Foundation (FAPESP), grant #2020/02044-9.

2:00 PM NM02.02.03
Semiconducting van der Waals Nanocarbon on Boron Nitride Nanotubes Boyi Hao[1], Shiva Bhandari[1], Haiying He[2], Ravindra Pandey[1], Dongyan Zhang[1] and Yoke Khin Yap[1]; [1]Michigan Technological University, United States; [2]Valparaiso University, United States

The use of nanocarbon in future electronics is promising and has gained significant attention after the discovery of carbon nanotubes (CNTs) and graphene. The major obstacles are that not all single-walled CNTs are semiconducting as their properties are chiral-dependence, and graphene is metallic and not applicable for digital switching.

In contrast to CNTs and graphene, BNNTs are electrically insulating and optically transparent [1, 2]. The unique properties of BNNTs have enabled the formation of single-electron transistors (SETs) without semiconductors [3]. We have also demonstrated the formation of 2D gold with tunable optical band gaps [4], field-effect transistors (FETs) by Tellurium (Te) atomic chains inside BNNTs [5], and high-brightness fluorophores that could be 1000X brighter than existing dyes [6-8]. Here we will introduce a novel class of carbon electronic materials, nanocarbon functionalized BNNTs with semiconducting characteristics.

Van der Waals nanocarbon is selectively coated on BNNTs without using any catalyst. Raman spectroscopy, scanning transmission electron microscopy (STEM), and electron energy loss spectroscopy (EELS) are used to analyze the structural properties of this nanocarbon. Four-probe scanning tunneling

microscopy further characterized the as-grown nanocarbon on BNNTs for their electronic properties (4-probe STM). Non-linear current-voltage (I-V) characteristics are detected, suggesting that these carbon are not metallic. Furthermore, the transport properties of this nanocarbon are evaluated at various transport lengths ranging from 300 to 800 nm. Interestingly, the turn-on voltages of this nanocarbon drastically decreased with the decrease of the transport lengths. The details of the experimental results and the theoretical modeling will be discussed in the meeting.

Dynamic Assembly of Liquid Crystalline CNT and Graphene into Fiber Won Jun Lee; Dankook University, Korea (the Republic of)

One classic strategy for functional fiber is to merge nanomaterials and a thermoplastic/thermoset matrix. Relatively low performance examples based on thermoplastics exist and motivate model systems for studies of the critical constituent parameters and design. To create high performance embodiments, high surface area, longitudinal and interfacial strength should be considered; these fibers will ultimately be combined with the specifically-designed polymeric matrices. State-of-the-art, high performance constituents, based on graphitic carbon nanomaterials such as carbon nanotubes and graphene, have an essentially static structural framework that fails irreversibly without any dynamic response. We propose to re-engineer the constituents to allow a dynamic response to stimulus without irreversible loss of mechanical performance as a fiber. To enable this approach, molecular interactions must respond at the certain levels and timescales without losing their features at the nanoscale. Recent advances in the chemistry of complementary nanomaterials will provide the means to adjust the strength of the interactions. For optimal performance, the constituents will need to be redesigned from the bottom up; however, in many cases, existing materials can be adapted by integrating new, dynamically responsive links, as part of the matrix structure. Whilst we are not intending to follow an explicitly classical approach, it is worth noting that most functional fiber systems integrate liquid crystalline materials with soft, dynamic molecular phases. Our strategy is to introduce strong dynamic (reversible) interactions in a variety of length scales and geometries, in order to explore new strategies for the fabrication of functional fibers. Indeed, precise control over orientational/positional ordering and complex interface of carbon nanotubes and graphene, has paved the hidden way for energy conversion and storage devices.

Carbon Nanotube Forest Synthesis by Hydrogen Free Approach Using Fe Catalyst Nanoparticles with Trace Amounts of Noble Metals Shunsuke Sakurai, Maho Yamada, Jinping He, Kenji Hata and Don N. Futaba; National Institute of Advanced Industrial Science and Technology, Japan

Although iron (Fe) represents one of the most industrially used metallic elements because of its abundance and low cost, the ease of Fe oxidation has been a huge energy and environmental burden to produce Fe metal (or steel) for centuries. For the synthesis of carbon nanotubes (CNTs), although Fe metal nanoparticle (NP) catalysts have been widely used, their sensitivity to oxidation requires reduction in a H_2-rich ambient to prepare the metallic Fe catalyst and prevent exposure to oxidative species, before and during the catalytic chemical vapor decomposition (CCVD) of the carbon feedstock and the precipitation of CNTs.
Here, we report a novel hydrogen-free approach to enable the synthesis of tall and vertically aligned CNTs (forest) by fabricating reduced, highly active, and corrosion-resistive Fe-based NP catalysts [1]. We incorporated the trace levels (< 1 at%) of noble metals, such as iridium (Ir) into Fe oxide NPs. The efficient synthesis of tall (>500 μm) CNT forest has been achieved with as little as 0.3 at% Ir by means of a completely hydrogen-free CCVD process, suggesting only a few Ir atoms was required to reduce hundreds of Fe atoms in one Fe oxide NP. Ex-situ X-ray photoelectron spectroscopy (XPS) revealed the reduction of Fe in a hydrogen-free ambient, and also suggested that metallic Ir^0 catalytically reduced the surrounding Fe oxide.

Ferromagnetism Due to Spontaneous Symmetry Breaking in a Twisted Bilayer Graphene Nanoflex Ranjit Pati; Michigan Technological University, United States

Twisted bilayer graphene exhibits many intriguing behaviors ranging from superconductivity to anomalous Hall effect to ferromagnetism at a magic angle close to 1°. In this talk, I will demonstrate ferromagnetism in a twisted bilayer graphene nanoflex (TBGNF) arising from spontaneous symmetry breaking. A first-principles density functional theory that does not make any assumption of the electronic structure is used to study the zero-dimensional twisted nanoflex. Our result shows that when the energy gap of a TBGNF approaches zero, electronic instability-induced spontaneous reorganization of electrons leads to the emergence of a stable ferromagnetic gap state with p-orbitals at the boundary of the nanoflex contributing to ferromagnetism [1].

Numerical Study of a Quantum Graphene Gyroscope Aron Cummings[1], Aleandro Antidormi[1], Grzegorz Hader[2] and Eui-Hyeok Yang[3,3]; [1]Catalan Institute of Nanoscience and Nanotechnology (ICN2), CSIC and BIST, Spain; [2]US Army DEVCOM, United States; [3]Stevens Institute of Technology, United States

Today, most personal navigation relies on the Global Positioning System (GPS). This system is quite accurate under open sky, but this accuracy can be significantly degraded when satellite signals are blocked by terrain or buildings, or when the receiver is indoors or underground. In daily situations these issues are mostly a minor inconvenience, but in critical situations such as disaster relief or medical emergencies, this can become a matter of life and death.

For this reason, there is a need for personal location and navigation systems that do not rely exclusively on GPS signals. Such a system can be constructed with a combination of accelerometers and gyroscopes – by tracking changes in velocity and in orientation, this would provide accurate location information from a known starting point. This system would also ideally be lightweight, compact, robust, low power, and highly accurate, making it useable in personal handheld devices. The goal of our current research is to develop a gyroscope based on graphene that meets all these requirements.

In this talk, I will present numerical simulations of graphene gyroscopes that can detect rotation through purely electrical means. This is accomplished with the Sagnac effect, a quantum mechanical effect where angular rotation induces quantum interference that results in a modulation of current through a graphene ring, analogous to the Aharonov-Bohm effect.

As revealed by our simulations, we find that a simple ring structure is not sufficient for gyroscope design, and that alternate device configurations are required. I will discuss the potential device configurations that we have discovered, as well as our efforts to optimize the performance of gyroscopes based on such designs.

First-Principles Insights for Light-Ion Microscopy of Graphene Alina Kononov[1], Alexandra Olmstead[1], Andrew Baczewski[1] and Andre Schleife[2]; [1]Sandia National Laboratories, United States; [2]University of Illinois at Urbana-Champaign, United States

The properties of 2D materials are notoriously sensitive to defects and nanostructure, requiring precise characterization methods to verify desirable features. Ion-beam techniques including helium ion microscopy are a promising tool for this purpose. However, optimizing ion beam parameters for 2D materials requires improved understanding of their highly pre-equilibrium response to ion irradiation, which can fundamentally differ from their bulk counterparts. To this end, we simulate single impacts of 0.25 – 200 keV protons and helium ions in free-standing monolayer graphene using real-time time-dependent density functional theory. We find a channel-dependent anomalous effect in the energy transferred by ~6 keV protons that we associate with electron capture from σ and π bands. Furthermore, our first-principles results confirm analytic estimates of a threshold proton energy near 1 keV below which electron emission vanishes. Most importantly, we predict that anisotropic electron emission mechanisms result in up to 3 times stronger signal and 5 times higher contrast for exit-side (forward) emission than the typically detected entrance-side (backward) emission. At the same time, the ion-induced electronic excitations within the graphene delocalize on a sub-fs time scale, rendering their contribution to damage processes negligible. These findings will advance high-resolution, nondestructive imaging techniques for 2D materials.

This material is based upon work supported by the National Science Foundation under Grant No. OAC-1740219. SNL is managed and operated by NTESS under DOE NNSA contract DE-NA0003525.

Strain Effect on Optical and Magnetic Properties of Zigzag Two-Dimensional Passivated GaN Nanoribbons: An *Ab Initio* Study Vijay Kumar Gudelli, Naresh Alaal and Iman S. Roqan; King Abdullah University of Science and Technology, Saudi Arabia

In this work, systematic studies are conducted to investigate the electronic, magnetic, and optical properties of oxygen- and sulfur-passivated zigzag GaN nanoribbons (Z-GaNNRs) using first-principles density-functional theory. Simulation investigations pertaining to Z-GaNNRs of 0.9−5 nm width reveal that edge passivation increases GaNNR stability, whereby O-Z-GaNNRs are more stable than S-Z-GaNNRs and bare Z-GaNNRs. We demonstrate that the stability increases with the GaNNR width. Spin-polarized band structure analyses further show that bare Z-GaNNRs of all widths exhibit metallic properties with an antiferromagnetic (AFM) phase. In contrast, owing to their half-metallic and semiconducting nature, oxygen-passivated NRs (O-Z-GaNNRs) are characterized by ferromagnetic (FM) and AFM phases, respectively. Finally, S-passivated NRs exhibit ferromagnetic metal properties irrespective of their width. We found that the strain significantly affects the entire band structure of Z-GaNNR compared to bulk GaN, allowing the optical and magnetic properties of the material to be modulated. When the effect of strain on the electronic structure of all three GaNNR materials was investigated, at -4% applied strain, metal-to-semiconductor abrupt transitions were observed in bare Z-GaNNR. For O-Z-GaNNR, the applied -4% and -6% strains allow a transition of the magnetic properties from AFM to FM, showing a metal characteristic band structure. In contrast, no change in the electronic and magnetic properties of S-Z-GaNNR with strain is observed. The optical investigations and electron energy loss (EELS) analysis predict that these NRs have weak absorption potential but exhibit plasmonic vibrations in the 10−11 eV range. Although the refractive index of the bare Z-GaNNRs is equal to that of the bulk GaN, the applied strain and chemical passivation modulate its refractive index value. Thus, our results pave the way for novel one-dimensional GaNNR-based optical, magnetic, and photonic applications.

Magnetic Field Alignment of Fe_3O_4 Functionalized Boron Nitride Nanotubes for Polymer Nanocomposites Adesewa Maselugbo and Jeffrey Alston; North Carolina Agricultural and Technical State University, United States

Boron nitride nanotubes (BNNTs) are electrically insulating nanomaterials with unique intrinsic properties such as high thermal conductivity, high oxidation resistance, and superior mechanical strength. Polymer matrixes have low thermal conductivity, while BNNTs have excellent axial thermal

conductivity and poor off-axis thermal conductivity. So, there is great interest in using aligned BNNTs as composite filler to increase thermal conductivity for use in aerospace and other advanced thermal interface materials. However, current BNNT nanocomposite thermal transport properties are far from expected and theoretical values. Low thermal performance is largely due to the random orientation of BNNTs within the composite. Controlling the orientation of the BNNTs in the composite is therefore critical for optimizing its performance. The purpose of this work is to manipulate and eventually align BNNTs in nanofluids and polymer composites using magnetic fields.
Magnetic manipulation is accomplished by first modifying BNNTs with iron oxide nanoparticles (Fe_3O_4, magnetite) to induce paramagnetic susceptibility. Afterwards, functionalized BNNTs are magnetically aligned. This presentation highlights our method of BNNT functionalization with F_3O_4 nanoparticles. During the magnetite synthesis process, magnetite nanoparticle growth occurs on the BNNT surface via electrostatic interaction with the iron oxide nanoparticles, ensuring that the intrinsic properties and structure of the BNNT are not affected. Under external magnetic fields the magnetite functionalized BNNT exhibit magnetic responses that allow control over their orientation and position.

NM02.04.02
Tuning Dielectric Properties of Polymer Nanocomposites by Orientation Control of 2-Dimensional Fillers Maninderjeet Singh[1], Priyanka Das[2], Farzana Likhi[1], nihar pradhan[2] and Alamgir Karim[1]; [1]University of Houston, United States; [2]Jackson state university, United States

2D materials provide unique opportunities to design and develop next-generation materials and technologies for applications in energy storage, electronics, sensors, separations, and so on. In this work, we discuss the application of 2-D materials for enhancing the capacitive energy density of polymer-2D material-based nanocomposites. We demonstrate using layered 2D materials in the polymer matrices, the dielectric strength, dielectric permittivity, and hence the capacitive energy density can be tuned to develop high energy density capacitors. In particular, we show that using layered 2D Mica materials, the permittivity of the nanocomposites increases by ~100% with filler fraction as low as ~2 wt. % and the dielectric strength increases by ~80%, resulting in a ~400% increase in capacitive energy density. Furthermore, we show the dielectric properties of graphene oxide-based polymer nanocomposites can also be tuned by using nanoplatelet orientation control dictated by confinement effects in thin films. We believe these “orientation controlled” 2D nanofillers in polymer nanocomposites can help design futuristic materials with tunable properties.

NM02.04.03
Acetylene Chain Length Dependence of the Elastic Properties of Graphynes Guilherme B. Kanagae and Alexandre F. Fonseca; State University of Campinas, Brazil

Graphyne (GY) is the name given to a one-atom-thick carbon allotrope composed of acetylene chains of length n, $[-C\equiv C-]_n$, directly connected to themselves, by aromatic rings or sp2 carbon-carbon (C=C) bonds. Seven types of GY structures were originally proposed in the eighties, but the interest on them only increased in the last decade in view of the quest for new 2D materials with non-null band-gap. As the synthesis of graphynes are advancing, it is important to understand and predict the physical behaviors of GYs. Most of the studies about graphynes and their properties are concentrated on $n = 1$ and $n = 2$. Few works reported results on some individual types of GY having $n > 2$. Here, by means of classical molecular dynamics (MD) simulations, a comprehensive study of the dependence of the elastic properties of graphynes on the number, n, of acetylene chains is presented. Young's modulus, shear modulus, Poisson's ratio and linear compressibility of the seven originally proposed types of GYs with $1 \leq n \leq 10$ are calculated. The results are interpreted in terms of structural models and the dependence of these properties on the density of the structures. Some interesting results are: i) the Poisson's ratio of the GY known as α-graphyne with $n = 10$ is about 0.95, the largest value predicted for a 2D symmetric crystal by MD simulations; ii) linear compressibility of all seven types of GY as function of n are calculated for the first time; iii) the GYs known as 14,14,14- and 14,14,18-graphynes present negative linear compressibility along zig-zag direction whose absolute values increase with n; iv) the 14,14,14-graphyne presents Poisson's ratio larger than unit. Except for the Poisson's ratio, we show that the acetilene length dependence of the elastic properties of all seven types of GYs could be modeled by a simple serial association of n elastic springs. This work was supported by São Paulo Research Foundation (FAPESP), grant #2020/02044-9.

NM02.04.04
Nanostructured High Voltage Insulation Antigoni Konstantinou, Hiep Nguyen, Yifei Wang and Yang Cao; University of Connecticut, United States

A major challenge for power grids and electric drives for electric vehicles is the reliability of insulation systems for their electrical components. Defects related electrical partial discharges are highly undesirable and should be avoided in an insulation system. Such discharges can lead to aging and progressive degradation, resulting in a complete failure of the insulation system and the power apparatus. Polymer composite materials are being developed to tackle this issue by providing higher lifetime of insulation systems with improved performance. Currently, the state-of-the-art material, mica, is used for insulation in today’s high voltage power generators, motors and specialty capacitors. Although mica has renowned electrical discharge and high temperature withstanding capabilities, it is limited in use and performance by its brittle and mechanically weak nature. Attempts to strengthen pure mica have been made by incorporating and/or reinforcing with other materials, but the electrical and heat resistance of the final product/material suffer. To address this gap, polymer composites stand out as the ideal candidates to replace mica while offering all the desired properties. Epoxy-based dielectrics are widely used in modern microelectronics as electrical insulation, adhesive, packaging components and in grid-connected energy systems. High thermal conductivity (λ) (W/(m×K)), high breakdown strength, low dielectric constant (low-k) and low dielectric loss factor at both ambient and high temperatures are some of the key points that need to be addressed. This work aims to create a nanostructured insulation leading to better insulation performance for future applications such as motors with high-torque density for all-electric propulsion. Therefore, in this study, inorganic fillers were used to enhance an epoxy matrix. One such filler was hexagonal boron nitride (h-BN), a 2-dimensional material with surprisingly high λ of 751 W/mK at room temperature and excellent electrical insulative properties. On the other hand, zinc oxide (ZnO), which is a renowned semiconductive inorganic material, was also added to provide field grading. Samples were prepared with different ratios of inorganic fillers and studied with scanning electron microscopy (SEM), X-ray diffraction (XRD), voltage endurance tests in accordance with IEC 60343 standard, and thermal conductivity measurement (DTC). This work has the potential to address the insulation needs for transportation electrification and renewable energy conversion and integration.

NM02.04.05
Additive Manufacturing of Carbon Nanotube-Filled Thermosetting Resins Via Direct Ink Writing and Radio Frequency Heating and Curing Anubhav Sarmah, Suchi Desai and Micah Green; Texas A&M University, United States

Direct Ink Writing (DIW) is an extrusion-based additive manufacturing method where the print medium is a liquid-phase ‘ink’ dispensed out of small nozzles and deposited along digitally defined paths. Conventional DIW methods for thermosetting resins rely on the use of viscosity modifying agents, novel crosslinking chemistries, and/or long curing schedules in an oven. Here we demonstrate the use of a co-planar radio frequency applicator to generate an electric field, which can be used to rapidly heat and cure DIW- printed, CNT-filled composite resins. This method avoids the need of an oven or post-curing step. This process consists of a layer-by-layer, print-and-cure cycle which allows for printing of high-resolution, multi-layered structures. Every extruded layer is partially cured using RF before depositing the next layer; this allows the printed part to maintain structural integrity without buckling

under its own weight. The process enables both increased throughput and decreased touch time relative to traditional part manufacturing. Commercial epoxy resin with varied CNT-filler loadings were examined as DIW candidates. Rheological characterization was used to assess both curing kinetics and printing behavior. After printing, the thermo mechanical properties, surface finish, and shape retention of RF-cured samples were evaluated and found to be comparable against samples conventionally cured in an oven. This method of manufacturing establishes RF heating as a suitable alternative to conventional methods, facilitating rapid, free-form processing of thermosetting resins without a mold.

Laponite Nanodisks as Platform for Water Purification Arne T. Skjeltorp[1,2] and Larysa Anisimova[3]; [1]IFE, Norway; [2]Giamag Technologies, Norway; [3]Institute of Geotechnical Mechanics, Ukraine

Safe and clean drinking water is essential for every human being. However, clean water is sometimes scarce and not readily available due to industrial pollutant activity or runoff from natural geochemical processes. In the present work, it is shown that water quality can be improved by using Laponite as an adsorbent because of a large surface area. Laponite is a synthetic hectorite clay composed of disk-shaped nanoparticles with a diameter of about 20 nm and a thickness of about 1 nm. In a sample of 1 g laponite, there are about 10^{18} particles. The total surface area for adsorption of pollutants will be about 1000 m^2 with this amount of Laponite.
The underlying idea in the present work was thus to use functionalized laponite decorated with magnetic nanoparticles. This could enable removal of oil and soluble contaminants such as heavy metals, emulsifiers, surfactants, and micro-nano plastic from water flowing in a pipe. To succeed this, one must have magnets with efficient and high yield separation capabilities. For this it is important to have a strong force F acting on the magnetic bodies, given by the following equation:
$F = V\Delta\chi BgradB/\mu_0$.
Here, V is the volume, $\Delta\chi$ is the difference in the susceptibility of the magnetic particles and the surroundings,
BgradB is the product of the magnetic field B and field gradient gradB, and μ_0 is the vacuum permeability.
Many permanent magnets on the market have large magnetic fields B, but weak field gradients. The GIAMAG magnets have unique and patented designs that produces both very large magnetic fields and high field gradients, resulting in the most forceful magnetic separation available on the market [1,2]. Qualitative and quantitative measurements of water purification will be reported, in particular removing small oil droplets.

Acknowledgments
We wish to acknowledge Henrik Høyer and Keiko Yakabi Diosdado for the initial investigations in the project..

Carbon Nanotubes and Graphene Flakes Grown Synchronously in the Confined 2D Nanospace of a Layered Silicate Barbara Pacakova[1], Marian Matejdes[2,3], Paulo H. Michels Brito[1], Konstanse Seljelid[1], Leander Michels[1], Josef Breu[4], Steinar Raaen[1] and Jon Otto Fossum[1]; [1]Norwegian University of Science and Technology, Norway; [2]Slovak University of Technology, Slovakia; [3]Slovak Academy of Sciences, Slovakia; [4]University of Bayreuth, Germany

Carbon nanotubes are typically grown on metal precursors[1–3], upon formation of metal-containing nanoparticles[4,5] that serve as nucleation centers for nanotube formation, such as Fe_3C in the case of Fe as precursor. This process introduces unwanted properties into this pure graphitic system – for example, to introduce intrinsic magnetism into the carbon nanotubes, metal catalyst has to be completely removed, which is not possible in the most cases. However, several studies showing growth of carbon nanotubes on metal free substrates has been reported so far[4].

As there are no metal nucleation centres in clays, carbon nanotubes grow directly on the edges of the clay SiO2 nano-sheets. These SiO2 sheets sandwich octahedral sheets with Mg and Li inside the octahedra, which constitutes the nano-layered structure of the synthetic clay mineral fluorohectorite.

Here we report formation of the metal-free carbon nanotubes in the interlayer of synthetic fluorohectorite clay, by intercalation and subsequent pyrolyzation of different metal-free dyes. Detailed characterization by XRD, XPS, AFM, Raman spectroscopy, as well as magnetic property measurements allow us to describe this system, and postulate possible mechanisms for formation of carbon nanotubes.

Synthesis and Characterization of Protein-Derived Graphene Aerogels Bridget Denzer, Mohd Shaharyar Wani and Craig Arnold; Princeton University, United States

Graphene aerogels (GAs) are promising candidates for applications such as energy storage and water purification due to their exceptional porosity, high electrical conductivity, and absorption capabilities. GAs can be synthesized through chemical vapor deposition (CVD), in which the starting materials are freeze-dried then pyrolyzed at high temperatures and atmospheric pressure. The benefit to this method is that many carbon-based precursors can be used as starting materials, making it an extremely promising method for expanding the production of GAs. In this study, we show the successful synthesis of GAs via a template-free CVD method at 900°C using four different proteins precursors: α-lactalbumin, β-lactoglobulin, bovine serum albumin (BSA), and myoglobin. Through SEM, EDS, and Raman Spectroscopy analysis, we show that all four proteins form GAs when pyrolyzed, although their morphologies vary. The pyrolyzed BSA and α-lactalbumin show ordered graphene networks, but β-lactoglobulin and myoglobin have more amorphous structures. Thus,

when changing the protein precursor, the developed GAs show interesting trends in structural morphology, thus suggesting the tunability of GAs based on precursor selection.

NM02.04.11

3D Graphene Based Architectures for Environmental Applications Rabita Mohd Firdaus[1], Claudia De Melo[1], Jean-Francois Pierson[1], Sylvie Migot[1], Mélanie Emo[1], Abdul Rahman Mohamed[2] and Brigitte Vigolo[1]; [1]Institut Jean Lamour, France; [2]Universiti Sains Malaysia, Malaysia

Three-dimensional (3D) graphene-based macrostructures, GBMs, also referred to as aerogels, foams or sponges, have drawn immense interest these last ten years due the combination of interesting properties such as high surface area and porosity, chemical tunability and stability [1]. These GBMs offer high application potential including CO_2 adsorption, water treatment, batteries, sensors, catalysis, etc. However, due to lack of control of the self-assembling process, GBMs often suffer of restacking phenomenon during the assembly phenomenon which significantly lessens the outcome accessible surface. Exploiting the high surface of graphene within these GBMs is particularly important to develop efficient absorbents for water or air depollution. From literature, it is still not clear which of the physical (pore size, surface area) or the chemical (nature of the surface functional groups or other chemical modification) properties of GBMs impact their absorption capacity [2]. More recently, combination of graphene with inorganic compounds such as metal-based nanoparticles or thin films to develop hybrid porous nanomaterials is gaining of attention for environmental applications.
In this paper, we will provide a comprehensive study about the main issues to overcome development of GBMs and the investigation of their structural properties. Several 2D and 3D all-graphene based materials have been prepared and chemically modified for the purpose to be used for CO_2 capture. Our results show a significant enhancement of CO_2 absorption capacity after activation. The possible involved mechanism will be discussed [3]. Based on more recent results, preparation of alumina-graphene porous hybrids for depollution application will been as well described. Alumina is here deposited by atomic layer deposition providing a well-suitable deposit method for such porous graphene support. Thanks to an in-depth characterization of the prepared 3D graphene-alumina hybrid material by means of high resolution transmission electron microscopy analysis carried out on a thin foil lamella prepared by focused ion beam, we report here a successful preparation of highly porous alumina by a well-controlled method rarely reported.

NM02.04.12

Ternary Transition Metal Chalcogenide $Nb_2Pd_3Se_8$—A New Candidate of One-Dimensional van der Waals materials for Field-Effect Transistor with Its Controlled Doping Characteristic Byung Joo Jeong[1], Kyung Hwan Choi[2] and Jae-Young Choi[1]; [1]Sungkyunkwan University, Korea (the Republic of); [2]Sungkyunkwan University Advanced Institute of NanoTechnology, Korea (the Republic of)

Two-dimensional (2D) van der Waals (vdW) materials with a strong in-plane covalent bond and weak interlayer interaction have been intensively studied due to its unique and superior electrical, optical, and thermal properties. However, a complicated and diverse manufacturing process should be required to apply 2D vdW materials into future electronic devices in which various dimensional structures would be mixed. Mixed-dimensional vdW heterostructures have been studied in order to overcome integration limits of 2D materials by converging other *n*D materials, where *n* is 0,1 and 3. However, one-dimensional (1D) ternary transition metal chalcogenides containing a noble metal such as Pd or Pt have provided great potential in the field of electronic and optoelectronic applications due to their outstanding structural scalability, transport properties and high stability. In this work, we introduce a new ternary transition metal chalcogenide, $Nb_2Pd_3Se_8$, which was successfully synthesized via chemical vapor transport (CVT) method using iodine as a transport agent. It is demonstrated for the first time that single or few-ribbon $Nb_2Pd_3Se_8$ nanowires can be effectively isolated by micromechanical exfoliation due to the weakly bonded vdW interaction between the repeating unit structures. Interestingly, density functional theory (DFT) calculation revealed that this thickness-scalable $Nb_2Pd_3Se_8$ displays a semiconducting characteristic with an indirect band gap of 0.44 eV in bulk and a direct band gap of 0.73 eV in single-ribbon, exhibiting a tunable band gap with indirect-to-direct transition. For further verification, the work functions of $Nb_2Pd_3Se_8$ nanowires were characterized by scanning Kelvin probe microscopy(SKPM). Given the applicability to electronic devices, FETs were fabricated on the exfoliated $Nb_2Pd_3Se_8$ nanowires to evaluate electrical transport property, and high performance of n-type semiconducting behavior was achieved with electron mobility as high as 31 $cm^2 V^{-1} s^{-1}$, I_{on}/I_{off} ratio of $>10^4$ and long-term stability (up to 60 days) in ambient condition.
Furthermore, these series of materials have not been studied for controlling its electrical properties as a field-effect transistor. In general, charge transfer on a dangling bond free surface is the most appropriate approach using chemical doping method since direct infiltration of dopant atoms is difficult to adopt for modulating the electrical properties of nanomaterials as their most atoms are exposed to the environment. Therefore, n-type transport characteristics of $Nb_2Pd_3Se_8$ is modulated through p/n-type chemical doping method using $AuCl_3$/-Nicotinamide adenine dinucleotide (NADH), respectively. As a result of $AuCl_3$ doping, high performance p-type field-effect transistor (PFET) showing hole mobility up to ~8.6 $cm^2V^{-1}s^{-1}$ was obtained. For the proof of conception, we fabricated homogenous p-n junction diode with ideal rectifying behavior by applying half-doped device structure using encapsulation process. In addition, n-doped $Nb_2Pd_3Se_8$ shows the high field-effect mobility of 41 $cm^2V^{-1}s^{-1}$ with maintaining I_{on}/I_{off} values of $>10^4$ with long-term stability using NADH. Finally, all of the atoms related to each doped properties were discussed in detail through SKPM and X-ray photoelectron spectroscopy(XPS). We believe that this work can highlight a controllable electrical characteristic of 1D vdW semiconductors in nanoelectronic applications.

Sensitive Taste Sensors Using Graphene Decorated with Metal or Nafion for High Selectivity to Glucose and pH Chung Won Lee and Ho Won Jang; Seoul National University, Korea (the Republic of)

In recent days, taste sensing have been an important issue in terms of, detecting food quality or sensing various chemical substances from specific materials. This kind of taste sensor mainly uses 2-Dimensional materials such as graphene for sensing rather using lipids or other biological substances. The aim of using 2D materials rather lipids is for longer use; bio-substance based taste sensors have very high selectivity and sensitivity but the life span of the device is short and it is sensitive to external atmosphere. For long term use and daily usage, 2D material based sensors have the advantage to bio-based sensors. Here in, we report graphene based taste sensors graphene decorated with gold for glucose sensing and nafion spin coating on graphene for pH sensing. Graphene is the main source of sensing and the decorated materials help to enhance selectivity by absorbing or penetrating the target material. Gold is well known to have selectivity to glucose and nafion has the ability to selectively penetrate cations. Gold is decorated with e-beam deposition; which thickness is about 2nm. On the other hand, nafion is spin coated onto a graphene transferred substrate.

NM02.04.15
Growth and Morphology Evolution of Plasma-Synthesized Few-Layer Graphene Claudia-F. Lopez Camara, Paolo Fortugno and Hartmut Wiggers; Universität Duisburg-Essen, Germany

Graphene flakes are an attractive material due to their unique properties, making them promising to use for a wide variety of applications. Examples of these applications are using them as additives (to alter electrical, thermal, and mechanical properties of other materials e.g., polymer composites) or to improve the electrochemical performance in supercapacitors and batteries. However, these applications require industrial mass-production quantities of graphene powder, which are still challenging to achieve. To overcome the current batch-to-batch drawbacks from the commonly-used exfoliation processes for mass-production of graphene powder, substrate-free gas-phase plasma synthesis has emerged during the last years as an effective method to continuously synthesize freestanding few-layer graphene (FLG). This technique has the advantage to operate in a continuous mode and the potential to be scalable. During the plasma synthesis, a hydrocarbon precursor is pyrolyzed within a high-temperature plasma region. Downstream of this region, the gaseous carbon species nucleate and form FLG, leading to carbon yields as high as 10 wt%.

This work examines the evolution of growth and morphology of few-layer graphene (FLG) synthesized in a microwave-plasma reactor. Aerosol particles were sampled and characterized from various positions downstream of the plasma zone by spatially-resolved thermophoretic sampling and transmission electron microscopy (TEM), Raman spectroscopy, and BET surface area analysis (BET-SSA).

The initial carbon nucleation has been found to commence close to the plasma zone (at less than 12.4 cm downstream from the plasma nozzle) and at a temperature of ≥ 2500 °C. The initially formed flakes show an increasing level of crumpling with increasing distance downstream from the plasma zone. From the TEM images of samples collected at different heights above the plasma nozzle, we observed a growth and self-folding pattern for FLG, providing a hypothesis for their formation from single- to few-layer graphene when the materials are carried downstream the plasma region. This hypothesis consists of the creation of one-layer ovalene-shaped graphene flakes that self-folds from the sides and crumples while it continues to grow, creating wrinkled FLG flakes as these move further away from the plasma nozzle.

NM02.04.16
Processing Parameters and Their Influence on the Mechanical and Morphological Properties of Non-Woven Polyacrylonitrile/Carbon Nanotube Composite Thin Films Conor Doyle and Marilyn L. Minus; Northeastern University, United States

This research details observations of the influence of processing parameters on the formation and mechanical performance of non-woven polyacrylonitrile (PAN)/single wall carbon nanotube (SWNT) composite thin films. Solvent-based phase separation promotes the formation of an extended-chain PAN interphase at the SWNT surface as well as a hybrid through-thickness morphology. Previously reported work has documented the mechanical and electrical properties of various weight ratios of SWNT filler and PAN matrix films produced using this method. This current work reports changes in film mechanical and morphological properties resulting from modifications made to several process parameters, namely the overall film diameter and environmental conditions at which residual solvent is removed from films after the initial filtration step. Environmental conditions tested include the drying temperature and clamping pressure used during residual solvent removal. Dynamic mechanical analysis was used to evaluate the development of tensile strength and modulus (i.e., storage and loss moduli). Morphological changes were characterized using optical and electron microscopy. The results to be presented demonstrate the influence of selected processing parameters on the mechanical and morphological quality of non-woven PAN/SWNT composite thin films.

NM02.04.17
AI Toolkit for Accelerated Nanoporous Material Discovery Jonathan Booth[1], Dan Cunnington[2], Flaviu Cipcigan[2], Rodrigo F. Neumann[3] and Breanndan O Conchuir[2]; [1]Science and Technology Facilities Council, United Kingdom; [2]IBM Research Europe, United Kingdom; [3]IBM Research Brazil, Brazil

Crystalline nanoporous materials are widely recognised as promising candidates for carbon capture, due to their large surface area and highly porous structure. Also, there is a vast number of constituent materials which can be synthesised, enabling precise tuning of various chemical and geometric properties. As a result, there is a large design landscape which has triggered extensive research in the community, and the search continues for the best performing candidates. In this work, we present an artificial intelligence toolkit aimed at improving the discovery of materials such as zeolites, metal-organic frameworks, and zeolitic imidazolate frameworks with good adsorption of greenhouse gases, such as CO2. The toolkit consists of 3 software packages that respectively implement: (1) a linear regression pre-screening of candidate materials using gravimetric surface area as the independent variable. (2) A crystalline graph convolutional neural network that acts as a computationally cheaper surrogate model for in-silico adsorption simulations, and (3) a pair of neural-symbolic techniques for learning the adsorption isotherm as a symbolic function of pressure and temperature, as well as learning logical rules that identify material features and values that constitute good adsorption performance.

For the initial pre-screening, we use a training set of many nanoporous materials, with various geometric features together with a simulated adsorption value, and fit a linear regression model using each feature as the independent variable. This enables simple rules to be created, such as filtering out materials with a gravimetric surface area below a certain threshold. Meanwhile, the crystalline graph convolutional neural network is trained to predict adsorption from an input Crystalographic File (CIF) format, using a similar training set of in-silico adsorption simulations. During inference, the idea is that the linear regression model can act as a (very) cheap pre-screen, before the neural network surrogate model performs additional downstream screening of candidates. This will greatly prune the space of possible candidates that require more computationally expensive simulations, to accurately determine the adsorption.

The neural-symbolic techniques investigate the feasibility of using AIFeynman, a state-of-the-art symbolic regression technique for learning physical equations from a low number of samples that associate pressure and temperature with adsorption. Should a suitable isotherm expression be learned, the obvious benefit is that the adsorption profile can be quickly evaluated for a variety of pressure and temperature values, which will be of interest to industrial applications when performing experiments, since a given implementation may only be able to achieve certain temperature and pressure values. Also, this work explores the use of FastLAS, a state-of-the-art symbolic machine learning technique that learns interpretable, logical rules from training examples. The goal is to supplement the linear regression pre-screen by exploring a search space of possible rules that can be used to filter out materials that lead to poor adsorption. The inherit interpretability enables further analysis of the learned rules by domain experts, to avoid overfitting the pre-screening check to a given training set, which would result in good candidate materials being filtered out.

This work presents an overview of each of the techniques used, alongside experimental results.

Suspended, Self-Tearing and Strained Graphene Nanostructures Formed by Nanoindentation Daniel Sanchez[1], Graham L. Cross[2] and Robert Carpick[1]; [1]University of Pennsylvania, United States; [2]Trinity College, Ireland

The nanoindentation of substrate-supported graphene has recently been shown to lead to the formation of spontaneously self-tearing nanoribbons up to several micrometers in length, known as 2D material pleats (2DMPs) [1]. The physical mechanisms driving this phenomenon are not yet fully understood. Moreover, this unprecedented mechanical behavior has potential to be exploited to produce novel stacked structures made of graphene and other 2D materials without the need for traditional transfer methods that suffer from any limitations, such as the polymer contamination of constitutive flakes. In previous work, the yield and uniformity of 2DMPs are modest, and the factors that predict successful 2DMP growth were not established. Here we explored the statistics of 2DMP formation through nanoindentation. We studied graphene of various thicknesses ranging from monolayer to bulk graphite exfoliated on 300 nm SiO_2/Si, facilitated by using protocols that permit large, uniform exfoliated areas. We then created arrays of indents in a periodic grid formation consisting of tens to hundreds of indents on a single flake. We conducted a postmortem analysis of each indent using atomic force microscopy to categorize the indented graphene sites into distinct types of nanostructures. This permits us to quantify, for first time, the percent yield of 2DMPs as a function of multiple parameters including maximum applied load, graphene thickness, and indent spacing. We discovered two previously unseen graphene nanostructures formed through nanoindentation in addition to 2DMPs. Specifically, we observed the formation of unbroken, suspended graphene, as well as graphene that fully conformed to the plastically deformed substrate, establishing a new method for producing suspended graphene and strained graphene. We then explored how proximity between nearest-neighbor indents affects the statistics of which nanostructures form in the indent arrays, demonstrating the role of elastic strain in 2DMP formation. Our analysis provides insight into the stochastic nature of nanostructures formed through nanoindenting, and explores the experimental conditions that affect the yield of desired nanostructures.

NM02.04.19
Plasma-Induced Biocompatible NGQD-Based Hydrogels as Smart and pH Responsive Cancer Therapeutic Agents Darwin Kurniawan[1], Jacob Mathew[1], Michael Ryan Rahardja[1], Hoang-Phuc Pham[1], Neralla V. Rao[1], Kostya (. Ostrikov[2] and Wei-Hung Chiang[1]; [1]National Taiwan University of Science and Technology, Taiwan; [2]Queensland University of Technology, Australia

Cancer is none arguably one of the world's most dreadful diseases striking everyone without any exceptions. Current treatments rely on surgical intervention, radiation, and chemotherapeutic drugs which usually not only kill the cancers cells, but also affect healthy cells causing toxicity and severe side effects to the patients or even death. Therefore, it is urgent to develop a drug delivery system (DDS) capable of either passively or actively targeting cancer cells only to avoid all those possible occurring side effects during therapy. Resembling physicochemical and biological properties of extracellular matrix coupled with their biocompatibility and biodegradability, hydrogels with stable 3D hydrated network emerge as suitable candidate for many biomedical applications, including drug delivery, scaffold engineering, wound treatment, antibacterial, and antioxidant.

Here we report rapid and environmental-friendly plasma engineering of microporous carbon-based NGQD hydrogels from a single chitosan biomass using non-thermal microplasmas at ambient conditions without toxic chemicals and high temperature treatment. The highly reactive species derived from the non-equilibrium plasma regime allows simultaneous conversion of NGQDs and initiation of covalent bond formations within the polymeric chitosan network in a short time. Moreover, synergistic effect manifested by the inclusion of NGQDs in the chitosan matrix framework coupled with energetic plasma treatment can accelerate the cross-linking of chitosan to form a robust 3D porous composite without any toxic chemicals and harsh conditions. Endowed by the presence of NGQDs, the fabricated composites have enhanced anticancer drug loading capacity and pH-controlled sustained drug release. Since the fabricated composites also exhibit stable solid-state PL properties, it is envisaged that our method can advance toward a novel combination of therapeutic and monitoring. Our work provides a rational design of carbon-based composite with defined structures and properties suitable not only for biomedical application, but also other emerging applications.

NM02.04.21
The Synthesis and Characterization of Homogeneous High-Quality Graphene Encapsulated Metallic Powders via Plasma Enhanced Rotating CVD Deniz Cakir[1], Omer R. Caylan[1,2], Tarik C. Turkoglu[1], Ogulcan Akgun[3], Gunce Dugan[3], Halil O. Tugrul[3], Benat Kockar[3] and Goknur Cambaz Buke[1]; [1]TOBB University of Economics and Technology, Turkey; [2]Bilkent University, Turkey; [3]Hacettepe University, Turkey

Graphene added Cu composites are mostly produced by mixing of graphene flakes (synthesized by Hummer's method and derivatives) and Cu powders through methods like ball milling. However, this approach has many issues related to:
- dispersion of graphene in matrix
- formation of interfacial bondings and interfacial products
- presence of structural defects in graphene
- the number of carbon layers in graphene
- presence of defects in the final product (e.g. porosity or interstitials)
- orientation of graphene relative to the loading direction
- weigth or volume ratio of graphene

Hence, it is difficult to directly examine the effect of graphene on mechanical properties with this method, and there are conflicting results in the literature. The problems mentioned above are related to the processing, and within the scope of this study, a process design and development has been made by focusing on the homogeneity and reproducibility of the graphene distribution. To produce uniformly dispersed high quality graphene reinforced copper composites: 1 micrometer spherical Cu powders were coated via plasma enhanced CVD (PECVD), then pressed and sintered at 1000 C. The results show that the yield strength and stress values at different strain values of samples produced from graphene powders are considerably higher than the samples without graphene: At room temperature, the yield strength of the graphene samples increased by about 3 times, and the stress values obtained at 30 percent constant strain increased by about 2 times … achieving a breakthrough in the performance of copper-based materials. The increase in mechanical performance was evaluated with the discussion of Grain size reduction and Strain hardening. This study is supported by TUBITAK grant number 118F491.

NM02.04.24
Graphene-Based Fracture Diodes Levi C. Felix and Douglas S. Galvao; State University of Campinas, Brazil

In nature, it is not rare to find materials with anisotropic fracture strength, such as wood and graphite. Although this anisotropy occurs along very distinct axes of symmetry, they are all centrosymmetric, meaning that such strength values remain unchanged upon inversion along a given axis. It is possible to break this symmetry in fracture behavior by manipulating the microstructure, for instance, with the insertion of triangular-shaped voids. This idea was recently experimentally realized for polymeric plates [1], where linear arrays of triangular holes created a fracture-rectification effect. In this work, we exploited similar ideas for monolayer graphene to determine whether this behavior also occurs at the nanoscale. By inserting triangular voids in graphene membranes, we investigated their fracture patterns under mechanical strain using fully-atomistic reactive molecular dynamics simulations. A preferential direction to fracture propagation was observed, confirming a robust rectification-like behavior [2]. We can design the voids in configurations that can guide the fracture propagation along specific directions but not in their reverse directions, thus characterizing a mechanical (fracture) diode. We also observed

that there is an optimal value spacing between each triangular defect, which enhances the rectification.

Effect of Deposition of Graphene Based Nanocomposite Electrodes on Performance of Ultracapacitors Duy Pham, Mohamed Elkholy, Quang Lam and Ashish Aphale; Kennesaw State University, United States

Supercapacitors, also known as ultracapacitors have gained considerable interest due to fast charge/discharge capacity, and superior specific energy and power density. Dual charge storage mechanisms such as electrochemical double layer capacitance (EDLC) and redox based Faradaic processes have been investigated to enhance the performance of supercapacitor devices. Further, the use of hybrid electrodes comprising of polymer or metal oxides along with 2D materials such as graphene, have been studied extensively to demonstrate increase in electrode performance. In this work, potentiostatic polymerization of pyrrole (Py) along with graphene has been conducted to develop freestanding electrode for supercapacitor application. The role of deposition cycles during electrochemical polymerization is investigated and its effect on gravimetric capacitance is studied in aqueous electrolyte. Changes in capacitive behavior of electrode material as a function of deposition cycle will be discussed. Surface/interfacial morphology and chemical characterization results will be discussed to show the effect of deposition cycle during electrode film formation. Results from electrochemical techniques including cyclic voltammetry (CV), galvanostatic charge-discharge (GCD) and electrochemical impedance spectroscopy (EIS) will be presented.

NM02.04.26
Energy Dissipation and Rate-Dependent Deformation Behavior of STF-Integrated PU Foam Nanocomposites Emre Gunduz, Bunyamin Karagoz, Ipek Osken, Kaan Yildiz and Hulya Cebeci; Istanbul Technical University, Turkey

The transportation industry requires high safety at lower weight to protect human life with engineered solutions. Designing energy dissipative polymeric foam composite structures is essential for many applications to withstand impact loadings. Compared to honeycombs, polymeric foams receive great attention as structural components with their outstanding effective stress transfer, viscoelastic properties and increased surface area. Among several polymeric foams, rigid polyurethane foams (PURs) are good candidates presenting high strength and lightweight characteristics. To achieve multifunctionality in PURs, several reinforcing strategies have been applied to integrate micro and nanomaterials through tuning the PUR microstructure. Under impact loadings, shear thickening fluids (STFs) exhibit strong toughening behavior. STFs are Non-Newtonian fluids demonstrating different flow behaviors under applied shear. STFs are colloid suspensions, at low shear rates, particles are oriented, STFs flow easily, thus viscosity decreases. After critical shear rate, hydroclusters occur due to applied shear rate and particle interactions, resist to flow, hence viscosity increases drastically. The minimum viscosity is observed at the critical shear rate. The ratio of minimum to maximum viscosity is specified as the thickening ratio. Viscosity, critical shear rate and thickening ratio are essential performance parameters of STFs.

In this study, we aim to investigate energy dissipation and rate-dependent deformation behavior of STF-integrated PURs (STF/PURs) under cyclic compression tests, dynamic mechanical analysis and impact forces. Fumed silica particles (11 nm) were dispersed in ethylene glycol (EG) under a constant mechanical mixing rate of 500 rpm and sonicated to form the concentrated colloidal suspension for 2.7 to 5.4 h. The process was performed with the similar procedure for all concentrations of STFs and optimized to achieve the best dispersion of silica particles inside EG. Silica nanoparticles at varying weight fractions of 19, 22, 24, 26, and 28 were dispersed in EG to observe the effective shear-thickening phenomenon. Rheological measurements of the STFs were carried out, presenting a thickening ratio between 22.6 to 67.6. The highest thickening ratio was obtained with 26 wt.% silica content.

STF/PURs were prepared with 0.5, 1 and 3 wt.% STFs with 26wt.% silica content. Polyol was the chosen media for dispersion of STFs and was firstly mixed by a mechanical stirrer at 300 rpm for 4.5 h. Then PMDI was evenly stirred with the mixture.

The load-carrying ability of cellular polymer foams relies on their morphological features. Cell edge lengths decrease and density increases with STFs integration. Quasi-static cyclic compression tests were performed in a strain-controlled mode, up to 10%, 40%, and 80% strains with 10 cycles. The applied strain rates were chosen as 0.002, 0.02, and 0.2/s in order to investigate the rate dependency. Compression and specific compression strength were improved by 33% and 10.4% with 1.wt% STF/PURs at 0.2/s, respectively. Loss factors were calculated from cyclic compression test results, 6% enhancement was obtained at 10% strain whereas no significant changes were apparent at higher strains.

Dynamic mechanical properties of STF/PURs were also measured using a dual cantilever fixture. First, strain-sweep tests were performed in order to determine the linear viscoelastic region. Then, frequency sweep tests were performed with 35 μm amplitude. The linear viscoelastic region was found to be increasing with increasing STFs content. The storage modulus also increased by more than 50% while no significant changes in the loss factor were observed.

In conclusion, STF/PURs demonstrated higher mechanical properties than neat PURs. Energy absorption capabilities of STF/PURs at high strains and strain rates will be investigated by drop weight impact tests in future studies.

NM02.04.28
Effect of Chemical Vapor Deposition Condition on the Aspect Ratio of Vertically-Aligned Carbon Nano Tubes (VACNTs) Fahd M. Rajab; Najran University Faculty of Engineering, Saudi Arabia

Vertically Aligned Carbon Nanotubes (VACNT) are promising core elements in advanced devices of various applications. Their uniform growth can be achieved by chemical vapor deposition (CVD) at specific process conditions using metal seed catalysts. Catalyst lifetime depends on the synthesis processes used to make the catalytic substrates and CVD process conditions. In electron-beam physical vapor deposition, silica oxide substrates are coated with an alumina barrier layer and a catalyst layer. Further diffusion of the catalyst in the barrier layer in the heating step of CVD and insufficient catalytic oxidation can impede catalyst distribution and suppress the growth of VACNT.
CVD is performed at controlled process conditions to grow VACNT utilizing iron seed catalysts of selected layer thicknesses. CVD conditions such as hydrocarbon and water vapor rates are varied to investigate their effect on VACNT structures. The analytical studies include spectroscopic ellipsometry to measure wafer substrate layer thickness, Raman spectroscopy to assess the structures of carbon nanotubes, as well as scanning electron microscopy (SEM) to evaluate VACNT growth density and patterns. Findings show Fe catalyst/Al_2O_3 buffer layer thickness-position effect, and a highly dependent VACNT G/D ratio on reaction conditions and reactant flow ratios.

NM02.04.29
High-Performance Photothermal Conversion of Electrospun Polymer/Carbon Composite Materials Fangqi Chen, Yanpei Tian, Andrew Caratenuto,

Xiaojie Liu and Yi Zheng; Northeastern University, United States

The usage of the abundant solar energy has attracted significant interest in the recent years, and the photothermal absorber with a high energy conversion efficiency due to its broad solar absorption has become a key component in many solar-harvesting applications, such as solar-driven steam generation. In this work, a polycaprolactone nanofiber composite with incorporation of carbon nanotubes or carbon nanoparticles is introduced with an average absorptance of 0.94 and 0.93 in the wavelength of visible and near-infrared light, serving as an excellent broadband solar absorber. The refractive indices of the composite are determined using a Lorentz−Drude oscillator model based on the experimental transmittance spectra. The composite yields an ultrahigh solar absorptance that contributes to an interfacial evaporation rate of 2.00 kg m^{-2} h^{-1} and 1.95 kg m^{-2} h^{-1} for carbon nanotubes and nanoparticle composites, respectively. Compared with other nanofabrication methods, electrospinning has the advantages of simplicity, cost effectiveness, and high efficiency, and it enables scalable fabrication of nanostructured materials. This work sheds light on a low-cost and high-output fabrication method for a nanofiber photothermal absorber composed of a biocompatible and biodegradable polymer and carbon materials.

NM02.04.30
Confinement Effects on the Dielecrtic Properties of Graphene and Reduced Graphene Oxide Dispersed Polymer Nanocomposite Films Farzana H. Likhi and Alamgir Karim; University of Houston, United States

Much recent research efforts have studied how the incorporation of graphene oxide (GO) and reduced graphene oxide (rGO) impact the frequency dependent dielectric properties in polymer nanocomposite materials. However, few studies explore the effect of film confinement in the micron to sub-micron range of thin film regime. In this film thickness range, that is comparable to the lateral dimensions of the platelet GO and rGO nanomaterials, we can expect film confinement effects on platelet orientation, that also impacts its relative projection area to the applied electric field. Pristine graphene can be achieved by reducing graphene oxide, which has a similar honeycomb structure with both sp^2 and sp^3 carbon imbuing the surface with limited oxygen-based functional groups that can interact with the polymer matrix via a nanometric interfacial zone. In this work we present the nanomaterial loading-frequency dependence of these two fundamental properties, in thin polyvinylidene fluoride (PVDF) film containing GO and rGO of thicknesses ranging from 1 µm to 100 µm. Controlled microwave was used for reducing graphene oxide in a laboratory environment. We will discuss the film finite size effects on the relative response of GO vs. rGO vs. pristine PVDF in terms of their dielectric constant, loss tangent, and AC conductivity data over the frequency range of 1 kHz to 1 GHz using a dielectric spectrometer. We observed that the AC electrical conductivity tends to increase with frequency, but the dielectric permittivity tends to decrease in general, and that the dielectric properties are more frequency sensitive for the 1 µm film than the 100 µm films. AFM and SEM were used to ascertain the film morphology and quality of these nanocomposite films. This study may provide an insight for development and utilization of GO and rGO based polymer thin films in future electronics

NM02.04.32
Large Polycyclic Aromatic Hydrocarbons as Graphene Quantum Dots—New Ultra Stable and Bright Emitters for Photonics Giuseppe M. Paternò[1,2], Qiang Chen[3], Francesco Scotognella[1,2], Guglielmo Lanzani[2,1] and Akimitsu Narita[4]; [1]Politecnico di Milano, Department of Physics, Italy; [2]Istituto Italiano di Tecnologia, Italy; [3]University of Oxford, United Kingdom; [4]Okinawa Institute of Science and Technology, Japan

Synergistic research efforts in multistep chemical synthesis and state-of-the-art optical spectroscopy have permitted the realization of graphene quantum dots (GQDs) with defined structures, edge configurations and properties, paving the way towards their possible applications in photonics and optoelectronics. One such fruitful feedback loop between synthesis and spectroscopy is represented by the recent development of stable GQDs with zigzag edges, displaying excellent spectral features such as optical gain and strong absorption/emission in the visible/near-infrared regions, which are appealing for applications in photonics.[1]
In this talk, I will provide an overview of the latest developments in the advanced spectroscopic investigations of atomically precise GQDs, with particular emphasis on those with zigzag-edged structures. Finally, I will discuss on their application as stable and efficient gain materials in laser devices and as ultrafast optical switcher.

NM02.04.34
Rapid, Multianalyte Detection of Opioid Metabolites in Wastewater Michael Geiwitz and Narendra Kumar; Boston College, United States

By monitoring opioid metabolites, wastewater-based epidemiology (WBE) could be an excellent tool for real-time information on the consumption of illicit drugs. A key limitation of WBE is the reliance on costly laboratory-based techniques that require substantial infrastructure and trained personnel, resulting in long turnaround times. Here, we present an aptamer-based graphene field effect transistor (AptG-FET) platform for simultaneous detection of three different opioid metabolites. This platform provides a reliable, rapid, and inexpensive method for quantitative analysis of opioid metabolites in wastewater. The platform delivers a limit of detection 2–3 orders of magnitude lower than previous reports, but in line with the concentration range (pg/mL to ng/mL) of these opioid metabolites present in real samples. To enable multianalyte detection, we developed a facile, reproducible, and high-yield fabrication process producing 20 G-FETs with integrated side gate platinum (Pt) electrodes on a single chip. Our devices achieved the selective multianalyte detection of three different metabolites: noroxycodone (NX), 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine (EDDP), and norfentanyl (NF) in wastewater diluted 20× in buffer.

NM02.04.35
Construction of Nitrogen-Abundant Graphyne Scaffolds via Mechanochemistry-Promoted Cross-Linking of Aromatic Nitriles with Carbide Towards Enhanced Energy Storage Juntian Fan[1], Zhenzhen Yang[2] and Sheng Dai[2]; [1]University of Tennessee, United States; [2]Oak Ridge National Laboratory, United States

The two-dimensional (2D) graphyne-related scaffolds linked by carbon–carbon triple bonds are an important category of conjugated organic networks demonstrating promising applications in the field of catalysis and energy storage fields. The mechanochemistry-driven methods could afford graphyne-related materials under neat and ambient conditions by leveraging the energy input from mechanochemical treatment to promote the nucleophilic attack reaction of CaC_2 with aromatic halides. However, the scaffolds construction was still limited to the cross-linking of CaC_2 with aromatic halogens and afforded graphyne materials with none or low content of heteroatom doping (e.g., nitrogen), which cannot meet the high charge storage requirements in the electrochemical fields. Development of alternative approaches to afford nitrogen-abundant graphyne materials via the facile mechanochemical procedure is a long-standing challenge.

In this contribution, towards the construction of nitrogen-doped graphyne materials via the mechanochemistry-driven procedure under neat and mild conditions, multiple substituted aromatic halides with enhanced reactivity with CaC_2 were deployed by introducing extra electron-withdrawing cyano groups on the benzene ring, to achieve efficient graphyne scaffolds construction and simultaneous nitrogen-doping. The as-afforded nitrogen-doped graphyne materials delivered enhanced energy storage behaviors in supercapacitor-related applications. Furthermore, the facile mechanochemical treatment

pathway was extended to a non-halogenated monomer with multiple aromatic nitrile groups and electron-deficient properties, which could efficiently react with CaC_2 via the ball milling procedure. Efficient cross-coupling polymerization could be conducted with a low feeding mass ratio (CaC_2 : monomer) of 1:8 in almost quantitative yield. The as-afforded nitrogen-doped graphyne materials were featured by abundant nitrogen-containing species with nitrogen content up to 29.31 wt%, high surface areas up to 865 $m^2 g^{-1}$, and hierarchical architectures composed of micro- and mesopores, which could be tuned by varying the mechanochemical parameters. The unique properties of these materials worked together to deliver promising capacitance (up to 254.5 F g^{-1}) in supercapacitor-related applications, together with good rate performance and attractive cycling stability. The achievements made in this work not only provide monomers with highly conjugated structures coupled with high nitrogen content to construct task-specific graphyne materials, but will also extend the application of related materials in other under-explored fields.

NM02.04.36
The Structure Dependence on the Mechanical Properties of Spiked-Shell Aerographite Particles YueXuan Li, Hiromu Hamasaki and Kaori Hirahara; Osaka University, Japan

Aerographite particles have a micrometer-sized unique shell structure, consisting of radially-aligned hollow carbon nanorods seamlessly connected at their bottoms [1]. Such a morphology brings excellent flexibility under large compression. When the particles were fully-compressed with strain >70%, they can recover their original shapes after unloading. However, the particles tended to accumulate small cracks at strain >40%, which sometimes leads to fracture or fatigue damages on particles in the repetitive compression. We consider that the mechanical properties of aerographite particles can be improved by controlling the properties of their graphitic structures. In this study, we focus on two structural parameters, crystallinity, and thickness of the graphitic layers consisting the aerographite particle, influencing on the mechanical properties. Crystallinities of individual particles were improved by annealing above 1,600°C with keeping their flexible shell morphologies, although the excess heating at 2,000°C caused damage to the shell structure. On the other hand, the layer thickness was controlled by changing the feeding time of the acetylene gas in the fabrication process. The effect of these structural changes on mechanical properties was investigated by performing single-particle-level compressive tests in a scanning electron microscope with the use of nanomanipulation techniques. Experimental results for particles annealed at different temperatures showed that the annealing at 1,600°C had suppressed the fracture of aerographite particles, due to the restraint of crack propagation caused by crystallinity improvement. For particles fabricated with various thicknesses (4-9 nm), all particles with 5 nm layer thickness did not exhibit fracture, even under fully compressed conditions. The decrease of layer thickness induced buckling of the shell along the compressive axial direction when the compressive strain was over 40%. In addition, such a buckling may be related to reducing the accumulation of residual strain during the cyclic compression. Accordingly, improving crystallinity by annealing at 1,600 °C and controlling the thickness of the graphitic layers to 5 nm are revealed to be effective options to realize further superior mechanical properties of aerographite particles.

NM02.04.37
Electrical Resistance Measurement of a Single Interface Between Carbon Nanotubes Hiromu Hamasaki and Kaori Hirahara; Osaka University, Japan

As carbon nanotubes (CNTs) possess superior thermal and electrical transport properties, they have broad potential applications for flexible devices such as thermoelectric generators. However, the conductivities in CNT assemblies are reduced by several orders of magnitude and strongly depend on the alignment of individual nanotube axes [1]. This is mainly due to the difference of the conductance between intratube and intertube bondings in assemblies. Probably due to the difficulty of the experimental approaches, less is known about transport via a single contact between two neighboring nanotubes than about transport within an isolated nanotube, despite their likely equivalent importance for CNT assembly applications. To deepen understanding of contact transport, a systematic study of the effects of contact length (or area) in simple, parallelly contacted CNTs would be of great importance. Moreover, they could have enormous implications for the transport of other nanomaterial-based assemblies and composites. In this study, we experimentally investigate the electrical resistance of a single parallel contact between two multi-walled CNTs. A nanomanipulation system, equipped in a transmission electron microscope, enables the performance of in situ measurements of electrical resistance for a range of contact lengths [2].
In all cases for MWCNTs with different diameters, the measured resistances as a function of contact lengths showed the same trend; the electrical resistance decreased with increasing contact length. This is qualitatively reasonable as the contact area increases in proportion to the contact length. Here, we cannot directly attribute the measured resistance values to the contact resistance between the CNTs as they were obtained by the two-terminal method. The total resistance can be divided into three elements, namely, the resistance of the individual CNTs, the interfacial resistance between CNTs, and other resistance. Other resistance is generated by components independent of the nature of both CNTs and CNT-CNT contact, therefore it can be assumed to be a constant value. The contact-length-dependent behaviour can be derived from the first two terms, the resistance of the individual CNTs and the interfacial resistance between the CNTs. We found that the measured electrical resistance exhibited two different dependences as a function of the contact length; it was inversely proportional to the contact length when the contact length was small, whereas, it was proportional to the contact length with a negative gradient when the contact length was sufficiently large. We found that the former and latter dependences can be attributed to the resistances of the interface and CNTs, respectively, and derived the electrical conductivity of the single interface and single CNTs from the measurements. The conductivities of a single CNT were comparable to the previous reports. The interface between nanotubes exhibits intermediate conductivity between those of pyrolytic and single-crystal graphite along c-axis. These findings suggest that the interfacial effect becomes effectively small at contact lengths longer than a few hundred nanometers. The present study has fundamental implications for the physics of CNT-based electronics and their applications.

Design and 3D Printing of Optimized Electrodes for Supercapacitor Applications Mariana Desireé Reale Batista[1], Swetha Chandrasekaran[1], Bryan Moran[1], Miguel Salazar de Troya[1], Anica Pinongcos[2], Zhen Wang[3], Ryan Hensleigh[3], Adam Carleton[1], Manhao Zeng[1], Thomas Roy[1], Dun Lin[2], Xinzhe Xue[2], Victor Beck[1], Daniel Tortorelli[1], Michael Stadermann[1], Rayne Zheng[3], Yat Li[2] and Marcus A. Worsley[1]; [1]Lawrence Livermore National Laboratory, United States; [2]University of California, Santa Cruz, United States; [3]University of California, Los Angeles, United States

Supercapacitors have attracted considerable attention within the automotive, aerospace, and telecommunication industries due to their fast charging/discharging ability. The high electrical conductivity and surface area of porous carbons make them attractive candidates for supercapacitor electrodes. Maximizing porous carbon in electrodes (I.e., thick electrodes) is one strategy to further increase energy density of these devices. However, these porous carbons suffer from sluggish charged species transport in thicker electrodes, which limits them to thin electrode designs. In this work, we investigate the use of computer-guided optimization and additive manufacturing to design and print thick porous electrodes with improved performance. Electrodes with optimal performance were designed by topology optimization and printed by projection micro stereolithography (PμSL) using PR48 resin. The PR48 resin was then pyrolyzed (PR48-P) to create the final conductive electrode. The PR48-P electrodes with optimized design exhibited improved capacitance compared to those control electrodes printed as cubic lattice structures. To further improve performance, a new resin was synthesized by

combining graphene oxide (GO) and trimethylolpropane triacrylate (TMPTA). Electrodes printed with 3 wt% GO in TMPTA exhibited improved capacitance retention after pyrolysis compared to PR48-P electrodes. This work demonstrates the benefits of using topology optimization to design electrodes and material development to improve functional properties of 3D printable resins. This work was performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under contract DE-AC52-07NA27344. Lawrence Livermore National Security, LLC.

NM02.04.39
Cellulose Acetate-Assisted Fibrous Carbon Nanotube Networking Film for Scalable Binder-Free Electrodes in Flexible Li-Ion Batteries Ji Hyun Han and Yun Jung Lee; Hanyang University, Korea (the Republic of)

A freestanding cellulose acetate-carbon nanotube (CA-CNT) film electrode is given here to build very flexible and high-energy lithium-ion batteries (LIBs). CA acts as a CNT dispersion agent and a binder-free network former. Simple washing can eliminate practically all of the CA in the CNT electrode while preserving the fibrous CNT network within the electrode. Furthermore, because the CA-CNT film is treated using a standard casting method rather than area-limited vacuum filtering, the CNT film electrode can be produced on a wide scale. The improved electrochemical performance and great flexibility of the complete cell built with CA-CNT-based electrodes are maintained even at high active material loading, which has proven challenging to achieve in the standard format of LIBs. Furthermore, by merely stacking six sheets of the freestanding CNT film electrode, a capacity of 5.4 mA h cm^{-2} is produced. Under considerable distortion, the pouch battery performs reliably. We show that a rational CNT electrode design may increase flexibility to greater energy than the conventional arrangement. We anticipate that the suggested freestanding CNT film electrode's low production cost, great flexibility, and outstanding electrochemical performance would hasten the adoption of wearable gears in daily life.

NM02.04.40
First-Principles Computational Study on Li_xC_{60} Nanoparticle—High-Performance Anode Material for Li-Ion Batteries Dong-Hwa Seo[1], Dae Hyung Lee[1], Linghong Yin[2], Jiung Cho[3], Su Jae Kim[2], Il Jeon[2], Injun Jeon[2], Mihee Park[2], Minjoon Park[2], Se-Young Jeong[2] and Chae-Ryong Cho[2]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Pusan National University, Korea (the Republic of); [3]Korea Basic Science Institute, Korea (the Republic of)

In the era of electric vehicles, lithium-ion batteries are demanded to have properties appropriate to electric vehicles, such as high energy density, superior rate performance, and long cycle stability. Unfortunately, current commercialized anode materials are not enough to fulfill all these requirements at once – graphite brings ~370mAh/g of capacity, which is insufficient to satisfy energy density demand, and silicon suffers from poor cycle performance due to severe volume expansion. In this work, the Li+ ion storage mechanism and structural evolution, which play a critical role in determining lithium-ion battery performances, are studied with first-principles calculation for face-centered-cubic (FCC) C60 nanoparticle, which is proposed as a high-performance anode material for lithium-ion batteries. Density functional theory (DFT) functionals are benchmarked for various LixC60 (x=0, 1, 2, 3, 4, 6, 8, 10, 12, 14) structures generated by genetic algorithm (GA) approach, and Li+ ion sites, electrochemical voltages, and phase transition behavior of LixC60 are predicted by SCAN+rVV10 DFT functional. These results are well-matched with the in-situ X-ray diffraction analysis and superior electrochemical performance of FCC C60 nanoparticles, the reversible specific capacity of 750 mAh/g at 0.1 A/g and retains coulombic efficiency of 98.7% after 1000 cycles at 5 A/g. Furthermore, it is figured out that competition between electrostatic repulsion and stress occurred by inserted Li+ ion governs phase transition behavior. We expect these atomic-level understandings will accelerate the development of superior lithium-ion batteries and electric vehicle dissemination.

Unconventional 2D Materials from Liquid Phase Synthesis Kimmo Mustonen[1], Christoph Hofer[2], Viera Skakalova[1], Alexander Markevich[1], Timothy Pennycook[2] and Jani Kotakoski[1]; [1]University of Vienna, Austria; [2]EMAT, Belgium

Current 2D materials largely derive from van der Waals -layered bulk structures. However, only a limited number of such structures exist under ambient conditions, and in total only a few dozen 2D crystals have been successfully synthesized or exfoliated. In contrast to previous contributions, in this talk I will discuss a so far unexplored scheme for liquid phase synthesis of 2D materials that is based on the use of graphene oxide (GO) bilayers acting as a template material and kinetic barrier. The GO layers in the presented scheme are of fundamental importance as they prevent crystal growth along out-of-plane high-symmetry directions, and thus the formation of bulk crystalline solids.

Among countless 2D materials that have been predicted based on first principle computations [1], the β-phase of CuI, which is only stable at a narrow temperature range of 645-675 K [2,3], is a prime example of a material that would be impossible to isolate in its monolayer form via exfoliation. In our recent contribution we have synthesized this particular material inside a GO envelope and via atomically resolved scanning transmission electron microscopy have subsequently characterized its structure in great detail [4]; these results will be discussed in the talk.

The applicability of our synthesis method, however, is not limited to this singular structure. Quite the contrary, we have already applied the same process to several other transition metal halides, including 2D silver iodide and magnetic nickel iodide crystals. Moreover, generalizing this concept should allow access to further exotic layered structures, which will vastly expand the currently available library of 2D materials and their incorporation in devices, hence facilitating their structure and properties to be studied in room temperature.

MXenes Expand the Range of 2D Materials Far Beyond Graphene Yury Gogotsi; Drexel University, United States

Discovery of new materials provides moments of inspiration and shifts in understanding, shaping the dynamic field of materials science. Following the graphene breakthrough, many other 2D materials emerged. Although many of them remain subjects of purely academic interest, others have jumped into the limelight due to their attractive properties, which have led to practical applications. Among the latter are 2D carbides and nitrides of transition metals known as MXenes [1]. The family of MXenes has been expanding rapidly since the discovery of Ti_3C_2 in 2011 [2]. More than 30 different stoichiometric MXenes have been reported, and the structure and properties of numerous other MXenes have been predicted. Moreover, the availability of solid solutions on M and X sites, multi-element high-entropy MXenes, control of surface terminations, and the discovery of out-of-plane ordered double-M *o*-MXenes (e.g., Mo_2TiC_2), as well as in-plane ordered *i*-MAX phases and their *i*-MXenes offer a potential for producing dozens of new distinct structures. This presentation will describe the state of the art in the manufacturing of MXenes, their delamination into single-layer 2D flakes and assembly into films, fibers and 3D structures. Synthesis-structure-properties relations of MXenes will be addressed on the example of Ti_3C_2. The versatile chemistry of the MXene family renders their properties tunable for a large variety of applications. In particular, the interaction of MXenes with electromagnetic waves can be controlled via their composition and structure. Many MXenes offer high electronic conductivity and outstanding electromagnetic interference shielding. They can also be used in telecommunication, energy, medical and electronic device applications.

Electrical Control of the Chemical Vapor Deposition of Graphene Jiangtao Wang, Ji-Hoon Park, Ang-Yu Lu and Jing Kong; Massachusetts Institute of Technology, United States

Chemical vapor deposition (CVD) is widely used for the efficient growth of low dimensional materials. The growth mechanism comprises the mass and heat transport, gas phase and surface chemical reaction, and the interaction between the product and the substrate/catalyst. Correspondingly, the controllable parameter space is conventionally focused on the mass flow of each component, the temperature of the reaction chamber and substrate, and the material and structure of the substrate/catalyst. Here, we report that applying voltage on the copper substrate has significant impacts on the growth of graphene. Electrochemical effect and ionic collision effect are observed in different conditions. With the assistance of negative and positive voltage applied on the growth substrate, selective growth and rapid growth of clean monolayer graphene film are achieved, respectively. We anticipate this discovery will open up a new dimension in methodology for the growth of 2D materials.

9:45 AM NM02.05.04
***In Situ* Observation of Dynamic Changes in Graphene by STEM** Hyunjeong Jeong[1], Dong Hoon Shin[2], Heena Inani[3], Kimmo Mustonen[3], Clemens Mangler[3], Yugyeong Je[1], Jani Kotakoski[3] and Sang Wook Lee[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Delft University of Technology, Netherlands; [3]University of Vienna, Vienna, Austria

We investigated *in-situ* observations of the dynamic changes in graphene by external stimuli such as Joule heating and electron beam irradiation. The carbon structure of graphene was directly observed under electron beam irradiation using a scanning transmission electron microscope (STEM). Suspended graphene was prepared on a Silicon nitride membrane substrate with a hole pattern and connected to electrodes. The Joule heating process by applying a high current can accumulate a high temperature in the middle of the suspended graphene region. In the case of the twisted bilayer graphene structure, the periodicity of the Moiré pattern was changed before and after the Joule heating process. This implies that small flakes of graphene may rotate at high temperature. We also report the observation of defect healing in graphene by electron beam irradiation and the Joule heating process.

10:30 AM *NM02.05.05
From Carbon Dots and Graphene Quantum Dots to HBCs and Beyond Dirk M. Guldi; University of Erlangen, Germany

Carbon is the key to many technological applications that have become indispensable in our daily life. Altering the periodic binding motifs in networks of sp^3-, sp^2-, and sp-hybridized C-atoms is the conceptual starting point for a broad palette of carbon allotropes. The past two decades have served as a test-bed for measuring the physico-chemical properties of low-dimensional carbon with the advent of fullerenes (0D), followed in chronological order by carbon nanotubes (1D), carbon nanohorns, and, most recently, by graphene (2D). These species are now poised for use in wide-ranging applications. Expanding global needs for energy have led to a significant effort to develop alternatives to fossil fuels. While alternative sources for energy are already in use, they comprise a small percentage of the energy demands needed to carry us through the 21st century. No single source will solve the global needs, but the development of photovoltaics has vast potential as a point-of-use power source. Recent work has shown that hybrid photoelectrochemical efforts with a percolation network of photon absorbers coupled to an electron/hole transporter in combination with advanced photon management are the ideal design for realizing breakthroughs in high photon conversion efficiencies suitable for the catalysis of water.
I will report on our efforts regarding a unifying strategy to use the unprecedented charge transfer chemistry of carbon dots and HBCs, together in a groundbreaking approach to solving a far-reaching challenge, that is, the efficient use of the abundant light energy around us.

11:00 AM NM02.05.06
The Correlation Effect Between Growth Parameters for Hexagonal Boron Nitride via Machine-Learning Approach Ji-Hoon Park, Ang-Yu Lu and Jing Kong; Massachusetts Institute of Technology, United States

The large-area, high-quality growth of monolayer hexagonal boron nitride (hBN) was realized by the epitaxy through the step-edge guided nucleation on the wafer-scale single-crystalline metal surface. However, a systematic understanding of the growth dynamics based on the growth parameters is required for not only a clear explanation of the growth mechanism but also the synthesis into the desired direction including the reproducibility and functionalization of materials. Here, we synthesized monolayer hBN on single-crystalline Cu (111) at low pressure by chemical vapor deposition method. The nucleation density and flake size of hBN were controlled by the concentration of borazine as a precursor of hBN during the growth process. Furthermore, we systematically investigate the growth mechanism from single parameter to two parameters effect by the Gaussian process method in Machine-learning, allowing us to explore the correlation between growth parameters. This approach will open new insight for the systematic understanding of the growth mechanism of novel materials.

11:15 AM NM02.05.07
Text Mining of CVD Synthesis Recipes for 2D Materials by Natural Language Processing Ang-Yu Lu[1], Richard Chen[1], Aijia Yao[1,2], Ji-Hoon Park[1], Tianyi Zhang[1], Xudong Zheng[1], Nannan Mao[1], Jiangtao Wang[1] and Jing Kong[1]; [1]Massachusetts Institute of Technology, United States; [2]ShanghaiTech University, United States

Tremendous and precious scientific knowledge is written in text format as journal articles. This enormous unstructured data is challenging for humans to analyze and develop comprehensive perspectives from the past. Recently, natural language processing (NLP) has made significant advances in word embedding, especially with the launch of pre-trained models (e.g., BERT, GPT). Materials science has attempted to apply this breakthrough by converting unstructured data into structured data, but so far this is limited to very general methods and materials, and the provided information is not yet beyond researchers' domain knowledge. In this work, we adopt the state-of-art NLP technique to collect synthesis recipes from journal articles for seven low-dimensional materials, including CNT, graphene, hexagonal boron nitride (hBN), molybdenum disulfide (MoS_2), molybdenum diselenide ($MoSe_2$), tungsten disulfide (WS_2), and tungsten diselenide (WSe_2). First, we deploy a fine-tuning BERT model without manual annotation by calculating the term frequency of the titles and combining them with our prior knowledge, allowing us to extract CVD-related titles. Furthermore, we apply keyword searching fusion with a fine-tuning BERT model to classify the CVD abstract as Correlation Output, such as monolayer, bilayer, multilayer, and nanostructures. Lastly, we implemented the BERT model for named entities recognition (NER) to extract experimental recipes as Correlation Input. Through statistical analysis, we discover the correlation among the recipes and their results for each material and unravel the synthesis trajectory between different materials. Our work may serve as a methodology for applying natural language processing in optimizing existing 2D materials and accelerating the exploration of new advanced materials.

11:30 AM NM02.05.09
All-Dry Transfer of Large-Area CVD-Graphene Using Vapor Phase Deposited Smart Thermally-Responsive Pressure Sensitive Adhesive Thin Films Kurtulus Yilmaz, Mehmet Gursoy and Mustafa Karaman; Konya Technical University, Turkey

Since its first isolation from graphite using the simple scotch tape method in 2004, extensive effort has been put by the researchers on graphene due to its intriguing properties, such as high electron mobility, superior electrical and thermal conductivity, extraordinary tensile strength and superior mechanical properties. The transparency of a single-layer graphene is excellent, with very low absorption of the incident light. The prerequisite for making use of such extraordinary properties in real-world applications is to synthesize single or few-layer graphene at large scales on different types of application surfaces. Among the different synthesis protocols, chemical vapor deposition (CVD) appeared to be the ideal bottom-up technique to synthesize graphene in large areas and at high qualities. In CVD, graphene is deposited on atomically smooth metallic substrates, which necessitates a post-deposition stage in order to transfer as-deposited graphene to the real application surface. The transfer of graphene from the metallic growth substrate to other substrates must be carried out perfectly without compromising the quality and properties. The conventional methods for the transfer of CVD-graphene adopt poly(methyl methacrylate) (PMMA) as the support layer. This multi-stage "wet" approach has many drawbacks including the structural degradation during the PMMA removing process. Instead of conventional wet approaches, this study demonstrates an all-dry transfer protocol, in which graphene is transferred using "smart" thermally-responsive polymeric thin films possessing switchable adhesive strength depending on the temperature. A pressure sensitive adhesive film based on poly(acrylic acid) and poly(ethylhexyl acrylate) was deposited on a flexible template material using initiated CVD (iCVD) technique. Thus, surface of transfer film coated with smart PSA became a suitable platform for the adhesive transfer of graphene. The structure and morphology of the as-deposited PSA film was tuned precisely by iCVD, which was verified by FTIR and AFM analyses, respectively. There was a sharp decrease in adhesive strength of the as-deposited PSA films with increasing temperature from 25 to 80 ºC, which allowed the design of a smart adhesive-based transfer surface acting like a pick&place gripper. In this way, it was possible to remove CVD-graphene from copper surface at large areas (100 mm x 100 mm) uniformly at room temperature and place the same graphene on glass substrates at 80ºC. The measurement of optical, electrical and morphological properties of the as-transferred graphene on glass substrates revealed that the PSA-based all-dry technique was superior to the conventional wet technique. PSA-based all-dry technique allowed the re-use of the copper at least three times without compromising the quality of as-deposited graphene, and it was applicable for the transfer of CVD-graphene to different flat application surfaces, including metals and plastic foils.

1:30 PM *NM02.06.01
Quantifying Adsorbed Dispersant Layers on Single-Wall Carbon Nanotubes in Simple and Complex Environments Jeffrey Fagan; National Institute of Standards and Technology, United States

Dispersion of single-wall carbon nanotubes (SWCNT) as individual objects in most liquid environments requires the use of an adsorbing dispersing agent such as a small molecule surfactant, dispersant such as DNA, or polymer chain to modulate the interactions with other nanotubes and the solution. The exact structure and density of these dispersing agents controls the stability of the dispersed nanotubes and affects their electronic and optical properties. Importantly, these molecules also enable a variety of separation methods for SWCNTs to purify them from impurities or to select for classes of SWCNTs such as semiconducting or metallic, or even for single species (n,m) structures. In particular, aqueous two-phase extraction using either cosurfactant competition or selective DNA sequences depend on the adsorbed interfacial dispersant layer to determine the achieved separation.

In this talk I will present the use of analytical ultracentrifugation to determine the adsorbed dispersant density on different nanotube species first for single species and surfactants, and then for complex environments including competing surfactants and polymer molecules. The quantification of the bound

surfactant quantity and identity as a function of solution concentration on the nanotubes enables the direct testing of separation mechanisms and a measurand for optimization of separation conditions.

2:00 PM *NM02.06.02
Electroluminescence from Single-Walled Carbon Nanotubes with Quantum Defects Min-Ken Li[1,2], Adnan Riaz[1,2], Martina Wederhake[3], Karin Fink[1], Avishek Saha[4], Simone Dehm[1], Xiaowei He[4], Friedrich Schöppler[3], Manfred Kappes[1], Han Htoon[4], Valentin Popov[5], Stephen Doorn[4], Tobias Hertel[3], Frank Hennrich[1] and Ralph Krupke[1,2]; [1]Karlsruhe Institute of Technology, Germany; [2]Technische Universität Darmstadt, Germany; [3]Julius Maximilian University Würzburg, Germany; [4]Los Alamos National Laboratory, United States; [5]University of Sofia, Bulgaria

Individual single-walled carbon nanotubes with covalent sidewall defects have emerged as a new class of photon sources whose photoluminescence spectra can be tailored by the carbon nanotube chirality and the attached functional group/molecule. Here we present electroluminescence spectroscopy data from single-tube devices based on (7, 5) carbon nanotubes, functionalized with dichlorobenzene molecules, and wired to graphene electrodes. We observe electrically generated, defect-induced emissions that are controllable by electrostatic gating and strongly red-shifted compared to emissions from pristine nanotubes. The defect-induced emissions are assigned to excitonic and trionic recombination processes by correlating electroluminescence excitation maps with electrical transport and photoluminescence data. At cryogenic conditions additional, gate-dependent emission lines appear which are assigned to phonon-assisted hot-exciton electroluminescence from quasi-levels. Similar results were obtained with functionalized (6, 5) nanotubes. We also compare functionalized (7, 5) electroluminescence data with photoluminescence of pristine and functionalized (7, 5) nanotubes redox-doped using gold(III) chloride solution. This work shows that electroluminescence excitation is selective toward neutral defect-state configurations with the lowest transition energy, which in combination with gate-control over neutral versus charged defect-state emission leads to high spectral purity.

2:30 PM NM02.06.03
Programmable Helicity in Optically Active One-Dimensional van der Waals Solids Dmitri Cordova[1], Kenneth Chua[1], Tyler Kerr[1], Toshihiro Aoki[1], David Knez[1], Grigorii Skorupskii[2], Dmitry Fishman[1] and Maxx Arguilla[1]; [1]University of California, Irvine, United States; [2]Princeton University, United States

Long-range helicity in condensed materials has sternly relied on the precise ordering of cooperative intra- and inter-molecular bonding interactions. The exclusivity of these interactions in natural, organic, or molecular systems has limited the conclusive demonstration of aperiodic helical motifs in densely packed solid state lattices. In this talk, we will present a class of 1D van der Waals solids that crystallize as weakly bound helical chains that possess atomic scale order consistent with an aperiodic tetrahelix. We will describe how precise atomic level control of the local coordination environment in these 1D vdW lattices induces helical aperiodicity in periodic helical motifs based on repeating screw axis symmetry motifs. We will also highlight herein that the modularity of vdW lattices allows for the systematic engineering of helical attributes (radius, rise, and twist angle) and band gap energies across the visible to the near-UV spectral window. Owing to the intrinsic non-centrosymmetry of aperiodic helices, we will show that these 1D vdW tetrahelices exhibit visible range second harmonic generation in freestanding crystals from the bulk down to the nanoscale. Lastly, we will demonstrate that the weak vdW interchain interactions in these 1D vdW tetrahelices enables the micromechanical exfoliation into single ~1 nm diameter helical chains. The realization of exfoliatable 1D vdW tetrahelices presents a unique materials platform towards understanding the synthetic design rules towards helicity and chirality in low-dimensional solids. Atomically-precise helicity along these length scales will facilitate new opportunities in designing solid state materials towards sub-nanoscale nonlinear chiroptics, long-range spin polarization via chiral induced spin selectivity, and 1D topological helicoid quantum states.

3:15 PM *NM02.06.04
Macroscopically Aligned Carbon Nanotubes for Photonics, Electronics and Thermoelectrics Junichiro Kono and Jacques Doumani; Rice University, United States

The remarkable flexibility, stable chemical structure, and extraordinary thermal, electrical, and optical properties of carbon nanotubes (CNTs) are promising for a variety of applications in flexible and/or high-temperature electronics, optoelectronics, and thermoelectrics, including wearables, refractory photonics, and waste heat harvesting. However, the long-standing goal in the preparation of CNT ensembles is how to maintain the extraordinary properties of individual CNTs on a macroscopic scale. The polydispersity and randomness remain two main challenges. Here, we will discuss different methods for creating macroscopically aligned CNTs, including spontaneous formation of wafer-scale aligned CNT films via controlled vacuum filtration and production of ultrahigh-conductivity CNT fibers and films through solution spinning and coating. We will then describe the optical, dc and ac electrical, thermal, and thermoelectric properties of these materials. These results are promising for device applications in various fields such as flexible CNT broadband detectors, spectrally selective thermal emitters, and thermoelectric devices.

Novel Techniques for Characterising Graphene Nanoplatelets Using Raman Spectroscopy and Machine Learning Vicente Orts Mercadillo[1,2,3], Ian Kinloch[1,2,3] and Mark A. Bissett[1,2,3]; [1]National Graphene Institute, United Kingdom; [2]Henry Royce Institute, United Kingdom; [3]The University of

Manchester, United Kingdom

A significant challenge for graphene nanoplatelet (GNP) manufacturers is meaningful characterisation in industrial environments. This has been further exacerbated by the recent push to functionalise GNPs for better compatibility within nanocomposite matrices [1]. Raman Spectroscopy is a fast, facile, and accessible technique for graphene characterisation. The heterogeneity of GNP powders requires that hundreds of Raman spectra are acquired and analysed, to achieve a representative sample [2].

In this work commercially available GNPs are plasma oxygenated, aminated and fluorinated. A peak fitting algorithm was developed to reliably fit hundreds of Raman spectra from mappings, and the curve parameters fed into a binary Random Forest classifier to discern between functionalised and unfunctionalised GNPs. This type of classifier can be used to identify which combination of features are most affected by functionalisation, e.g., fluorination primarily alters the I2D/IG ratio and the G peak FWHM.

Furthermore, computer vision was used to demonstrate a proof of concept for rapid factory floor quality control. A convolutional neural network (CNN) was trained to infer the presence of functional groups directly from Raman spectra with high accuracies.

Graphene-Based Metamaterial for On-Demand Spectral Absorption Tailoring in the Mid-Infrared Romil Audhkhasi, Mashnoon A. Sakib and Michelle Povinelli; University of Southern California, United States

We propose a graphene-based metamaterial to achieve electrically-tunable spectral absorptivity in the infrared. The metamaterial comprises of a periodic array of coupled metal-insulator-metal resonator pairs. Each of these has an electrically tunable resonance wavelength owing to the presence of graphene. The structural parameters of the two resonators in each unit cell are chosen to implement a dark-bright mode coupling scheme in the context of temporal coupled-mode theory. The relative spectral position, and in turn the coupling between consecutive resonators, can be tuned by modulating the Fermi energy of graphene. Using our metamaterial absorber, we demonstrate the ability to modulate the amplitude of spectral features in the infrared. The spectral response of the metamaterial can be tuned from single-peaked to double-peaked absorption or vice versa by tuning the bright resonator towards or away from the dark resonator, respectively. Our results thus suggest the possibility of achieving tunable multi-band absorption using metamaterials composed of multiple coupled resonators. This ability to dynamically modulate spectral absorptivity can potentially benefit several applications such as infrared imaging and thermal management.

Surface Charge Induced Exciton Localization in Surfactant-Wrapped Single Walled Carbon Nanotubes Erin E. Christensen, Trevor M. Tumiel, Mitesh Amin and Todd Krauss; University of Rochester, United States

As-synthesized, semiconducting single-walled carbon nanotubes (SWCNTs) are nominally charge neutral. However, ionic surfactants that are commonly used to disperse SWCNTs in solution lead to heterogeneous surface charge buildup along the nanotube. In this presentation, we will discuss how electrostatic force microscopy (EFM) was used to characterize the static-charge interactions between an individual SWCNT and its local environment. EFM is a modification of atomic force microscopy (AFM) which allows for a quantitative determination of localized charges at the nanometer scale. We found nonuniform spatial charge distributions along the nanotube length with wildly varying magnitudes ranging between ±15 *e* for dozens of long SWCNTs (> 1.5 microns) solubilized in aqueous suspension using standard ionic surfactants. EFM images after photoexciting the nanotubes show how these distinct, localized regions of charge on the nanotube can act as electrostatic potential barriers for exciton transport. Model calculations indicate that the large inhomogeneous surfactant aggregates along the nanotube warp the potential energy for the exciton which may lead to localized PL in a manner reminiscent of luminescent sp^3 defects, a result that is most apparent in our correlative AFM and single molecule optical measurements. We have been able to correlate single molecule photoluminescence (PL) spectroscopy and AFM images of the same individual SWCNTs and show that charged surfactant covered areas on the nanotube exhibit brighter, redshifted photoluminescence spectra relative to neutral charge regions. Altogether, our experimental results and theoretical work presents a possible explanation for the source of the potential energy minima along the nanotube that localize excitons.

Optical Properties of Bioresource-Derived Colloidal Nitrogen-Doped Graphene Quantum Dots as Biomarkers Elena D. Obraztsova[1,2], Pavel V. Fedotov[1,2], Darwin Kurniawan[3] and Wei-Hung Chiang[3]; [1]A.M. Prokhorov General Physics Institute, RAS, Russian Federation; [2]Moscow Institute of Physics & Technology, Russian Federation; [3]3 National Taiwan University of Science and Technology, Taiwan

The atmospheric pressure microplasma system was utilized to convert a natural low-cost and biocompatible chitosan into nitrogen-doped graphene quantum dots (NGQDs) with adjustable sizes controlled with Photoluminescence (PL) and Raman measurements. The nucleation, growth, and simultaneously N doping of GQDs were achived. The rapid synthesis does not need the strong acids and bases, toxic solvents and chemicals, as well as high temperature and vacuum conditions [1]. The appearance of NGQDs with diameter of 4-6 nm and graphene-like nuclei has been confirmed by high resolution transmission electronic microscopy (HRTEM) measurements. The QDs with 4 different diameters have been investigated. Then the PL maps (emission vs excitation) have demonstrated a size-dependent position of resonant PL signal. The size-dependent Raman signals were registered under excitation by radiation of He-Cd laser (325 nm). There was a strong PL background in the spectrum under excitation with longer-wavelength radiation. This effect confirms a 0-dimension structure of the material formed.
The synthesized NGQDs can be used for facile and sensitive pH detection with a broad range (pH 1.25 to 13.56) using PL, UV-Visible absorbance and Raman spectroscopies. By adjusting the pH condition during the detection, thereby establishing a rapid screening system for biomarkers, multiple biomolecules including uric acid (UA), folic acid (FA), epinephrine (EP), and dopamine (DA) can be simultaneously detected with high selectivity and sensitivity using a single material only.
This work opens a new approach in biomedical applications of NGQDs as well as in the early detection and diagnosis of diseases and in the development of new drugs.
The work was supported by RSF/MOST Grant no. 20-42-08004 (110-2628-E-011).

Size Fractionation of Graphene Oxide via Flow Field-Flow Fractionation for Reinforced Graphene Fiber Hee Jae Choi and Sang Ouk Kim; Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of)

Many interesting properties of 2D materials and their assembled structures are strongly dependent on the lateral size and size distribution of 2D materials. Accordingly, effective size separation of polydisperse 2D sheets is critical for desirable applications. Here, we introduced flow field-flow fractionation (FlFFF) for wide-range size fractionation of graphene oxide (GO) up to 100 μm. Two different separation mechanisms are identified for FlFFF, including normal mode and steric/hyperlayer mode, to size fractionate wide size-distributed GOs while employing a crossflow field for either diffusion or size-controlled migration of GO. We confirmed the chemical composition and defect density of GO are directly proportional to its size. Using size fractionated GOs, three different graphene fibers were fabricated. The microstructure of graphene fibers is strongly affected by their building block size. We also investigated the 2D sheet size-dependent mechanical and electrical properties of three different graphene fibers produced from size-fractionated GOs. This FlFFF-based size selection methodology can be used as a generic approach for effective wide-range size separation for 2D materials, including rGO, TMDs, and MXene.

NM02.07.02
Radial-Hierarchy Mesoporous Carbon Sphere with a Hollow Structure for High-Performance Supercapacitors Hojong Eom, Jihyeon Kang, Seohyeon Jang, Seyoung Choi, Ohhyun Kwon, Junhyeop Shin, Jongkwon Park and Inho Nam; Chung-Ang University, Korea (the Republic of)

Supercapacitors are one of the most ideal energy storage systems due to their fast charge-discharge rate, stable cycle performance, and power density. As the electrode materials, the physicochemical properties including surface area, pore size, and structural morphology influence the electrochemical performance of the system. Therefore, significant improvement has been made in the research field of electrode materials for supercapacitors. Various materials could be considered as the proper electrode materials for supercapacitors; however, the carbonaceous materials are the most commonly used as electrodes owing to their large surface area, adjustable pore structure, and high electrical conductivity abundant availability, and excellent electric double-layer properties.
To synthesize suitable carbonaceous materials for electric double-layer capacitors (EDLCs), the morphology of the porous structure is the main parameter. The carbonaceous materials which have proper pore size and structure provide a large surface area for accumulating electrostatic charges and a favorable diffusion pathway for electrolyte ions. Many previous studies have proven that mesoporous carbonaceous material can enhance their electrochemical properties such as adsorption, separation, catalysis, and energy storage capacity, thus broadening their applications. Especially ordered mesoporous carbons (OMCs) such as CMK, FDU, KIT, and MSU have received considerable attention in recent decades. However, the monotonous and relatively long porous channels diminish ion mobility in their form and result in the overall degradation of the energy storage system performance at the high current density. Herein, we report a facile method for the synthesis of a carbon allotrope based on a hollow sphere with a radial mesoporous hierarchy. There has been substantial research on both OMCs and hollow carbon spheres (HCSs), however, the combined structure of the thick mesoporous-shell and hollow-core has rarely been studied until recently. The mesoporous carbon hollow spheres (MCHSs) endow an ordered radial channel and space-saving stacking based on their spherical morphology. Compared to other carbonaceous materials, the MCHSs have the combined advantages of OMCs and shell-like carbon spheres, especially for application in supercapacitors.
To synthesize the MCHSs, hierarchically and radially mesoporous silica was utilized as a template. The dandelion-shaped mesoporous silica spheres have been exploited in various fields since their first report. Here, the mesoporous edge of the dandelion-like silicas (DSSs) was directly replicated, whereas the core of the DSSs was engraved as a hollow structure. This is referred to as the “Dual-templating method.” To optimize the structure of the MCHSs, the composition of templates and precursors was changed. The optimal condition (MCHS-0.5) shows well-developed hierarchical and radial mesopores in the carbon shell and hollow core in the center of the carbon sphere. The carbon shell with narrow pore-size distribution and large surface area (1319 m^2/g) provides a short ion-diffusion path and big specific capacitance. Also, the hollow structure endows the space for electrolyte penetration and retention. These structures play a role in improving their electrochemical performance in comparison to the existing carbonaceous materials. The MCHSs show a specific capacitance up to 135.9 F/g at 10 mV/s and present a well-developed EDLC shape at all scan rates (10 to 1000 mV/s) that qualified them as ideal electrode materials for EDLCs. The short pore length and radially interconnected pore structure combined with controlled surface chemistry would be beneficial for improving the energy density and electrical performance of supercapacitors without aggravating their high-power density and long lifecycle.

NM02.07.03
3D Printed Nanocomposites of Hexagonal Boron Nitride Nanosheets Mustafa C. Gorur, Doga Doganay, Mete Batuhan Durukan and Husnu E. Unalan; Middle East Technical University, Turkey

Additive manufacturing is a fast and cost-effective approach to prototype production. Complex shapes can be produced and the product can be optimized for maximum productivity using different print settings. Polylactic acid (PLA) is the most widely used polymer for additive manufacturing due to its easily formable and recycleable nature. In this study, we prepared thermally conductive and electrically insulating 3D printable filaments composed of hexagonal boron nitride nanosheets (BNNSs) and PLA matrix. A filament winder was assembled to produce filaments with a diameter of 1.75 mm. Simultaneously, BNNS additives were exfoliated with shear exfoliation method. Recycling process increased the fabrication yield, where mono or few layer BNNSs were obtained as revealed by detailed characterizations. Exfoliated BNNS showed better thermal diffusion rate in the composite structure compared to the pristine powder. This was due to the prevention of phonon scattering upon decreasing the number of BNNS layers. Detailed characterizations and 3D printed electronic devices that demonstrate the thermal effect of BNNS will be presented.

NM02.07.04
Electrical and Optical Properties of Suspended and Horizontally-Aligned Carbon Nanotubes Under Thermal Light Emission Hyeonhui Jeong[1], Hyunjeong Jeong[1], Yugyeong Je[1], Sungil Jo[2], Goowhan Jeong[2] and Sangwook Lee[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Kangwon National University, Korea (the Republic of)

We have studied the electrical and optical properties of thermal light emission in carbon nanotubes (CNTs). Aligned CNTs were synthesized by chemical vapor deposition on the ST cut single crystal quartz substrate and transferred on the predefined electrode with trench structures. A light emission phenomenon due to the joule heat occurs when a current flows through the suspended CNTs. A voltage was applied to the electrode pad to conduct a current-voltage characteristic and transport study. Based on these results, we found conditions for stable light emission in CNTs, and the optical and

electrical properties changed by light emission were confirmed. Moreover, the details of device fabrication and possible application of our device will be suggested in this presentation.

NM02.07.06
Fabrication of 3D Porous Anode Electrode for Fast Charging Lithium Ion Secondary Battery Using Dry Transfer and Laser Processing
Hyungcheoul Shim[1,2], Seungmin Hyun[1,2] and Jung Bin In[3,3]; [1]Korea Institute of Machinery and Materials (KIMM), Korea (the Republic of); [2]Korea University of Science and Technology (UST), Korea (the Republic of); [3]Chung-Ang University, Korea (the Republic of)

The development of next-generation secondary batteries hinges on the design of energy storage materials with high-rate properties capable of high-speed charge/discharge. For example, in order to eliminate 'range anxiety,' which is one of the key problems that makes people hesitate to acquire electric vehicles, it is necessary to build a rechargeable battery that can be recharged in minutes.
The high current density applied to the electrode during high-speed charging/discharging, however, generates a lithium ion concentration gradient inside the electrode, which causes a variety of issues. Furthermore, one of the key reasons for the difficulties in creating energy storage materials with high high-rate qualities is the material's inherent properties, such as ion transport restriction.
We used laser processing and a dry transfer procedure to create a negative electrode plate for a lithium ion secondary battery with a surface aligned in a certain orientation. When compared to the existing electrode plate, laser-induced graphene (LIG), a porous three-dimensional nanomaterial generated by laser processing, had a higher specific surface area and a three-dimensional network structure. The fracture surface of the LIG, whose plane orientation was configured in this easy-to-transfer direction, was discovered to have a significant impact on rate capabilities.
A commercially available polyimide (PI) film (thickness: 125 μm, Kapton) was used to make the LIG-based negative plate used in this investigation, which was treated with a CO_2 laser with a wavelength of 10.6 μm. The irradiated laser had a power output of 5.4 W, and the scan speed and pitch were kept at 200 mm/s and 125 μm, respectively. Press-type roll forming was used to transfer the so produced LIG to a copper substrate with a thickness of around 20 μm, with the distance between the rolls controlled between 70 and 200 μm and the specimen feed rate controlled between 10-100 mm/s. For electrochemical evaluation, the negative plate was made up of 2032 typed coin cells, and for material evaluation, scanning electron microscopy (SEM), transmission electron microscopy (TEM), X-ray diffraction (XRD) analysis, X-ray photoelectron spectroscopy (XPS), and Raman spectroscopy were used.
Despite applying a high current density of 20 A/g at a loading level of around 3 mg/cm^2, this electrode obtained a discharge capacity of 114 mAh/g within 3 minutes, corresponding to 95 percent of the material. The great specific surface area of nanomaterials like graphene, as well as the three-dimensional structure in which the surface is oriented in a precise direction due to dry transfer, account for the unusually high rate.
In other words, the lowered internal charge transfer resistance helps to realize high rate characteristics because the holey-structured graphene with high porosity due to laser processing is well stacked in a three-dimensional structure. Furthermore, because the electrode surface is structured in a structure with multiple edge plane exposures, it was feasible to create an anode material with high rate characteristics by shortening the lithium ion transport and diffusion distance.
This method can be easily applied to the current negative electrode material and electrode manufacturing process for lithium ion secondary batteries, and it has the potential to be extended and applied to material manufacturing methods for a variety of applications that improve charge and ion transport.

NM02.07.07
Infrared Thermal Management with Graphene Ihsan Uluturk; US Army Combat Capabilities Development Command Soldier Center, United States

The main purpose of textiles throughout history is to regulate heat flow and provide warmth or decrease excessive heat for the wearer. In recent times, the textile industry has developed new materials that can ensure the wearer stays dry in hot environments and that repel moisture. The main downside of these new textiles, however, is that their electromagnetic response has not been fully optimized, allowing too much radiation to be absorbed and radiated back to the skin, causing the wearer to overheat. Our work is composed of two parts: simulation and experimentation. Simulations will first be conducted to better understand graphene chemistry, as graphene will be screen printed onto textiles for testing.

In this work, heterostructures made of NPG-$FeCl_3$-Ag mirror are considered, where NPG is nanopatterned graphene. This system is a representative of a Fabry-Perot type of cavity, where incident infrared light interacts strongly with NPG. The thickness of $FeCl_3$ will be chosen to be a quarter of the infrared wavelength in order for the amplitude of the infrared light to be maximal at the position of the NPG sheet.
Finite-difference time domain (FDTD) simulations show narrow resonance peaks in the absorbance (=emittance) due to localized surface plasmons (LSPs) in NPG. $FeCl_3$ is intercalated in NPG in order to shift the Fermi energy of graphene to E_F=-0.6 eV.
The positions of the resonance peaks can be tuned in the range between 3 mm and 12 mm by means of the number of graphene layers.
When the number of graphene layers is increased, the conductivity is multiplied by the number of layers, which results in a blueshift of the LSP peaks. By increasing the radius of the holes and the period of the hexagonal lattice of holes, the LSP peaks are redshifted.
For highly doped graphene layers with a small layer of $FeCl_3$ of around 50 nm between graphene and the Ag mirror, the absorbance (emittance) between 3 mm and 12 mm is around 2%, independent of the number of graphene layers. Such heterostructures could be useful for thermal management systems.
Based on the simulation results, we will be fine tuning the graphene chemistry. Resultant graphene paste will be screen printed onto textiles in the form of different geometries. Graphene printed textiles will be characterized using in-house developed Delta T measurement system. In this system, anodized Aluminum with an emissivity of 0.77 is used, which is smaller than the emissivity of human skin (95% to 98%). The anodized aluminum is placed on a hot plate and a thermocouple. The hot plate is heated up to 38 C to simulate the body temperature and standoff is created between textile and hot plate. Thermocouples will be used to measure the temperature difference between the printed and plain textiles to see if the printing has a significant effect on the thermal management property of textiles.

NM02.07.08
Chiral Sorting of Carbon Nanotubes Using Tripeptides Jack W. Devlin and Isaac Macwan; Fairfield University, United States

There are many potential applications of carbon nanotubes (CNTs) in flexible electronics, biosensors, fuel storage materials and charge storage devices. CNTs can be categorized as either metallic or semiconducting depending on their chirality, which in turn is influenced by the electronic properties based on the delocalization of the fourth electron in the sp2 hybridized orbital. Before using CNTs in potential large-scale applications, it is required that they be sorted out and separated based on their chiral vectors into metallic or semiconducting to be used for their respective purposes in electronics and bioengineering. Other methods such as electrophoresis, ultracentrifugation and chromatography have been used in the past to separate CNTs, but have been found to be expensive and lacking efficiency. We propose a study with nine different tripeptides to sort through a mixture of multi-walled (50-90 nm diameter) and single-walled (0.78 average dimeter) CNTs. We analyzed the interactions of the tripeptides having glycine as the repeated amino acid at the center of each tripeptide and the positive, negative, polar and non-polar flanking residues. It is found that tripeptides with threonine as one of the flanking residues have a high affinity for metallic CNTs, whereas those with an uncharged polar group or negatively charged group have a high affinity for semiconducting CNTs. Based on our prior simulation data on the different scenarios with different tripeptides and CNTs, we understood the initial interactions between the tripeptides and different chirality CNTs. However, this has never been experimented in a laboratory before. In order to analyze our results, we used a UV/vis spectrophotometer and circular dichroism spectroscopy to show the chirality and hence the nature of the sorted CNTs. In future,

we plan on implementing the sorted metallic multi-walled and single-walled CNTs to fabricate a scaffold that can be electrically stimulated for bioengineering applications of cell culture and communication. The importance of having CNTs as the substrate is to be able to accurately measure the electrical stimuli of cells. CNTs are more suitable due to their sensitivity, greater surface area to volume ratio, and excellent electrical conductivity allowing for a wider range of applications and fabrication from electrodes for neural recording to substrates for stimulating biological cells.

NM02.07.09
Chiroptical Effect in Aligned Carbon Nanotube Films Jacques Doumani[1,1,2], Oliver Dewey[1,1], Minhan Lou[2], Yohei Yomogida[3], Matteo Pasquali[1,1,1], Kazuhiro Yanagi[3], Junichiro Kono[1,1,1] and Weilu Gao[2]; [1]Rice University, United States; [2]The University of Utah, United States; [3]Tokyo Metropolitan University, Japan

In this work, we investigate the unique chiroptical response of large-scale aligned films of racemic, chirality-mixture carbon nanotubes (CNTs) prepared using the controlled vacuum filtration technique. The prepared solid-state films display large circular dichroism (CD) signals (45 mdeg/nm) in the ultraviolet (UV) range, peaked at 264 nm and 317 nm. The strength and sign of CD signals depend on sample positions and vary from sample to sample. Detailed scanning electron microscopy studies revealed a rotation of alignment directors between layers in aligned CNT films. This spontaneously formed twisted stack of aligned CNT thin layers during vacuum filtration leads to a structure-induced optical chirality. Finally, we demonstrate that CD signals can be controlled - either enhanced or suppressed - by engineering the vacuum filtration processes, such as tweaking the shape of the filtration-funnel and adding mechanical vibrations.

NM02.07.10
Faradaic Reactive MoS2-Carbon Frameworks for Ultrahigh-Energy-Density Electrochemical Capacitors Jaehoon Ji and Jong Hyun Choi; Purdue University, United States

The demand for high-performance energy storage devices has grown at an astonishing pace for various applications including portable electronic gadgets and electric automobiles. Among diverse electrochemical energy devices, pseudocapacitors may be one of the promising candidates to fulfill the requirements of high power (e.g., > 3000 W/kg) and energy (e.g., > 50 Wh/kg) densities.[1] The pseudocapacitors can demonstrate not only large capacitive energy storage but also fast rechargeability and long cyclic stability. Despite the excellent characteristics, one major drawback of the pseudocapacitors has overshadowed their practical use. It is their low energy density compared to that of the ion batteries (over 100 Wh/kg).

To overcome the limitation, one may improve the energy storage mechanisms: surface-controlled electrical double-layer capacitance (SDC) and diffusion-controlled faradaic pseudocapacitance (DFC).[2] The SDC-driven mechanism is highly affected by the specific surface area of the electrodes since it is determined by the extent of accumulated charges at the electrode. On the other hand, the energy storage by the FPC process may originate from the charge transfer between the electrode and the ions via faradaic reaction. Therefore, the energy density of a pseudocapacitor may be boosted by enhancing the surface area and the faradaic reactivity of the electrode.

In this work, we introduce a ternary composite electrode made of carbon nanotubes (CNT), zeolitic imidazolate frameworks (ZIF), and molybdenum disulfide (MoS2) to improve SDC and DFC simultaneously. The hybrid electrode demonstrates an ultrahigh energy density that can rival those of lithium-ion batteries, while maintaining the excellent properties of capacitors. This was made happen by exploiting the distinct benefits of the heteromaterials and engineering the morphology of the composite. The percolated CNT provide a robust scaffold with high conductivity for a quick charge transfer.[3] The carbon networks are coated with porous ZIF structures, allowing a fast ion diffusion and offering a large surface area. In the CNT-ZIF-MoS2 composite, the MoS2 layer from topochemical synthesis presents densely-packed petal-like morphologies. The MoS2 structure was developed to bear many sulfur vacancies which may serve as active sites for faradaic reaction. The hierarchical pseudocapacitor electrode thus increase not only the specific surface area for SPC-based storage but also the considerable faradaic reactivity to boost electric currents and capacitance.

Our ternary pseudocapacitor demonstrates an ultrahigh energy density of over 100 Wh/kg which may be comparable to the performance of typical ion batteries. The composite electrode also demonstrates a quick charging/discharging behavior with a maximum power density of well over 10 kW/kg. Additionally, it shows a highly stable cyclic behavior over 25,000 cycles. The new approach presented in this work may open new possibilities for developing future electrochemical capacitors.

Highly Bendable Graphene Liquid Crystalline Fiber via Molecular Level Lubrication of 0D Nanodiamond Jin Goo Kim and Sang Ouk Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Graphene fiber, composed of 2-dimensional graphene sheets, is one of the new class of carbon-based fiber with distinctive material properties particularly useful for electro-conductive components for wearable devices. Nowadays, flexible graphene fibers are principally employing soft dielectric additives, such as polymers, which can significantly deteriorate the genuine electrical properties of pristine graphene-based structures. In this research, molecular level lubricating 0-dimensional nanodiamond as an effective physical property modifier is introduced to improve the mechanical flexibility of graphene fibers by relieving the tight interlayer stacking among 2-dimensioanl graphene sheets. Nanoscale sized nanodiamond effectively increases tensile strain and bending strain of graphene/nanodiamond composite fibers, while maintaining the genuine electrical conductivity of pristine graphene-based fiber. The molecular level lubricating mechanism is elucidated by friction force microscopy in nanoscale via atomic force microscopy as well as by shear stress measurement in macroscopic scale. Resultant highly bendable graphene/nanodiamond composite fiber is successfully weaved into all graphene fiber-based textiles and wearable Joule-heaters, proposing the potential for reliable wearable applications.

NM02.07.12
Development of Neural Network Interatomic Potential for Simulating Evolution of Pt_3Co Nanoparticles Under Electrochemical Conditions Jisu Jung[1], Suyeon Ju[1], Purun-hanul Kim[1], Wonseok Jeong[2,1], Jinhee Lee[3], Sungwoo Kang[4,1] and Seungwu Han[1]; [1]Seoul National University, Korea (the Republic of); [2]Lawrence Livermore National Laboratory, United States; [3]Hyundai Motors, Korea (the Republic of); [4]Samsung Advanced Institute of Technology, Korea (the Republic of)

The proton-exchange membrane fuel cell (PEMFC) converts chemical energy into electrical energy through an oxygen reduction reaction (ORR) in the cathode. However, costly pure Pt nanoparticles cannot meet the target activity for ORR in PEMFC operation for commercialization. While alloying with

non-noble metal reduces the cost and achieves higher activities, it exacerbates the long-term stability due to active dissolution of non-noble metal atoms. Over the last decade, the computational methods within the density functional theory (DFT) have played crucial roles in the rational design of durable alloy catalysts. However, demanding computational costs limited the DFT studies only for small nanoparticles (diameters of 1-2 nm) in comparison with those employed in the actual PEMFC (diameters of 3-4 nm). In this study, we develop neural network interatomic potentials (NNPs) for Pt_3Co nanoparticles with an aim to simulate the dissolution process of actual size nanoparticles. We train the NNPs over various structures in bulk, surface and cluster geometries. In particular, the present training set explicitly includes formation energies and migration barriers of vacancies, which is crucial for realistic simulation of morphological evolution of nanoparticles under electrochemical conditions. The present NNP has root-mean-squared-errors (RMSEs) of 3.8 meV/atom and 0.14 eV/Å, respectively, for the validation dataset. In addition, for out-of-training structures, the NNP produces vacancy formation energies at the surface with the mean-absolute-error (MAE) of 0.09 eV, and migration barriers of vacancies are predicted with MAEs of 0.19 and 0.26 eV at the surface and bulk, respectively, which provides enough accuracy for simulation of dissolution process and ensuing morphological changes. As a demonstration, we execute the kinetic Monte Carlo simulation by NNP and analyze the effect of size, shape, and atomic ordering on the structural evolution. We believe that the newly developed NNPs can contribute to rational design of durable alloy catalysts.

Development of Scalable Dispersion Technique of Graphene Nanoplatelets into Polymer Matrix to Improve Electrical and Thermal Conductivities Kazi Imran; SUNY Polytechnic Institute, United States

Fiber reinforced polymer (FRP) composites have exceptional advantage over traditional materials. A primary limitation of these composites for aircraft application is its susceptibility to lightning strike due to poor electrical, thermal properties. First step of this research was to develop processing method for graphene/epoxy nanocomposites. The most attractive property of graphene nanoplatelets is its high electrical conductivity. This conductive graphene may significantly enhance the electrical conductivity of the composites when used it as filler materials in the insulating polymer matrix. The fundamental criteria used for process development was electrical conductivity, process repeatability and scale up to a larger batch of material. The materials chosen in this study are graphene nanoplatelets (xGnP-25), epon 828 epoxy resin. Three types of exfoliation and dispersion techniques were investigated: conventional mechanical mixing, sonication and three-roll mill. The study showed that three-roll mill dispersion is most repeatable, consistent and scalable to larger batches. The optimized process consists of three gap settings (40, 30 and 25 μm) at 200 rpm and three passes for each gap setting. The percolation thereshold of xGnP graphene in epon 828 epoxy was found to be 1.0 wt. %. The xGnP/epon 828 nanocomposites showed an increase of eight log cycles in electrical conductivity, 93 % in thermal conductivity and 34 % in fracture toughness over the base epon 828.

NM02.07.17
Developing a Fiber Spinning Process for Ultra-High-Strength PVA/SWNT Composites Kenneth Benson and Marilyn L. Minus; Northeastern University, United States

In this research the interfacial relationship between a high molecular weight polymer polyvinyl alcohol (PVA) polymer and single walled carbon nanotubes (SWCNTs) are studied in order to push the boundaries for spinning a high-strength fiber. Previous research has shown success in such studies relating to the interactions between PVA and SWCNT. However, theses fibers were processed in small batches. These PVA/SWCNT systems showed an increased performance in mechanical properties of the spun and drawn fibers when compared to control samples. These increased properties show promising advantages in applications requiring high-strength fiber materials such as ballistics or protection equipment. The scope of this project was to expand upon this initial success and explore a more continuous processing route to process ultra-high-strength (>3 GPa) PVA/SWCNT composite fibers. With the primary goal of achieving the most optimized system for development of this fibers, the process is tailored and controlled to produce fine-tuned high-performance fibers. The results of this work will be discussed.

NM02.07.18
Solution-Processed Tellurium Nanowire Network Structure for Highly Sensitive P-Type Field-Effect Phototransistors Array Kyung Hwan Choi; Sungkyunkwan University, Korea (the Republic of)

Low-temperature-processed semiconductors are an emerging need for next-generation scalable electronics, and these semiconductors need to feature large-area fabrication, solution processability, high electrical performance, and wide spectral optical absorption properties. Although various strategies of low-temperature-processed n-type semiconductors have been achieved, the development of high-performance p-type semiconductors at low temperature is still limited. Here, we report a unique low-temperature-processed method to synthesize tellurium nanowire networks (Te-nanonets) over a scalable area for the fabrication of high-performance large-area p-type field-effect transistors (FETs) with uniform and stable electrical and optical properties. Maximum mobility of 4.7 cm^2/Vs, an
on/off current ratio of 1×10^4, and a maximum transconductance of 2.18 μS are achieved. To further demonstrate the applicability of the proposed semiconductor, the electrical performance of a Te-nanonet-based transistor array of 42 devices is also measured, revealing stable and uniform results. Finally, to broaden the applicability of p-type Tenanonet- based FETs, optical measurements are demonstrated over a wide spectral range, revealing an exceptionally uniform optical performance.

NM02.07.21
Bioelectronic Properties of Graphene Oxide Co-Immobilized with Penicillinase in Lipid Langmuir-Blodgett Films Luciano Caseli[1], Fabio A. Scholl[1] and José R. Siqueira Junior[2]; [1]Federal Univ of Sao Paulo, Brazil; [2]Federal University of Triangulo Mineiro, Brazil

Conjugating bioinspired systems with graphene oxide can provide systems with an active layer that combines materials with different functionalities. Bioinspired systems are particularly an interesting alternative for incorporating bioactive species, enabling a molecular environment favorable to some biomolecule properties, such as enzyme activity. In the same sense, graphene oxide (GO), in addition to presenting biocompatibility, has optical and electrical properties that encourage its application in systems of biological interest. In this work, the interaction of the enzyme penicillinase with the phospholipid di-myristoyl phosphatidic acid (DMPA), conjugated with graphene oxide (GO), was studied as Langmuir and Langmuir-Blodgett (LB) films. The incorporation of the enzyme and GO in the phospholipid floating monolayer was evaluated through measurements of surface pressure-area isotherms, surface elasticity, Brewster angle microscopy (BAM), and Polarization-Modulation Infrared Reflection-Absorption Spectroscopy (PM-IRRAS). The Langmuir films were stabilized with the presence of GO, as identified by the results obtained with the employed techniques. They showed that the enzyme was incorporated in the DMPA monolayers, with its secondary structure being preserved, as identified by PM-IRRAS. Also, the interaction of the mixed lipid-enzyme films with GO located in the aqueous subphase of the monolayers in the form of colloidal dispersion could be identified, forming homogeneous films as observed by BAM. The monolayer stabilization supported the transfer of these hybrid films onto solid substrates using the LB technique, characterized by fluorescence spectroscopy and transfer ratio. The enzymatic activities of the solid devices were then measured by using UV-visible spectroscopy. The approach was effective in co-immobilizing penicillinase and GO, which were co-transferred to solid supports as an ultrathin film with the phospholipid. The presence of GO allowed to improve the identification of the signals for penicillinase detection by electronic excitation and luminescent emission. Also, films with GO increased the catalytic efficiency of the devices towards the hydrolysis of the beta-lactam ring. The presence of

GO in the enzyme/lipid LB film not only tuned the catalytic activity of penicillinase, but also conserved its enzyme activity after weeks. The feasibility of the supramolecular device nanostructured as ultrathin films to detect penicillin was essayed in a capacitive electrolyte−insulator−semiconductor (EIS) sensor device. Viability as a penicillin sensor was demonstrated with capacitance/voltage and constant capacitance measurements, exhibiting regular and distinctive output signals for all concentrations used in this work. Therefore, these results may be related to the nanostructured system as an ultrathin film and the synergism between the compounds on the active layer, leading to a surface morphology that allowed a fast analyte diffusion owing to an adequate molecular accommodation, which preserved the penicillinase activity. Therefore, this work demonstrates that the incorporation of graphene oxide in LB films composed of penicillinase and DMPA boosts the biosensing properties of the hybrid ultrathin film as EIS devices for biosensing applications.

Development of "Electromagnetic Shielding Fabrics" Using Carbon-Nanotube-Composite-Fabrics Mashu Saito and Takahide Oya; Yokohama National University, Japan

We propose a unique electromagnetic shielding based on carbon-nanotube(CNT) composite fabrics that a composite material of the CNT and a fabrics. The electromagnetic wave environment surrounding us diversifies, and various problems are getting obvious currently. As the solution for them, the use of an electromagnetic wave shield (EMS) is attracting much attention. Nowadays, metal is used for the materials of EMS mainly, but the metal has a problem in the cost side or the processing side. For this, we focus on carbon-nanotube (CNT) with the conductivity that is high as substitute materials in this study. Although CNT has difficulty in treating it in a simple substance because CNT usually exists on a nanoscale and powdery state, our approach will solve above problems. Therefore, we may contrive to use it or develop the way for applications such as combining with other materials. In concrete, we compound with CNT and fabrics, fabricate "CNT-composite-fabrics" (CNTCFs) having a superior characteristic of CNT and facilitate the handling of CNT, and propose the "EMS fabrics" based on CNTCFs. To make our CNTCFs, we add 96 mg of multi-walled CNT and 500 mg of dispersant (Sodium Dodecyl Sulfate) in 60 ml of pure water at first. Next, this mixed solution is ultrasonically dispersed for 60 minutes by using an ultrasonic homogenizer to prepare a CNT dispersion. Moreover, we dip a fabric in the dispersion and drying in an oven until water of the dispersion is evaporated, repeat this process several times. As a result, our CNTCFs are obtained. They have unique properties, e.g., flexible and light weight, in addition to showing the shielding effective (SE). In the recent information society, EMS sheets for a high frequency band, the far field(more than a few GHz), are demanded because the information technology develops rapidly and spreads out all over the world.
In this study, we are aiming to develop the feasible level (SE > 30 dB) electromagnetic shielding fabrics. Because it is fabrics, we can apply it to a curtain and a carpet and intercept an electromagnetic wave easily. We perform a performance gain by the introduction of bridge materials and the removal of the dispersant.
As results of measurements, we have found that our CNTCFs has had the SE for the far field (from 0.5GHz to 18 GHz). Moreover, we have also found that the performance of our EMS fabric considerably changes by difference in material and structure of the fabric. In addition, we confirmed that the performance of CNTCFs is improved by increasing the fixation quantity of CNT. We consider that the bridge material is good for CNTCFs because it increases the fixation quantity of CNT by interaction with CNT. Although our CNTCFs does not reach the feasible level yet, obtained results give us hints to improve SE of our EMS fabric.
We believe our CNTCFs will get desired SE and be used as electromagnetic shielding fabrics in near future.

NM02.07.25

Fabrication of Hierarchically Structured Ultralightweight Graphene-Carbon Fiber Aerogel Networks and its Applications Mohd Shaharyar Wani[1,1], Sehmus Ozden[1,1,2] and Craig Arnold[1,1]; [1]Princeton University, United States; [2]Aramco Americas, United States

Seamlessly integrating 2D-graphene (G) and 1D-carbon nanofiber (CF) with hierarchical porosity as a new carbon structure has great potential to offer improved properties for a broad range of applications yet remains largely unexplored. We have developed a scalable and green approach for fabricating hierarchical G-CF aerogels in a covalently bonded network with a density two orders of magnitude lower than previously reported graphene aerogels. We have established insights into the surface structure and chemistry of the developed material and how it depends on the process conditions such as temperature, time, and the precursor protein. Atomistic reactive molecular dynamics simulations are used to explore the assembly mechanism and structural transformations of proteins during the fabrication process. We discuss the application of such materials to desalination and water purification, notably demonstrating that the G-CF-aerogel can significantly improve upon existing materials, removing 99.99% of nano/microplastic contamination from sea water and desalinate by over 98% in seawater using gravity-based filtration, making it promising for water filtration/desalination applications.

NM02.07.27

Mechanical Characterization of Electrospun Boron Nitride Nanotube-Reinforced Polymer Nanocomposite Microfibers Nasim Anjum[1], Ohood Q. Alsmairat[2], Zihan Liu[1], Cheol Park[3], Catharine C. Fay[3] and Changhong Ke[1]; [1]Binghamton University, The State University of New York, United States; [2]University of Texas at Tyler, United States; [3]NASA Langley Research Center, United States

Boron nitride nanotubes (BNNTs) possess many extraordinary structural and physical properties and are promising fillers for reinforcing polymers towards lightweight and high-strength nanocomposite materials. The interfacial load transfer in the bulk nanotube-reinforced polymer composite plays a critical role in property enhancement but is difficult to characterize quantitatively. This is in part because the added nanotubes are prone to aggregate and bundle due to inter-nanotube van der Waals interactions. These hard-to-avoid phenomena disrupt the seamless nanotube-polymer interfacial contact as well as nanotube alignment inside the composite, which decreases the bulk property enhancement. Here, we investigate the mechanical properties of electrospun BNNT-reinforced polymethyl methacrylate (PMMA) nanocomposite microfibers. The viscous force in the electrospinning process facilities the nanotube alignment, which is quantitatively characterized by using polarized Raman spectroscopy techniques. The local load transfer on the BNNT-PMMA interface inside the nanocomposite microfiber is characterized based on *in situ* Raman micromechanical measurements. The effective interfacial shear strengths of 0.1%, 0.5%, and 0.65% BNNT-PMMA microfibers are found to be about 78.4 MPa, 60.9 MPa, and 50.7MPa, respectively, which correspond to substantial improvements in Young's modulus and tensile strength. The study reveals the constitutive role of the nanotube-polymer interfacial strength in the composite's mechanical property enhancement. The findings contribute to a better understanding of the process-structure-property relationship and the reinforcing mechanism of nanotube-based nanocomposites.

NM02.07.28

Charge Transport in Covalently Functionalized Single-Walled Carbon Nanotubes for Tunable Electroluminescent Devices Nicolas F. Zorn and Jana Zaumseil; Heidelberg University, Germany

The controlled covalent functionalization of semiconducting single-walled carbon nanotubes (SWCNTs) with luminescent sp^3 defects gives rise to tunable emission in the near-infrared with increased photoluminescence quantum yields and single-photon emission at room temperature [*ACS Nano* **2019**, *13*, 9259]. To enable their application in electrically driven light sources, a detailed understanding of the impact of sp^3 defects on charge transport within individual nanotubes and nanotube networks is required. Here, we demonstrate that sp^3-functionalized, polymer-sorted (6,5) SWCNTs still support efficient ambipolar charge transport in nanotube network field-effect transistors (FETs). While both hole and electron mobilities moderately decrease with increasing degree of functionalization, the transistors remain fully operational with high on/off current ratios. Charge-modulated photoluminescence spectroscopy, which exclusively probes the mobile charge carriers in SWCNT networks, confirms that the defects are efficiently sampled by mobile carriers and consequently, sp^3-functionalized SWCNTs actively participate in the charge transport within the networks [*ACS Nano* **2021**, *15*, 10451]. We further employ optical-pump terahertz-probe (OPTP) spectroscopy, which probes the intrinsic and local charge transport properties (*e.g.*, carrier mobility) in a quantitative and contact-free fashion, to investigate the ultrafast carrier dynamics in sp^3-functionalized (6,5) SWCNT dispersions and thin films. The maximum photoconductivity and lifetime decrease upon functionalization, corroborating the direct impact of sp^3 defects on intra-nanotube charge transport. For low levels of functionalization (4-10 defects per micrometer), which are relevant for applications, the reduction of intrinsic carrier mobilities is still low. Through combination of (temperature-dependent) OPTP measurements of sp^3-functionalized SWCNT dispersions and films with electrical measurements of nanotube network FETs, we can separate the contributions of sp^3 defects (intra-nanotube) and nanotube junctions (inter-nanotube) to charge transport in SWCNT networks [*ACS Nano* **2022**, DOI 10.1021/acsnano.2c02199]. When operated in the ambipolar regime, FETs with sp^3-functionalized SWCNT networks exhibit red-shifted electroluminescence from the defect states that is tunable via the defect concentration. The selective introduction of defects with even further red-shifted emission [*Nat. Commun.* **2021**, *12*, 2119] or the functionalization of other nanotube species such as (7,5) SWCNTs enables us to fabricate electroluminescent devices with tunable emission in the near-infrared and paves the way towards electrically pumped single-photon sources at telecom wavelengths.

Synthesis and Structural Investigation of Holey Graphene Nitul Rajput, Meriam Mohammedture, Zineb Matouk, Shroq AlZadjali, Abdulla AlShehhi and Monserrat Gutierrez; Technology Innovation Institute, United Arab Emirates

Research on holey graphene (HG), a structural derivative of graphene has significantly increased in the recent few years. HG possess unique characteristics and properties such as, semiconducting nature, distinctive porous nature with increased surface area, superior chemical reactivity etc. These properties allow researchers and engineers to utilize and explore the material in DNA sequencing, water filtration, to enhance energy storage capabilities, carbon capture etc. However, challenges remain unresolved in controlled synthesis of mass scale HG production with homogeneous pores distribution and precise hole size with controlled defects. In this work, probe sonication and electro-chemical synthesis approaches are implemented to exfoliate few layers of graphene. Subsequently, pores are generated using normal thermal annealing and thermal shock procedures. The synthesized materials are systematically evaluated using various advanced characterization techniques such as, X-ray photoelectron spectroscopy, transmission electron microscopy and Raman spectroscopy. The characterization unfolds novel properties related to intrinsic nature of HG. Eventually, controlled manufacturing of HG with precise hole size and distribution could be obtained with the understanding of the material.

Nanoporous Carbon-Based Catalyst for Hydrogen Evolution Reaction Caique Campos and Pedro A. Autreto; Federal University of ABC, Brazil

Hydrogen is regarded as one of the future fuels due to its sizeable energetic content per unit mass and Eco-friendliness with the potential to fulfill the ever-growing energetic demand. Clean and renewable production of molecular Hydrogen (H_2) in the electrochemical *Hydrogen Evolution Reaction* (HER) is one of the most promising alternatives to Hydrocarbon reforming methods currently employed due to renewability and high purity H_2 yield [1]. However, large-scale implementation of this mechanism requires cheap, efficient, and earth-abundant catalysts as cost-effective alternatives to the benchmark scarce noble-metal materials. Metal-free Carbon-based catalysts have drawn considerable attention, and several graphene-based nanostructures have been extensively investigated [2]. In particular, porous nanostructures with enhanced ions and mass transport properties compared to graphene have interesting HER activity [3]. In this work, we investigate the catalytic activity of graphenylene, a sp^2 carbon allotrope with intrinsic in-plane nanoporous structure, in HERs using DFT as implemented in the *Quantum Espresso package*. We found that metal decoration is a possible strategy to enhance the catalytic activity, optimizing the Hydrogen adsorption free-energy

Nanomechanical Characterization of Boron Nitride and Carbon Nanotubes-Metal Interfaces Yingchun Jiang[1], Zihan Liu[1], Chenglin Yi[1], Ning Li[2], Soumendu Bagchi[3], Cheol Park[4], Huck B. Chew[2] and Changhong Ke[1]; [1]Binghamton University, The State University of New York, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Los Alamos National Laboratory, United States; [4]NASA Langley Research Center, United States

The light, strong and durable characteristics of nanofiber-reinforced metal-matrix nanocomposites (MMNC) hold promise for tackling some of the most demanding applications, such as the body of aerospace vehicles. The reinforcing mechanism in nanofiber-reinforced MMNC critically relies on adequate load transfer on the nanofiber-metal interface. Boron nitride nanotubes (BNNTs) and carbon nanotubes (CNTs) are two of the most promising reinforcing fillers for disruptive MMNC technology due to their ultra-strong, resilient, and low-density properties. However, the understanding of the interfacial load transfer on these nanotube-metal interfaces remains elusive, which has been a major scientific obstacle in the development of the nanotube-reinforced MMNC technology. Here we investigate the mechanical strengths of the interfaces formed by individual BNNTs/CNTs with aluminum or titanium matrices by using *in situ* electron microscopy nanomechanical single-nanotube pull-out techniques. By pulling out individual nanotubes from metal matrices using atomic force microscopic force sensors inside a high-resolution scanning electron microscope, both the pull-out force and the embedded tube length were measured with resolutions of a few nano-Newtons and nanometers, respectively. The load transfer on the nanotube-metal interface is found to follow a shear lag behavior and the interfacial strength is significantly influenced by thermal-induced reaction products. Density functional theory calculations provide insights into the binding interaction and sliding behavior on the nanotube-metal interfaces that are highly dependent on the electronic structure of the underlying chemical bonds. The research findings help to better understand the load transfer on the nanotube-metal interface and the reinforcing mechanism of nanotube-reinforced metal nanocomposites.

NM02.07.34
1D/2D Heterostructure of Gadolinium/*2*-Methylimidazole Metal-Organic Framework and Graphitic Carbon Nitride Nanosheet for Bifunctional

Electrocatalytic Oxygen Evolution and Reduction Reactions Saikat K. Kuila and Tarun K. Kundu; Indian Institute of Technology Kharagpur, India

The electrochemical energy generation, conversion, and storage devices are very promising for developing sustainable clean technologies. Fuel cells and metal-air batteries are emerging as powerful energy conversion devices for future energy requirements. Economically feasible electrocatalysts can be engineered to meet these requirements. In this work, a bifunctional electrocatalyst 1D-gadolinium-*2*-methylimidazole (1D-Gd-2-mim) metal-organic framework (MOF) functionalized 2D-graphitic carbon nitride (2D-g-C_3N_4) heterostructure (1D-Gd-2-mim/2D-g-C_3N_4) is demonstrated for electrocatalytic oxygen evolution reaction (OER) and oxygen reduction reaction (ORR). The electrocatalyst is synthesized through mixing and coprecipitation methods. The synthesized 1D-Gd-2-mim/2D-g-C_3N_4 is characterized using diffraction (X-ray diffraction (XRD)), spectroscopic (Fourier-transform infrared spectroscopy (FTIR) and X-ray photoelectron spectroscopy (XPS)), microscopic (field Emission scanning electron microscopy and corresponding energy dispersive X-ray spectroscopy (FESEM-EDS), high-resolution transmission electron microscopy (HR-TEM), atomic force microscopy (AFM)), thermal (combined thermogravimetry and differential scanning calorimetry (TG-DSC)), surface and pore measurements (Brunauer–Emmet–Teller and Barret–Joyner–Halenda (BET-BJH)) techniques and compared with pristine 2D-g-C_3N_4. XRD and FTIR studies assure the formation of the heterostructure. The synthesized sample shows a remarkably higher specific surface area (322.4 $m^2\ g^{-1}$) than the pristine 2D-g-C_3N_4 (69.12 $m^2\ g^{-1}$) and 1D-Gd-2-mim MOF (93.5 $m^2\ g^{-1}$). The FESEM and HR-TEM micrographs also confirm the (1D/2D) heterostructure formation where the growth of porous nanorod structured 1D-Gd-2-mim MOFs on 2D-g-C_3N_4 nanosheets is evident. High-angle annular dark-field-scanning transmission electron microscopic (HAADF-STEM) analysis of 1D-Gd-2-mim/2D-g-C_3N_4 confirms that all the elements C, N, Gd, and O are uniformly distributed in the nanoporous microstructure. A considerable weight loss (32%) is recorded within a temperature range of (0-900 °C) for 1D-Gd-2-mim/2D-g-C_3N_4, whereas 2D-g-C_3N_4 is fully dissociated after 610 °C, as confirmed by the TG-DSC study. Further, the ORR activity of the synthesized materials is confirmed through the CV plot in the O_2 and N_2 saturated 0.1 M KOH in the potential window of 0.2 to 1.2 V (vs. RHE). Although the ORR onset and ORR peak potential do not improve remarkably over the addition of La-2-mim and Ce-2-mim MOFs into 2D-g-C_3N_4, the limiting current density increases remarkably, confirming the improvement of ORR activity. The 1D-Gd-2-mim/2D-g-C_3N_4 shows a remarkable positive shift of the ORR onset and ORR peak potential along with enhanced limiting current density, which makes it the best ORR performing catalyst among all the synthesized materials. 1D-Gd-2-mim/2D-g-C_3N_4 exhibits higher stability and methanol tolerance capacity than the state-of-the-art catalyst Pt/C. Furthermore, an LSV study using RDE with various rotation speeds reveals that the catalyst follows a four-electron reduction pathway for ORR. Also, the electrocatalyst shows its superiority over the pristine 2D-g-C_3N_4 and state-of-the-art catalyst RuO_2 by depicting the lowest onset potential (1.25 V vs. RHE), overpotential (59 mV), Rct (7 Ω), Taffel's slope (17 mV $decay^{-1}$), and higher R_f (1.74), as obtained through several OER electrochemical characterizations. The catalyst is also stable from a morphological and OER performance perspective. So, the electrocatalyst executes the bifunctional activity very proficiently, which is highly demanding for fuel cell and metal-air batteries technology. 1D-Gd-2-mim/2D-g-C_3N_4 is a potential candidate as an alternative to the high cost and scares Pt/C and RuO_2 in energy conversions and storage applications.

NM02.07.35

Advances in the Solvothermal Synthesis of Red-Emitting Carbon Dots Towards Optoelectronic Devices Antonino Madonia[1], Gianluca Minervini[2,3,1], Annamaria Panniello[1], Carlo M. Carbonaro[4], Teresa Sibillano[1], Cinzia Giannini[1], Angela Terracina[5], Alice Sciortino[5], Fabrizio Messina[5], Maria Lucia Curri[3,1] and Marinella Striccoli[1]; [1]CNR, Italy; [2]Polytechnic of Bari, Italy; [3]University of Bari "Aldo Moro", Italy; [4]University of Cagliari, Italy; [5]Università degli Studi di Palermo, Italy

Designing functional nanomaterials useful for the development of optoelectronic devices is a challenging task. Industry standards demand careful control over both their structural and optical properties, as well as high reliability and resistance to degradation under real-world usage conditions. Furthermore, the development of cost-effective materials obtained from inexpensive, abundant, and environment-friendly sources is deemed a high priority.
In this context Carbon Dots (CDs) have gained much traction. These nanoparticles, mainly composed of Carbon and other readily available elements such as Oxygen, Nitrogen, and Hydrogen, are considered extremely promising for their enticing properties: it is thanks to their intense absorbance, bright photoluminescence, low toxicity and high biocompatibility that such nanomaterials have found their way into the fields of optoelectronics, photocatalysis, and nanosensing among the others.[1] In fact, CDs are renown for being able to couple molecular-like optical properties to an enhanced photostability,[2] characteristics which work in parallel to their electron-donating capabilities towards the development of hybrid and functional materials.[3]
In recent years the understanding of the relationship between synthetic conditions, structural features, and optical properties of CDs has witnessed impressive progress. Nonetheless, while we are now able to produce carbon-based nanoparticles with high photoconversion efficiencies both in the blue and green regions of the visible light spectrum,[4] the knowledge regarding how to control the synthesis of red-emitting CDs is still lagging behind;[5] as many optical applications necessitate full control over all visible wavelengths, we need to design new synthetic strategies allowing us to overcome this obstacle.
It is with this purpose in mind that we have explored novel approaches aimed at enhancing the red emission of carbon nanoparticles. By developing both synthetic and post-synthetic treatments we were able to isolate CDs displaying high photoluminescence quantum yields in the red region of the light spectrum. Moreover, we have been successful in finely tuning their optical properties by the careful choice of precursors used during the solvothermal synthesis: these results have been achieved by making use of both in-situ surface passivation strategies as well as post-synthetic purification approaches.
The synthesized red CDs possess exciting optical properties and result highly resistant to photobleaching under UV irratiation. An in-depth optical and morphological characterization has allowed to rationalize the mechanisms underlying the emission properties of CDs and isolate the centers responsible for the red photoluminescence. These advances can envisage the effective use of carbon dots as viable substitutes for the semiconductor nanoparticles currently used in the domain of optoelectronics, which are often based on toxic and polluting materials. As we are now able to cover the visible light spectrum in its full range, we have been exploring the possibility of using the carbon-based functional nanomaterials for the development of tunable or white light-emitting devices, as first step towards the application in many other photonic or optoelectronic devices.

Fe_3O_4/GO Magnetic Nanocomposite—A Selective Probe for Simultaneous Detection of Carbofuran and Carbendazim Residues by Electrochemistry and LDI-MS Jutiporn Yukird and Nadnudda Rodthongkum; Metallurgy and Materials Science Research Institute (MMRI), Thailand

Fe_3O_4/GO magnetic nanocomposite is synthesized and applied as a selective probe for simultaneous detection of pesticides (carbofuran and carbendazim) verifying by the high binding energies calculated by density functional theory. Electrochemistry and LDI-MS are selected for screening and quantitative determination of these pesticides. Fe_3O_4/GO modified on electrode enhances electrocatalytic activity of carbofuran and carbendazim and their oxidation

peak currents linearly increase upon the increase of their concentrations in a range of 1- 250 μM with LODs of 0.06 μM and 0.18 μM for CBF and CBZ, respectively. For LDI-MS, after magnetic separation, CBF and CBZ bound with Fe_3O_4/GO are readily ionized leading to high ion abundance with a linear range of 1- 1000 μM. Thus, using Fe_3O_4/GO magnetic nanocomposite along with our detection platform is effective to cover the required detection level of CBF and CBZ residues in the fruits, which are 0.45 μM and 2.5 μM, respectively. Ultimately, Fe_3O_4/GO bound with CBF and CBZ spiked in pear are successfully visualized by imaging-MS verifying the distribution of these pesticides in real pear peel samples.

Modification of Surface Tension of a Green Solvent and Surfactants to Enhance Graphene Synthesis Aditi Pangal, Sharada Kittur, Tze Tseng Soh, Jasper Zhang and Neelima Sangeneni; ASDRP, United States

Graphene is the single layer of graphite, made up entirely of carbon. With many favorable properties, such as high conductivity, incredible tensile strength, flexibility, and a lightweight structure, graphene is one of the first choices in the energy storage industry. The problem with graphene arises in its scalability and producability. Our research finds a process to create high-quality graphene in a cost-effective, scalable, and green manner, for use in supercapacitors. Many papers explore top-down and bottom-up approaches such as redox reactions, flash graphene, epitaxial growth, and chemical vapor deposition (CVD), but they use toxic solvents and costly equipment, both of which are neither good for the environment, nor widely accessible. The most viable solution seemed to be Liquid-Phase Exfoliation, which uses sonication in a solvent to exfoliate the layers of graphite to produce monolayered- or few-layered-graphene. We also tested variability in the time durations of our sonicating machines; the probe sonicator (direct sonication) and the bath sonicator (indirect sonication). By changing the solvent based on its surface tension and surface energy, we tweaked the solvent ratios so that the surface tension of the solvent was similar to the surface tension of graphite, which is 41 mJ/m2. This reduces the potential energy between the two materials and makes it easier to overcome the van der Waals forces. In addition, we experimented with different solvents such as dish soap, hand soap, and an ethanol and water mixture, and different surfactants such as curcumin to observe their effects on yield. We found that the hand soap yield had the most contaminants and was also very dense. The best quality graphene came from ethanol and water, and curcumin and water, with a measured CV capacitance of 13.1 F/g. We used different characterization tools such as FTIR, CV, SEM, and GCD to determine how much graphene we had, and what grade of graphene we had, as well as calculating the specific capacitance and long-term capacitance. In the future, we will test more green solvents and surfactants, and we will attempt with the process of magnetic separation to further exfoliate the graphene. We are also planning on using Raman Spectroscopy in the future to characterize graphene. Finding a simpler, greener, and cost-effective method in which graphene can be synthesized will greatly increase its usage in the electrochemical industry as the cost of manufacturing and its scalability is the main obstacle to the widespread use of graphene.

Thermodynamic Behavior of Fe Nanoparticles in the Catalyst Layer Controlling Reliable Direct Growth of Electrically Addressable Carbon Nanotube (CNT) Microstructures on Conductive Layers Kwangjun Kim, Minwook Kim and Jong G. Ok; Seoul National University of science and technology, Korea (the Republic of)

Carbon nanotubes (CNTs) are in the spotlight in next-generation energy conversion, toxic gas detection, and biomedical applications due to their excellent electrical and thermal properties. While manipulating individual CNT strands is effective for specific uses, direct growth of microscale (often nanoscale) bundles of CNTs can be practically useful for functional architectures for subsequent uses with higher throughput and wider compatibility. Namely, this approach could not only minimize mechanical and chemical defects occurring during post-growth manipulation, but make the best use of both nanoscale/nanoporous morphology and up-to-mm-scalable/well-aligned structural framework (i.e., CNT forest structure; CFS). However, it is still challenging to control the length, density, and alignment of CNT structures, especially when growing to micropatterned configurations. Addressing these issues in this work, we first have investigated the morphological properties of catalyst metal (Fe) nanoparticles in order to control the nanoporosity and growth length of CNT forests. As the distribution density of Fe nanoparticles increases, the density of the CNT forest increases (reduces the nanoporosity), which enhances the crowding effect between CNT strands and forms a stable CNT forest to facilitate control of growth length. On the contrary, the more decreased the distribution density, the more difficult to control CNT forest formation and growth length. Furthermore, as the diameter of the nanoparticles increases, decrease in both the catalyst lifetime and the distribution density is qualitatively examined. Therefore, we define the distribution density and diameter as morphologic factors, and these factors have been analyzed based on Ostwald-ripening and subsurface diffusion phenomena. As the effects of these phenomena increase, the nanoparticles' diameter-polarization increases while its distribution density reduces. Especially when the catalyst layer is patterned, the effects becomes more pronounced, which is caused by the thermal system change of the surface due to the increase in the thermal exposure area of the support layer and the substrate. Based on this approach, reliable microstructuring the CNT forest can be realized. For more practical and wider uses based on superb electrical/thermal properties of CNTs, growing the CNT microstructure directly on the conductive substrate is highly desired. To this end, we have also conducted morphological analysis of the nanoparticles on conductive titanium nitride (TiN) (instead of typical Al_2O_3). While keeping an eye on Ostwald ripening and subsurface diffusion, we have additionally developed two growth methods for securing the reliable growth length and porosity of CFSs on more rough TiN surfaces: catalyst-rich condition (CRC) and hydrogen-rich condition (HRC). Finally, we have quantitatively optimized the nanoparticle's diameter and distribution density, leading to the reliable direct growth of electrically addressable micropatterned CFSs on the conductive substrates.

Tungsten-Containing MXene ($W_2Ti)C_2T_x$ from a Nanolaminated Ternary Carbide for Hydrogen Evolution Reaction Anupma Thakur, Wyatt Highland, Brian Wyatt and Babak Anasori; IUPUI, United States

Two-dimensional transition metal carbides, nitrides and carbonitrides, known as MXenes, have shown great promise as active materials in catalytic applications such as hydrogen evolution reaction. Tungsten (W) containing MXenes are of particular interest as they are predicted to have overpotentials close to Pt based catalysts in the hydrogen evolution reaction (HER) making them candidates for a more sustainable clean energy application. However, the incorporation of W into MXene structure has proven difficult due to the calculated instability of its hypothetical precursor $M_{n+1}AX_n$ phases (W_3AC_2 and W_2AC). In this study, we discuss the synthesis of W-containing MXene ($W_2Ti)C_2T_x$, derived from a nanolaminated ternary carbide $(W,Ti)_4C_{4-x}$ precursor. The synergistic effect of the W-containing basal plane endows $W_2TiC_2T_x$ MXene with remarkable electrocatalytic HER performance in terms of lowest HER overpotential (~162 mV) and long-term stability of >24 hours under acidic conditions over other $W_{1.33}CT_x$ MXenes (~320 mV) and Mo_2CT_x MXenes

(~190 mV). This enhanced HER activity of $(W_2Ti)C_2T_x$ MXene may be linked to W's highly active and ordered basal-plane vacancies. In this direction, more efforts on the continuous exploration of W-containing MXenes with low overpotentials are significant toward the progress of HER catalysts for clean energy applications due to their highly active basal plane.

Molecular engineering of graphene-like two-dimensional conjugated polymers Jie Shen and Yu Han; King Abdullah University of Science and Technology (KAUST), Saudi Arabia

The discovery of graphene--a two-dimensional (2D) crystalline carbon monolayer, has stimulated interest in the rational synthesis of the 2D polymer. Such a promising class of novel organic 2D materials is expected to offer a greater degree of tunability in terms of composition, geometry, and chemical/physical properties compared with graphene, featuring intriguing application perspectives as membranes and in electronics[1]. However, the synthesis of crystalline 2D polymer with strong and stable linkages such as C-C bonds has met with limited success up to now. Taking the solution-based synthesis of graphdiyne (a 2D polymer with benzene rings linked by alkyne bonds) as an example, the free rotation of the alkyne–aryl single bonds leads to out-of-plane random growth of the skeleton during the growth and form disordered 3D structure rather than the desired 2D structure. Ultrahigh-vacuum deposition methods have also been reported to fabricate 2D polymers, but the lateral dimensions of the materials thus prepared are usually small (< 1 μm × 1 μm), which requires better control over the reaction thermodynamics and kinetics.

In this presentation, we will report our most recent progress that has been published in *Nature Materials*[2]: the design and fabrication of ultrathin, larger area, and ordered 2D conjugated-polymer-framework films (~ 5cm^2) with thicknesses down to 1 nm through C-C coupling between the designed monomers using surface-confined chemical vapor deposition (CVD). This method is characterized by the use of single-crystalline Cu (111) substrate with atomic flatness and the addition of an organic base into the CVD system, which have proven to be the key factors in promoting the formation of the ordered 2D structure. The fabricated 2D CPF—the organic analogue of graphene, demonstrated a fully π-conjugation and ultramicroporous structure with promising potential for electronic devices and molecular sieving membranes. We have shown that the CPF nanofilms inherently have regular rhombic sub-nanometer (10.3 × 3.7 Å) channels for achieving a superior water and ion separation performance that surpassed those of state-of-the-art membranes. Additionally, the porosity and surface charge of CPF membranes were finely tuned by controlling the CVD conditions, which were further engineered for ion sieving and osmotic energy harvesting. We envisage that the surface-confined CVD synthesis described here can be applied to other classes of monomers, opening a new avenue to construct novel graphene-like architectures at the atomic level with desirable chemical, physical and electronic properties.

Thermodynamics of Charge Regulation During Ion Transport through Silica Nanochannels Cody Ritt[1,2], Pedro de Souza[1], Michelle G. Barsukov[2], Shari Yosinski[2], Martin Bazant[1], Mark Reed[2] and Menachem Elimelech[2]; [1]Massachusetts Institute of Technology, United States; [2]Yale University, United States

Ion-surface interactions can alter the properties of nanopores and dictate nanofluidic transport in engineered and biological systems central to the water-energy nexus. The ion adsorption process, known as “charge regulation”, is ion-specific and is dependent on the extent of confinement when the electric double layers (EDLs) between two charged surfaces overlap. A fundamental understanding of the mechanisms behind charge regulation remains lacking. Herein, we study the thermodynamics of charge regulation reactions in 20 nm SiO_2 channels via conductance measurements at various concentrations and temperatures. The effective activation energies (E_a) for ion conductance at low concentrations (strong EDL overlap) are ∼2-fold higher than at high concentrations (no EDL overlap) for the electrolytes studied here: LiCl, NaCl, KCl, and CsCl. We find that E_a values measured at high concentrations result from the temperature dependence of viscosity and its influence on ion mobility, whereas E_a values measured at low concentrations result from the combined effects of ion mobility and the enthalpy of cation adsorption to the charged surface. Notably, the E_a for surface reactions increases from 7.03 kJ mol^{-1} for NaCl to 16.72 ± 0.48 kJ mol^{-1} for KCl, corresponding to a difference in surface charge of −8.2 to −0.8 mC m^{-2}, respectively. We construct a charge regulation model to rationalize the cation-specific charge regulation behavior based on an adsorption equilibrium. Our findings show that temperature- and concentration-dependent conductance measurements can help indirectly probe the ion-surface interactions that govern transport and colloidal interactions at the nanoscale—representing a critical step forward in our understanding of charge regulation and adsorption phenomena under nanoconfinement.

A Wavelength-Induced Frequency Filtering Method for Fluorescent Nanosensors *In Vivo* Michael S. Strano and Volodymyr Koman; Massachusetts Institute of Technology, United States

Fluorescent nanosensors hold the potential to revolutionize life sciences and medicine. However, their adaptation and translation into the in vivo environment is fundamentally hampered by unfavourable tissue scattering and intrinsic autofluorescence. Here we develop wavelength-induced frequency filtering (WIFF) whereby the fluorescence excitation wavelength is modulated across the absorption peak of a nanosensor, allowing the emission signal to be separated from the autofluorescence background, increasing the desired signal relative to noise, and internally referencing it to protect against artefacts. Using highly scattering phantom tissues, an SKH1-E mouse model and other complex tissue types, we show that WIFF improves the nanosensor signal-to-noise ratio across the visible and near-infrared spectra up to 52-fold. This improvement enables the ability to track fluorescent carbon nanotube sensor responses to riboflavin, ascorbic acid, hydrogen peroxide and a chemotherapeutic drug metabolite for depths up to 5.5 ± 0.1 cm when excited at 730 nm and emitting between 1,100 and 1,300 nm, even allowing the monitoring of riboflavin diffusion in thick tissue. As an application, nanosensors aided by WIFF detect the chemotherapeutic activity of temozolomide transcranially at 2.4 ± 0.1 cm through the porcine brain without the use of fibre optic or cranial window insertion. The ability of nanosensors to monitor previously inaccessible in vivo environments will be important for life-sciences research, therapeutics and medical diagnostics.

Nanotube-Based High Brightness Fluorophores with Controllable Brightness Yoke Khin Yap[1], Nazmiye Yapici[2], Rodney Oakley[2], Xiuling Liu[2], Steve Tokarz[2] and Dongyan Zhang[1]; [1]Michigan Technological University, United States; [2]StabiLux Biosciences, United States

Nanotubes have been used for various mechanical, electrical, and biomedical applications. Here we describe a new nanotube technology for producing high brightness fluorophores (HBFs) that can be 1000 times brighter than any known dyes [1]. The brightness of HBFs is widely tunable, with a molar extinction coefficient (e) ranging from 10^7 to 10^9, more than three orders of magnitude higher than existing dye. The physics and chemistry in designing these HBFs will be presented in the meeting. Results indicated that the brightness of HBFs based on boron nitride nanotubes (BNNTs) is 450% higher than those based on carbon nanotubes (CNTs).

Biomedical detection relies on various non-invasive techniques such as fluorescent microscopy and flow cytometry. Organic dyes and fluorescent proteins are widely used for these applications where fluorophores are specifically bound to the target biomolecules. The brightness of dyes is important for sensitive and accurate detection. Organic dyes are low cost but not as bright as protein dyes such as PE (extinction coefficient, $\varepsilon = 2.5x10^6$ M^{-1} cm^{-1}; quantum yield, QY= 0.8) and APC ($\varepsilon = 7.0x10^5$ M^{-1} cm^{-1}, QY=0.68). According to the physics of fluorescent brightness, one can produce bright dyes by enhancing QY and ε [2]. There have been tremendous effort reporting the design of new molecules with high quantum yield (QY ranging from 0 to 1). In contrast, we focused on designing HBFs by controlling ε, which can be tuned across several orders of magnitude. Our HBFs are constructed by organizing arrays of organic dye with polymeric linkers. Nanotubes are used as the nano-carriers of these dye-linker structures. We found that the brightness of HBFs based on BNNTs can be 450% higher than that based on CNTs. Such enhancement is due to the electrically insulating and optically transparent (band gap of 6eV) nature of BNNTs [2-5]. As a result, we can maintain the QY of dye molecules organized on BNNTs without fluorescent quenching. Furthermore, the conjugation efficiency of the dye-linkers on BNNTs is much higher than that on CNTs. All these contribute to the higher brightness of HBFs based on BNNTs.

Demanding More from Graphene-Based Sensors—Design and Development of a Multi-Functional GFET with Dielectrophoresis Enhanced Sensing Capabilities Nezhueyotl Izquierdo, Ruixue Li and Steven Koester; University of Minnesota, United States

The demand for low-cost, rapid readout, point-of-care medical diagnostics was exposed by the SARS-CoV-2 pandemic. Graphene-based field-effect transistor (GFET) sensors have emerged as an effective platform for medical diagnostics of clinical biomarkers, such as DNA, RNA, proteins, and antibodies. Commercialization of sensors requires target specificity, sensor sensitivity, and a short sensor response time for target analyte detection.

Our group's previous work on graphene-based DEP devices has demonstrated an ultra-strong (> 10-times) DEP force compared to metal electrodes, as the DEP force magnitude is dependent on the electrode thickness [1]. An applied dielectrophoresis (DEP) force imparts a pseudo-selective trapping mechanism. Target analytes, such as DNA, are mobilized from suspension and localized at the graphene channel DEP trap sites. Graphene provides advantageous material properties for both a GFET sensor and DEP device applications. Graphene, a semi-metal with high carrier mobility and surface-to-area ratio, is well suited as a FET sensor channel material. Functionalized GFET sensors have demonstrated high specificity, sensitivity, and stability in biological buffers [2]. However, detecting low concentrations of biomolecules (e.g., DNA) with GFETs typically requires a long incubation time (>30 minutes) and is therefore not suitable for rapid readout detection.

Here we present our recent work to improve the standard three-terminal GFET sensor by incorporating dielectrophoresis as a strategy to reduce the required response time and improve the sensor sensitivity. The novel 4-terminal graphene-based sensor device structure can operate in three distinctive modes: DEP, GFET, and dielectrophoresis-assisted GFET (DEP-GFET). The DEP-GFET device is realized and capable of sensing shifts in the graphene channel's electrical properties (e.g., V_{Dirac}, I_{DS}). An applied DEP force attracts particles suspended in the solution and traps target particles at the graphene channel edge region. The GFET component of the DEP-GFET device thereby measures the electrical response to the trapped particles. Fluorescence microscopy analysis of the DEP-GFET device demonstrates the effectiveness of DEP-trapped fluorescent particles (i.e., fluorescent polystyrene beads and DNA-YOYO-1) at the graphene channel edge. After 10 seconds of applied DEP, the fluorescence intensity at the graphene channel trapping edges is increased by 25-times. Trapped particles are sensed by measuring V_{Dirac} shifts after two minutes of applied DEP. Thus, the target analyte is locally concentrated at the graphene channel edges, reducing the required sensing response time by up to 30-times. Compared to GFETs that rely on diffusion, the DEP-GFET device overcomes diffusion limitations by increasing target analyte concentrations locally at the graphene sensor channel region by 25-times and reducing the response time by approximately 30-times. These findings support a strategy for significantly reducing response time, a crucial metric for sensor performance, via the development of a 4-terminal GFET with dielectrophoresis enhanced sensing capabilities.

10:30 AM NM02.08.06
Penta Nitrogen Coordinating Single Atomic Cobalt with Oxidized Carbon Black to Boost 2-Electron Oxygen Reduction Reaction for H_2O_2 Mass Production Jae Won Choi and Jong Min Kim; Korea Institute of Science and Technology, Korea (the Republic of)

The process of two-electrons ($2e^-$) oxygen reduction reaction (ORR) offers a sustainable and decentralized alternative to the traditional multi-step anthraquinone process and hazardous direct synthetics for hydrogen peroxide (H_2O_2) production. However, considering the future commercialization, high-performance H_2O_2 electrocatalysts with economical cost should be designed rationally. Single-atom catalyst (SAC) has been attracting attention as a

promising candidate for 2e- ORR catalyst due to its maximum atom-utilization efficiency, and unique and tunable electronic structure. Among the transition metal candidates such as Fe, Ni, and Co which lead to 2e- ORR, it has been proven experimentally and theoretically that Co has the most favorable binding free energy with intermediate for H2O2 generation. Co-N_4, a metalloenzyme that exists in nature, is a representative Co SAC. However, Co-N_4 is kinetically favorable for the 4e-ORR pathway, resulting in H2O as a final product. Thus, a strategy to improve the selectivity and activity for H2O2 generation by tailoring the coordination environment around the Co SAC is required. Here, the Co-N_5-O-C single-atom catalyst (SAC) combined with highly coordinated Co-N_5 moieties and electro-withdrawing epoxides group nearby is developed by anchoring cobalt phthalocyanine (CoPc) on oxidized carbon support through the coordination of metal complex. The synergy effect between sufficient neighbor epoxy O and Co–N5 centers can help boost both selectivity and activity for H2O2 production significantly. Specifically, the epoxy-rich Co-N_5-O-C structure shows excellent selectivity (85.6% at 0.75 V vs. RHE) in alkaline electrolytes, exceeding more than 15% higher selectivity than that of epoxy-deficient Co-N_5-C. Meanwhile, an ultrahigh mass activity was achieved, exceeding all other reported catalysts for $2e^-$ ORR by far. Supported by theoretical calculations, it is found that Co-N5 moiety shows a lower overpotential of $2e^-$ ORR than Co-N_4 and the presence of epoxy groups near the Co–N_5 centers further decrease the overpotential, resulting in the enhanced activity of H_2O_2 electrosynthesis. Besides, a comparable high H_2O_2 production rate was also obtained by applying the Co SAC in a three-phase flow cell device, with around 80% faradaic efficiency remaining under 24 hours of testing.

10:45 AM NM02.08.07
Electrochemical Exfoliation and Chemical Functionalization of 2D Materials Mark A. Bissett, Yuling Zhuo and Ian Kinloch; University of Manchester, United Kingdom

Two-dimensional (2D) materials such as graphene and molybdenum disulfide (MoS_2) have been investigated widely for applications in energy storage, including supercapacitors, due to their high specific surface area, potential redox activity, and mechanical flexibility. Although graphene is an ideal material for supercapacitor electrodes due to its high specific surface area, most of the surface area is not accessible to ions due to the restacking of graphene, thus leading to low specific capacitance. Recently, many reports have been published on graphene composites and functionalized graphene to improve this ion-accessibility. In this work, we demonstrate several examples of simultaneous electrochemical exfoliation and functionalization of 2D materials in which the restacking can be reduced (for example, the inter layer spacing between graphene layers is increased by grafted diazonium salts) and the electrochemical properties of these electrodes (such as energy density) can be improved.

Additionally, electrodes comprising either solely graphene or MoS_2 have previously failed to reach their potential due to restacking of the layered structure and poor electrical conductivity. In our work we demonstrate composite electrodes formed by electrochemically functionalizing the graphene so that the negatively charged surface can self-assemble with positively charged chemically exfoliated MoS_2 (1T-MoS_2) to give an alternating layered structure. These alternately restacked 2D materials were then used to produce supercapacitor electrodes, and their energy storage properties were characterized.

Finally, we report a facile and scalable procedure of fabricating chemically functionalized thin (~4 nm) MoS_2 layers. We demonstrate that 2H-MoS_2 can be simultaneously electrochemically exfoliated and functionalized along with graphene. The aryl diazonium salts used for functionalization have not only been successfully grafted onto the 2H-MoS_2, as verified by X-ray photoelectron spectroscopy (XPS) and Raman spectroscopy, but also aids the exfoliation process. These electrochemical exfoliation and functionalization techniques could be extended to other types of 2D materials, introducing different functional species to adjust to specific application requirements.

Functional Single-Walled Carbon Nanotubes for Real-Time Wireless Chemical Sensors Seung-Ho Choi, Joon-Seok Lee, Won-Jun Choi and Seon-Jin Choi; Hanyang University, Korea (the Republic of)

Carbon nanotubes (CNTs) are attractive nanomaterials considering their high electrical conductivity and aspect ratio, leading to the development of innovative electronic devices. In particular, CNTs are widely employed as sensing layers for application in chemical sensors due to their efficient electrical transduction properties. Nevertheless, the stable surface chemical property of pristine CNTs with sp^2 bond hybridization hinders sensitive and selective detection of a target analyte. In this regard, various surface modification techniques are proposed by altering surface chemistry and imposing chemical reactivity toward analytes. There are two types of surface functionalization techniques of CNTs; covalent and non-covalent functionalization techniques. The covalent functionalization technique results in the disruption of the electrical property of CNTs by breaking sp^2 carbon bonds, which limits the degree of surface modification. On the other hand, the non-covalent functionalization of CNTs can induce a high degree of surface modification while maintaining high electrical conductivity, thereby leading to sensitive detection of analytes.
In this presentation, I will introduce the recent progress of non-covalently functionalized single-walled carbon nanotubes (SWCNTs) for applications in chemiresistive sensors.[1-4] Functional polymers were synthesized by decorating selector groups, which can have a chemical interaction with target analytes such as gas molecules and ionic species in solution. In particular, a functional polymer of poly(4-vinylpyridine) (P4VP) was employed and further modified by introducing dual-hydrogen bond donors (e.g., thiourea, squaramide, and croconamide) as selectors. The chemiresistive sensing layer of SWCNTs was non-covalently functionalized by wrapping with functional polymers. As a result, real-time electrical transduction was achieved upon the injection of a chemical analyte with high sensitivity and selectivity. For example, a large resistance transition of functional P4VP-SWCNT composite was obtained with the sensitivity $[(R-R_0)/R_0\ (\%)]$ of 120% at 16.7 mM toward acetate anion. The chemiresistive sensor was integrated with a wireless sensing module for application in real-time wireless detection. The proposed SWCNT-based sensing platform with functional polymers can be applied in various fields such as environmental monitoring and healthcare.

1:30 PM NM02.09.01
Electrochemical Performances of Nickel Nitride/Buckypaper Hybrid Materials Salah Eddine Ben Razzouq[1], Mélanie Emo[1], Sylvie Migot[1], Zafar Ibupoto[2], Jean-Francois Pierson[1] and Brigitte Vigolo[1]; [1]Univ of Lorraine, France; [2]University of Sindh, Pakistan

The production of hydrogen using clean processes is one of the main challenge of the next decade. Water electrolysis is a promising method to produce green hydrogen. However, platinum-based materials are the state of the art electrocatalyst for the hydrogen evolution reaction (HER). Among the platinum free materials suitable for such application, transition metal nitrides are efficient and cost effective materials for hydrogen production. Buckypapers (BPs) are thin self-supported sheets of interlaced carbon nanotubes (CNTs) that show interesting high flexibility and chemical stability in electrolytes. The objective of the present work is to determine electrochemical performances of nickel nitride (Ni_xN) thin films deposited on buckypaper substrate. To the best of our knowledge, such hybrid carbon-nitride has never been reported before. In this work, a special attention is devoted to evidence the beneficial combination and synergistic effects between the rough BP and the nickel nitride thin film for their efficiency in HER, including crystallographic and microstructure aspects.
BPs with a thickness of approx. 80 µm have be prepared by the widely known dispersion-filtration method after dispersing CNTs by sonication in water with the help of an anionic surfactant (sodium dodecyl sulfate). In a second step, the outcome BP disks of 40 mm diameter have been coated by nickel nitride thin films using a reactive magnetron sputtering process. By varying the deposition duration, the thickness of the nickel nitride layer was fixed to 150, 200 and 300 nm. Ni_xN thin films have been also deposited on flat substrates (silicon wafer and polished nickel foil). The films deposited on these various substrates have been characterized by scanning electron microscopy, X-ray diffraction (XRD) and Raman spectroscopy. Thin foil lamella prepared by focused ion beam have been characterized by transmission electron microscopy and electron energy loss spectroscopy.
Our results show that the stoichiometry of the nitride films strongly depends on the nitrogen flow rate introduced into the sputtering chamber. At low nitrogen flow rate, pure Ni_3N films have been evidenced by XRD and Raman, while Ni_2N films have been formed at high nitrogen flow rate. Whatever the nature of the substrate (BP, Si or Ni) the sputtered films exhibit a columnar microstructure. Using flat substrates, the columns clearly grow along the direction perpendicular to the surface. Due to the BP roughness, the growth of nickel nitride on BP show an inclination which leads to a less dense and porous microstructures. Contrary to the commonly used liquid phase approach used to prepare the electrocatalysts of poorly controlled morphology and composition, such Ni_xN / BP hybrid materials of well controlled microstructure, rarely reported in the field, are highly desired for electrochemical reactions.

Enhancing $LiNi_{0.6}Mn_{0.2}Co_{0.2}O_2$ Based Lithium Battery Electrode Performance by Incorporating SWNTs Seyedabolfazl Mousavihashemi, Katja Lahtinen and Tanja M. Kallio; Aalto University, Finland

Enhancing lithium batteries cycle life and efficiency are essential from both economic and sustainability perspective. On the other hand, battery energy and power densities have to be improved to meet increased energy storage capacity expectations for portable and mobile applications. Today $LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ is the most popular lithium battery positive electrode active material because of its relatively high energy density. However, it suffers from relative low conductivity limiting the achieved power density and efficiency at high power operation. Moreover, durability of nickel rich active material calls for enhancement. Preparing a 3D composite electrode form the active material and single-walled carbon nanotubes (SWNTs) is an attractive approach to solve these issues as SWNTs can offer the electrode such desired properties as high electrical conductivity and excellent mechanical and (electro)chemical durability.

In this study, we have investigated implications of incorporating SWNTs in a lithium battery positive electrode. The focused is on optimizing performance of $LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ based battery electrodes by adjusting the SWNT amount, but also SWNT surface treatment is considered. The relevance of adding SWNTs in the composite electrode structure is verified in various electrochemical half cell experiments. The origin of the favorable properties and effects brought by SWNTs have been investigated using various structural analysis methods and in-situ electrochemical characterizations.

By optimizing the composite electrode structed, a 3D SWNT network around the active battery material particles is shown to improve the wiring between the particles, and the particles to the current collector. This results in enhanced electron transfer leading to an increment in the positive electrode power density and energy efficiency. That is relflected as enhanced electrochemical lithium (de)insertion reactions, in particularly at high charge/discharge currents. The best performance is reached when the SWNTs are subjected to a mildly oxidizing pre-treatment to increase the electrode wetting tough this has an adverse effect on the electron transfer properties.

Our investigations reveal that another benefit brought by SWNTs for the 3D composite electrode is mitigation of mechanochemical aging. This results from hindering electrode volume changes during lithium (de)insertion in the active battery material as SWNTs entangled around the $LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ particles decreases irreversible height changes occurring during both the formation cycle and continuous cycling. Our results suggests that this is also reflected as suppression of harmful side reactions indicated by an increase in the coulombic efficiency.
Summarizing, incorporating an optimized amount of modified SWNTs in a $LiNi_{0.6}Co_{0.2}Mn_{0.2}O_2$ based lithium battery positive electrode simultaneously enhances electrode power and energy density and cycling stability. Hence, all the above-mentioned important properties can be improved by incorporating highly conductive and durable carbon nanomaterials in a battery positive electrode structure.

Electronic Sensitivity of Individual SWCNT as a Model to Distinguish the Internal Confined Water from Adsorbed Water Said Pashayev[1,2], Romain Lhermerout[1,3], Christophe Roblin[1], Rudy Desgarceaux[1,4], Rémi Jelinek[1], Saïd Tahir[1], Vincent Jourdain[1], Rasim Jabbarov[2], François Henn[1] and Adrien Noury[1]; [1]Laboratoire Charles Coulomb (L2C) - UMR5221 du CNRS, Montpellier, France, France; [2]Institute of Physics, Azerbaijan National Academy of Sciences, Baku, Azerbaijan, Azerbaijan; [3]Laboratoire Interdisciplinaire de Physique, Univ. Grenoble Alpes & CNRS, Grenoble, France, France; [4]Institut d'Electronique et des systèmes (IES), Univ. Montpellier & CNRS, Montpellier, France, France

Carbon nanotubes (CNTs) possess extraordinary mechanical, thermal, and electrical properties due to their atomically perfect structure and sp2-hybridization. Recently, Single-wall CNTs (SWCNTs) have become an interesting host for the nanoscale confinement of fluids, with a wealth of surprising phenomena appearing: spontaneous filling, frictionless mass transport, unusual phase diagram, etc[1]. Most of these phenomena are still under debate and call for experimental confirmation. But the field is struggling with finding experimental approaches sensitive enough to carry out measurements at the level of individual nanotubes. SWCNT field effect transistors (SWCNT-FETs) showed that the electronic properties of SWCNTs are sensitive to their diameter,

defects, doping, adsorbates, and environment[2], [3].
In this contribution, we demonstrate that individual carbon nanotube field effect transistors (CNTFET) are excellent tools for this aim, for the first time allowing to precisely identify water confined inside the nanotube. By studying the electrical performances of several unopened and opened CNTFETs submitted to various atmosphere and temperature treatments, i.e. dry air, humidity, secondary vacuum, and current annealing, we show that it is possible to distinguish water being outside and inside the nanotube, just outside, or the nanotube free from water. We thus observed that for opened SWCNT both secondary vacuum and current annealing move threshold gate voltage towards more negative values, while for closed SWCNT secondary vacuum had no effect compared to current annealing. To sum up, the current annealing treatment is essential to distinguish water adsorbed outside from water confined inside. We show that this behavior is universal, as all devices' metallicities behave similarly, provided that the surface of the nanotube is pre-cleaned by current annealing. We will also discuss the mechanisms behind the coupling of electronic transport and the presence of water.
Our results open up the possibility to use CNTFET for instance reliable, selective, and sensitive chemical and biological sensors, and also, to resolve the long-standing questions in the nanofluidic community about the behavior of water under nanoscale confinement.

Carbon Nanotube-Based Flexible Memory Devices for Neuromorphic Computing Yutaka Ohno, Takeshi Watanabe, Koki Tatsumi, Atsushi Kawaguchi and Adha Sukma Aji; Nagoya University, Japan

The increasing information needed to be processed in the artificial intelligence (AI) era requires a breakthrough in a novel computing paradigm. Brain-inspired computing using hardware-based synaptic devices, such as memristors, is gaining attention due to its ability to mimic the biological synapse connections. Reservoir computing is a novel neural network computing method that has advantages in processing a high amount of data at a short computing time and low training cost while maintaining low power consumption. Here, we report physical reservoirs based on carbon nanotube (CNT) memory devices, such as memristors and thin-film transistors (TFTs) with hysteresis. First, CNT/HfO_2/CNT memristors were fabricated by sandwiching a thin HfO_2 insulator between two CNT network films. Ultra-dense memristors can be obtained by connecting multiple electrodes to the bottom and top CNT films. Each combination of two electrodes can act as a memristor because the current path will be different for each due to the network structure of the CNT films. We demonstrated Pavlov's dog training regime to the system. We also explored the potential of CNT TFTs with hysteresis as a memory device for reservoir computing. NARMA (nonlinear autoregressive moving average) tasks have been demonstrated by using CNT TFTs with multiple nodes.

All-Carbon Nanomaterial Inks for Print-in-Place, Recyclable and Water-Based Electronics Aaron D. Franklin; Duke University, United States

For decades we've been hearing about the promise of printing electronics directly onto any surface. However, despite significant progress in the development of inks and printing processes, reports on fully, direct-write printed electronics continue to rely on excessive thermal treatments and/or fabrication processes that are external from the printer. In this talk, recent progress towards print-in-place electronics will be discussed; print-in-place involves loading a substrate into a printer, printing all needed layers, then removing the substrate with electronic devices immediately ready to test. A key component of these print-in-place transistors is the use of inks from various nanomaterials, including: 2D graphene and hexagonal boron nitride, and 1D carbon nanotubes. Using an aerosol jet printer, these mixed-dimensional inks are printed into functional 1D-2D thin-film transistors (TFTs) without ever removing the substrate from the printer and using a maximum process temperature of 80 C with most processing occurring at room temperature. Using a similar print-in-place process, completely recyclable printed transistors will be discussed, fabricated entirely using nanoscale carbon-based inks. These recyclable devices exploit a printed crystalline nanocellulose (CNC) ionic dielectric. Finally, the same set of carbon-based inks will be demonstrated for use in all-aqueous (completely water-based) printed CNT-TFTs, eliminating dependence on processing with harsh solvents. These demonstrations give evidence for an electronic future involving devices with fabrication and/or function that goes beyond what is possible with traditional semiconductor technologies.

Screen-Printed Resistive Gas Sensors Based on Functionalized Carbon Nanotubes and Electronic Design for Selective Detection of Carbon Monoxide and Hydrogen Christopher Landorf, Marriana Nelson, Rebekah Baggett and Zun (Cathy) Chen; Brewer Science, Inc., United States

Often the most challenging aspect of research in nanostructured materials is getting the materials into a form where they can be manipulated without changing the desired properties of the nanomaterial. Brewer Science has developed a unique method for solving this problem by using solubilizing pi-bonders reacted with the carbon nanotubes in a superacid environment. The resulting carbon nanotubes can be dispersed in water, alcohols, and other polar solvents without the need for surfactant, producing a novel environment for the functionalization of the solubilized carbon nanotubes.
Films made of these materials are remarkably conductive, achieving less than 400 Ω/square at 85% transmittance. These carbon nanotubes can be spray coated, placed in alcohols for ink-jet printing, or dispersed in glycols for screen printing. The resulting films can support short current pulses, which, by modulating their frequency, can be used to control the temperature of the film.
In addition to making good inks, these dispersions can be used as a reaction medium to functionalize them with active materials, such as metal oxides, peptides, or polymers, to make them respond electronically to a targeted analyte or environment. In this talk, I will describe how we made tin(IV) oxide–functionalized carbon nanotubes and how we used our pulsed temperature control scheme to sense multiple analytes with only one screen-printed pixel by distinguishing the different optimal reaction temperatures of carbon monoxide and hydrogen.

4:15 PM NM02.09.07
Solution Processable Carbon Nanotubes on Shrinkable Polymer for Enhanced Porosity and Conductivity for Sensing Application Lana Joharji and Nazek El-Atab; King Abdullah University of Science and Technology, Saudi Arabia

Carbon nanotubes (CNTs) have a huge potential in electronic devices applications such as sensors and transistors due their high electric conductivity and stability. More specifically, a wide range of carbon-based nanomaterials, including carbon nanotubes (CNTs), have been used as humidity sensing medium due to their high conductivity, electrical sensitivity, and chemical stability. In terms of fabrication, various methods for coating/depositing CNTs on various substrates have been previously demonstrated, however, they are either complicated with a lot of material waste, or they require stamping to achieve dense

and uniformly dispersed CNTs. In this work, we report a new process flow for achieving a porous, yet more conductive mesh of solution processable CNTs with minimized waste based on drop casting on a shrinkable polymer. Thus, even when a single droplet of the solution is used, the shrinking effect allows improving the resulting film conductivity. Metrology showed that by increasing the heating time at a specific temperature (e.g., 110°C), the CNTs channel area decreases (e.g., 1.3% after 1 min), however, the volume overall increases. This was confirmed using the profilometer where the thickness of the film was increased by 42% at 110°C after 1 min. Moreover, the overall increase in the volume was verified using the porosity test which showed an increasing in the CNTs surface area ~10 times when heated at 130°C for 3 min. Due to the shrinking effect, the CNTs experience a compressive stress which was confirmed by Raman spectroscopy, which showed a shifting of the G peak from 1571 to 1575 after 1 min of heating at 110°C. Moreover, Hall measurements using the physical property measurement system (PPMS) showed that the conductivity of the CNTs film increased by 92.4% after shrinking while the mobility decreased by 44.9%. In fact, the charge density in the CNTs increases under the experienced compressive strain which makes its effect dominant on the overall increase in the film conductivity, despite the degradation in the charge mobility. As an application, the CNTs mesh was used in humidity sensing application. A micro probe system was used to test the device at different humidity levels. The system was connected to the humidity control system, N_2 supply, DI water, and Keithley 4200A-SCS system. The resistive based sensors were tested with and without the shrinking effect. The humidity level was changed from 10% to 90% with a step of 10% and the devices showed a higher change in resistance after shrinking and thus a higher sensitivity compared to the initial intact devices. For instance, with a 30% relative humidity (RH), the resistance increased by 16.3% after 3 min of heating to achieve the shrinking effect compared to 8.7% for the initial device, while at 70% RH, these numbers change to 25.4% and 20.7%, respectively.

Measuring TCR of High Purity Semi-Conducting CNT Networks for Super Sensitive Bolometric Infrared Detectors Tomo Tanaka[1,2], Miyamoto Toshie[1,2], Megumi Kanaori[2], Norika Fukuda[1] and Ryota Yuge[1,2]; [1]NEC Corporation, Japan; [2]National Institute of Advanced Industrial Science and Technology (AIST), Japan

Uncooled infrared sensors of bolometer type have a wide range of applications such as security, military, food inspection, health care, and automotive camera. Currently, the highly sensitive and low-cost device development is key issue for further expansion of demand. The bolometer is an infrared detector for radiant heat by means of an infrared absorber having a temperature sensitive electrical resistance material. Infrared radiation strikes the absorber material heating it and thus changing resistor material resistance. Therefore, bolometer's performance is strongly limited by temperature coefficient of resistance (TCR) of the resistor. The conventional resistor is generally based on vanadium oxide (VO_x) with TCR of about -2%/K [1] and an outstanding resistor is essential to achieve highly sensitive infrared detectors. Recently, single-walled carbon nanotubes (SWCNTs) have been expected as promising materials with high TCR, low resistivity, and high chemical stability. The TCR of -2.1%/K has already been obtained by semiconducting SWCNT films extracted by density gradient method [2]. Further, conventional bolometer which is named microbolometer has a suspended structure for heat separation between the absorbing layer and the substrate, and these are suspended structure with micro electro mechanical system (MEMS) process.

Therefore, we have tried to develop low-cost and high sensitivity bolometer with SWNCTs as resistor material [2]. In this study, we fabricated high TCR bolometer with printed process that was not MEMS process by using the high purity semiconducting SWCNT network films above 98% and the parylene C film which is the low thermal conductivity material as a thermal separation layer and evaluated its device structure and electrical property.

The pristine SWCNTs are fundamentally a mixture of both semi-conducting and metallic SWCNTs. To extract the semi-conducting SWCNTs, "Electric-field inducing Layer Formation (ELF)" method was used, which is our original method [3]. ELF method is the remarkable promising technique to extract semi-conducting SWCNTs with high purity and excellent electrical transportation property by carrier-free electrophoresis using non-ionic surfactant. To show capability of SWCNT bolometers, we measured TCR of the semi-conducting CNT networks which are extracted from various type of commercial SWCNTs.

The sample fabricating process is described below. First, Ti/Au electrodes as a source drain were deposited on a Si substrate, and SiO_2 was sputter-deposited on the surface. Each electrode was exposed by SiO_2 etching. Then a (3-Aminopropyl) triethoxysilane monolayer was formed on the SiO_2 which remaining between the two electrodes, and semi-conducting SWCNTs which is extracted by ELF method were dispersed. The Si chip was mounted on a ceramic carrier, and the temperature dependence of the electrical characteristics of the CNT network between the source and drain electrodes was measured in a liquid nitrogen cryostat at around room temperature. TCR was calculated using each temperature's resistance. The maximum TCR was close to -6%/K, which was larger than the commercial bolometer's resistor material. This shows the superiority of high purity semiconducting SWCNTs extracted by the ELF method. Furthermore, the relationship between the morphology of CNT networks and its electrical characteristics was also obtained.

Acknowledgments: This study was supported by Innovative Science and Technology Initiative for Security Grant No. JPJ004596, ATLA, Japan.

Highly Antistatic Polypropylene/Polyaniline Coated Graphene Nanocomposites Pralhad Lamichhane, Dilli Dhakal, Siddhesh Chaudhari, Clinton Switzer and Ranji Vaidyanathan; Oklahoma State University, United States

Polypropylene (PP) is a commodity polymer widely used for many practical applications including structural materials for electronic devices and automobiles, packaging, and fuel cells. Reinforcing PP with graphene nanoplatelets (GNP) increases the multifunctionality of PP. Higher GNP content in PP enhanced the electrical properties of the material. However, a uniform mixture of GNP in the material is difficult to achieve because of the poor dispersion compatibility between PP and GNP. The GNP tends to agglomerate due to inherent van der Waal forces. In this study, GNP was encapsulated with polyaniline (PANI) to improve the dispersion as well as compatibility with PP. The PANI-GNP nanocomposites were synthesized by in-situ polymerization, and concentrations of nanofiller in PANI-GNP/PP composites were varied at 5, 10, 15, and 20 wt%. The dispersion and compatibility were

validated by various characterization techniques such as FTIR, Raman spectroscopy, XRD, and SEM. In addition, mechanical and electrical properties were studied using DMA, DSC, TGA, flexural test, un-notched impact strength, and resistivity. The electrical conductivity and mechanical tests confirmed that 10 wt% PANI-GNP filled PP can make the best antistatic material with improved mechanical strength.

NM02.10.03
Electrochemical Sensitive Determination of Chemotherapeutic and Immunomodulator Agent Methotrexate Enabled by Novel Graphitic Nano-Heterostructure Material Reham G. Elfarargy, Mahmoud A. Saleh and Nageh K. Allam; American University in Cairo, Egypt

In this study, we report the electrochemical voltametric determination of methotrexate (MTX) chemotherapeutic and immunomodulatory agent with a novel graphitic nano-heterostructure (GNHS) material. In comparison with the previous studies, it shows a higher and enhanced peak transduction. In our research, our GNHS/CPE exhibits superior electrochemical oxidation and detection of MTX in buffer and biological fluids (plasma, urine) than bare Carbon Paste Electrodes (CPE). The synthesized GNHS material has been characterized using X-ray powder diffraction (XRD), X-ray photoelectron spectroscopy (XPS), UV-visible absorption spectroscopy, scanning electron microscopy, Raman spectroscopy, cyclic voltammetry, square wave voltammetry, and electrochemical impedance spectroscopy. In addition, the electronic structure, adsorption energy, band gap, type of interaction, and stable configuration of the used GNHS/CPE have been studied by using density functional theory (DFT). Under optimized conditions, the GNHS/CPE platform showed a linear response for the MTX concentrations in Britton Robinson Buffer (BRB) solution, urine, and plasma with high recoveries and lower limit of detection (LOD) and Limit of Quantification (LOQ) in comparison to the current literature. In addition, reproducibility, stability, and selectivity studies show promising results for the modified GNHS/CPE electrode.

NM02.10.04
Molecular Interactions at the Interface of C - Reactive Protein (CRP) and Poly Vinyl Alcohol (PVA) in the Presence of Carbon Nanotubes Ryan Baker and Isaac Macwan; Fairfield University, United States

Many diseases typically trigger an immune response producing biomarkers, which are largely proteins present in blood, other body fluids or tissues indicating the presence of that disease. A common detection method for certain diseases is therefore, the detection of abnormal amount of a certain protein in the body. One example of this is a cardiac inflammatory C-reactive protein (CRP), which is commonly seen to result from a heart disease. Nanotechnology and biosensors can be used to detect the levels of CRP in blood plasma before they get to more extreme levels, leading to an early detection of the disease as pointed out by previous studies. The goal of this project is to simulate the interactions between the inflammatory protein, CRP, a polymer, Polyvinyl Alcohol (PVA), and Carbon Nanotubes (CNTs) using molecular dynamics through simulation software called Visual Molecular Dynamics (VMD) and nanoscale molecular dynamics (NAMD). Atomic-level models (coordinates) of the CRP protein and PVA are acquired through the protein data bank database while the pristine 20nm long CNTs with chirality (15,15) and (12,20) are modeled through the Nanotube builder modeling program within VMD. Molecular simulations of the individual PVA, CRP and CNT controls as well as an entire system with PVA and CRP interacting between the two CNTs are carried out based on the CHARMM (Chemistry at HARvard Molecular Mechanics) parameters. Furthermore, TIP3 water model along with neutralizing salt concentration is used to create a waterbox for real-time interactions as currently such data is lacking in the literature. Stability analysis is performed using RMSD (root mean square deviation), distance between center of mass, salt bridges, hydrogen bonds, secondary structure analysis and conformational energies of the system using VMD plugins and TCL scripts. Exhaustive analysis involving electrostatic energy evaluation of individual molecules, Van der Waals energies between the molecules, optimal adsorption cut-offs using the criteria of interaction energies and number of participating adsorbed atoms as well as interfacial water molecules and their hydrogen bonds is also performed on the simulated molecular trajectories at the nano-bio interface. It is expected that the information obtained from these simulations will be used to develop electrospun PVA/CNT nanofibrous scaffold based electrochemical biosensor to detect biomarkers similar to CRP.

NM02.10.07
Reliable Carbon Nanotube Paste Emitters Producing High Current Density for X-Ray Tubes by Improving Cohesion and Adhesion Through Chemically Reactive Fillers SeonAe Byun[1], Sayed Zafar Abbas[1], Jeung Choon Goak[1], Sora Sim[2], Choul Ho Lee[2] and Naesung Lee[1]; [1]Sejong University, Korea (the Republic of); [2]Vatech, Korea (the Republic of)

Carbon nanotubes (CNTs) with one-dimensionally rolled-up graphene structures have been spotlighted as an electron emission material for cold cathodes, thanks to their extremely high aspect ratios of lengths to diameters, excellent electrical conductivity, superior mechanical strength and outstanding chemical stability. A paste screen printing method, which has been mostly used to fabricate commercial CNT field emitters, is engaged in this study. The paste, usually composed of CNTs, inorganic nanoparticle fillers, organic binders and solvent, should be made to possess an appropriate viscosity for easy printing. Performance of CNT paste emitters is mainly determined by two factors: dispersion of CNTs and fillers; adhesion to a substrate and cohesion of paste. When adhesion and cohesion are weak, the paste may be peeled off from the substrate or partly from the paste by strong electrostatic forces exerted on CNT emitters during field emission, which may unfortunately cause catastrophic arcing and permanent damage. If adhesion and cohesion are too strong, it can be difficult to carry out surface activation to expose CNTs above the surface by delaminating the topmost surface layer of the paste. Thus, the paste adhesion and cohesion should be controlled in an appropriate range. The pastes were fabricated using Al, Ni and AlN nanoparticle fillers. This study made effort to impart appropriate adhesion and cohesion of CNT pastes by controlling formation of intermetallic compounds of aluminides at the paste-substrate interface and inside the paste. The paste was screen-printed on Kovar (54Fe-29Ni-17Co) substrates, fired at 400°C in air to remove organic matters and annealed in vacuum at 830°C to form intermetallic compounds. High-temperature vacuum annealing produced nickel aluminides on the substrates and also inside the paste. Al seems to react with Ni of the Kovar substrate and Ni filler inside the paste, improving the paste-substrate adhesion and the paste cohesion, respectively. X-ray diffraction, transmission electron microscopy, energy dispersive x-ray spectroscopy, and x-ray photoelectron spectroscopy were engaged to characterize the aluminide formation. Vacuum-sealed x-ray tubes were fabricated using the CNT paste emitters with high adhesion and cohesion which generated high current density. The x-ray tubes were normally operated at high current density for an extended period of time.

NM02.10.09
High Quality Growth and Transfer of Bilayer Graphene on Sapphire Sivasakthya Mohan, Yuqian Gu, Dmitry Kireev, Deji Akinwande and Kenneth Liechti; The University of Texas at Austin, United States

Dry transfer of graphene from its growth substrate through mechanical delamination is a quick, effective, and clean transfer method that overcomes the disadvantages of traditional wet transfer approaches such as long processing times, polymeric residues, and harsh chemical exposure of the transferred films [1]. However, it is difficult to use graphene grown on a copper foil, which is a widely used growth substrate, in the dry transfer process due to its lack of mechanical rigidity and relatively high adhesion energy. Thin copper films deposited on silicon wafers have been used to overcome this challenge. However, a very high initial thickness of copper film needs to be deposited to avoid dewetting problems that occur at the high graphene growth temperatures. To this end, we have studied the metal-free synthesis of graphene on sapphire substrates, which has been shown in literature to have a sufficiently low adhesion energy with graphene [2].

In this work, we have performed atmospheric pressure chemical vapor deposition growth of bilayer graphene directly on sapphire at conventional metal CVD temperatures. The as-grown graphene was characterized using Raman spectroscopy, scanning electron microscopy (SEM), atomic force microscopy (AFM) and X-ray photoelectron spectroscopy. Prior to growth, the sapphire substrates were annealed in air at high temperatures to achieve a suitable surface reconstruction of the sapphire surface needed to grow high quality graphene. The annealing improved the quality of the as-grown graphene as confirmed by the reduction in the D/G Raman peak ratio of the graphene. With annealing we have achieved a D/G ratio as low as 0.15 for the graphene grown at 1050C, which is among the lowest reported values in literature, thus proving the graphene to be of high quality. Graphene based transistors were fabricated from the as-grown films and electrical characterization was done to extract field-effect mobility.

Furthermore, fracture experiments have been conducted over a range of mode-mixes on laminated beam specimens consisting of a sapphire/graphene/epoxy/sapphire stack, using a dual actuator loading device. At each mode-mix, we extracted the toughness and normal and shear components of the traction-separation relation of the interface between graphene and sapphire. The high quality of the transferred films was confirmed by Raman mapping, SEM and AFM and electrical characterization. The variation of the interactions with mode-mix adds the potential of switchable adhesion for 2-step dry transfer processes, where higher adhesion is required to remove the graphene from the growth substrate but lower adhesion is required to deposit it on the target substrate.

3D Bioprinting of Soft Polymeric Nanocomposites Subha Parvathi Madamuthu, Nikshiptha Mulagada, Roshan Kumar Bhatta and Prabir Patra; University of Bridgeport, United States

3D bioprinting uses a combination of natural and synthetic materials for a useful tissue scaffold. 3D Printing of biomaterials is a customized method to provide a chance to diffuse different cell types at desired locations. Using the in-situ bioprinting tissue scaffold could be made. Alternatively in ex-situ bioprinting, there is a need for cross-linking of cell formulation. Here we report the 3D printing of a photocurable nanomaterial scaffold using Flavin mononucleotide, a synthetic equivalence of DNA with graphene nanoparticles.
Flavin is an important coenzyme for a few oxidative enzymes. It is the principal form in which RIBOFLAVIN is found in cells and tissues. Flavin Mononucleotide (FMN) is a biomolecule produced from vitamin B2 and is an important luciferin (i.e., bioluminescent cofactor).
Graphene-based materials are non-toxic and demonstrate excellent electrochemical and optical properties, as well as the capability to adsorb a variety of aromatic biomolecules through a π–π stacking interaction and/or electrostatic interaction, which make them ideal materials for constructing biosensors and loading drugs. Graphene's biocompatibility, large surface area, excellent mechanical properties, and ease of functionalization make it a unique material for bone tissue and stem cell research. GO substrates allow cell adhesion and proliferation and have been shown to be capable of increasing the differentiation of stem cells into the osteogenic lineage.
It is also anticipated that graphene scaffolds could play a role in tissue engineering and regenerative medicine. A graphene scaffold with stem cells has been studied and explored by researchers thus the cells not only did survive, but also divided, proliferated, and morphed into neuron-like cells.
In this research, 3D bioprinting of the mixture of graphene nanoparticles, flavin mononucleotide, and gelatin was performed. We used the R3BEL Mini printer which runs on extrusion-based printing technology, and pronterface as a printer control software tool. Using the same tools, a mixture of Alginate, Bowmans Albumin, and Hydroxyapatite as a nanocomposite has also been synthesized to print bone-like structure.
The customized photocuring nanomaterial was prepared at room temperature. A 5ml syringe with a 22-gauge blunt-tip needle was filled with 4ml photocurable nanomaterial. We printed FMN containing graphene and gelatin biomaterial on a petri dish (100 mm diameter). To print the bone-like structure we used a G-code printer file.
This research is still in progress; after overcoming the existing obstacles, we plan to use FTIR, UV-Vis, XRD, and SEM to analyze the surface properties of our custom-made photocurable nanomaterial scaffold.
This work presented stable structures of 3D printed hydroxyapatite and photocurable polymers as soft nano composite biomaterials.

NM02.10.12

Multifunctional Inorganic Nanomaterial Aerogel Assembled into fSWNT Hydrogel Platform for Ultraselective NO2 Sensing Hee-Jin Cho[1], Il-Doo Kim[1] and Sung Mi Jung[2]; [1]Kaist, Korea (the Republic of); [2]Korea Institute of Toxicology, Korea (the Republic of)

Facile fabrication of multifunctional porous inorganic aerogels remains an outstanding challenge despite the considerable demand for extensive applications. Here, we present the production of a multifunctional porous inorganic nanomaterial aerogel by controllable surface chemistry of a functionalized SWNT (fSWNT) hydrogel platform for the first time. The versatile functional inorganic nanoparticles can be incorporated uniformly on the porous 3D fSWNT hydrogel platform through a facile dip coating method at ambient conditions. The morphology of the multifunctional inorganic aerogel is manipulated by designing the fSWNT hydrogel platform for different requirements of applications. In particular, Pt-SnO2@fSWNT aerogels exhibit high porosity and uniformly distributed ultrafine Pt and SnO2 on the fSWNT platform with controllable particle size (1.5−3.5 nm), which result in significantly high surface area (393 m2 g−1). The ultrafine Pt-SnO2@fSWNT aerogels exhibit highly sensitive (14.77% at 5 ppm) and selective NO2 sensing performance even at room temperature due to the increased active surface area and controllable porous structure of the ultrafine aerogel, which can provide fast transport and penetration of a target gas into the sensing layers. The newly designed multifunctional inorganic aerogel with ultrahigh surface area and high open porosity is a prospective materials platform of high performance gas sensors, which could be also broadly expanded to widespread applications including catalysis and energy storages.

NM02.10.13

Advanced Polymer Hybrid Materials with Anisotropically Aligned Carbon Nanotubes Sunwoo Kim and Woo-Jae Kim; Ewha Womans University, Korea (the Republic of)

Carbon nanotubes (CNTs) have been reported their high tensile strength, electrical conductivity, and thermal conductivity. Even though CNTs are utilized as conductive materials in various fields, the studies are focused on CNT-dispersed conductive sheets. However, the anisotropic property of CNTs enables vertically aligned CNTs to have much higher mechanical strength and electrical conductivity. Despite the versatility of polymers, their applications are limited due to the weak strength and the poor electrical conductivity. Thus, some studies have improved their properties by adding conductive materials like CNTs. Particularly, the anisotropic properties of CNTs can fortify polymers to lightweight hybrid polymers with high strength and electrical conductivity. For this purpose, a method of coating polymers on vertically synthesized CNT forests was suggested, but the process is complicated, and it is very difficult to produce the hybrid polymer of large area. We suggest a much more simple and effective process for anisotropically aligned carbon nanotubes (A-CNT)-polymer hybrid materials. In the pre-polymer solution, mildly oxidized CNTs were arranged in the vertical direction by electrophoresis. Electric fields for the arrangement were formed by alternating currents through indium tin oxide (ITO) electrodes. The polymer was

subsequently cured by ultraviolet radiation and the aligned CNTs were fixed in the polymer. The A-CNT-polymer showed higher strength in compression tests compared to the CNT-polymer before the arrangement. In addition, the parallel direction to A-CNT promoted the much lower resistance for the electric current. Low-weight composition of CNTs can efficiently fortify the mechanical and electrical properties of the polymer. The excessive addition of CNTs seems to reduce the mechanical strength of the photocurable polymer. This low-weight and multi-functional hybrid materials can be developed to bodies of vehicles, ballistic materials, or membranes for fuel cells.

Covalently Functionalized Graphene for Chemical Separation Membranes Taishu Yoshinaga, Shao-Xiong Lennon Luo, Quynh P. Ngo and Timothy Swager; Massachusetts Institute of Technology, United States

Chemical modifications of graphene oxide (GO) afford functionalized graphene with versatile characteristics. A Johnson-Claisen rearrangement is one of [3, 3] sigmatropic rearrangements to synthesize covalently functionalized graphene. Specifically, allylic alcohols on the GO surface are applied to the Claisen rearrangement to form ethyl ester groups anchored to the GO sheet through a robust carbon-carbon bond. These functional groups and robust carbon bonds survive in thermal and reductive conditions, indicating this functionalized graphene's significant potential in applications in harsh conditions.

GO-based membranes are promising candidates as a pressure-driven non-thermal method to mitigate global energy use and to cope with environmental concerns in water purification and chemical separations because of their favorable characteristics: high water permeability, two-dimensional structures, and mechanical strength. There is a particular need for energy-intensive weak black liquor (WBL) concentration in the kraft pulping process. WBL is a high alkaline corrosive fluid with polymers, other organic molecules, inorganic salts, and total solids of ~18% and is processed at high temperatures of up to 95 °C. Although WBL is concentrated to ~75% solids via the evaporation processes to create biofuels, even partial concentration with non-thermal technology to ~30% solids significantly reduce energy requirements and are beneficial for economics and environments.

We herein focused on further chemical modifications of the robust graphene material prepared by the Claisen rearrangement of GO to apply its membrane for WBL concentration that is processed in the harsh conditions. To increase the hydrophilicity and water permeability of the graphene, we saponified the ester groups under base conditions to generate carboxylic acid groups. A narrowed interlayer spacing of the graphene sheet also lowers water permeation; therefore, we then amidated the hydrophilic graphene under mild conditions using linear diamines. These diamines can contribute to not only the expansion of the interlayer spacing but also the cross-linking between the graphene sheets. Water-dispersible graphenes with various interlayer spacings were successfully synthesized, and we prepared membranes from each graphene material. Large molecules (~1 kDa) were selectively excluded, and WBL was concentrated at a stable rate and water permeation thanks to the expanded interlayer spacing and hydrophilicity. These versatile water-dispersible graphenes represent promising membrane materials in WBL concentration and other chemical separations.

Development of Graphene/Silicon Composite Based Lithium Ion Battery Anode Tarik C. Turkoglu, Eren Atli, Omer R. Caylan and Goknur Cambaz Buke; TOBB University of Economics and Technology, Turkey

The need for energy storage devices is growing constantly, requiring the development of more efficient, high-capacity batteries. Due to their superior properties compared to conventional batteries, lithium-ion battery cells have become the most popular energy storage units, and they are now widely used in our daily lives. The most common application area for Li-ion batteries is electric vehicles. The Li-ion battery cells used in electric cars are expected to have a short charging time, a long cycle life, a low weight per volume, and a large storage capacity. The anode structure of Li-ion batteries should be enhanced to obtain these desirable features. The most commonly utilized active material in the battery anode structure is graphite. Although graphite's electrical conductivity and extended service life are superior to those of its alternatives, its low charge capacity and small surface area require further development. Silicon is another common component in Li-ion batteries. Silicon can store ten times more Li ions than graphite; nevertheless, anodes made of Si rather than graphite degrade more quickly and have a shorter service life due to structural fragmentation produced by high-volume fluctuations during charge/discharge cycles. Because of its enormous surface area, mechanical and electrical capabilities, and chemical resistance, graphene, a two-dimensional honeycomb structure of carbon atoms, has a lot of potential to solve these challenges. As a result, the purpose of this research is to use a Gr/Si composite structure to improve the energy storage capacity, mechanical characteristics, and chemical resistance of a battery anode. Top-down processes such as high vacuum furnaces, wet chemistry, and the flash method are used to make Gr for Gr/Si composites. The morphology of synthesized materials is examined using OM, TEM, and SEM. Raman spectroscopy is used to examine their structure. BET analysis is used to determine the surface area of the composite anode material. Electrochemical characterization methods will be used to determine the charge capacity of Gr/Si composites, which will be reported.

NM02.10.16
Ultrashort Pulsed Laser Induces Graphene on Woods and Leaves for Green Electronics Truong-Son D. Le, Han Ku Nam, Dongwook Yang, Younggeun Lee, Young-Ryeul Kim, Seung-Woo Kim and Young-Jin Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

In recent years, we have witnessed a tremendous demand for electronic devices that leads to a massive amount of electronic waste and rapid exhaustion of non-renewable resources. Accordingly, green electronics has received much attention to minimize the negative impact of electronic waste and pave the way toward the sustainable development of our society. Functional nanomaterials are essential components in green electronics in which graphene is highly attractive owing to outstanding electrical, mechanical, and thermal properties. Graphene has been used in various advanced applications ranging from academia to industry. Until now, graphene can be synthesized via liquid-phase exfoliation, mechanical exfoliation, chemical vapor deposition, and reduction of graphene oxide. Nevertheless, there is a lack of an efficient, low-cost, and eco-friendly synthesis method to realize the full potential of graphene.

Herein, we have developed a facile fabrication of pre-designed graphene electrodes on arbitrary woods and leaves in ambient conditions utilizing ultraviolet femtosecond laser pulses. Compared with conventional lasers, the femtosecond laser shows distinct advantages due to ultrashort pulse durations, extremely high peak intensities, and nonlinear interactions with carbon materials. The mechanism of LIG formation was extensively studied in which the heat accumulation of repetitive laser pulses increases the base temperature at the laser-irradiated area to carbonize the precursors, and the intense ultrashort laser pulses induce sufficiently high temperature to transform amorphous carbon into LIG. The formation of LIG was confirmed and characterized using electrical measurement, scanning electron microscopy (SEM), transmission electron microscopy (TEM), Raman spectroscopy, and X-ray diffraction (XRD). The resultant LIG electrodes on woods and leaves exhibited sheet resistances of 10 and 23.3 Ω/sq, respectively. Especially, the sheet resistance of LIG electrodes could be easily controlled via the laser writing parameters. SEM images revealed three-dimensional porous structures formed during the laser-induced carbonization and graphitization processes. These porous structures possess a high active surface area which enhances ion diffusion and is beneficial for sensing and energy storage applications. High-resolution TEM images showed graphene flakes with a typical lattice spacing of 0.355 nm. In order to demonstrate the potential of LIG on woods and leaves, we fabricated green graphene thermistors, micro-supercapacitors, and pseudo-capacitors. The as-produced devices exhibit comparable or better performance than other state-of-the-art graphene-based devices. Thus, the use of low-cost, abundant,

renewable, and biodegradable green materials not only allows the mass production and commercialization of green electronics but also develops a sustainable future.

NM02.10.17
Twisted Graphene Growth on Graphene/SiC Template Using Sequential Thermal Processes in Vacuo Without Air Exposure Yao Yao[1], Taiki Inoue[1], Yoshihiro Kobayashi[1], Makoto Takamura[2] and Yoshitaka Taniyasu[2]; [1]Osaka University, Japan; [2]NTT Basic Research Laboratories, Japan

Twisted few-layer graphene (FLG) has recently attracted great attention due to the emergence of exotic electrical properties [1]. In a previous study, we reported that the FLG was synthesized by overlayer growth of graphene on a monolayer graphene template (MLGT) using a chemical vapor deposition (CVD) method. We found that moiré pattern appears in the lattice structure of the grown graphene two-dimensional (2D) island and the grown 2D graphene islands have random twisted angles. The coalescence process of graphene islands with various twist angles was indicated by temperature and pressure dependence of graphene island size [2]. In this study, based on understanding the growth mechanism of twisted FLG, we further developed the growth conditions of SiC to optimize the MLGT. By reducing the nucleation sites on the MLGT, large-area lateral growth of twisted graphene can be realized.
The MLGT used in previous studies was possibly contaminated with adsorbates due to air exposure during the step-by-step processes of MLGT formation and overlayer graphene growth in different vacuum chambers. In order to obtain a cleaner MLGT surface with fewer nucleation sites, the epitaxial growth process on SiC and the CVD process on MLGT/SiC were continuously performed in an argon atmosphere in an infrared heating furnace. Raman spectroscopy, atomic force microscopy (AFM), and scanning tunneling microscopy (STM) were used to evaluate the surface features and morphology of the samples.
We obtained high-quality MLGT on 6H-SiC (0001) surfaces at 1700 °C in an argon environment at ~1 bar. We verified the uniform single crystal surface of MLGT by STM and Raman spectroscopy under the epitaxial growth process. Graphene islands with twisted structures were sequentially synthesized in vacuo without air exposure with optimized CVD conditions. Using AFM to measure several representative locations on the surface, we observed twisted FLGs on the MLGT grown under the CVD process. By comparing with previous results [2], the twisted FLG under sequential thermal processes shows a significant reduction in nucleation sites and step-edge nucleation.
The coalescence growth process shows that twisted graphene islands nucleate very closely in the initial nucleation stage. Then, graphene islands gradually approach each other in lateral directions as they grow [2]. This mechanism is exactly the opposite of the thermodynamics-based energetics principle that the chemical potential of carbon atoms and their diffusion length on the graphene surface should be reduced. This suggests that the roughness of the surface directly affects the nucleation efficiency in our growth model. Therefore, in the study of sequential thermal processes in vacuo without air exposure, the clean MLGT surface with reduced initial nucleation sites can effectively provide enough space for lateral growth. It is expected to make further progress in the large-area lateral growth of twisted graphene.

Scanning Nonlinear Dielectric Microscopic Investigation of Mechanically Exfoliated WSe_2/SiO_2 and Suspended WSe_2 Koki Takano, Kohei Yamasue, Toshiaki Kato, Toshiaki Kato and Yasuo Cho; Tohoku University, Japan

Transition metal dichalcogenides (TMDs) have semiconductor properties that make them applicable to various devices even at a thickness of a few atomic layers or less. However, the electrical characteristics of ultra-thin TMD devices are often affected by the quality of the interface between the TMD layers and the substrate. TMD based field-effect transistors may exhibit hysteresis phenomena in their transfer characteristics due to high trap density at the interface. In this context, a suspended structure making TMD layers off the substrate may be effective for avoiding the influence from the interface. To demonstrate the effectiveness of the suspended structure, here we investigate the field-effect carrier doping on a suspended WSe_2 by scanning nonlinear dielectric microscopy (SNDM). SNDM is a near-field microwave based scanning probe microscopy method permitting the dominant carrier concentration imaging (dC/dV imaging) through the detection of the variation in the tip-sample capacitance [1]. The dC/dV image can reflect the polarity of the dominant carriers (p- or n-type) and their concentrations in a nanoscale. We measured three-layer WSe_2 suspended on 40 nm-height Au wires on a SiO_2/Si substrate. For comparison, we also observed 3-10 layer WSe_2 on the same substrate, which was prepared by a Scotch method. Ideally, WSe_2 shows an ambipolar characteristics on dc-bias voltages. To avoid the carrier injection from the tip to the sample during the measurement, we used a special tip insulating the tip apex from the sample. The insulating tip was prepared by forming a 10 nm-thick SiO_2 layer on a commercial conductive microcantilever. We obtained dC/dV images for different dc-bias voltages to investigate field-effect carrier doping. The WSe_2/SiO_2 sample showed a highly hysteretic carrier doping effect. In contrast, the suspended WSe_2 showed an ideal ambipolar behavior without significant hysteresis. We also investigate the spatial density distributions of interface trap by local deep level transient spectroscopy (local DLTS) based on SNDM. Local DLTS showed that interface trap density was high at the WSe_2/SiO_2 interface, while it was below the detectable level in the suspended WSe_2. These results demonstrate that the suspended structure is effective for exploiting the intrinsic characteristics of atomic-layer WSe_2 without the influence from the interface. This work is supported in part by a Grant-in-Aid for Scientific Research (20H02613, 16H06360) from JSPS, Japan.

Measurements of the Intrinsic Bending Stiffness of Ultrathin 2D Materials Yingchun Jiang[1], Dingli Wang[1], Wenyang Qu[1], Sri Sridhar[2], Soumendu Bagchi[3], Huck B. Chew[2] and Changhong Ke[1]; [1]Binghamton University, The State University of New York, United States; [2]University of Illinois at Urbana-Champaign, United States; [3]Los Alamos National Laboratory, United States

Bending stiffness is one of the intrinsic fundamental mechanical properties of two-dimensional (2D) van der Waals materials (such as graphene, hexagonal boron nitride (h-BN), and molybdenum disulfide (MoS_2)) and is relevant to many of their applications. While their in-plane elastic properties have been investigated extensively, their bending rigidity remains not well-understood which is mainly due to the elastic anisotropy of these 2D crystals. Individual sheets in 2D crystals are stacked together by weak van der Waals interactions, and interlayer shear deformations result from the out-of-plane deformation. Repeatable experimental measurements of the bending stiffness of 2D materials remain a difficult task because of their small sizes. Remarkable scattering among the reported values in the literature poses challenges to consensus understanding and application of the 2D materials. Here we investigate the intrinsic bending stiffness of monolayer or few-layer graphene, h-BN, and MoS_2 by probing their self-folding deformation on flat substrates using atomic force microscopy (AFM) and by molecular dynamics simulations and density functional theory (DFT) calculations. The self-folding deformation of 2D materials is formed as a result of an energy balance between bending deformations and adhesion interactions. The bending stiffness is obtained from the measured folding deformation using a nonlinear continuum mechanics model. The results show that the bending stiffness of few-layer 2D materials follows a power function with thickness, and h-BN flakes of two to six layers are found to possess much higher bending rigidities than their carbon analogy,

graphene, which are in good agreement with atomistic simulations. Despite that MoS_2 reportedly possesses a lower tensile modulus than graphene and h-BN, its bending stiffness is found to be much higher than that of same-layer graphene and h-BN. The study reveals quantitively how the interlayer shear interaction contributes to the out-of-plane deformability of multilayered 2D materials.

From Structures to Applications—Designing Diverse Architectures of 3D Porous Graphene Oxide and Reduced Graphene Oxide Through Pickering Emulsion Templating Yiwen Chen, Gabriele Capilli, Thomas Szkopek, Simon D. Tran and Marta Cerruti; McGill University, Canada

Graphene oxide (GO) is an oxidized graphene derivative containing hydrophilic oxygen functional groups and hydrophobic sp^2 graphene domains. GO sheets are stable in water; thus, they are ideal building blocks to assemble the 2D GO from aqueous suspensions into 3D architectures with large surface area and availability for functionalization. GO is an interesting starting material as one can further reduce GO and obtain reduced graphene oxide (rGO) to restore the properties of graphene, such as mechanical strength and electrical conductivity. The broad applications of graphene-based porous materials demand fabrication methods that are simple and yet can create complex architectures and compositions. However, it remains a challenge to assemble GO into porous materials mainly based on GO or rGO with controllable pore size, different interconnectivity, and tunable compositions. GO Pickering emulsion templating is a potential solution to fabricating well-defined graphene-based architectures. GO sheets can stabilize Pickering emulsions because of their amphiphilicity. By controlling the formation of emulsions, one can directly prepare porous GO templated by emulsion droplets. In this study, we used GO Pickering emulsion strategy to obtain porous GO and rGO materials with complex architectures, interconnected or closed pores, and tunable compositions tailored to different applications. We first introduced a dual-templating approach involving emulsion and ice as templates, to create GO, rGO, and composite scaffolds which have interconnected hierarchical structures with variable pore size and composition designed for bone tissue engineering. We developed stable GO emulsions in which GO flakes serve as both stabilizers and matrix builders. Upon freezing and drying these emulsions, large pores are templated by the oil droplets, and small pores by ice crystals formed in the water phase, whose sizes can be controlled by freezing temperatures. The complex architectures are tailored for bone tissue engineering, and we showed GO scaffolds are excellent substrates for mesenchymal stem cell penetration and growth. We subsequently introduced rGO/cobalt oxide porous electrodes for selective seawater electro-oxidation through GO emulsion templating. By adjusting the GO assembly on emulsion droplets, we generated closed pores templated by GO emulsions enclosing Co_3O_4 particles in the oil droplets. After reduction, the pore walls composed of rGO are permeable to water and gases while limiting the diffusion of dissolved ions like chloride to the cobalt oxide particles deposited on the internal walls of rGO pores. The closed rGO pores and the enclosure of cobalt oxide particles improved the electrode's selectivity for water oxidation application. In summary, our study based on GO Pickering emulsions allows us to control the architecture and composition of GO, rGO and composite porous materials. With appropriate design of the GO Pickering emulsions and the architecture of porous materials, one can enhance the performance of GO and rGO based porous materials for a variety of applications.

NM02.10.21
Electrical and Mechanical Properties of Homogeneous CNT/Cu Composite Wire Made from Copper Nanoparticles Supported CNT Yarn Yoku Inoue, Kosuke Tanaka, Takayuki Nakano and Yoshinobu Shimamura; Shizuoka University, Japan

Compositing highly conductive copper with lightweight, strong carbon nanotubes (CNTs) is expected to produce innovative materials that possess all of these characteristics. In this work, we fabricated a homogeneous composite of aligned CNTs and copper by nanoparticle-functionalized CNT dry spinning. Copper complexes were reacted with CNTs in the gas phase to support copper nanoparticles a few nm in diameter on CNT forests. Then the dry-spun CNT webs were fabricated into yarns, introducing Cu nanoparticles inside the yarn structure. The copper nanoparticles decorating the CNTs enabled high-yield copper electroplating inside the CNT yarn. By DC electroplating copper on the CNT yarn, homogeneous CNT/Cu composite wires were fabricated. The electrical conductivity of the composite wire at room temperature was found to be of a magnitude that followed the proportion of copper, and the current flowed through the copper portion. However, since the temperature coefficient of resistance was smaller than that of copper, the composite wire showed superior specific conductivity in the high-temperature region above 350 K compared to the conductivity of commercial copper. Since the resistance was less likely to increase on the high-temperature side, the current capacity was higher than that of copper. On the other hand, the tensile strength was significantly higher than that of copper in the tensile properties. The results followed the mixing rule of CNT bundles and copper, indicating a good homogeneous mixture of CNTs and copper.

NM02.10.22
Direct Laser Conversion of Transparent Polymers into Laser-Induced-Graphene for Realizing Ultra-Thin Optics Younggeun Lee, Dongwook Yang, Han Ku Nam, Truong-Son D. Le, Young-Ryeul Kim, Seung-Woo Kim and Young-Jin Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Optical systems include refractive, reflective, and diffractive optical elements. Modern industries have mostly adopted refractive lenses out of these. Fundamentally, the optical lens has evolved from glasses for correcting the human eye's imaging capability, to miniaturized cameras inside the mobile phones for taking pictures or face-recognition-based unlocking, also to LIDAR sensors for image processing in autonomous vehicles. Although such refractive lens systems are widespread, they cannot be reduced in terms of the weight and size due to the required geometrical thickness of the refractive material and the volume for performance. Here, we suggest a direct-laser-patterning of diffractive optical elements by converting transparent polymers into laser-induced-graphene (LIG) to realize ultra-thin and light-weight optical system. Colorless polyimide (CPI) was used as the transparent polymer, which is one of the well-known materials for its strong chemical and abrasion resistance. A femtosecond pulse laser was utilized to pattern a diffractive lens to enable non-thermal laser patterning with higher patterning resolution and minimal material damage. CPI is transparent in the visible wavelength region, so it is difficult to process the CPI using a visible laser system (e.g., green laser at 532 nm). Therefore, we imposed an ultra-violet laser (at 343 nm center wavelength) in this fabrication process through the third harmonic generation of a 1030-nm ytterbium-doped fiber femtosecond laser. The transparent CPI film has relatively a high absorption coefficient in ultraviolet region, so it is possible to convert CPI to LIG efficiently even at low laser intensities. An ultra-thin Fresnel zone plate was patterned successfully with a 5-μm linewidth. The resulting diffractive optics have focal lengths ranging from a few millimeters to hundreds of millimeters.
Two key applications of the realized ultra-thin diffractive optics will be introduced in the presentation; the first one is the micro-endoscopic optical coherence tomography and the other one is the micro-satellites optical communication. Firstly, a more compact micro-optical coherence tomography (OCT) was realized by replacing the existing graded-index (GRIN) lens to an ultra-thin diffractive LIG lens with the astigmatism correction capability. Secondly, we applied ultra-thin LIG optics to satellite applications where weight and volume reduction is crucial. Solar sensors for satellite position control were realized with LIG lens with a 10-μm thickness and 10-g weight while providing a higher attitude control resolution.

NM02.10.24
Graphene-Based Nano-Electro-Mechanical Resonator for Radio Application Yugyeong Je[1], Dong Hoon Shin[2], Hyunjeong Jeong[1] and Sang Wook Lee[1]; [1]Ewha Womans University, Korea (the Republic of); [2]Delft University of Technology, Netherlands

In this work, the electro-mechanical properties and RF (Radio Frequency) applications of graphene nano-electro-mechanical resonators have been studied.

The graphene resonators were fabricated in suspended structures on the PMMA (poly(methyl methacrylate)) trench. The resonance frequency of the graphene resonators was measured by an optical measurement method using a laser interferometer. The resonance frequency of the graphene resonators was measured in the megahertz range, which could be tuned by electrostatic actuation. For radio applications, the audio signal was mixed with the input AC frequency by Frequency Modulation (FM). The resonance frequency shift by FM changed the amplitude of mechanical resonance of the graphene resonators. The graphene nano-electro-mechanical radio reproduced the input audio signal audible to the human ear by amplitude demodulation.

NM02.10.25
Stretchable Strain Sensors Fabricated Using a Highly Crystalline Reduced Graphene Oxide/Carbon Nanotube Composite Yuna Himura[1], Chikako Ishiguro[1], Zizhao Xu[1], Taiki Inoue[1], Yuta Nishina[2] and Yoshihiro Kobayashi[1]; [1]Osaka University, Japan; [2]Okayama University, Japan

Graphene and carbon nanotubes (CNTs) have excellent electrical and mechanical properties as well as biocompatibility, making them attractive materials for electronic components of wearable devices. Freeze-dried graphene forms a highly porous three-dimensional structure which retains high conductivity and elasticity due to a 3D network, making it an effective material for strain sensors [1]. Superior properties of graphene for the sensors have been reported to improve by composite formation with the CNTs [2]. In previous studies, however, graphene has been produced in a large scale from graphene oxide (GO) by chemical process or thermal treatment at relatively low temperatures below 1000 °C. Consequently, crystalline quality of reduced graphene oxide (rGO) remains low due to insufficient reduction, and it should be improved for enhancing the sensor performance. By using our unique thermal process under ethanol at 1500°C to produce the high-quality rGO [3], this study developed a stretchable strain sensor using highly crystalline and porous 3D graphene [4]. Sensor performance was improved by introducing CNTs in our devices, after optimizing the sensor structure.
Water dispersions of GO [5] and CNTs synthesized by the super-growth method were mixed and freeze-dried at two different freezing rates to form 3D sponge structures. Then, the sample was thermally treated at 1500 °C in an ethanol atmosphere to reduce and repair the GO. Scanning electron microscopy (SEM) was used to observe the sample structure, and Raman spectroscopy was used to evaluate the crystallinity of graphene and CNTs. To fabricate the strain sensor, the sponge sample was connected to copper wires and sandwiched between polydimethylsiloxane (PDMS) films, followed by curing at 80 °C. The sensor performance was evaluated based on the gauge factor (GF) value, which is calculated as the ratio of resistance change to strain change. SEM observation revealed that the porosities of the sponge and the size of aggregated rGO flakes were changed by the freezing rate. The composite sponge of rGO and CNTs formed by rapid freezing resulted in increased sensor durability. The initial resistance of the sensor is on the order of several ohms because of the low defect density of rGO and CNTs. The addition of CNTs improved the linearity of the sensor response, but the GF value decreased. By optimizing the sensor thickness and the connection direction of the copper wires, the sensor durability and sensitivity were significantly improved. The optimized sensor showed a GF value of 15 for over 10 trials at 150 % strain. The stretchable strain sensor demonstrated the constant resistance change in response to finger bending and stretching. High-porosity and high-quality composites of rGO and CNTs are promising as stretchable conductive materials for strain sensors with potential applications in wearable devices.

NM02.10.26
Hydrogen Storage Material of Fe-Doped Magnesium Supported by Graphene Yuto Hosono and Mitsuo Notomi; Meiji University, Japan

Magnesium (Mg) is an abundant resource of all elements and one of the most prospective hydrogen storage materials because of its large hydrogen storage capacity (7.6 wt.%). Magnesium hydride (MgH_2) has a high dehydrogenation temperature (approximate 450 °C), which restricts broad applications and should be reduced for a wide range of applications. There is one of the solutions that we compound Fe and/or graphene into Mg. Fe, which has electrons in the *d* orbital and plays the role of a catalyst for hydro- and dehydrogenation, can promote the dissociation of one hydrogen molecule adsorbed on the surface to two hydrogen atoms and the desorption of absorbed hydrogen from the interface with MgH_2 (called overflow effect and hydrogen-pump effect respectively). Graphene, which generally has a higher specific surface area and electron mobility, is expected not only to be a scaffold but also to facilitate hydrogen absorption and desorption reactions as electron source. Since graphene oxide and defects of graphene have significantly lower electron mobility, one may have to prepare the perfect structure of graphene with fewer defects. Although there are some studies to discuss the effect of the addition of graphene by computer simulation, there are few studies to evaluate the effect of the damage degree of graphene structure on its hydrogen desorption properties with some experiments and to obtain any quantitative results.
Firstly, we prepare less-defected graphene by liquid-phase exfoliation (LPE) method in the procedure as follows. We mix up graphite with salt by ball milling and dissolve as-milled graphite in an organic solvent. The graphite in the solvent separates each layer, i.e., graphene, by sonication and centrifugation in the solution for 5 and 30 minutes respectively, and then we dry the only supernatant of the solution for a little powder. Secondly, we compound Mg, Fe, and graphene by high-energy ball milling under an Ar atmosphere for 5-25 hours and then complete the samples as nano-sized powder. In this preparation of the compounds, we consider some conditions to achieve the most effective dispersion of Fe and graphene around Mg, which are the appropriate state of graphene before adding into Mg and the order of adding each material.
The degree of perfect structure in graphene may be estimated quantitatively from the intensity ratio (I_D/I_G) of the disorder and defect peak (D peak), which is derived from *sp3* defect, vacancy-like defects and/or edge defects, to the carbon-*sp2* peak (G peak), which is derived from planar configuration bonding, with Raman spectroscopy. We use the graphene with under $I_D/I_G = 0.4$ (graphene oxide: around 1.0, reduced graphene oxide: 0.8 ~ 1.5) in this experiment. The particle size and surface morphology in the samples may be observed with scanning electron microscopy (SEM). The layer spacing and crystallinity of graphene, as well as crystalline phases such as hydrides before and after hydrogenation, may be determined by X-ray diffraction (XRD). The hydrogen storage capacity may be obtained by pressure-composition-temperature (PCT) measurement (based on JIS H 7201) using the Sievert apparatus designed by ourselves under lower hydrogen pressure (< 1.0 MPa). The dehydrogenation temperature may be measured with differential scanning calorimetry (DSC). From the results, we may find making conditions of the most appropriate compound with the processing.

NM02.10.27
Micro-Mechanical Characterization on Amorphous Carbon and Its Nanoporous Structures Zhongyuan Li[1], Ayush Bhardwaj[2], James J. Watkins[2] and Seok-Woo Lee[1]; [1]University of Connecticut, United States; [2]University of Massachusetts Amherst, United States

Carbon-related nanostructured materials have a strong potential as a mechanical reinforcement material due to their strong ionic/covalent C-C bond, which restricts the motion of dislocation, the carrier of plasticity. However, their brittleness and relatively high density limits their structural application. In this study, therefore, we have developed amorphous carbon with almost no short-range ordering and its nanoporous structures, where the ligand thickness is only around 10nm, by rapid thermal annealing of Brush block copolymer and Phenol formaldehyde. To evaluate the mechanical response, we perform the nanoindentation tests and in-situ compression tests on a micropillar, which was fabricated by utilizing focused-ion-beam milling. Both fully dense and nanoporous structures exhibit a large compressive fracture strain up to ~40% with a significantly high work hardening rate. Raman spectroscopy before and

after compression test revealed that this unusual plasticity results from dynamic change in distribution of sp2 and sp3 bonds. During plastic deformation, the number of sp2 bonds decreases but the number of sp3 bonds increases. Carbon atoms, which have sp2 bonds, seem to be reconfigured to form sp3 bond, which is thermodynamically preferable under compression. In addition, we found that both compressive fracture strength and compressive maximum strength are nearly independent of porosity unlike the hardness that scales with the porosity. We think that the porosity-independent strength could be related to the size-affected strength of nanoscale ligand. Larger pores reduce the density, but the size reduction of ligand enhances its strength. These two contributions compensate each other, leading to the negligible change in strength of the entire nanoporous structure. Interestingly, all structures, both fully dense and nanoporous structures, in our study demonstrate the modulus of resilience much higher than most engineering materials due to their low Young's modulus, implying that amorphous carbon materials have an exceptional capability to absorb and release the mechanical energy per a given volume. However, yield strength of our fully dense amorphous carbon was found to be slightly lower than that of amorphous carbon published in other works. Complete diffuse diffraction pattern indicates that our amorphous carbon possesses the almost complete random arrangement of carbon. This liquid-like structure could be beneficial to lower mass density but does not seem to be desirable to obtain high strength. It would be necessary to control the distribution of a short-range ordering to obtain the improved yield strength without sacrificing the mass density and the ductility much by optimizaing the synthesis condition or performing the post thermal-mechanical treatment. All these efforts will pave a new pathway to create light, strong, and tough carbon nanostructures for their future structural applications.

Deposition of Multilayer Graphene Using Pulsed Laser Deposition Yuxuan Wang, Neil Alford and Peter K. Petrov; Imperial College London, United Kingdom

Since being discovered in 2004, graphene keeps on gaining more and more attention from various research areas. While the wide application of single-layer graphene is still challenging due to the intrinsic defect of traditional mechanical exfoliation and CVD method, the multilayer (2-10 layers of graphene) graphene (MLG) thin films are becoming more and more popular in applications that require a replacement of traditional metals. Multilayer graphene attains a better trade-off between expense and physical property. It is not to mention the unconventional superconductivity in the magic-angle bilayer graphene that was discovered recently[1]. Thus, it is important to develop a quick and simple method to grow multilayer graphene on the desired substrate.

In this study, MLG thin films are grown without catalyst on Si/SiO_2, strontium titanate (STO) and boron nitrate substrates by pulsed laser deposition (PLD). The substrate is heated to 800ºC at the rate of 50ºC/min in the vacuum level of 3 10^{-5} Torr. Then 500 pulses of a 248nm excimer laser with a frequency of 10Hz are shot to a graphite target. Once the deposition is finished, the substrate is cooled at various rates to 300ºC before a further natural cooling to room temperature. To explore the effect of the annealing process on the quality of graphene, the samples were subject to a 5min annealing at 800ºC before the cooling process. Finally, to examine the influence of deposition mode on graphene, the 500 laser pulses were divided into 5 groups of 100 pulses, separated with a 10s time interval in between.

The Effect of cooling rate and laser energy on the property of MLG is studied using the samples grown on Si/SiO_2 substrates, while the influence of the annealing process and deposition mode on the MLG is studied on the samples grown on STO substrates. For characterisation, a Raman spectrometer, atomic force microscope and 4x probe electrical measurement are used.

The measured thickness of the MLG grown on Si/SiO_2 substrate was about 2nm indicating that the number of graphene layers is approximately 6. The mean roughness of all the graphene samples measured using AFM was in the range of 100-300pm.

We found that the MLG on all the three substrates show a high D peak and broadened 2D in the Raman spectrum. This can be explained as wrinkled MLG with defects and disorder[2]. According to the Raman result, cooling rate, annealing process and different deposition modes have a marginal effect on the MLG quality.

The electrical measurements have further confirmed this observation. The resistance of graphene on Si/SiO_2 is at the same level when 30-90ºC/min cooling rates were used. High resistance of the graphene was measured when cooled at a rate of 10ºC/min. However, the measurement uncertainty associated with this experiment was much higher. The post-deposition treatment (annealing process and the altered deposition mode) had a negative effect on the resistance of the graphene grown on the STO substrate.

The graphene resistance improvement occurs only when the laser energy was increased from 435mJ to 735mJ. Then the corresponding resistance of the graphene on the Si/SiO_2 substrate was reduced by three folds. This result was attributed to the improved compactness of MLG.

Thus, we propose the PLD technique as a quick and simple method to produce MLG thin films with electrical conductivity similar to the one of the commercial CVD graphene.

Nanoarchitected Schwarzites and Tubulanes with Ultrahigh Energy Absorption and Resilience Peter Serles[1], Alianna Maguire[2], Jun Lou[2], Pulickel Ajayan[2] and Tobin Filleter[1]; [1]University of Toronto, Canada; [2]Rice University, United States

Nanoarchitected materials represent the frontier of low-density metamaterials that can achieve specific strengths and specific stiffnesses beyond the theoretical limit for solid materials. These nanoarchitected materials combine three synergistic effects – nanoscale size effects of individual elements, high performance constituent materials, and optimized shape factors – which are enabled through nanoscale additive manufacturing by two photon polymerization (2PP).[1] Of particular interest, post-2PP pyrolysis enables the printed 3D design to be converted to a mechanically high-performance carbon which has demonstrated rubber-like behaviour due to its nanoscale size and flaw tolerance.[2,3]

Leveraging the high mechanical performance of nanoarchitected carbon produced by 2PP and pyrolysis, we form Schwarzite and Tubulane structures which are designed from p-type Schwarz minimal surfaces and aligned cross-linked carbon nanotube architectures, respectively. These structures are optimized to minimize stress concentrations and therefore demonstrate specific strengths beyond the theoretical limit when subject to compression testing with failure strengths of several GPa at =50-70%. It is demonstrated that the strength and stiffness increase by nearly an order of magnitude as the wall-thickness of the architecture is reduced from several micron to several hundred nanometers, indicating the role of nanoarchitecture and size effects.

Due to the flaw intolerance of the constituent pyrolyzed carbon, the nanoarchitectures exhibit ultra-high failure strain often exceeding ε=40% when the wall-thickness is on the order of several hundred nanometers. This equates to an enormous absorption of mechanical energy and the structures demonstrate nearly complete recoverability when subject to cyclic loading up to σ_y=95%. The modulus of resilience (U_R) represents the elastic energy absorption, and it is demonstrated that the nanoarchitected Schwarzite and Tubulane structures exhibit U_R more than an order of magnitude greater than Kevlar and other defence materials.

We thus employ the nanoarchitectures towards absorption of dynamic energy including micro-ballistic impact testing at sub- and super-sonic velocities and atomic force microscope vibration damping from kHz to MHz frequency ranges. Both of these unique dynamic loading conditions demonstrate clear applications where the high dynamic performance of these nanoarchitected materials is vastly superior to conventional materials such as Kevlar and rubber. Nanoscale additive manufacturing of these optimized Schwarzite and Tubulane geometries thus demonstrates that the successes achieved in nanoarchitected materials can be further extended towards dynamic loading conditions with wide-reaching implications from vibration control and damping in device design, to resilient materials for aerospace, or lightweight ballistic impact materials for defence.

Copper Single-Atom Catalyst on N-Doped Carbon Nanoparticle for Methane Partial Oxidation Hyesung Lee and Sang-Yup Lee; Yonsei University, Korea (the Republic of)

Methane is an abundant natural resource whose reserve is estimated as 187 trillion m^3. Global methane gas production increases rapidly every year, however, methods of long-distance transportation of the liquefied methane and conversion into valuable chemical products are lagged behind because of the high binding energy of a C-H bond (about 100 kcal/mol). Conversion of methane to methanol is one strategy to overcome transportation and economic issues. Currently, methane is generally converted to methanol via a two-step process; first, methane is converted to syngas at a high-temperature and high-pressure condition and then transformed further into methanol. To make this energy-consuming process simple, various catalysts have been explored that convert methane into methanol in a single step. In nature, the enzyme of methane monooxygenase (MMO) found in methanotrophs converts methane directly into methanol during the metabolic process. Recent progress in structural biology revealed that the active site of MMO, specifically particulate MMO (pMMO), has a single-atom copper active center coordinated with three histidine imidazoles and a carboxylate. Inspired by this enzyme structure, a single-atom copper catalyst is developed on the N-doped carbon support and is examined for its catalytic activity. The catalyst is prepared by pyrolysis of the copper-doped zeolitic imidazolate framework-8 (Cu-doped ZIF-8). For the synthesis of the catalyst, single-atom copper sites are constructed at the nods of ZIF-8 first by doping and then pyrolyzed to convert the imidazole linkers into N-doped carbon. The N-doped carbon stabilizes single-atom copper by coordinating with the nitrogen species and provides a large specific surface area and high physical/chemical stability in acid/base solutions. Due to the stability of the N-doped carbon, oxidative degradation of the catalyst support is reduced remarkably. The coordination structure and oxidation state of the copper active center are extensively scrutinized to have a CuN_4 structure, which is similar to that of pMMO. Catalytic conversion of methane to methanol is promoted with the increase of copper content; however, excessive copper doping generates metallic copper clusters that repress the methane partial oxidation. Besides the copper content, other reaction parameters such as reaction temperature, the concentration of oxidants, and carbonization conditions are influential for the catalytic activity. Too high temperature and oxidant concentrations result in the overoxidation of methane to produce CO_2 and formic acids. This study offers a way to synthesize a catalyst for methane partial oxidation producing liquefied products and contributes to accounting for the reaction pathway of pMMO.

Tunable Nonreciprocal Electrical Transport in 2D Tellurium with Different Chirality Peide P. Ye; Purdue University, United States

Tellurium (Te) is an elemental semiconductor with a simple chiral crystal structure. Te is fundamentally a 1D van der Waals material. Te in a two-dimensional (2D) form synthesized by solution-based method shows excellent electrical, optical, and thermal properties. In this work, the chirality of hydrothermally grown 2D Te is identified and analyzed by hot sulfuric acid etching and multi-angle high-resolution transmission electron microscopy. The gate-tunable nonreciprocal electrical transport is observed in 2D Te with different chirality, providing a possibility for the realization of controllable polarized spins for spintronic applications. The opposite band evolution of different-handedness 2D Te under magnetic field reveals the fundamental relationship between the spin-orbit coupling and the symmetry of the crystal structure. Our work shows that 2D Te is an ideal material system for studying the chirality-related electrical transport properties and crystal growth mechanism.

9:00 AM NM02.11.02
Molecular Doping of Bottom-Gate/Top-Contact Nanotube Network Field-Effect Transistors for Flexible Electronics Jan M. Gotthardt and Jana Zaumseil; Universität Heidelberg, Germany

Due to their electrical and mechanical properties, networks of semiconducting single-walled carbon nanotubes (SWCNTs) are of interest as active layers in low-power, low-voltage, high-frequency flexible electronics. However, their intrinsically ambipolar charge transport leads to high power dissipation in integrated circuits.
Here, we report the fabrication of bottom-gate/top-contact field-effect transistors (FETs) with SWCNT networks as semiconducting layer and an ultrathin hybrid dielectric consisting of 5 nm aluminium oxide and a self-assembled monolayer (SAM) of an alkyl phosphonic acid. These FETs show ambipolar behaviour and can be operated at low voltages (less than 2 V). Charge carrier mobilities and contact resistance can be optimized by the choice of SAM[1] and SWCNTs. The influence of contact and gate electrode overlap on the parasitic capacitance and the contact resistance is investigated. With the use of molecular organic dopants, *e.g.* ttmgb[2,3] or F4TCNQ, purely n- or p-type channel FETs can be realized. These thin film FETs can be fabricated on rigid glass substrates and also on thin polyimide (PI) films with no change in the device performance upon removing the PI film from the support substrate. With their bendability and purely n- or p-type performance these transistors are suitable for the application in integrated complementary circuits for flexible electronics.

9:15 AM NM02.11.03
Freestanding Electrode for Wearable Supercapacitor Enabled by Sole Carbon Nanotube Liquid Crystalline Fiber Hayoung Yu[1,2], Dong-Myeong Lee[1], Nam Dong Kim[1], Seung Min Kim[1] and Hyeon Su Jeong[1]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Gwangju Institute of Science and Technology, Korea (the Republic of)

With the development of wearable devices and the miniaturization of various home appliances, fiber-type solid-state supercapacitors(FSSCs) are attracting a lot of attention as a wearable storage device. As an electrode material in FSSCs, CNT fibers (CNTF) based on liquid crystal (LC) spinning have been considered as a promising candidate due to the remarkable properties of electrical conductivity (~10 MS m^{-1}), excellent mechanical strength (~4 GPa), light weight and good flexibility. However, ironically, the highly densified structure of LC CNTF with clean sp^2 carbon surface acts as disadvantages to directly apply as an electrode for FSSCs. Efforts have been made to increase the electrochemical activity of CNTF mainly by enlarging the specific surface area of CNTF and/or complexing the fibers with pseudocapacitive materials (e.g. metal oxide and conducting polymers). Unfortunately, these post treatments not only require additional complicated process, but also deteriorate intrinsic properties of CNTF. Thus, it is desirable to enhance the electrochemical activity of CNTF without additional material or post-process.
In this study, we fabricate LC CNTF from surface functionalized CNTs, followed by investigating its electrochemical activity without any additional materials for direct use as a freestanding electrode for wearable supercapacitors. Oxygen-containing functional groups (–COOH and –OH) are introduced onto the surface of CNTs by well-known acid treatment and lyotropic LC phase thereof is developed for use as a dope for wet-spinning. The structure, properties of CNTFs and its electrochemical activity are systemically investigated as a function of the degree of fictionalization. Interestingly, functionalized CNTF shows better mechanical property of 0.67 N tex^{-1} and electrical property of 3 MS m^{-1} than those of pristine CNTF (0.25 N tex^{-1}, 1 MS m^{-1}). Moreover, the functionalized CNTF exhibits a specific capacitance of 140 F g^{-1} at 0.5 A g^{-1} while the pristine CNTF shows 21 F g^{-1} at 0.5 A g^{-1}, demonstrating that it is possible to enhance electrochemical activity without additional material or post-process. A solid state FSSCs prepared with symmetric structure shows reasonable energy density of 9.2 Wh kg^{-1} at a power density of 700 W kg^{-1}. The study on the electrochemical activity of CNTF as a function of functionalization provide a new insight for the development of fiber-shaped energy storage device.

9:30 AM NM02.11.04
Large Thermoelectric Power Factor in Flexible and Robust Few-Walled Carbon Nanotube Yarn by Ultra-High Temperature Annealing Yasuhiko Hayashi[1], Jun Kametaka[1], Shinya Nakahori[1], Takeshi Nishikawa[1], Aung Ko Ko Kyaw[2] and Hiroo Suzuki[1]; [1]Okayama University, Japan; [2]Southern University of Science and Technology, China

Carbon nanotube (CNT) yarn is one of the potential thermoelectric (TE) materials owing to its narrow band-gap energy, high charge carrier mobility, and excellent mechanical property, which is conducive for flexible and wearable devices. One of the critical challenges is the tuning of electrical and thermal transport since they interrelate against the high performance of TE properties. Although the thermal and electrical properties of CNT yarns are likely to enhance their properties by the extremely high-temperature annealing using Joule heating process, the phenomena underlying the improvement of properties have not clarified yet.
Here, we propose a way to improve the power factor of CNT yarns fabricated from few-walled carbon nanotubes (FWCNTs) by two-step method; Joule-annealing in the vacuum followed by doping with p-type dopants, 2,3,5,6-tetrafluo-7,7,8,8-tetracyanoquinodimethane (F4TCNQ). FWCNT yarns (15 - 20 μm) were fabricated from the CNT array using a dry spinning method with a rotation speed of 500 rpm and a drawing speed of 300 mm/min. Joule-annealing was accomplished by passing a current of ~ 73 mA and voltage of ~ 56 V under vacuum condition at around 1-2 × 10^{-4} Pa for 1 min. Doping was performed with various concentrations of F4TCNQ such 1, 2.5, 5 and 10 mg/ml, respectively. Then CNT yarns were dipped into the F4TCNQ solution for 6 hrs. Seebeck Coefficient Measurement System was used to measure the thermoelectric properties such as Seebeck coefficient, electrical conductivity and power factor, which has a special sample-attachment to measure the thin film or wire specimen.
Results show that doping after Joule-annealing can lead to a higher thermoelectric power factor of CNT yarn. Specifically, FWCNT yarn doped with 2.5 mg/ml F4TCNQ exhibited a power factor of 2250 μW m^{-1} K^{-2}, which is one of the highest values among the p-typed doped CNT yarn. Moreover, pretreatment by Joule-annealing is confirmed to be an effective way to improve Seebeck coefficient due to the transformation of (semi) metallic to semiconductor behavior. The significant improvement of Seebeck coefficient and electrical conductivity after Joule-annealing followed by p-type doping can be qualitatively explained by applying the power-law model on relaxation time approximation to the single band. Fermi energy of the pristine CNT yarn is −0.0037 eV, which is very near to the top of the valence band. After Joule- annealing, Fermi level rises to 0.071 eV and it behaves like an intrinsic semiconductor, dominating phonon scattering. Therefore, Seebeck coefficient improves significantly after Joule-annealing. After doping, the location of Fermi level moves down to −0.053 eV.
Based on our results, the combination of Joule-annealing and doping can pave a way to enhance the thermoelectric properties of FWCNT yarn.

Spin Splitting of Dopant Edge State in Magnetic Zigzag Graphene Nanoribbons Felix R. Fischer[1,2,3]; [1]Univ of California-Berkeley, United States; [2]E O Lawrence Berkeley National Laboratory, United States; [3]Kavli Energy NanoScience Institute, United States

Since their original inception the class of ZGNRs, graphene nanoribbons lined by hydrogen terminated zigzag edges, have been associated with unusual magnetic edge states. Computational models predict that the zig-zag edges in ZGNRs host spin-polarized edge-states that are coupled ferromagnetically along one edge and antiferromagnetically coupled across the width of the ribbon. Despite recent advances in the bottom-up synthesis of GNRs the unique magnetic edge-structure of ZGNRs has long been obscured from direct observation by an unusually strong hybridization of the zigzag edges with the surface states of the underlying support. To access the elusive edge magnetism in ZGNRs we developed a novel and broadly applicable technology that effectively decouples the highly reactive spin-polarized edge states of ZGNRs from the underlying metallic growth substrate. Introduction of a superlattice of substitutional nitrogen-atom dopants along the edges of a ribbon not only facilitates the electronic decoupling but introduces a highly sensitive local magnetic sensor. Differential conductance scanning tunneling spectroscopy shows a “Zeeman-like” spin splitting of the two electrons in the nitrogen lone-pair by the spin-polarized frontier bands of ZGNRs revealing a large exchange field corresponding to Beff ~ 1000 T lining the edges of the ribbon.

10:45 AM NM02.11.06
In-Liquid Dual-Harmonic KPFM for the Study of Electronic Properties of Single Layer Graphene Marta D. Fernández[1], Elena del Corro[1], Liam Collins[2], Martí Checa[2], Xavier Illa[3], Antonio P. Pérez[1] and Jose A. Garrido[1,4]; [1]Catalan Institute of Nanoscience and Nanotechnology, Spain; [2]Oak Ridge National Laboratory, United States; [3]Centro de Investigación Biomédica en Red en Bioingeniería, Biomateriales y Nanomedicina (CIBER-BBN), Spain; [4]ICREA, Spain

Graphene, a biocompatible 2D material with unique properties – electrical, optical, mechanical and chemical- is widely investigated as a key part of electronic devices aimed to perform in the biomedical field. More specifically, electrodes and transistors are fabricated using graphene as the active

material for sensing and brain activity recording, among other applications[1,2].
Dual-Harmonic Kelvin probe force microscopy (DH-KPFM) is used in this work to measure the work function of chemically-grown single layer graphene, deposited on different substrates, in contact with an aqueous electrolyte to evaluate its dependence on the electronic nature of the substrate, the pH and the ion strength of the electrolyte. In-liquid DH-KPFM is also used in this project to obtain information about the surface potential distribution along a device (graphene transistor) in a liquid environment, and the measurement of the contact resistance values in that media. Contact resistance in graphene transistors affects its performance and is caused, among other parameters, by the work function differences between graphene and the contacting metals[3]. Knowing the values of the contact resistance of a standard fabricated device will enable the optimization of the fabrication procedure. To the best of our knowledge, this parameter has never been measured using in-liquid DH-KPFM. Hence, the novelty of this work and its contribution to the field is remarkable.
Other techniques such as Raman spectroscopy, electrochemical impedance spectroscopy, X-ray and ultraviolet photoelectron spectroscopy complement the experimental work, providing information about graphene's doping level and its dependence on the ionic environment and the substrate; furthermore, we will also discuss the effect of chemical residues present on the graphene surface.

Advanced Fuel Cell Catalyst Based on Graphene Marie Heitzmann[1,2], Gerard Gebel[1,2] and Laure Guetaz[1,2]; [1]Commissariat à l'énergie atomique et aux énergies alternatives, France; [2]Université Grenoble Alpes, France

Carbon blacks supported Pt, currently widely used as electrocatalysts in Polymer Electrolyte Membrane Fuel Cells (PEMFC) are thermochemically unstable in PEMFC operating conditions. This is especially true at the cathode side where, on top of relatively elevated temperature (80°C) and acidic conditions, both the potential and the relative humidity may be high. The resulting carbon oxidation is partially responsible for the PEMFC performance decrease observed over time. Hence, long term durability still needs to be improved in order to consider PEMFC as credible alternatives to conventional power sources for automotive, stationary or portable applications.

Much effort have been directed to identify and synthesize alternative carbon materials as catalyst supports for PEMFCs. One strategy to decrease carbon support corrosion is to use carbon with high extent of graphitization, which is supposed to decrease defect sites on the carbon structure, where carbon oxidation starts [1], [2]. However high graphitic content of carbon can be a brake for particle nucleation and dispersion. Among the different forms of carbon, graphene, a monolayer of graphite, has attracted increasing attention because of its unique two-dimensional (2D) single sheet of sp^2 carbon in a hexagonal arrangement. Graphene possesses unique properties, such as high charge-carrier mobility (up to 10^5 cm^2 V^{-1} s^{-1}), super conductivity, ambipolar electric field effect, high mechanical strength (130 GPa), quantum Hall effects at room temperature, and high surface area (2,600 m^2 g^{-1}). These properties make graphene ideal for a wide potential applications such as in nanoelectronics, electrode support for catalysts in electrochemical energy systems, chemical and biological sensors, composite materials and biotechnology.

Although graphene exhibits an attractive range of properties as catalyst supports for fuel cells, it suffers from a serious issue. Integration of such catalyst in catalyst layer (CL) is complex due to the high cohesive van der Walls attractions between graphene sheets, named also pi-stacking of graphene layers, leading to serious blocking of the active surface area. To overcome this phenomena, one solution consists to add spacers or additives in graphene sheets such as carbon black, carbon nanotube or urea to be intercalated into Pt/graphene [3].

In this work, platinum catalysts were synthetized on Graphene support, nanocharacterised, processed in ink and incorporated in fuel cell. Several techniques of MEA fabrication were used: CCB (catalyst coated backing), CCM (catalyst coated membrane) or CCM by decal (transfert on inert substrate). We investigated these new active layers at the cathode side in term of electrocatalytic performance and compared the electrochemical properties of these hybrid materials with a commercial Pt/C catalyst using carbon blacks as carbon support. Moreover, the use of additive was also studied to enhance performance by aerate active layer and avoid pi-stacking of graphene layer.

The goal of this work is to demonstrate that MEA fabrication has an huge impact on performance but also on durability, and the use of graphene based carbon supports can be promising in effectively reducing the carbon corrosion and then increase lifetime of the cell if CL are assembled correctly. Accelerated stress test has been done in 25 cm^2 fuel cell setup with two types of test : AST for carbon support from DOE and fuel cell Dynamic Load Cycle, FC-DLC cycles.

The GrapheneCore3 European program funds this work.

11:15 AM NM02.11.08
II-Orbital Mediated Charge Transfer Channels in Functionalized Graphene Andrea Casotto[1,2], Giovanni Drera[1], Daniele Perilli[3], Sonia Freddi[1,4], Stefania Pagliara[1], Michele Zanotti[1], Luca Schio[5], Alberto Verdini[5], Luca Floreano[5], Cristiana Di Valentin[3] and Luigi Sangaletti[1]; [1]Università Cattolica del Sacro Cuore, Italy; [2]University of Notre Dame, United States; [3]Università degli Studi di Milano-Bicocca, Italy; [4]KU Leuven, Belgium; [5]CNR-IOM, Lab. TASC, Italy

Functionalization makes graphene (Gr)-based materials extremely appealing for several applications, such as photonics, optoelectronics, and sensing, [1,2] provided that clear information on the charge transfer mechanisms at the interface can be obtained. Indeed, in the case of layered materials or two-dimensional semiconductors, the operation of electronic devices cannot be separated from the control of the generation and flow of charge carriers at the surface or through the junction that is present at the interface between two layers.
Organic molecules are often chosen to functionalize Gr since they can form covalent bonds with the carbon atoms of the lattice after chemical [3] or electrochemical [4] treatments, but also can be deposited on the surface through physisorption, as done in this work with the formation of a single-molecule thick layer of Nickel Phthalocyanine (NiPc) on a monolayer Gr substrate. Moreover, the selection of aromatic scaffolds allows the formation of π-stacked layers, whose electronic properties are possibly altered by the π-orbitals interactions, even when there is no formation of chemical bonds.
Indeed, in this presentation, I will deal with the characterization of the interlayer electron transfer channels in a NiPc-Gr heterointerface, probed by the employment of both experimental techniques (Resonant Photoelectron and X-Ray Absorption Spectroscopies) and DFT calculations. The discussion will bring evidence that the relaxation pathway, which occurs in the femtosecond timescale, involves only π-symmetry orbitals, that are opportunely oriented in a π-stacked flat layer. This allows the transfer of electrons from the molecules, selectively excited thanks to the synchrotron radiation's photon energy tunability, to the p-doped Gr layer, unveiling the potential of this particular nanoarchitecture for the application in electronic devices.

Tunable WS_2 Nanotubes from Ga-Ion Seeding Sabrya E. van Heijst and Sonia Conesa-Boj; Delft University of Technology, Netherlands

Two-dimensional layered materials have attracted a lot of attention following the discovery of graphene and the demonstration of its remarkable properties. This renewed interest resulted in the discovery of numerous new 2D layered materials, including 2D materials of the transition metal dichalcogenide (TMD) family. A key feature of these materials is that the reduction of the number of layers is accompanied by the modification of the local electrical and optical properties. Furthermore, it has also been shown that this tunability is not restricted to two-dimensional nanosheets, but is also present within the one-dimensional configuration. In this context, TMD-based one-dimensional nanotubes benefit from unique properties that strongly depend on their chirality, diameter, and number of walls. The ability to control these parameters, and thus tune the properties of the nanotubes, is an essential requirement to deploy TMD nanotubes for realistic application, yet achieving such tunability at the nanofabrication level remains a challenge. Here we report on an approach by means of which WS_2 nanotubes of uniform diameter were fabricated and the investigation of their local electronic properties. We find that by implanting gallium ions in a tungsten film and subsequent annealing, highly uniform tungsten oxide nanowires could be fabricated. The sulfurization of these nanowires results in multiwall, close-ended WS_2 nanotubes with similar diameters. These WS_2 nanotubes are then characterised by using advanced transmission electron microscopy techniques, including high resolution electron energy loss spectroscopy. Our results demonstrate how the proposed gallium-assisted synthesis method provides an efficient way of controlling the morphology of WS_2 nanotubes, and thus tuning the electronic properties of these one-dimensional TMD structures, paving the way for the use of WS_2 nanotubes in nanotechnology applications.

Water is essential to live organisms and human societies as the primordial solvent of life. The primordial role of water can be related to its unique physical properties particularly due to the structure of its hydrogen bond network or its dipolar moment. In extreme confinement situations, such as inside nanoscale channels, important modifications of these features are expected. Thus, many theoretical works predicted that confined water in extremely small diameter pores exhibits both unusual phase behavior[1] and structure, compared to bulk water. Thanks to their stiffness, hydrophobic smooth surface, and high aspect ratio, Single Wall Carbon Nanotubes (SWCNT) can be considered as a model nanochannel to get insight into the confinement of water molecules. For instance, it was calculated that the phase of confined water in SWCNT whose diameter is smaller than 1.4nm, behaves as ice-like water with structures from single-file water chains to pentagonal or hexagonal structures depending on the SWCNT diameter [2]. On the other hand, it has been shown from experimental [3] and theoretical [4] calculations that water diffusion in SWCNT is significantly enhanced. Expanding our fundamental understanding of water properties when it is confined in SWCNTs can yield substantial progress in desalination, drug delivery, energy harvesting, etc. applications. Although there are many numerical simulations reported on this system, only a few experimental works have been achieved and it remains a challenging task to get experimental proof of water behavior in such a confined environment.
One of the main challenges to experimentally measuring the properties of nanoconfined water is to be able to fabricate fully sealed microchips. Sealing is a central process for micro and nanofluidic chip fabrication, yet only a few materials can be used, as they must be chemically inert, vacuum compatible, resistant to temperature change, and must have no electrical effect.
In this presentation, I will present a new sealing technology based on SU8 epoxy resist. We show that our bonding method is reliable and versatile for microfluidic, as it can be patterned by photolithography down to micrometric dimensions. It is thus found that a 30 µm high and 20 µm thick wall made of SU8 can sustain relatively pressures up to ~5 bars. We also measured ions permeation through the SU8 walls and found that it is similar or even better to PDMS. The electrical test shows no significant perturbation of electrical devices down to the sensitivity of our measurement set-up, i.e. pA, which makes the SU8 wall resistivity several orders of magnitude higher than that of carbon nanotubes. In addition, our sealing technology turned out to be chemically stable even at high temperatures. Importantly, it does not require plasma activation (contrary to PDMS), therefore it is perfectly suited for the fabrication of delicate nanochannels such as carbon nanotubes.
I will discuss ongoing work to distinguish the effect of water confined inside of the individual single-wall NT based on analyzing the change of the conductance shape. Our preliminary data show that water confined inside the NT mainly influences the gate hysteresis (charge transfer or dopping) of NT, rater that its conductance or the carriers mobilities.

Nanofibrous Carbon Hybrids for Low-Cost Tailored Device Production Mark Atwater; Liberty University, United States

Carbon nanostructures have great potential, which has been largely unrealized in a significant commercial sense. The primary challenges are often related to efficient production at scale and control of device architecture. Carbon nanofibers (CNFs) are a potential alternative to carbon nanotubes, albeit with some loss of performance in terms of electrical or mechanical properties. The countervailing assets, however, are their simplicity in production and diversity in morphology. They have been studied in various aspects of synthesis and functionality for decades, but in recent years a new process for creating bulk devices in situ has been developed. This technique, the constrained formation of fibrous nanostructures (CoFFiN) process, allows free-standing, nonwoven carbon structures to be created repeatedly and reliably at low cost. A recent adaptation has also demonstrated the ability to create hybrid structures incorporating other carbon materials into the fibrous network, which results in a shorter processing time and higher surface area. These CNF hybrids can be made with precise geometries, are strong and robust, and can be tailored to possess a diverse range of properties, making them suitable for electronic devices, composite reinforcement, filtration and purification, etc. The current state of the art, comparison to other nanofibrous structures, and ongoing developments will be discussed.

10:45 AM NM02.12.04
Effects of Mechanochemical Activation on the Structural, Magnetic and Optical Properties of Yttrium Iron Garnet-Graphene Nanoparticles Monica Sorescu[1], Sarah Glasser[1], Felicia Tolea[2], Andrew Craig[1], Mihaela Sofronie[2] and Jennifer Aitken[1]; [1]Duquesne University, United States; [2]National Institute of Materials Physics, Romania

Yttrium iron garnet nanoparticles have potential applications in sensing and microwave devices. In this study, nanoparticles systems were exposed to mechanochemical activation by high-energy ball milling for 0, 2, 4, 8 and 12 h. The samples were subsequently characterized by Mossbauer spectroscopy, X-ray powder diffraction (XRPD), magnetic measurements and optical diffuse reflectance spectroscopy. The 0-h specimens were analyzed by considering 2 sextets in the Mossbauer spectra, corresponding to the tetrahedral and octahedral sites of the yttrium iron garnet structure. The spectra of the milled samples were fitted with a third sextet with the hyperfine magnetic field characteristic to hematite and a quadrupole-split doublet representing superparamagnetic particles of the yttrium iron perovskite (yttrium orthoferrite) phase. The mechanism of the ball milling activation was found to be consistent with the decomposition of the garnet into yttrium iron perovskite and iron oxide phases. A different set of yttrium iron garnet samples was milled with graphene nanoparticles (3 nm in diameter) and analyzed using the same techniques. Examination of the quadrupole doublet's abundance as function of ball milling time indicated that graphene slowed down the precipitation of the perovskite. The increased linewidth of the doublet showed that the carbon from graphene preferentially entered the lattice of the yttrium orthoferrite. The coercive field of the sample milled with graphene is greater than that of the garnet and is even greater when longer milling times are employed and the particle size is smaller. The saturation magnetization decreases with decreasing particle size for prolonged milling due to the occurrence of the antiferromagnetic yttrium iron perovskite phase. The enhanced absorption in the infrared region could be associated with the incorporation of carbon from graphene in the lattice of the yttrium orthoferrite.

10:50 AM NM02.12.05
3D Printing of 3D Graphene—Material Characterization, Properties, Applications and Post Processing to Enhance the Properties Vamsi Krishna Reddy Kondapalli[1], Derek DeArmond[1], Kyle Brittingham[1], Xingyu He[1], Mahnoosh Khosravifar[1], Safa Khodabakhsh[1], Boyce Collins[2], Sergey Yarmolenko[2], Ashley Paz y Puente[1] and Vesselin Shanov[1,1]; [1]University of Cincinnati, United States; [2]North Carolina A&T State University, United States

Over the years multiple efforts resulted in the development of various versions of 3D Graphene via chemical and non-chemical routes. 3D printing of graphene-based polymer inks and aerogels has been considered efficient and promising among the other processes given the advantages of this approach. However, the resultant 3D graphene structures highly rely on a binder or ice support to stay intact. The presence of a binder or another non-graphene phase hinders the translation of the excellent graphene properties into the 3D structure. Here we report 3D-shaped 3D graphene ($3D^2G$) synthesized by combining 3D printing with atmospheric pressure chemical vapor deposition (CVD) process. $3D^2G$ structures produced in various shapes and sizes were characterized using scanning electron microscopy, image analysis, X-Ray Diffraction, micro-CT, 2D Raman spectroscopy, thermogravimetric analysis (TGA), and electrical and electrochemical measurements. By changing the printing design, properties like electrical conductivity, electrochemical behavior, mechanical strength, and structural porosity can be tailored without any requirement for doping or chemical post-processing. The obtained material consists of close to 100% 3D graphene and reveals high thermal stability of up to 500ºC in air. As synthesized, $3D^2G$ can be exposed to mechanical compression which converts it to a shiny thin sheet thus causing a significant increase in its density, electrical conductivity, tensile strength, and Young's modulus. This work brings together two advanced manufacturing approaches, CVD and 3D printing, thus enabling the synthesis of high-quality, binder-free $3D^2G$ structures with a tailored design and properties that appeared to be suitable for multiple applications.

Visualizing Current Pathways for the Evaluation and Improvement of the CNT-Polymeric Composite Properties Naoyuki Matsumoto; National Institute of Advanced Industrial Science and Technology, Japan

At AIST, our mission is to bring or "bridge" invention with industry and to contribute to society through the development of new technologies. With this in mind, over the past few years, our team has placed significant effort in developing carbon nanotube (CNT)-polymeric composites, mainly rubber and resin, using our proprietary "Super Growth" CNTs [1] and other commercially available single and multi-walled CNTs. Thus far, we have reported the successful development and commercialization of CNT rubber composites (O-rings) possessing long lifetime, high heat resistance, and high-pressure resistance [2] as well as CNT resin composites exhibiting excellent heat resistance and impact resistance using PEEK, a super engineering plastic [3]. The development of these fabrication technologies enables application of these materials in manufacturing and mainstream uses. In this way, we are able to fulfil our mission to contribute the development of materials and technologies for the betterment of society.

To best design the material to possess the required mechanical, electrical, or thermal properties, understanding of the pertinent governing mechanisms is necessary. Furthermore, the nature of the CNT dispersion in the composite matrix is well known to have significant effect on the formation of a 3-D network structure, i.e., percolation, but evaluation of the dispersion state within a composite for a nano-sized filler is challenging.
In this presentation, I will show CNT rubber/resin composites that we have developed and put to practical use, as well as evaluation techniques we have used to visualize and understand the dispersion of CNTs in these composites. Specifically, I will introduce an analysis method using actual rubber/resin composites, focusing on lock-in heat analysis [4-6] and nano-indentation [7]. Through this approach, the homogeneity of the dispersion within the rubber can be characterized through the visualization of the distribution in current pathways. I will show how the application of this these characterization techniques aids in the property improvement of our fabricated composites.

9:30 PM *NM02.13.03
The Material Systems and Performance Limits of CNT Radiofrequency Devices Li Ding and Lian-Mao Peng; Peking Univ, China

Carbon nanotube (CNT) is considered a promising material for building radiofrequency (RF) field-effect transistors (FET) up to terahertz frequencies. This is because CNT has extremely high carrier mobility and saturation velocity, as well as ultra-small intrinsic gate capacitance. Earlier studies on the electronic properties of CNT FETs used individual semiconducting CNTs. But FETs built on individual CNTs can provide at best tens uA which is too low for real applications and the output impedance of the device cannot match the conventional 50 Ω RF measurement standards. Chemical vapor deposition (CVD) based CNT arrays with high-quality were also extensively examined for building RF devices. While promising results were achieved, for example on frequency doublers and mixers, the performance of devices based on CVD arrays of CNTs is severely limited by the low array density and material purity.

Currently, most research efforts are focused on using solution-derived CNTs for preparing thin films. Before 2020, only randomly oriented network of CNTs were widely available for research, and in few cases parallel arrays of CNTs were reported but with limited purity of 99.99% and density of lower than 100 CNT/um. Steady progress on RF performance had been made using these network and low-purity and density arrays, and in particular researchers in Carbonics Inc. pushed the current-gain and power-gain cut-off frequencies of CNT RF FETs to f_T=75GHz and f_{max}=102 GHz using CNT arrays; and researcher from Peking University achieved f_T=103GHz and f_{max}=107 GHz using network of CNTs. An important breakthrough was made in 2020 by reearchers from Peking University, they first developed a multiple-dispersion and sorting process that resulted in extremely high semiconducting purity of better than 99.9999%; and then a dimension-limited self-alignment procedure for preparing well aligned CNT arrays with a tunable array density of 100 to 200 CNTs/um. Top-gate FETs fabricated on the so prepared CNT arrays show a current-gain and power-gain cut-off frequencies of 540 GHz and 306 GHz respectively.

In addition to the channel material, the choice of substrate is also of crucial important for achieving the ultimate performance limit of CNT based RF FETs. The substrate may affect the RF performance of a FET via dielectric permittivity for high speed and dielectric strength, and thermal conductivity for high power. Among all insulating materials, diamond is of particular interest for carbon-based electronics because it is composed of the same carbon element as CNT and has suitable low dielectric permittivity (5.5), strong dielectric strength (1000 kV/cm) and high thermal conductivity (2000 W/mK). Diamond substrate is thus the most suitable substrate for CNT RF devices. Our preliminary results show that we can indeed fabricate well-aligned CNT array-based RF devices on diamond and achieve respectively 245 and 200 GHz of current-gain and power-gain cut-off frequencies. These values are still lower that that achieved using silicon as the substrate, which might be due to the process divergence derived from different substrates. And the device fabrication processes needs to be further optimized on diamond substrate. It is expected that significant improvements on both speed and power could be achieved in RF devices based on aligned CNT arrays on diamond substrate, further pushing the limit into the ballistic terahertz regime in the near future.

10:00 PM NM02.13.04
ML Prediction of Nano-Porous Aerogels Material Properties Omid Aghababaei Tafreshi, Zia Saadatnia, Shahriar Ghaffari-Mosanenzadeh, Chul Park and Hani E. Naguib; University of Toronto, Canada

Due to the high prediction performance and low computational cost, machine learning (ML) based tools have been widely implemented in the field of material science for materials innovation, material design, deriving insights, and material properties prediction. In this context, the application of ML in the field of porous materials, particularly nanostructured aerogels, only rose to prominence recently. Despite many attempts to tailor and optimize the performance of nanostructured aerogels, the current methodologies mostly rely on experimental approaches, and thus further development of novel aerogels with optimum performance is greatly restricted. Considering the prolonged synthesis process, costly materials and equipment, and the necessity of analyzing microstructure and properties of aerogels, developing a ML platform can facilitate data-driven materials innovation and accelerate prediction of the material properties of nanostructure aerogels. Therefore, in this study, we report the application of artificial neural network (ANN) as an effective ML tool for properties prediction of nanostructured organic aerogels. Through optimizing the ANN network parameters, ANN architecture is constructed. Data mining is performed, and selected descriptors are chosen as the input for the model. Various properties, namely compressive modulus, density, and porosity of nanostructured aerogels, are predicted, and ANN performance is analyzed via evaluation metrics.

10:05 PM NM02.13.05
Boron Nitride Nanosheets Can Induce Water Channels Across Lipid Bilayers Leading to Lysosomal Permeabilization Xuliang Qian; Nanyang Technological University, Singapore

While the interaction between 2D materials and cells is of key importance to the development of nanomedicines and safe applications of nanotechnology, still little is known about the biological interactions of many emerging 2D materials. Here, an investigation of how hexagonal boron nitride (hBN) interacts with the cell membrane is carried out by combining molecular dynamics (MD), liquid-phase exfoliation, and in vitro imaging methods. MD simulations reveal that a sharp hBN wedge can penetrate a lipid bilayer and form a cross-membrane water channel along its exposed polar edges, while a round hBN sheet does not exhibit this behavior. It is hypothesized that such water channels can facilitate cross-membrane transport, with important consequences including lysosomal membrane permeabilization, an emerging mechanism of cellular toxicity that involves the release of cathepsin B and generation of radical oxygen species leading to cell apoptosis. To test this hypothesis, two types of hBN nanosheets, one with a rhomboidal, cornered morphology and one with a round morphology, are prepared, and human lung epithelial cells are exposed to both materials. The cornered hBN with lateral polar edges

results in a dose-dependent cytotoxic effect, whereas round hBN does not cause significant toxicity, thus confirming our premise.

10:10 PM NM02.13.06
Reservoir Computing Using Vertically Aligned Graphene/Diamond Heterojunctions Yuga Ito[1], Akiho Nakazuru[1] and Kenji Ueda[2,1]; [1]Nagoya University, Japan; [2]Waseda University, Japan

Recently, reservoir computing (RC) using various physical phenomena such as laser light, rippling water surface, memristors, etc., which have complicated dynamics, has been paid much attention. Higher speed learning and prediction with lower calculation cost is expected to be realized by implementing the physical phenomena to the reservoir system. However, the research on physical RC had only just started, and physical reservoir systems suitable for high speed and high efficiency computing has been seeking.
In this study, we show that it is possible to perform physical RC by using vertically aligned graphene (VG)/diamond heterojunctions, which are found to show multiple photo-memory [1] and brain-mimic optoelectronic memory functions [2], recently, and recognize simple digits (0~9) by using the junctions for the first time.
Heterostructures of VG and boron-doped semiconducting diamond were grown *in situ* by using microwave plasma CVD. VG/diamond junctions were fabricated using the heterostructures by a standard photolithographic process and reactive ion etching (RIE). Current-voltage characteristics of the VG/diamond junctions were measured at room temperature (R. T.) in air with or without photo-irradiation by using visible LEDs.
Conducting behaviors of various VG/diamond junctions formed in different growth conditions were examined during and after irradiating 10 optical pulses with positive bias voltage. Conductivity values of the junctions were increased step-by-step in response to each optical pulse and decayed with different relaxation time (τ). From results of Raman spectroscopy and TEM measurements, the relaxation time of the junctions were decreased as the interlayer distances of interfacial graphene layers were increased. It is suggested that the distances were controlled by the volume of sp^3 type defects in the layers, and photo-memory functions of VG/diamond junctions were changed depending on the sp^3/sp^2 ratio of the VG layers, which could be controlled by changing the growth temperature and the oxygen ratio during CVD growth. VG/diamond junctions with shorter-term memory functions (τ= 1.9 s) could be fabricated based on these results.
RC using the VG/diamond junctions was performed. First, simple digits (0~9) were shown by binary 5*4 images as shown below. As a note, you can see number “2” by tracing the positions of 1 in the images.
----- (5*4 images (= 20 pixels) of the number “2” shown by 1 or 0 (binary image)) -----
0 1 1 0
1 0 0 1
0 0 1 0
0 1 0 0
1 1 1 1

These images were decomposed into each raw containing 4 sequential pixels, like 0110, 1001, …, and optical pulses correspond to each raw were irradiated to the junctions. For example, in the case for first line of number “2”, the junctions were irradiated by sequential pulses of light-off (0), on (1), on (1), and off (0) because the first line of the images of “2” was shown by “0110”. Each conductivity value of the junctions was memorized after irradiation by each sequential pulse, and five conductivity values were obtained. The conductivity of the junctions was changed in a complex way because of short-term memory functions of them. The five conductivity values are different for each digit, and it is possible to recognize each digit (0~9) after transferring them to the simple, two-layered neural network. In this study, 50 images of simple digits were used to evaluate recognition accuracy. As a result, we have obtained excellent recognition ratio of above 90%. These results indicate that the VG/diamond photomemristors work as physical reservoirs and can be used as novel brain-mimic devices with both photo-memory and computing functions.

10:15 PM NM02.13.07
Modification of Hexagonal Boron Nitride to Control Vanadyl Species for Selective Catalytic Reduction of Nitrogen Oxides with Ammonia Myeung-Jin Lee[1,2], Bora Jeong[1,3], Hangyu Im[1,3], Su-Jin Kim[1,2], Bora Ye[1], Seungho Cho[2] and Hong-Dae Kim[1]; [1]Korea Institute of Industrial Technology, Korea (the Republic of); [2]Ulsan National Institute of Science and Technology, Korea (the Republic of); [3]Pusan National University, Korea (the Republic of)

Hexagonal-BN is generally known as stable material from RT to 1000 °C at air atmosphere, and has high chemical stability. It is, therefore, used in fields to need thermal and chemical stability, and porous structure obviously gives a variety of properties in ceramic. In this work, modification to porous structure can be confirmed and intentionally obtained from h-BN by catalytic etching of TMOs below 1000 °C. Catalytic etching occurs during calcination which can be confirmed via intersection of between theoretical Ellingham diagram and experimental TGA. At that temperature, TMOs move in a specific preferred direction, and porous h-BN thereby has stuck particles. Existence of highly dispersed TMOs in final product makes it possible to be used as selective catalytic reduction (SCR) catalysts, one of green technologies, through only single step process. A commonly abatement technology of NOx is selective catalytic reduction with NH_3 (NH_3-SCR) as reductant, and vanadium-based catalyst is commercialized with titanium dioxides (TiO_2) and tungsten as promoter, V_2O_5-WO_3/TiO_2. However up to present, because operating temperature of V-based catalyst is the range from 300 to 380 °C, the necessary of modified V-based catalyst capable of operation in the lower temperature due to further tighten environmental regulation in various fields in the future. Generally, vanadium exists in four common oxidation states (+5, +4, +3, and +2), among which V^{4+} is the better SCR performance than general oxidation state, V^{5+}. Therefore, the vanadyl oxidation states are main factor in modifying V-based catalyst for widening to lower temperature drive. The ratio of V^{4+} is further higher proportion by interacting between vanadium and tungsten oxides on a hexagonal boron nitride (h-BN) during calcination. The doped vanadium oxides can be confirmed in tungsten oxides structure via theoretical Hume-Rothery rule and experimental results. We can also confirm the enhanced performance of deliberately etched catalyst in both of powder and green-body states, honeycomb and coated type.

Single Crystal Metal Foils and Single Crystal Graphene and Single Crystal F-Diamane Rodney S. Ruoff[1,2]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Institute for Basic Science, Korea (the Republic of)

We have converted polycrystalline foils (copper, nickel, cobalt, platinum, palladium) to single crystal foiils (Science 2018) and used single crystal Cu(111) foils to synthesize single crystal graphene having folds (several articles in ACS Nano and Advanced Materials), while single crystal Cu-Ni(111) "alloy" foils have yielded fold-free and wrinkle free single crystal graphene (Nature 2021), and at higher nickel concentrations, relatively large area single crystal AB-stacked bilayer graphene (Nature Nanotechnology 2020) that was converted to fluorinated diamane (C2F) by exposure to XeF2 (Nature Nanotechnology, also 2020). Our Ni(111) foils were used to make large area single crystal hexagonal boron nitride films in collaboration with Hyeon Suk Shin and team members (Nature 2022). I look forward to presenting these topics and to the interesting questions from colleagues. Our work supported by IBS-R019-D1.

8:30 AM NM02.14.02
Nano-Nanocomposite Membrane Based on Cellulose-Nanofiber and Carbon Nanotubes for Low-Pressure Reverse Osmosis Systems Juan L. Fajardo Diaz[1], Aaron Morelos-Gomez[1,1], Rodolfo Cruz-Silva[1,1], Kazuki Ishii[2], Tomoharu Yasuike[2], Takahiro Kawakatsu[2], Ayaka Yamanaka[3], Syogo Tejima[3], Kazuo Izo[1], Shigeru Saito[1], Jun Maeda[1], Kenji Takeuchi[1,1] and Morinobu Endo[1,1]; [1]Shinshu University, Japan; [2]Kurita water industries LTD, Japan; [3]Research Organization for Information Science & Technology, Japan

A nano-nanocomposite polymeric membrane based on multiwalled carbon nanotubes (CNT), cellulose nanofibers (CNF), and polyamide was used to produce high purity water in a low-pressure reverse osmosis system. The PA-CNT/CNF membranes were physicochemically characterized in order to track the influence of adding different loads of cellulose nanofiber, the influence of isopropanol (IPA) used as a diluting agent, and a sodium nitrate ($NaNO_2$) post-treatment applied after membrane synthesis. The mixture of CNF/CNT had a significant influence on membrane roughness, hydrophobicity, and the type of functional groups at the surface compared with a plain PA membrane. The incorporation of CNF improves the water permeation while the CNT structure supports the salt rejection at low pressure (0.75 MPa) RO filtration. A significant amount of experiments showed how the concentration of isopropanol also positively influenced the water permeation and salt rejection at low concentrations but negatively impacted both rejection and permeation at higher concentrations. In the case of the post-treatment with $NaNO_2$, this improves both water permeation and salt rejection. In the end, a CNF concentration between 3 wt. % to 6 %, IPA concentration between 4% to 6%, and treated with $NaNO_2$ revealed salt rejections above 99 % and water flux above the 1 m^3/m^2day. The best performance showed a salt rejection of 99.47% and water permeation of 1.65 m^3/m^2day, very competitive compared with commercial systems like ES20, ES40 (From Nitto-Denko), and BW60 (Dupont). Rejection analysis of selective ions like Ca, Si, and B salts was performed. The PA-CNT/CNF membrane expands the operation time compared with NSF-certified commercial systems for high-purity water production tested with a Si, Ca, and Na mixed solution. The PA-CNT/CNF membrane maintains a Ca rejection of 97.5% with an increased permeability by 1.8 times and a boron rejection of 50.4%. A 2 inches module was built using the PA-CNT/CNF membrane and was tested in a more realistic environment. Its performance compared with a commercial module (TW30), the PA-CNT/CNF module showed an increase of 14.3% over the water flux production before its saturation. This PA-CNT/CNF polymeric nanocomposite has shown a very competitive performance for the rejections of Si, Na, Ca ions and the production of HPW in a low-pressure RO system.

8:45 AM NM02.14.03
Multimodal Artificial Intelligence System for Virtual Screening of Complex Nanocomposite Materials Shun Muroga[1], Yasuaki Miki[1], Takashi Honda[2], Hiroshi Morita[1], Toshiya Okazaki[1] and Kenji Hata[1]; [1]National Institute of Advanced Industrial Science and Technology, Japan; [2]Research Association of High-Throughput Design and Development for Advanced Functional Materials (ADMAT), Japan

Eternal challenge for materials scientists is exploring high-performance materials from the vast expanse of chemical space for targeted properties. Recent progress of data-centric science (i.e. materials informatics or process informatics) accelerate the discovery of new materials, especially in the fields of chemical compounds, solid-state inorganic materials, and materials with periodic ordered structures. Since conventional methods are machine learning of descriptors from atoms or chemical bonds in the structures, the material structures must be precisely defined. However, complex composite materials are dominant in our daily life, such as polymer composites, metal alloys, slurry, fabrics, and so on. Their whole structures cannot be defined by atoms and chemical bonds due to their complexity of multiple phases, hierarchy of structures, and non-periodic features. Therefore, advanced methodology of materials and process informatics for such complex composite materials would enlighten materials scientists to overcome the limitations of materials discovery.
In this study, we propose a method for virtual screening of complex composite materials, namely multimodal artificial intelligence system. Multimodal AI means inference from different inputs like human's perception simultaneously using multiple senses (e.g., visual, auditory, haptic), which has not been investigated in the fields of materials. Our concept of multimodal AI of materials is that integrating the multiple different data of characterizing physical structures and chemical structures leads to sufficient inference of properties of complex composite materials.
Here, polymer nanocomposite thermosets are fabricated as model materials. The polymer nanocomposites consist of complex components: five different matrices of acrylate curing monomers, two curing additives, and three reinforcing fillers including single-walled carbon nanotube, chopped carbon fiber, spherical alumna. Both physical structures (arrangements of fillers) and chemical structures (matrices and additives and their interactions) were evaluated to achieve the prediction of mechanical and electrical properties of polymer nanocomposites. The physical structures of polymer nanocomposites were measured by optical microscope, while the chemical structures of those were characterized by attenuated total reflection mid-infrared spectroscopy and Raman spectroscopy.
Proposed multimodal AI system can be divided into two steps. First step is generation of multiple characterization data. Characterization data (image, IR spectrum, Raman spectrum) of corresponding conditions (e.g., compositions of matrices, additives, fillers) can be virtually generated by generative adversarial neural networks. Second step is prediction of properties of materials from characterization data. Eight different (mechanical, electrical) properties of materials can be estimated by a deep learning model of integrating the inputs of image, IR spectrum, and Raman spectrum. By introducing these two steps using deep learning models, we have achieved the virtual screening dealing with such complexity of structures. Our system can generate characterization data and predict properties of 100,000 conditions of materials, which is equivalent to 20,000 times faster than real experiments. We strongly believe that the proposed concept of multimodal AI for complex composite materials overcomes previous limits and has a potential of applying to various materials and processes.
This work was supported by a project (JPNP16010) commissioned by the New Energy and Industrial Technology Development Organization (NEDO). Computational resource of AI Bridging Cloud Infrastructure (ABCI) provided by National Institute of Advanced Industrial Science and Technology (AIST) was used.

9:00 AM NM02.14.04
Production and Characterization of Arc-Discharged Carbon Nanotubes Using High Purity Natural Vein Graphite as Electrodes Himasha Appuhami, Tharaka Dissanayake and Asurasinghe Kumarasinghe; University of Sri iayewardenepura, Sri Lanka

Carbon nanotubes (CNTs) have garnered worldwide attention in the past few years due to their exceptional electrical, thermal, elastic, and functionalization

properties. CNTs are a tubular form of carbon made up of a lattice of carbon hexagons folded into nanometer-scale multi-walled(MWCNTs) or single-walled (SWCNTs) tubes. Manufacturing high-quality carbon nanotubes have been expensive and challenging for industrial applications. Although production methods such as chemical vapor deposition (CVD) are currently used for large-scale production of CNTs, their quality and purity do not meet the demands of specific applications. Therefore, the arc-discharge method has been suggested as a practical approach to alleviating this problem in producing CNTs. In the arc-discharge process, carbon electrodes generate the arc between the two electrodes inside the inert gas-filled chamber where CNT is built on the cathode while consuming the anode. The cost associated with purchasing high-purity carbon electrodes hinders the production of high-quality CNT using the arc discharge method. Alternatively, high purity natural graphite electrodes, readily available in some parts of the world, can be used as electrodes obviating the need to use commercially purchased carbon electrodes. Hence an arc-discharge system was built using high-purity vein graphite as electrodes (Carbon purity of > 99.5 % wt, obtained from the Bogala mines in Sri Lanka). The two electrodes were mounted inside a closed vessel (14.34 L), where the position of the anode was fixed, and the cathode was moved back and forth using a linear actuator consisting of a stepper motor. The arc-discharging was performed inside the closed vessel filled with Argon (Ar) under the pressure of 100 mmHg and with a direct current (DC) supply of 100 A and 70 V, maintaining a 1-2 mm gap between the electrodes. Thus, by varying the arc-discharging time, CNT samples were prepared and collected carefully by scraping the cathode tip. Without further purification, the as-produced samples were characterized using Raman spectroscopy and Scanning electron microscopy (SEM). G band, D band, and noticeable radial breathing mode (RBM) were observed in the Raman spectrograph of the sample produced at 40 s(Sample A) constant arch-discharging. A slight D` split was also observed in the G band peak, indicating that the CNTs should be MWCNTs; Moreover, the D/G ratio was 0.83 (83%), which revealed a high depletion ratio, but the samples were unpurified and contained copious of amorphous carbon. In contrast, only G and D band peaks were recognizable in the sample produced with 60 s (Sample B) constant arc discharging, where no distinguishable RBM peak was observed, which is a sign of the non-existence of CNTs. The above results were confirmed by the further characterization of samples using SEM, where the dispersed CNTs were observed in the SEM image of sample A, while no CNTs were observed in sample B. In conclusion, the newly-home-built arc-discharge system was capable of producing CNTs; however, further research is required to determine the correlation between production variables and characteristics of CNTs.

Investigation of the Formation of Free-Standing Graphene Nanoflakes from Ethanol in a Pilot-Scale Plasma Reactor Frederik Kunze[1], Ivan Radev[2], Edward Nürenberg[2], Fabian Puslat[2], Tim Huelser[1] and Sophie Marie Schnurre[1]; [1]Institut für Energie- und Umwelttechnik e.V.(IUTA), Germany; [2]The Hydrogen and Fuel Cell Center ZBT GmbH, Germany

The interest in 2D materials has increased enormously since the discovery of graphene in 2004. The extraordinary electrical, mechanical and optical properties offer a great potential to improve a wide range of applications. However, this requires a deeper fundamental understanding of the formation of graphene and a resulting synthesis pathway that provides the necessary process conditions for efficient graphene formation.
A potential synthesis route for the continuous production of few-layer graphene is the plasma-assisted gas-phase synthesis. In this work, we utilize a pilot-scale microwave plasma reactor with a frequency of 915 MHz and a maximum power of 50 kW [1] to convert ethanol into few-layer graphene to work out the influence of the carbon concentrations on the characteristics of the formed few-layer graphene. For that purpose, ethanol is evaporated and subsequently passed through an argon-hydrogen plasma. To increase the carbon concentration, the feeding rate of EtOH is stepwise adjusted from 200 g/h to 800 g/h. The produced graphene powders are collected on filter membranes and then analyzed ex-situ by different methods.
Imaging measurement methods such as scanning and transmission electron microscopy are used to determine the general shape and morphology of the different graphene samples. At low carbon concentration in the plasma, typical graphene sheets are formed almost exclusively. If the carbon concentration increases due to an increased EtOH feeding rate, there is a shift towards the formation of soot-like particles between the graphene sheets.
Raman spectroscopy shows peak intensity ratios of 0.85 to 0.86 for I_D/I_G ratio and 0.94 to 0.99 for I_{2D}/I_G ratio for all samples, indicating relatively high sp2 hybridization, low defect density as well as low number of layers. However, the results reveal that Raman spectroscopy is not able to clearly distinguish and display the fraction of soot-like particles seen on SEM and TEM images by different peak intensity ratios.
A better indicator is the electrical conductivity of the material, which is in the end also a crucial factor for potential applications. Therefore, the electrical conductivity and the apparent density of the graphene powders as a function of compression force were investigated in a specially designed powder conductivity test cell by a quasi-four electrode test principle. The measurement of the electrical conductivity shows a similar trend as already suspected from the evaluation of the SEM and TEM images. A decreased carbon concentration leads to a reduced formation of soot particle-like structures and thus also to a higher electrical conductivity of the material. The highest specific conductivity of σ = 3,19 S/cm and ρ = 0.23 g/cm^{-3} at 100 N cm^{-2} is obtained for graphene produced with the EtOH feeding rate of 200 g/h, which is 8.6 times higher than the commercial graphene CP-0080-HP-0010 (IoLiTec Ionic Liquids Technologies GmbH, thickness 1-10ML; size 0.5-3 µm; 250 €/g, σ = 0.37 S/cm and ρ = 0.12 g/cm^{-3} at 100 N cm^{-2}).
This work demonstrates that low-defect graphene can be produced continuously in a pilot-scale plasma reactor at production rates up to 2.5 g/h. However, it is also shown that the production of graphene from ethanol with conversion rates in the range of 0.6 to 1.2 % based on the carbon mass flow rate is currently still very inefficient and cannot be easily increased by using a pilot-scale reactor. Nevertheless, this synthesis route remains one of the most promising for the production of high-quality few-layer graphene.

Work is performed under the scope of IGF-Project 21784 N funded by the Federal Ministry for Economic Affairs and Climate Action on the basis of a decision by the German Bundestag (IGF-Project 21784 N) and by the German Research Foundation (DFG) (SCHN 1387/1–2, 651051).

Oxidative Chemical Vapor Deposition (oCVD) Synthesis of Molecularly Imprinted Polypyrrole Nanotube for the Detection of CA-125 Protein Faruk Can[1], Tugce Akkas[1], Hazal Sakar[2], Lokman Uzun[3] and Gozde O. Ince[1,2]; [1]Sabanci University Nanotechnology Research and Application Center, Turkey; [2]Sabanci University, Turkey; [3]Hacettepe University, Turkey

Field-effect transistor (FET) based biosensors have been widely used in various applications such as medical diagnosis, health and environmental monitoring. The performance of the FET biosensors are determined by anchoring specific probes on the conducting channel for target biomolecules. In the past two decades, molecularly imprinted polymers (MIPs) have attracted much attention as a robust and cost-effective alternative to natural bioreceptors such as enzymes and antibodies. MIPs are artificial template-made receptors which have the ability to recognise specific target molecules. Here, we present a novel FET biosensor incorporated with a molecularly imprinted polypyrrole nanotube (MIPN) for the selective detection of CA-125 ovarian cancer biomarkers. Polypyrrole (PPy) nanotube used in the FET biosensor has been obtained via oxidative chemical vapor deposition (oCVD) which is a highly efficient solvent-free, vacuum-based technique for the synthesis of conductive polymers. Thanks to the flexibility of this method, MIPN has been conveniently synthesized by coating conformally the sacrificial porous structured templates in the presence of target protein. Particularly, imprinting the target molecule on the nanotube surface has provided extremely high surface area which leads to enhancement in selectivity of the sensor. Furthermore, the oCVD synthesis has enabled higher electrical conductivity for the resulting PPy nanotube by tuning deposition parameters such as oxidant/monomer ratio, substrate temperature and reaction pressure. Synthesized MIPN has been integrated onto the interdigitated array Au electrode to make a conductive bridge between source and drain terminals and biosensor platform has been assembled from chip device, microfluidic channel and custom made chip holder for

real-time measurement. The present study has provided useful insight into preparing a novel molecularly imprinted polymer nanotube with various target protein molecules by using oCVD technique.

MWCNT/Rubber Composites for Pressure Sensing Application Dilusha J. De Silva, Hansini Abeysinghe, Thusitha N. Etampawala and Indhika Wanniarachi; Faculty of Applied Sciences, University of Sri Jayewardenepura, Sri Lanka

The development of various types of sensors to make our living much more comfortable has become a forefront research topic in the modern world. Pressure sensor is one such development. Even though there are different pressure sensors, developing an easy handle, and low-power sensor specifically to measure in-situ pressure change of passenger and industrial tires in motion remains a challenge. Developing a sensing material with flexibility and stretchability to withstand the harsh conditions of tires while being compatible with the tire material is one of the main challenges faced during the production of such pressure sensors. The use of piezoresistive sensing materials is quite a significant approach for this matter. Therefore, in this work, rubber-based piezoresistive materials, which could embed to the tire, were developed. Since rubber materials are electrically insulative, highly conductive Multi-Walled Carbon Nanotubes (MWCNTs) were incorporated to the rubber matrix to obtain the piezoresistive effect. π orbitals of MWCNTs being more delocalized to the outer area of their cylindrical structure and having σ bonds slightly out of the plane, σ-π rehybridization occurs making them mechanically stronger, electrically and thermally more conductive. Therefore, it was assumed that the use of MWCNTs to develop piezoresistive rubber compounds, which could withstand the high loads and harsh conditions as a more promising solution. Since rubber is flexible and stretchable, once a certain amount of pressure is applied on the material, it tends to compress. The rubber vulcanizate obtained after milling MWCNTs with rubber would have evenly spread MWCNTs across the rubber matrix. Therefore, when the rubber matrix gets compressed under certain pressure, the electron tunneling distances between the MWCNTs would reduce. Since MWCNTs are nanoscale 1D cylindrical tubes with delocalized π-electron cloud, under the applied pressure they would form more conductive networks across the rubber composite resulting in low resistance compared to its original form. It was identified that the types of rubber and composition of MWCNTs of the composite would affect the piezoresistive behavior of the composite. Therefore, in this study, 20 phr MWCNT incorporated natural rubber (NR), ethylene propylene diene monomer rubber, nitrile rubber, butadiene rubber, and styrene-butadiene rubber composites were tested for their piezoresistive behavior to identify the most suitable rubber matrix. MWCNT/NR composite showed the highest resistance change of more than 1000 folds of its original resistance when a load of 200 kN was applied and removed in a certain time interval. Therefore, it became evident that NR shows better flexibility and relaxation compared to other synthetic rubber lattices. Then, MWCNT/NR composites with varying MWCNT compositions of 10, 20, 30, and 40 phr were developed to observe their piezoresistive behavioral change under a range of loads. All these composites showed a similar pattern in exponential decrease of their resistance with increasing pressure. However, when applying high-pressure values in the range of 2000 – 12000 kNm^{-2} their logarithmic resistance (log R) showed a linear reduction with increasing of pressure. At low-pressure values, log R reduced exponentially and move to a plateau around 500 kNm^{-2}. However, a linear relationship is expected even at low-pressure values, if the MWCNT composition is comparable with the percolation threshold value. Since the resistance values depend on the thickness of rubber composites, all these data were collected under a constant thickness. Currently, the development of a digital prototype of a piezoresistive pressure sensor to measure the real-time, in-situ pressure changes based on the obtained data is in progress. Here the analog signal is converted to a voltage signal via a potential divider under a low power supply and obtaining the real-time pressure reading to a display via Bluetooth.

High-Brightness Fluorophores for Cell Phenotyping Nazmiye Yapici[1,2], Rodney Oakley[1], Xiuling Liu[1,2], Dongyan Zhang[2] and Yoke Khin Yap[2]; [1]Stabilux Biosciences, United States; [2]Michigan Technological University, United States

Flow cytometry (FCM) is a laser spectroscopy technique that detects, counts, and sorts thousands of cells per second. For example, FCM enables cell phenotyping by characterizing the population of clusters of differentiation (CD) on cells. Laser-induced fluorescence from fluorophores conjugated with antibodies can identify various CD on cell surfaces. The multiparametric and high throughput capabilities have made FCM a standard technique for research and clinical laboratories to characterize stem cells, cancer cells, nucleic acids, etc.

We have developed a platform technology to produce high-brightness fluorophores (HBFs, NovoLux dye) for use in FCM. Our unique technology allows us to tune the fluorescent brightness of HBFs to desired levels (10X to 1000X brighter than commercial dyes). We can use any organic dye molecules to formulate HBFs to emit at desired fluorescent wavelengths. To date, we have developed Four types of HBFs: NovoLux 405, NovoLux 488, NovoLux 560 and NovoLux 640. The molar extinction coefficient (e) of NovoLux dyes can be as high as 10^7 to 10^{10} M^{-1} cm^{-1} [1-3]. It is several orders of magnitude higher than any existing dye (e for FITC is $7.8x10^4$ M^{-1} cm^{-1}, for Rhodamine B is $7.5x10^4$ M^{-1} cm^{-1}, for Cy5.5 is $2x10^5$).

This unique property allows our HBFs to increase the staining index of some rare biomarkers (CD127, CD 19, etc.) in FCM measurements. The spectral properties, fluorescent brightness tunability, and application of NovoLux dyes in FCM will be presented in the meeting.

Carbon nanotubes have a helical structure where the chirality determines them to be metallic or semiconducting. Using in situ transmission electron microscopy,[1] we applied heating and mechanical strain to alter the local chirality and thus to control the electronic properties of individual carbon nanotubes. A transition trend towards larger chiral angle region was observed and explained in terms of orientation-dependent dislocation formation energy. Controlled metal-to-semiconductor transition was realized to create nanotube transistors with a semiconducting nanotube channel covalently bonded between metallic nanotube source and drain. In addition, quantum transport at room temperature was demonstrated for the fabricated nanotube transistors with the channel length down to 2.8 nanometers.[2]

Towards CO_2 Electroreduction into Carbon Nanotubes in Molten Salt Electrolytes Andrew B. Wong; National University of Singapore, Singapore

This talk will detail our efforts to study and control the electroreduction of CO_2 into nanostructured carbons such as carbon nanotubes and present our insights about factors that are relevant to morphology control. In the high-temperature molten salt electrolytes, the role of experimental conditions will be discussed in the context of controlling the morphology of the products. Moreover, the role of this high-temperature approach to CO_2 reduction within the broader efforts toward scalable electrochemical CO_2 conversion also will be discussed.

9:45 PM NM02.15.03
Evaluation of Hole Doping Performance of Single-Walled Carbon Nanotubes with Boron Compounds Naoki Tanaka[1,2], Aoi Hamasuna[1] and Tsuyohiko Fujigaya[1,2,3]; [1]Kyushu university, Japan; [2]WPI-I2CNER, Japan; [3]Center for Molecular Systems, Japan

Neutral organoboron compounds often show electron acceptance due to the vacant 2p orbital on boron and act as p-type dopants for organic semiconductors with electron-donating properties.[1] Therefore, most of the organic semiconductors have heteroatoms such as nitrogen, oxygen, and thiophene with lone pair electrons that can coordinate to vacant orbitals on the boron. On the other hand, for carbon materials such as single-walled carbon nanotubes (SWCNTs) consist of only carbon atoms without lone pair electrons, the effect of doping with organoboron compounds has not rarely been studied. In this study, we investigated p-type doping of SWCNTs by monoboranes and diboranes as organoboron compounds and the thermoelectric properties of the p-type doped SWCNT sheets.
P-type doped SWCNT sheets were prepared by immersed SWCNT sheets (4 mm × 14 mm × 30 μm) into THF solution of boron compounds and shaking at 30 °C for 24 hours. Electrical conductivity measurements of the SWCNT sheets revealed a significant increase in conductivity compared with pristine SWCNT sheets when using tris(pentafluorophenyl)borane (BCF) and bis(catecolato)diboron (B_2cat_2). In addition, the Seebeck coefficient of the SWCNT sheets were lower than that of pristine SWCNT. From these results, these dopants can serve as efficient hole-dopants for SWCNTs. Interestingly, the electrical conductivity of these doped SWCNT sheets increased with exposure to air. We considered that the proton generated by the reaction of boron dopants on the surface of SWCNTs with water in air caused hole doping in the SWCNTs.[2]

Development of Air-Stable n-Type Doped Single-Walled Carbon Nanotube Sheet by Lewis Acids and Bases Naoki Tanaka[1,2], Aoi Hamasuna[1] and Tsuyohiko Fujigaya[1,2,3]; [1]Kyushu university, Japan; [2]WPI-I2CNER, Japan; [3]Center for Molecular Systems, Japan

The chemical doping of single-walled carbon nanotubes (SWCNTs) using electron donor and acceptor molecules is a crucial step for controlling the frontier orbital energy gap of SWCNTs. This means that SWCNTs are promising materials for electronics applications such as thermoelectric conversion and thin-film transistors, due to their flexibility, stability, and light weight.[1,2,3] For efficient thermoelectric generation, both p-type and n-type thermoelectric materials are required. However, SWCNTs act as p-type semiconductors owing to the hole doping by water and oxygen in air. Therefore, many efforts to develop n-type SWCNTs have been performed mainly by chemical doping using electron donors.[4,5,6] Recently, our group reported that the boryl radical produced by cleavage of the boron-boron bond of bis(pinacolate)diboron (B_2pin_2) by coordinated pyridines to boron can serve as an electron dopant in SWCNTs.[7] However, the n-doped SWCNTs did not show long-term air stability. In this study, we used tetrahydroxydiboron ($B_2(OH)_4$) in place of B_2pin_2 as the boron source and various pyridines to study the effect of the chemical structure of the boron to the n-doped air-stability.
Electron doping of SWCNTs was performed by mixing SWCNT sheets (4 mm × 14 mm × 30 μm), $B_2(OH)_4$ (1.0 eq.), and pyridine derivatives (0.5 eq.) in THF solvent and shaking at 40 °C for 24 hours. Upon using 4-cyanopyridine (4-CNPy), 4-phenylpyridine (4-PhPy), and 4-carboxypyridine (4-COOHPy), the doped SWCNT sheets showed negative Seebeck coefficient values and higher electrical conductivity than pristine SWCNTs, indicating the electron-doping from the corresponding boryl radicals to SWCNT. Interestingly, the n-doped SWCNT sheets prepared with $B_2(OH)_4$/4-Phpy revealed n-type properties for more than 50 days in air. X-ray photoelectron spectroscopy of the n-doped SWCNTs with $B_2(OH)_4$/4-Phpy showed that the dopant coverage on SWCNTs was much higher than that of other dopants. In addition, the distance between the dopant cation and the SWCNT was shorter than when B_2pin_2/4Phpy was used as a dopant. Therefore, we consider that n-type stability is not only related to the amount of coverage, but also to the interaction between SWCNT and dopant.

9:55 PM NM02.15.05
Mechanics of Biosurfactant Aided Liquid Phase Exfoliation of 2D Materials Xuliang Qian[1], Matteo Andrea Lucherelli[2], Céline Corcelle[2], Alberto Bianco[2] and Huajian Gao[1,3]; [1]Nanyang Technological University, Singapore; [2]CNRS, Immunology, Immunopathology and Therapeutic Chemistry, UPR 3572, University of Strasbourg, ISIS, 67000, France; [3]Institute of High Performance Computing, A*STAR, Singapore

Biosurfactant-aided liquid-phase exfoliation (LPE) is emerging as a biocompatible, green, economical, safe, and efficient approach to prepare two-

dimensional (2D) materials for biomedical applications. However, relatively little is known about the molecular mechanisms of this process. Herein, we present the first study of how flavin mononucleotide (FMN) interacts with hexagonal boron nitride (hBN) nanosheets in the context of LPE. We demonstrate that FMN molecules can self-assemble on hBN via π-π interactions, as well as intermolecular hydrogen bonds (H-bonds) between the isoalloxazine moieties. Binding free energy analysis has shown FMN to be an efficient surfactant for LPE of hBN in water. According to the theoretical simulations, stable water suspension of hBN were experimentally obtained by LPE using FMN. With this work, we aim to exemplify how molecular dynamics (MD) simulation can predict and guide empirical LPE experiments, direct the surfactant screening and improve scalable production of 2D materials for biomedical applications.

As climate change stresses global agricultural production, there is urgency to understand auxin signaling, particularly Indole-3-Acetic Acid (IAA), in living plants – a hormone critical for plant growth and yield, as well as the response to environmental stimuli such as phototropism or gravitropism. This goal is confounded by the lack of reversible sensors that report IAA directly, instead indirect visualization of IAA has relied on downstream genetic or metabolic reporters. Herein, we demonstrate a novel near infrared (nIR) fluorescent nanosensor for the spatial and temporal measurement of IAA *in planta* using Corona Phase Molecular Recognition (CoPhMoRe). The IAA nanosensor shows high specificity in detecting IAA *in vitro* and was validated *in planta* by measuring IAA levels in β-estradiol induced *XVE::iaaM Arabidopsis* plants. The sensor works across different plant species and allows the visualization of dynamic changes to IAA distribution and movement in leaf tissues, validating a reaction and diffusion model for IAA. We also demonstrate the application to the detection of transient IAA concentrations and its spatial diffusion in *Nicotiana benthamiana* leaf at the early stage of shade avoidance syndrome, observing preferential transport along the leaf margins. The results obtained from nanosensor measurements suggest different kinds of auxin transport between the vascular and non-vascular tissue in *N. benthamiana* leaf, and highlight the overall utility of this type of sensor to understand plant signaling pathways.

10:05 PM NM02.15.07
A Near Real-Time Physics-Informed Machine Learning-Based Solution of the Reaction-Diffusion Equation for Lithium Intercalation in Nanostructured Silicon Anodes Using Lower-End Computational Hardware Tarun Bijanapally, Tanish S. Tak, Tejveer S. Anand and Madhusudan Singh; Indian Institute of Technology Delhi, India

Analytical modeling of intercalation of lithium in silicon anodes is expected to be valuable in understanding the role of various kinds of resulting stress in failure of batteries based on these high capacity anodes. Recent work[1] has indicated that it is challenging to obtain the exact solution of lithium concentration as a function of space (r) and time(t), using conventional methods that involve reducing the order of the governing partial differential equation (PDE), even in the natural geometry of the problem: spherical polar coordinates. While exact analytical solutions were obtained with some effort due to the inherent symmetry of the problem, this is expected to be impossible for more realistic models of operation that may involve the use of asymmetric Li injection and extraction contacts in battery devices, interaction of electrolyte with anodes, etc. In this work, we report on the application of a physics-informed neural network model using a loss function expressed as the sum of the residuals of the PDE operator (f), initial value function, and boundary conditions, with backward propagation of node weights (implemented using Python Torch and TensorFlow libraries running on Google Colab to mimic the use of low-end hardware). The model uses spacetime (r,t) coordinates as inputs, and the lithium concentration in a host material (C(r,t)) as the output vector of the neural network. In the initial training, we have used the previously obtained exact solutions for a hollow silicon sphere (inner and outer radii: 200 and 500 nm, respectively) exposed to [Li]=1 mol/m^3. The model includes: number of datasets for r (N_r) and t (N_t), training data sets for boundary conditions (N_u=1000), and PDE collocation points (N_f=10000) for calculation of residuals(f). A moderate sized dataset of size [2000,2000] when used for (N_r,N_t) results in an average training loss ($E_{A,tr}$) of 1.021x10^{-5} and an average test loss ($E_{A,te}$) of 0.0163 (2 hidden layers, 5 iteration loops, 32 nodes / layer). When the number of points for each dataset is doubled ([4000,4000]), $E_{A,tr}$ is reduced to 6.45x10^{-6} and $E_{A,te}$ to 0.0106. As the number of hidden layers is increased from 2 to 3 in an effort to reduce the testing loss further, memory limitations forced us to limit the maximum dataset size to [3000,3000]. This process actually doubled the testing loss from 0.014 to 0.028, which might suggest an over-determined backpropagation problem in the neural network. Reduction of number of hidden layers to 1 slightly increases the testing loss. The optimal dataset parameters for the problem are thus for dataset size [4000,4000], N_u = 1000, N_f = 10,000, with two hidden layers of 32 nodes each. An increase in the sampling of the residual function f to 100,000 points does not lead to significant changes in testing loss with significant increase in training time, suggesting that the parameters obtained are near optimal. This initial work has thus been useful in establishing optimal starting points for potential near real-time (~120 seconds) distributed cloud computing of intercalation of lithium in silicon. Conventional machine-learning based predictive systems with high precision are often implemented on high performance computing environments, which is inconsistent with real-time monitoring and predictive maintenance needs of automotive batteries without relying on ubiquitous high-end networked computing. We are currently training the model for various boundary conditions to the surface of the hollow silicon sphere with variable diffusion coefficient and its coupled application with diffusion-induced stress (DIS), reaction-induced stress (RIS), etc. The method developed in this work opens an approach to analyzing electrode stress evolution during charging and discharging cycles in near real-time, with applications in on-board prediction of preventative maintenance/replacement schedules of batteries.

Salicylic acid (SA) is an important plant hormone, which controls various aspects of development and mediates plant response to mainly biotic stress. In this work, we developed a SA plant nanobionic sensor, which enables non-destructive and real-time monitoring of SA in living plants. The SA nanosensor is discovered by *in vitro* screening of single-walled carbon nanotubes (SWNTs) wrapped with different cationic co-polymers, against a list of common plant hormones analytes. This sensing strategy is known as corona phase molecular recognition (CoPhMoRe) which relies on amphiphilic co-polymers acting as synthetic antibodies that bind to specific target analytes, as well as disperse SWNTs in aqueous medium. Upon binding to SA, the SA nanosensor achieved a selective 35% near-infrared (nIR) fluorescence quenching response whereas nIR fluorescence remains relatively invariant upon addition of other key plant hormones. *In planta* validation of the sensor was achieved in *Arabidopsis thaliana* (A. thaliana) mutants with altered SA levels, and in non-

model *Brassica rapa subsp. chinensis* (Pak Choy) vegetable infected with black rot causing bacteria. To unravel the interplay between SA and redox signals during biotic and abiotic stress responses, the SA nanosensor is further multiplexed with a H_2O_2 nanosensor in the same leaf to monitor the unique ROS and SA signaling waveforms simultaneously, in response to bacterial infection and wounding. This resolves a longstanding goal of the plant biology field to uncover the sequential links between different plant signaling pathways with the nanosensors providing spatiotemporal information as the plant mounts an integrated stress response.

SESSION NM03.01: QD Synthesis I
Session Chair: Dmitri Talapin
Monday Morning, November 28, 2022
Hynes, Level 2, Room 209

10:30 AM *NM03.01.01
The Dream of the Perfect Nanocrystal David J. Norris; ETH Zurich, Switzerland

Quantum dots are nanometer-sized crystallites of semiconductor that have a roughly spherical shape. Due to extensive research, quantum dots are now commercially used as a robust fluorescent material in displays and lighting. However, even with our best procedures, state-of-the-art samples still contain particles with a distribution in size and shape. Because this causes variations in their optical properties, their performance for applications is reduced. This leads to a fundamental question: can we achieve a sample of semiconductor nanocrystals in which all the particles are exactly the same? In this talk we will discuss this possibility by examining two classes of nanomaterials. First, we will consider thin rectangular particles known as semiconductor nanoplatelets. Amazingly, nanoplatelet samples can be synthesized in which all crystallites have the same atomic-scale thickness (e.g., 4 monolayers). This uniformity in one dimension suggests that routes to monodisperse samples might exist. After describing the underlying growth mechanism for nanoplatelets, we will then move to a much older nanomaterial—magic-sized clusters (MSCs). Such species are believed to be molecular-scale arrangements (i.e., clusters) of semiconductor atoms with a specific (“magic”) structure with enhanced stability compared to particles slightly smaller or larger. Their existence implies that MSC samples can in principle be the same size and shape. Unfortunately, despite three decades of research, the formation mechanism of MSCs remains unclear, especially considering recent experiments that track the evolution of MSCs to sizes well beyond the “cluster” regime. Again, we will discuss the underlying growth mechanism and its implications for nanocrystal synthesis. Finally, we will present an outlook if perfect nanomaterials can be obtained.

11:00 AM *NM03.01.02
Designing Polymer Ligands to Enable Stabilization, Inter-Phase Transfer, Encapsulation and Structural Transformations of Colloidal Nanocrystals Nikolai Gaponik; TU Dresden, Germany

In this talk, I will discuss how the embedding of colloidal nanocrystals into polymer matrices can be governed by the proper choice of ligands. The ligands can be designed to contain specific polymer or oligomer chains providing direct and unlimited compatibility with desired polymers. The specially designed ligands may not only improve colloidal stability, but also influence the crystallinity of the inorganic colloidal nanoparticles and their composition. Combination of various polymers as co-ligands or the application of custom-designed co-polymers are also powerful tools for controlling the nanoparticle processability. The designed nanoparticle/polymer hybrids can be processed in the form of inks for printing and spraying, in the form of solutions suitable for shaping and casting and as functional bulk solids. Their potential for the applications in the solid-state-lighting, display technologies and photovoltaics will be demonstrated.

11:30 AM NM03.01.03
Self-Driving Fluidic Laboratory for Autonomous Development of Metal Halide Perovskite Nanocrystals Fazel Bateni[1], Kristofer G. Reyes[2] and Milad Abolhasani[1]; [1]North Carolina State University, United States; [2]University at Buffalo, The State University of New York, United States

Fully-inorganic lead halide perovskite (LHP) nanocrystals (NCs) have recently been demonstrated to outperform conventional II-VI semiconductor NCs in printed photonic devices. The solution-processability and ionic nature of LHP NCs have resulted in intriguing optical and optoelectronic properties, including near-unity photoluminescence quantum yield (PLQY) and narrow emission linewidth. Despite their potential, the widespread adoption of LHP NCs by clean energy technologies have been limited due to the high content of lead (Pb^{2+}) ions in the NCs. One potential solution to reduce the high Pb content of LHP NCs is to incorporate metal cation dopants that have similar optoelectronic properties (*e.g.*, manganese, Mn^{2+}) to not only reduce the toxicity level but also introduce new properties into the host LHP NCs. However, the high-dimensional design space of metal cation-doped LHP NCs impedes comprehensive mapping of the colloidal reaction space and search for the best-performing material with desired phase stability and optical properties one-at-a-time trial-and-error experimentation approach.
The recent emergence of artificial intelligence (AI)-assisted experiment-selection strategies provide an accelerated route to explore the synthesis universe of novel advanced functional (nano)materials. However, the conventional batch reactors utilized for synthesis, development, and characterization of LHP NCs are time-, material- and labor-intensive and their process efficiency is limited due to their irreproducible heat/mass transport rates, high precursor consumption/waste generation rates, and lack of proper NC in-situ characterization probes for the real-time and rapid process control and optimization. Microfluidic platforms with their reproducible and intensified heat and mass transfer rates, small reactor footprint, facile in-situ characterization, and reduced reagent consumption/waste generation provide a miniaturized and reliable alternative to batch reactors for integration with AI-assisted experiment selection strategies. The result of such integration is a closed-loop 'self-driving fluidic lab (SDFL)'.
In this work, we present a modular SDFL for the accelerated development and fundamental mechanistic studies of pristine and metal cation-doped LHP NCs. The SDFL utilizes, for the first time, a two-stage strategy for the sequential halide exchange and cation doping of LHP NCs to autonomously explore the synthesis and doping design space of LHP NCs. The SDFL utilizes active learning to build an accurate "digital twin" of the multi-stage LHP NC synthesis chemistry (prediction accuracy>85%) within a limited experimental budget (60 experiments). We then employ the digital twin to study the fundamental formation and doping mechanisms of LHP NCs and identify the key process parameters controlling the optical/optoelectronic properties of the in-flow synthesized NCs. The SDFL uses the active learning-guided surrogate model to autonomously manufacture metal cation-doped LHP NCs with the targeted optical properties in less than 90 min per target material. The modularity of the developed SFDL makes it uniquely suited for accelerated formulation-synthesis-property relationship mapping required for discovery and development of next-generation of printable clean energy materials.

11:45 AM NM03.01.04
Accelerated Synthesis of Colloidal Quantum Dots in Multi-Stage Microfluidic Reactors Fernando Delgado-Licona, Robert Epps and Milad Abolhasani; North Carolina State University, United States

Since their discovery more than three decades ago, quantum dots (QDs), have been used as a high-performing solution-processed optical/optoelectronic material in a multitude of applications across energy, chemical, and biomedical industries. The success of QDs in devices has been driven by their intriguing optical and optoelectronic properties that can be precisely tuned via controlling their morphology, size, and chemical composition. However, recent environmental and health restrictions have prioritized the synthesis of potentially benign QD alternatives (*e.g.*, indium phosphide, InP) to QDs containing carcinogenic elements. Specifically, core-shell InP/ZnSe/ZnS heteronanostructure is considered a promising non-toxic material candidate that could reach desirable optical properties (high quantum yield and narrow emission linewidth) similar to the cadmium-based QDs. Despite the potential of InP-based QDs for next-generation photonic devices, their high-dimensional design space because of the multi-stage synthesis nature makes it extremely challenging for manual batch reactors to comprehensively explore. An attractive platform for the accelerated synthesis space exploration and intensified manufacturing of emerging colloidal QDs are continuous flow strategies, due to their facile integration with in-situ characterization techniques, intensified heat and mass transfer rates, high material efficiency, and superior reproducibility when compared to traditional batch synthesis techniques. However, matching the QD quality obtained in multi-stage batch reactors and microfluidic reactors remains a challenge. Due to the significant difference in the microreaction environments of batch and flow reactors, solely "translating" the synthetic process parameters and protocol such as temperature profiles as well as rate and sequence of precursor addition and residence times in continuous multi-stage flow reactors is not sufficient to achieve high performing QDs.
In this work, we present a modular library of 2D and 3D flow reactors to achieve maximum flexibility and reconfigurability for the controlled and intensified synthesis of InP QDs. We demonstrate the significance of both time- and temperature-to-distance transformations achieved through the reconfiguration of our flow reactor modules to optimize the multi-stage QD synthetic route. Thus, achieving high-quality InP QDs in continuous flow reactors. We report a systematic study of the multi-stage flow synthesis of InP QDs, utilizing *in-situ* absorption spectroscopy *via* both hot-injection and heat-up synthesis methods followed by the analysis and optimization of reaction cycling for sequential core growth. Furthermore, the resulting continuous flow synthesis protocol is up to an order of magnitude shorter than previously reported batch protocols. Further adoption of the developed modular flow chemistry strategies in this work could provide access to the unexplored design and synthesis space regions of the other colloidal QDs beyond InP QDs.

SESSION NM03.02: QD Synthesis II
Session Chair: Justin Caram

1:30 PM *NM03.02.01
Nanocrystal-Derived Inorganic Aerogels and Their Applications Alexander Eychmueller; TU Dresden, Germany

The focus of my talk will be laid on gels and aerogels manufactured from a variety of different (semiconductor and metal) colloidal nanoparticles. These "New inorganic aerogels"[1] carry an enormous potential for applications which is largely related to their extremely low density and high porosity providing access to the capacious inner surface of the interconnected nanoobjects they consist of.
This will be exemplified with electrocatalytic applications of metal aerogels. An example is the recently developed facile strategy for the controllable synthesis of nanoparticle-based bimetallic Pt–Ni aerogels with high surface area and large porosity, which act as highly active and stable catalysts for the oxygen reduction reaction in polymer electrolyte fuel cell cathodes.[2] For gaining highest performance of these catalysts the surface chemistry[3] as well as the formation mechanisms have to be studied and tuned.[4,5]
Further applications[6] I will touch upon include a continuous droplet reactor for the production of millimeter sized spherical aerogels,[7] hybrid plasmonic-aerogel materials as optical superheaters with engineered resonances,[8] size-tunable Gold aerogels as durable and misfocus-tolerant 3D substrates for multiplex SERS detection,[9] and the catalytic activity and selectivity in methanol steam reforming by of intermetallic compounds.[10]

2:00 PM NM03.02.02
Single Photons from Silver Dopant Cations in CdSe Nanoplatelets William F. Girten, Mitesh Amin and Todd Krauss; University of Rochester, United States

Quasi-two-dimensional cadmium selenide (CdSe) nanoplatelets (NPLs) have garnered significant research attention in recent years due to their extremely narrow band-edge exciton photoluminescence (PL) linewidths, well-defined absorbance features, and short PL lifetimes. Adding small amounts of aliovalent dopant ions to the NPLs, such as silver, gives rise to a broad and red-shifted dopant-related emission. However, the origin and photophysical properties of the dopant-related emission are not well understood for NPLs. We will discuss NPL photophysical measurements of Ag-doped 4.5 monolayer CdSe NPLs as a function of their lateral size and relative dopant concentrations. We have found that that NPLs with the same concentration of incorporated silver ions but varying lateral areas show large differences in the PL efficiency (relative to the excitonic PL) from the dopant. Furthermore, PL from individual NPLs show dual emission from both the band edge exciton and the dopant state, indicating a homogeneous doping process across the ensemble. Dopant PL intensity and spectral fluctuations across individual NPLs indicate a dynamic hole trapping process which may reflect a heterogeneous distribution of Ag atoms substitutionally placed across the lattice, which is supported by high-resolution electron microscopy images. Under ambient conditions, the dopant emission state also exhibited pronounced photon antibunching with a g2(0) = 0.24, potentially providing a bright, efficient single photon source, which would have potentially important implications for the transmission of quantum information using light. Overall, our findings illustrate the importance of NPL morphology as it relates to the unique single particle photophysics of doped CdSe NPLs.

2:15 PM NM03.02.03
Liquid-Based Ternary Colloidal Nanoparticles for Tunable Phase Change Optics Dhananjeya Kumaar Vsa, Helena Weigand, Matthias Can, Simon Wintersteller, Florian Schenk, Artemios Kavounis, Olesya Yarema, Rachel Grange and Maksym Yarema; ETH Zurich, Switzerland

Phase change memory (PCM) materials have gained major interest and revival since their utility in optical data storage discs. This is due to the tunable contrast in material properties such as complex refractive index and electrical conductivity between amorphous and crystalline states. The most heavily studied PCM materials fall in the pseudo-binary tie line of GeTe and Sb_2Te_3. Aside from Sb, doping GeTe with elements such as Pb, Bi, Cu, and Sn has been shown to improve power efficiency, induce faster crystallization, and enhance phase-contrast during switching.
Currently, vacuum technology is heavily used for the fabrication of PCM. Despite having the advantages of producing high-quality thin film and good stoichiometry control, vacuum technology has limited combinatorial throughput and flexibility for new materials discovery. Colloidal inorganic nanoparticle chemistry has shown great promise for versatility in synthesizing new materials and cost-effective translation to device applications through liquid-based fabrication routes.
Here, we report a facile hot injection synthesis approach to prepare a library of ternary nanoparticles, $M_xGe_{1-x}Te$ (where M is Sn, Cu, Pb, Bi), which are promising for PCM applications. We then investigate two material systems, namely SnGeTe (SGT) and CuGeTe (CGT), in more details. We utilize the chemical tunability of the synthesis to achieve varied compositions and phases in the SGT and CGT nanoparticles. Using high-temperature *in-situ* XRD experiments we find that increasing the Sn-doping lowers the crystallization temperature while Cu shows the opposite with respect to stoichiometric GeTe nanoparticles. We explain these observations from the viewpoint of local atomic arrangements of SGT and CGT nanoparticles, using X-ray absorption spectroscopy. Furthermore, we present thin-film fabrication through an inorganic ligand-exchange route and spin coating, which we characterize for optical properties in the amorphous and crystalline state using ellipsometry. From this we identify a reflectivity contrast and that SGT and CGT show the most pronounced difference in the refractive index of 0.9 at 1070 nm and 0.51 at 1490 nm respectively. Finally, we demonstrate an optical utility by fabricating a simple reflective stack with SGT nanoparticle thin film sandwiched between ITO layers of tunable thickness on Al mirror. We discuss the change in reflection spectra and optical contrast of the stack in the context of reflective display applications. Our work paves the way to simple fabrication of other photonic PCM applications, including near-IR metalenses, tunable filters, and beam steerer.

3:00 PM NM03.02.04
Zinc-Free Synthesis of High-Quality Indium Phosphide Quantum Dots Covering a Large Size Range Ranjana Yadav[1], Winnie Ling[2], Céline Rivaux[1], Christine S. Pierre[1] and Peter Reiss[1]; [1]CEA Grenoble, IRIG/SyMMES (UMR5819 CEA-CNRS-UGA), France; [2]Institut de Biologie Structurale (IBS), France

Indium phosphide QDs hold great promises for use in displays and LEDs and are widely considered a safer alternative to toxic Cd-based QDs.[1] Even though significant progress has been made in their synthesis, using non-pyrophoric phosphorus precursors it is still highly challenging to achieve narrow emission linewidths and to reach the near-infrared spectral range. The addition of zinc carboxylates to the synthesis of InP QDs has become commonplace with the goal to reduce the size distribution and increase the PLQY [2]. However, lattice doping by zinc can lead to shallow hole traps inducing spectral broadening, large Stokes shift, and long PL lifetimes.[3]

We present a novel Zn-free synthetic pathway for high-quality InP QDs. As-synthesized InP QDs are tetrahedral-shaped with tunable sizes from 3 nm to 9 nm without secondary additions of precursors. The first excitonic is tunable from 450 nm to 700 nm by changing the reaction conditions. These core QDs

have been subsequently overcoated with a thin ZnS shell at a temperature as low as 140°C to avoid alloying and doping of the core lattice. The emission of the InP/ZnS QDs was tunable up to 728 nm with a NIR PL linewidth of only 48 nm (FWHM). The obtained InP/ZnS QDs also exhibit a much lower Stokes shift and significantly shorter PL lifetime compared to the reported data. Finally, the reaction mechanism underlying the novel synthetic scheme was elucidated by NMR spectroscopy.

Synthesis and Characterization of Cu-Doped PbS Nanocrystals Patrick Yee, Sarah Brittman, Paul Cunningham, R Stroud, Katherine Burgess and Janice Boercker; U.S. Naval Research Laboratory, United States

Excitonic PbS nanoparticles have shown excellent infrared photosensitivity, but their limited diffusion lengths of photoexcited charge carriers result in poor device efficiencies. They also have slow radiative recombination rates that limit the performance of light-emitting diodes. To counter some of these limitations, we have developed a synthetic method for incorporating copper into PbS nanocrystals starting with $Cu_{2-x}S$ core nanocrystals. Time-resolved photoluminescence spectroscopy shows a shorter photoluminescence lifetime relative to PbS nanocrystals but a comparable photoluminescence quantum yield, indicating faster radiative decay rates. HAADF-STEM EDS maps show two populations of nanocrystals: plasmonic Cu-rich nanocrystals and excitonic Pb-rich nanocrystals. This ratio of these populations can be tuned by changing the starting $Cu_{2-x}S$ core size or changing the reaction concentration. When smaller $Cu_{2-x}S$ cores and higher reaction concentrations are used, we can create a single population of Cu-doped PbS nanocrystals. With larger $Cu_{2-x}S$ cores and lower reaction concentrations, we can create a single population of plasmonic $Cu_{2-x}S$/PbS core/shell nanocrystals.[1] ICP-OES measurement show that the atomic Cu:Pb ratio in these new Cu-doped PbS nanocrystals is as low as 0.005:1. In addition to controlling the population ratio of plasmonic Cu-rich nanocrystals and excitonic Pb-rich nanocrystals, we also see a blueshift of the exciton energies with decreasing size. These new Cu-doped PbS nanocrystals lie on a sizing curve (1st exciton transition energy vs nanocrystal diameter) distinct from that of pure PbS nanocrystals, while also showing shorter photoluminescence lifetimes and faster radiative decay rates making them a promising as a new material for infrared single-photon emitters.

3:30 PM NM03.02.06
Cadmium-Free and Efficient Type-II InP/ZnO/ZnS Quantum Dots and Their Application for LEDs Guncem O. Eren[1], Sadra Sadeghi[1], Houman Bahmani Jalali[1], Maximilian Ritter[2], Mertcan Han[1], Isinsu Baylam[1], Rustamzhon Melikov[1], Asim Onal[1], Fatma Oz[1], Mehmet Sahin[3], Cleva W. Ow-Yang[4], Alphan Sennaroglu[1], Rainer T. Lechner[2] and Sedat Nizamoglu[1,1,1]; [1]Koç University, Turkey; [2]Montanuniversitaet Leoben, Austria; [3]Abdullah Gul University, Turkey; [4]Sabanci University, Turkey

Because of the spatial separation of electron-hole wavefunctions, type-II quantum dots (QDs) are considered to have a poor photoluminescence quantum yield (PLQY). In recent studies, cadmium-based type-II QDs with high PLQY have been reported[1]. However, due to its toxic environment, it is required to develop non-toxic and efficient type-II QDs. Herein, we demonstrate highly efficient heavy toxic metal-free type-II InP/ZnO/ZnS core/shell/shell nanostructures[2].
InP core structure is synthesized by the hot injection technique. Consecutive ZnO and ZnS shells are grown by thermal decomposition and successive ionic layer adsorption (SILAR), respectively. Optimization studies of ZnO and ZnS shell thickness result in a highly efficient nanostructure that has a PLQY of 91%. The effect of ZnO and ZnS shell growth on the non-linear absorption and ultrafast decay properties is investigated via femtosecond pump-probe spectroscopy.
Small-angle X-ray scattering (SAXS) and transmission electron microscopy (TEM) measurements were used to determine the size and shape of the core/shell/shell QDs. The SAXS analysis shows that multiple ZnS shell growth induces the transition of nanocrystals from spherical to ellipsoidal shape which is in accordance with TEM results. Finally, we integrate the core/shell/shell QDs into light-emitting diode (LED) die in liquid state to reduce the host-material effect. The resulting liquid-LED device exhibited 9.4% of external quantum efficiency (EQE) and 6.8% of power conversion efficiency (PCE), respectively, making it the most efficient type-II-based LED to date. This research found that cadmium-free type-II QDs can achieve significant levels of efficiency, which could lead to new devices and nanomaterials for bioimaging, display, and lighting.

Molecular and Nanostructured Semiconductors—Unique Opportunities for Light Harvesting and Light Emission Richard R. Lunt; Michigan State University, United States

The presence of excitons in organic, molecular, and nanocluster materials offer new opportunities for low-cost photovoltaics (PV) and light-emitting systems and provide prospects for unique energy applications. In the first part of the talk, I will introduce our pioneering work on developing transparent photovoltaics (TPV) and transparent luminescent solar concentrators (TSLC) that are creating new paradigms for solar harvesting. These devices are specifically enabled by the manipulation of excitonic semiconductor materials with selective and tuneable harvesting in the near-infrared and ultraviolet components of the solar spectrum. I will discuss key photophysical properties, outline the thermodynamic and practical limits to these new classes of materials and devices, and discuss their optimization and commercialization for a range of applications from buildings to agricultural spaces. I will also outline key protocols necessary to accurately characterize TPVs and TLSCs. In the second part of the talk, I will describe our work on developing phosphorescent nanocluster based light emitting diodes and describe the role of cation/halogen/ligand substitutions on the electroluminescent properties. These inorganic phosphorescent emitters are based on metal halide nanoclusters and nanocluster salts, which have high stability, high abundance, and high quantum yield, and therefore have strong potential as a low cost alternative to organic phosphorescent emitters in a range of applications

9:00 AM NM03.03.02
Near-Unity Biexciton Emission Quantum Yield in CdS/CdSe/CdS Quantum Shells Andrew Marder[1], James Cassidy[2], Dulanjan Harankahage[2], Mikhail Zamkov[2] and Anton Malko[1]; [1]The University of Texas at Dallas, United States; [2]Bowling Green State University, United States

Non-radiative Auger recombination is the primary multiexciton loss mechanism in colloidal nanocrystals and an impediment for prospective optoelectronic applications. Recent developments of new core/shell nanocrystal quantum dots (NQDs) with suppressed Auger recombination rates has opened the possibility for studying multicarrier states using single particle time-resolved photoluminescence (PL) spectroscopy. We recently developed a new class of semiconductor NQDs, CdS/CdSe/CdS “nanoshells” where excitons are localized in a large spherical CdSe shell, rather than in a small volume of the core of a conventional “core/shell” NQD. Here, we demonstrate that a quantum shell geometry strongly inhibits Auger processes, resulting in extraordinary improvements to biexciton (BX) quantum yield (QY) and multiexciton (trions and BX) lifetimes. From time-correlated PL of multistate blinking trajectories, the lifetimes and QY of neutral and charged excitons (trions) in individual dots are experimentally measured and a non-statistical scaling model is employed to calculate multiexciton QYs, radiative lifetimes and Auger decay rates. These results are corroborated by second-order correlation (“antibunching”) statistics of BX QY to confirm the validity of the scaling model. By varying the quantum well volume in CdS_{bulk}/CdSe/CdS quantum shells (CdS core diameter ranging from 4.5 to 8 nm), we demonstrate that larger-core nanoparticles exhibit the strongest suppression of Auger decay, corresponding to BX QY of nearly 100%. A combination of ultralong (>15 ns) BX emission lifetimes and strong exciton-exciton repulsion in large-core samples allowed demonstrating low-threshold amplified spontaneous emission (ASE) and large modal gain values for BX transitions. The observed combination of long BX lifetimes and large quantum yields makes the quantum shell geometry a promising candidate for light-emitting and lasing applications.

Interpretation of Heteroepitaxy Process on Colloidal III–V/II–VI Nanocrystals Yeongho Choi, Donghyo Hahm, Wan Ki Bae and Jaehoon Lim; Sungkyunkwan University, Korea (the Republic of)

Construction of heterostructures on colloidal nanocrystals (NCs) is one of essential strategies to apply them for various optoelectronic applications such as biomarkers, displays, lightings or solar cells. Many literatures on the heteroepitaxy of NCs have focused on proper processing conditions like ligand types, precursors, or reaction temperatures to accomplish desired morphology and interface. The functionality and its performance of heterostructured NCs are primarily determined by the quality of interface, whether it contains undesired defects or not. In solution phase heteroepitaxy, unfortunately, detailed picture is veiled how elements are participating in epitaxial layer formation and how interfacial defects can be eliminated during the growth. Use of long hydrocarbon ligands may hinder adsorption, surface diffusion, and epilayer formation of metal ions delivered from precursors. We merely perform trial-and-error approaches to find optimal synthetic conditions to realize defect-less heterointerfaces.
In this study, we will propose III-V/II-VI heteroepitaxy on colloidal NCs associated with transfer of surface ligands to alkylphosphine intermediates. Using InP and ZnSe as a III-V seed and a II-VI epitaxy material, we probed association and dissociation of surface ligands as well as organometallic precursors using varied temperature ^{31}P, ^{77}Se and ^{1}H nuclear magnetic resonance. We confirmed that trioctylphosphine selenide, representative anion precursor, transfers Se to NCs’ surface by accepting carboxylate ligands to form oleyloxytrioctylphosphonium. And incoming zinc oleate leaves Zn to NCs’ surface by donating oleate ligands to oleyloxytrioctylphosphonium to form dioelyltrioctylphosphorane. Absence of ZnSe vibrational mode in InP NCs covered with Zn and Se adatoms implies that they form loose Zn-Se monomer networks, not crystalline epitaxial layer. We confirmed the presence of energetic barrier to convert the Zn-Se monomer network to the ZnSe epitaxial layer. This transformation barrier is primarily associated with the oxidized sites preventing association of Zn-P and In-Se bonds and the steric hinderance on the adsorption of zinc oleates.
Understanding on surface chemistry of heteroepitaxy allowed us to devise novel heteroepitaxy process quoting uniform and defect-less III-V/II-VI heterointerface. We chose type-I InP/ZnS core/shell NCs as our test bed because of intrinsic difficulty in uniform ZnS epilayer growth originating from large lattice mismatch of 7.8%. We accomplished near unity photoluminescence quantum yield despite very thin, 1~2 ZnS epitaxial layers. Nearly defect-free heterointerface can be inferred from monoexponential photoluminescence decay. We believe that our finding will contribute to realize heterostructure NCs with superb optoelectronic properties.

Carbon Quantum Dots—A Sustainable Nanoplatform in Sensing and Energy Applications Rafik Naccache; Concordia University, Canada

significant interest for the development of novel applications in the physical and life sciences. This is especially true for luminescent nanoparticles, which have been investigated for the development of sensors, imaging/diagnostic probes, display and solar cell applications. Recently, a relatively new class of luminescent nanomaterials, namely carbon dots, has come to light. Carbon dots, sometimes known as carbongenic dots, are carbon, oxygen, nitrogen and hydrogen containing materials with the first two elements typically accounting for ~90% of their elemental composition. Moreover, they are water dispersible and can be prepared from an abundant number of inexpensive sources including small molecules such as citric acid, amino acids, sugars and even waste. While they are small in size (typically 1-10 nm), they can offer a high quantum yield of fluorescence, a process that is controlled through passivation of the surface with an organic reagent. Of particular interest are their optical properties, which can be tailored via careful selection of the starting precursors and the desired synthesis route resulting in the ability to generate fluorescence from the blue to the near infrared regions of the spectrum. In addition to their versatile optical properties, these carbon dots are generally known to have low cytotoxicity and good biocompatibility. Combined with their small size and versatile optical properties, developing carbon dots as a nanoplatform can be achieved as these nanodots lend themselves for integration in a myriad of applications most notably in sensing and catalysis, among others. Our work focuses on achieving a fundamental understanding of the synthesis of these carbon dots in order to control their size and achieve homogenous surface chemistry and optical properties. We take advantage of the large surface area to volume ratio and study their binding to heavy metals in water in an effort to develop novel environmental sensing tools. Finally, we

exploit their surface chemistry and study their catalytic behaviour in the transformation of refined and waste oils to clean biofuel.

Colloidal Chemistry in Molten Inorganic Salts Justin Ondry, Aritrajit Gupta, Wooje Cho and Dmitri V. Talapin; University of Chicago, United States

Many functional nanomaterials used for catalysis, healthcare, solid-state lighting, and displays are synthesized by colloidal techniques. The scope of chemical transformations accessible to colloidal chemists is determined by the stability and compatibility of solvents and surfactants used as a reaction medium. For example, very few traditional solvents can handle temperatures above 400C, while many inorganic phases require even higher temperatures to form. We are developing comprehensive understanding of a novel class of colloidal systems, colloids in molten inorganic salts. Nanoparticles of different transition metals, semiconductors, oxides, and magnetic materials can form true colloids in molten inorganic salts. The colloidal stability of nanoparticles in molten salts could not be explained by traditional electrostatic and steric stabilization mechanisms. Our experimental and computational studies point to the importance of the long-range ion correlations in the molten salt near the nanocrystal interface.
In addition to the fundamental exploration of new colloidal systems, molten salts expand the boundaries for solution synthesis of many nanomaterials that have been out of reach for colloidal chemists. We have used molten salts to synthesize colloidal GaAs, $In_xGa_{1-x}As$, $In_xGa_{1-x}P$ and GaN quantum dots, which resisted numerous synthetic attempts for over two decades. By further developing colloidal chemistry in molten salts, we hope to enable synthetic routes toward various functional nanomaterials previously considered unsynthesizable by colloidal methods.

11:00 AM NM03.03.06
Lifetime Blinking in InP/$ZnSe_xS_{1-x}$/ZnS Quantum Dots Yu Jin Lee[1], Dae-Yeon Jo[2], Taehee Kim[1], Jung-Ho Jo[2], Jumi Park[1], Heesun Yang[2] and Dongho Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Hongik University, Korea (the Republic of)

We report the observation of 'lifetime blinking' in interface alloyed environment-friendly InP/$ZnSe_xS_{1-x}$/ZnS quantum dots (QDs) with optimal composition. Auger recombination is known to be one of the major drawback factors for self-emitting quantum dot light-emitting diode (QLED) devices. When unwanted Auger recombination is sufficiently suppressed, the charged states of QDs emit comparably to the neutral states of QDs. Rather than common blinking properties of QDs where the charging and discharging results in fluctuation in photoluminescence (PL) intensity, only lifetime variations were observed under substantial suppression of Auger recombination. The lifetime fluctuation despite nonblinking emission is referred to as 'lifetime blinking' and is only observed in high-quality QDs with high trion quantum yields and low non-radiative auger rates. To the best of our knowledge, this study is the first to observe lifetime blinking in non-Cd-based QDs.

We scrutinize the effect of various ZnSeS midshell compositions on QD performance and uncover the relationship between shell structure/composition and QD performance. Negative trion Auger recombination dynamics are studied through ensemble photoelectron doping experiments and single-dot analysis. Interface alloying successfully reduces lattice difference and smoothens confinement potential, and therefore, substantially suppresses unwanted Auger recombination. Non-radiative Auger rates drastically decrease from 0.41 ns^{-1} to 0.022 ns^{-1} with the introduction of a smooth shell interface. As the Auger process is suppressed, 'lifetime blinking' is observed since the trion quantum yield of gradient shell QD is enhanced to 81% by a factor of 4.5 compared to that of the discrete QD. Properties regarding PL peak width, including spectral diffusion and single-dot PL peak width, are also improved with the introduction of gradient shells due to reduced lattice mismatch between shells and increased charge trapping energy barrier. Yet, these performance improvements are found to be composition-dependent, requiring ZnSe rich midshell to prevent lattice strain in the interface of the core and the shell from arising. We anticipate the presented result to act as a stepping-stone towards developing environmentally friendly QLEDs with high performance.

Shape-Tuned Multiphoton Emission in Single-Crystalline InP Nanotetrapods Taehee Kim[1], Youngsik Kim[2], Seongmin Park[3], Kyoungwon Park[4], Zhen Wang[3], Sang Ho Oh[3], Sohee Jeong[3] and Dongho Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Samsung Display, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of); [4]Korea Electronics Technology Institute, Korea (the Republic of)

Semiconductors are essential building blocks of modern lifestyles. As their properties are dictated by the fate of photogenerated exciton, manipulating exciton behavior has been a primary goal of nanomaterials[1]. Analogous to molecular chemistry, in which the functionality of a molecule is dictated by the intramolecular exciton-exciton interactions, it is inevitable to expand this understanding into the framework of semiconductor nanomaterials. Strong spatial confinement in nanocrystals (NCs) and quantum dots gives rise to their unusual excitonic characteristics. When highly confined at all three dimensions (i.e. spherical NCs), tightly bound multiexciton states rapidly decay via Auger recombination. As confinement becomes released as in rod- or wire-shaped NCs, recombination mechanism of multiexciton states is altered due to the change in a way multiple excitons interact. This inspired a straight-forward strategy of NC shape tuning to tailor interactions between adjacent excitons[2].
Nanotetrapods exhibit unique branched geometry that enabled a precise control over their excited-state orientation and provided a novel dimensional configuration for exciton-exciton interactions. Time-resolved single particle spectroscopy revealed a transition from single to multiphoton emitter occurring at the critical tetrapod arm length ($L_{arm} = a_B$) of the material. This transition was mediated by the geometry-driven arm-localization of individual exciton. Excited-state anisotropy dynamics was unveiled by polarization-controlled ultrafast spectroscopy, by which the evolution of exciton confinement dimension from 3D(dot)-like to 2D(rod)-like confinement was observed as the arm length increased. Collective behavior of interacting multiple excitons in long-armed ($L_{arm} > a_B$) nanotetrapods enabled the unprecedented geometric manipulation of memory effect in single NC luminescence. Tunability of exciton-exciton interactions prove nanotetrapods a useful system to explore the interplay of multiple quantum states, extending the applicability of the new class of single-crystalline nanomaterials[3].

11:30 AM NM03.03.08
Facile Synthesis of Giant CdHgSe/Cd(Hg)SeS Core/Shell Quantum Dots with Large-Stokes-Shift High-Quantum-Yield Near-Infrared Photoluminescence via Chlorine-Mediated Ripening Gyudong Lee[1], Wonseok Lee[2], Andrew M. Smith[2] and Sung Jun Lim[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]University of Illinois at Urbana-Champaign, United States

Emitters having high photoluminescence quantum yield (QY), controllable absorption and emission wavelengths and minimal fluorescence intermittency are required for various applications, including biomedical imaging and optoelectronic devices. One of the promising emitters that satisfies these requirements is a giant quantum dot (GQD) having a core/thick shell structure. In a GQD, absorption and emission wavelengths can be tuned independently by controlling the composition and dimension (diameter or thickness) of the core and the shell, respectively. Moreover, the thick shell effectively decouples the electronic states of the core from the surface states and suppresses Auger recombination to improve QY and photostability. These advantages allowed GQDs to be served as light sources for solid state lightening and fluorescent probes for traking individual biomolecules in biological environment. However, conventional methods for the synthesis of core/thick shell QDs, such as successive ionic layer adsorption and reaction (SILAR) or continuous precursor injection, were time-consuming processes.
In this work, we fabricated a new GQD having a CdHgSe/Cd(Hg)SeS core/thick shell structure exhibiting a large-Stokes-shift high-QY NIR emission. Unlike conventional GQDs synthesized from aforementioned time-consuming processes, our GQDs were prepared via a facile route utilizing chlorine-mediated ripening. The new ripening synthesis can grow CdHgSe/Cd(Hg)SeS core/thick shell (>20 monolayers, MLs) QDs in a short time (<1 h) through a single heat-up reaction. Briefly, CdHgSe/CdS core/thin shell QDs (~1.6 MLs) (average diameter ~4.5 nm) with NIR emission (λ_{em} ~900 nm; QY > 40%) were prepared by the SILAR process, then heated to ~240 °C in the presence of a small amount of chloroform to initiate ripening. The core/thin shell QDs were stable at elevated temperatures before chloroform addition. Also, mass spectrometry analysis of the intermediate species showed the production of metal chlorides and chalcogen species during ripening, confirming that chlorine plays a crucial role in ripening. The ripening process increased the average QD diameter to ~15 nm, suggesting that only ~3 % of the initial CdHgSe/CdS core/thin shell QDs were grown into GQDs by consuming the rest as the shell precursors. Interestingly, little change in the photoluminescence spectra was obsersed during ripening, whereas NIR emission QY were increased > 70%. In addition, the effective absorption onset showed a significant blueshift to ~600 nm during ripening due to the rise of an intense absorption band of the thick Cd(Hg)SeS shell, increasing the Stokes shift to ~300 nm (~0.7 eV). The new synthetic process based on chlorine-mediated ripening will enable facile synthesis of various types of core/shell QDs and our GQDs will be used as efficient light sources in various applications including bioimaging and optoelectronic devices.

Understanding the Blinking Mechanism in Strongly Confined Lead Bromide Perovskite Quantum Dots Chenjia Mi, Matthew Atteberry and Yitong Dong; University of Oklahoma, United States

Strongly confined lead bromide perovskite quantum dots (PQDs), benefit from their high photoluminescence (PL) quantum yield, defect tolerance and fast radiative emission rate, possess the potential of making high purity single photon emission sources that are “bright and blue” (high emission rate with high energy of emitted photon), which can be used directly in photonics for quantum information technologies, or as a quantum excitation light source to trigger quantum photon emission from traditional emitters.
The phenomenon that the quantum dots (QDs) have PL intermittency greatly exceeds their radiative lifetime, commonly known as “blinking”, hinders their potential applications. Decades of effort has been put on studying the blinking mechanism of traditional QDs and currently three types of mechanisms are widely acknowledged: 1. Auger recombination from trions formed by exciting a charged QD (with the opposite charge carrier being deep-trapped or ejected), namely “Auger-blinking”; 2. photoactivation of interband states causing the band-edge charge carriers to non-radiatively recombine, namely “BCNR-blinking”; 3. photo- or electrical activation of intraband states causing the interception of hot-carriers, namely “HC-blinking”. However, few studies have focused on strongly confined colloidal PQDs, of which the materials are just recently made available by advances in syntheses. Compared to traditional II-VI or III-V QDs, PQDs are more ionic with friable surface, and are believed free from deep hole traps that commonly exist in II-VI QDs to cause Auger-blinking.
In this work, the blinking mechanism of a model type of single $CsPbBr_3$ PQDs were studied in comparison to commercial CdSe/ZnS core-shell QDs. The latter is considered standard samples to make lateral comparison with previous studies. Mono-dispersed colloidal PQDs with >80% PL quantum yield (75% for single PQDs, estimated with PL lifetime) are prepared. The single PQD emission was measured, and the blinking statistics associated with fluorescence lifetime-intensity distribution (FLID) analyses were performed to study the PL “on”/“off” states distribution and corresponding lifetimes.
The PL quantum yield of single CdSe/ZnS QDs varies from 90% to 50%, and there coexist Auger-blinking and BCNR-blinking. FLID analyses show that the BCNR-blinking is dominating at low excitation power, while Auger-blinking become more significant at increased power, where the “off” state also increases. We have not observed HC-blinking in CdSe QDs. The results are consistent with previous reports.
In $CsPbBr_3$ PQDs, higher excitation power also leads to higher “off” time. However, the blinking mechanism is different in almost all other aspects. At low power, the FLID analyses suggest Auger blinking is the major contributor. Surprisingly, despite the trion Auger recombination is expected to be fast due to the small size, the “off” probability of PQDs is rather insignificant compared to CdSe QDs with similar “on” brightness that show Auger-blinking. The result indicates that the Auger-like behavior in PQDs stems from a “weak trion”, which consists of a charge in PQD is partially stabilized by the distortion of the lattice (a polaron) with an exciton. The latter weakly couples with the polaron and yields a slow Auger pathway compared to radiative recombination. With increased power the PQDs show BCNR-blinking which is attributed to the friability of the un-shelled PQDs surface.
In conclusion, our strongly confined PQDs exhibit suppressed blinking, despite Auger process is expected to be fast as a result of their small size. The blinking suppression is achieved possibly by formation of polaron that weakens the Auger effect. These results illustrate the direction for rational design and optimization of lead halide PQDs towards this application.

Ultrafast Spectroscopy to Reveal the Origin of Double Emission, Optical Gain and the Role of Dopants in Engineered Semiconductor Nanocrystals Margherita Zavelani-Rossi[1,2], Andrea Camellini[1], Haiguang Zhao[3], Sergio Brovelli[4], Ranjani Viswanatha[5], Isabella Concina[6] and Alberto Vomiero[6,7]; [1]Politecnico di Milano, Italy; [2]CNR, Italy; [3]Qingdao University, China; [4]Università degli Studi di Milano-Bicocca, Italy; [5]Jawaharlal Nehru Centre for Advanced Scientific Research, India; [6]Luleå University of Technology, Sweden; [7]Università Ca Foscari, Italy

Semiconductor nanocrystals (NCs) are appealing materials for a variety of photonics applications. Key advantage is the possibility to tailor their optical response by controlling the electronic structure ("wave function engineering") through the synthesis. Beyond single wavelength band-edge photoluminescence (PL), other regimes have been demonstrated such as intragap emission, simultaneous emission on two different wavelengths, amplified spontaneous emission and laser emission. Relevant results have been obtained with heterostructured and doped NCs. The luminescent properties are primarily governed by exciton decay, which can follow different routes. Exciton relaxation occurs on few-picosecond timescale, so ultrafast techniques are required to follow the process.
In this talk, we present studies carried out by broadband ultrafast pump-probe spectroscopy technique, with 100-fs time resolution. We analysed different CdSe/CdS and PbS/CdS NCs (core/shell, dot-in-rod, dot-in-bulk, with sharp or graded interface) [1-4] and CdSeS and CdZnSe doped NCs [5,6], showing single and dual colour PL, optical gain, laser emission and intragap emission. We studied the exciton dynamics to get insights on the photophysics.
Studies on CdSe/CdS and PbS/CdS heterostructures allowed us to access the decoupling of core and shell excitons and to reveal the exciton barrier known as "dynamic hole-blockade effect". We clarified the photo-physics of double emission, suppression of Auger recombination and optical gain, describing the role of the volume and of the interface [1-3].
Experiments on CdZnSe NCs doped with Mn and on CdSeS NCs with sulfur vacancies, enabled us to disclose the emergence of a transient Mn3+ state, in the relaxation process, responsible for intragap emission [5] in the first case, and a donor state below the conduction band [6] in the latter case.
Moreover, we studied ZnO NCs decorated with Ag nanoparticle and we described the carrier redistribution in the plasmonic hot-electron/semiconductor junction [7]. We retrieved information for efficient light harvesting/detection schemes, combining high photon absorption with high carrier transfer/generation.
In conclusion, we discussed the ultrafast exciton dynamics in different NCs and we showed that the information retrieved are important for the control of NC functionalities and so for the design of devices such as lasers [8], photovoltaic and photoelectrochemical (PEC) cells [9], ratiometric sensors [10].

The Study of Magnetically Doped Metal-Chalcogenide and Halide-Perovskite Nanocrystals, by Optically Detected Magnetic Resonance Spectroscopy Efrat Lifshitz; Technion-Israel Inst of Tech, Israel

The incorporation of magnetic impurities in semiconductor colloidal nanocrystals has garnered broad scientific and technological interest during the past decade due to their tunable magneto-optical properties and consequent potential utility in various spin-related technologies. This work brings a comprehensive study of a few different magnetic dopants (Mn^{2+}, Ni^{2+}, Cu^{2+}) in metal-chalcogenide and halide perovskite nanocrystals, utilizing optically detected magnetic resonance (ODMR) spectroscopy. This methodology directly sees individual spins, uncovering spin-exchange interaction between resident carrier and a dopant spin at a local site, and thus, reflecting knowledge on long-standing debates about the involvement of the dopants in the photo-physics of the semiconductors. More specifically, Mn^{2+} dopant in CdSe/CdS seeded rods enhanced the electron-dopant spins by selective positioning of the dopant at the CdS-shell regime. Ni^{2+} dopants in $CsPbBr_3$ perovskite materials showed a spin-exchange interaction with a hole-resident spin, whose existence could be detected due to the reduction of motion fluctuations by the dopants at the substituted position. The ODMR Cu^{2+} doped CdSe/(CdS, ZnS) were recently investigated compared to that of $CuInS_2$ QDs. This study showed a joint involvement of a Cu-activated center in the two families of compounds however via a different mechanism; A band-to-Cu recombination with a weak electron-hole spin-exchange interaction was found in the Cu-doped QDs, but, a self-trapped exciton emission with a strong electron-hole exchange constant in Cu-based QDs. Furthermore, nuclei spin effects were pronounced in the magnetic resonance transitions. The described studies exposed spin interaction on atomistic local sites, uncovering information blurred by simple optical methodologies.

Photo-Induced Charge Carrier Dynamics at Semiconductor Quantum Dots/TiO_2 Interface Yasuhiro Tachibana[1,2]; [1]RMIT University, Australia; [2]Osaka University, Japan

Semiconductor quantum dot (QD) is one of the most attractive nanomaterials to be applied for solar energy conversion devices. With their relatively large extinction coefficients and a wide light absorption range over visible wavelengths, QDs can be effective light absorbers. However, despite their attractive optical properties, when they are employed in solar cells, their function, particularly exciton states, charge separation and recombination dynamics has not been well understood. Their relations to the solar cell function are still not clear.

We have reported charge separation and recombination dynamics at the QD and TiO_2 interface,[1] and relationship of the nanostructures with the solar cell performance.[2,3] We have also reported novel synthesis of several types of QDs with a narrow size distribution to control the potential energy levels of the conduction and valence bands [4,5]. In this presentation, we will discuss underlying key parameters such as interfacial nanostructure controlling charge carrier dynamics at QD / TiO_2 interface.

This work was partly supported by JSPS KAKENHI Grant (19H02813) and (22H02182), and the Collaborative Research Program of Institute for Chemical Research, Kyoto University (grant number 2021-78 and 2022-99), Japan. High-Efficiency Two-Step Spin-Exchange Auger Photoemission from Manganese-Doped Quantum Dots Valerio Pinchetti[1], Clement Livache[1], Ho Jin[1,2], Whi Dong Kim[1], Igor Fedin[1] and Victor I. Klimov[1]; [1]Los Alamos National Laboratory, United States; [2]The University of New Mexico, United States

Photoemission is a process wherein a material emits free electrons upon its illumination with electromagnetic radiation. Typically, it requires energetic ultraviolet or even X-ray photons. Here we show that using CdSe colloidal quantum dots (CQDs) heavily doped with manganese (Mn), we can realize this process with visible light. The observed effect is enabled by extremely fast (<300 femtoseconds) spin-exchange Auger energy transfer from excited Mn ions to an intrinsic CQD exciton. Since the rate of this process outpaces that of intra-band cooling, the high-energy 'hot' electron produced by the first Auger-excitation step can be efficiently promoted further into the external 'vacuum' state via one more Mn-to-CQD energy-transfer step. This CQD ionization pathway exploits exceptionally large up-hill energy gain rates associated with the spin-exchange Auger process (>10 eV ps^{-1}) and leads to photoemission efficiencies of more than 3%, orders of magnitude greater than in the case of undoped CQDs. We demonstrate that using this phenomenon, we can achieve high-yield production of solvated electrons (>3% internal quantum efficiency), which makes it of considerable utility in visible-light-driven reduction photochemistry. Other potential applications include low-cost, visible-light-driven photocathodes and advanced photoconversion.

Semiconductor Nanocrystals as Photooxidative Catalysts in Organic Media Xiao-Min Lin[1] and Elena Shevchenko[1,2]; [1]Argonne National Laboratory, United States; [2]The University of Chicago, United States

Semiconductor nanocrystals (NCs) are extensively studied for photocatalytic applications. CdSe/CdS nanorods (NRs) with a CdSe core and CdS shell enable maximization of solar absorption and convertion of a broad range of visible spectra to chemical energy. The spatial separation of the electrons and holes reduces the recombination rate and increases the probability of photogenerated carries to be extracted. Photocatalytic reaction utilizing both photogenerated electrons and holes could lead to synthesis of a broad range of high value products in organic solvents. Majority of photocatalytic studies on cadmium chalcogenide heterostructures are mainly conducted in aqueous media (*e.g.*, hydrogen generation), with holes scavenged by sacrificial electron donors to prevent oxidation of semiconductor NCs. Using aerobic oxidative coupling of thiophenol in organic media as a model reaction, we show that photogenerated holes in CdSe/CdS core–shell nanorods can be efficiently extracted and CdSe/CdS nanorods can serve as an efficient visible-light photocatalyst at a very low concentration ($\sim 1.5 \times 10^{-4}$ mol%). We show that primary amines play an important role in the transformation of thiols into disulfides by forming a soluble thiolate in nonpolar solvent. Using time-resolved optical spectroscopy and electron paramagnetic resonance spectroscopy, we show that thiolate can efficiently extract the photogenerated holes from CdSe/CdS nanorods and transform into disulfide in organic solvent. Our data indicate that there are two reaction pathways responsible for S–S coupling of thiolate upon illumination of CdSe/CdS nanorods. We show that instead of scavenging of photogenerated holes by sacrificial species for prevention of photo corrosion of CdSe/CdS nanorods, the photogenerated holes can be efficiently used for oxidative organic synthesis.[1] We will discuss discus the perspectives of photoopxidative catalysis in organic solvents using semiconductor NCs.

Temperature and Magnetic Field Dependence of Photoluminescence Lifetimes Reveal the Electron-Hole Recombination Mechanism in Colloidal $CuInS_2$ Quantum Dots Malgorzata Szymura[1], Magdalena Duda[1], Miriam Karpinska[1], Tomasz Kazimierczuk[2], Roman Minikayev[1], Magdalena Parlinska-Wojtan[3] and Lukasz Klopotowski[1]; [1]Institute of Physics, Polish Academy of Sciences, Poland; [2]Faculty of Physics, University of Warsaw, Poland; [3]Institute of Nuclear Physics Polish Academy of Sciences, Poland

We present experimental evidence that the photoluminescence (PL) in copper indium sulphide ($CuInS_2$) quantum dots (QDs) occurs through a recombination of a delocalized electron and a localized hole (i.e., a free-to-bound mechanism). More specifically, we study the PL dynamics in a temperature range between 2 and 300 K and in magnetic fields up to 10 T and demonstrate that the results cannot be explained by assuming a recombination of band-edge excitons. On the other hand, the results are consistent with the free-to-bound mechanism in which the hole is localized at the d-shell of copper ions.

$CuInS_2$ QDs (and I-III-VI compound QDs in general) attract significant attention as more environmentally friendly alternatives to cadmium and lead chalcogenide QDs. Despite years of research, the optical properties of these nanostructures are not fully understood. Although most experimental results point to the free-to-bound process as the underlying mechanism of electron-hole recombination, some theoretical and experimental reports claim that the PL can be due to an excitonic process.

In this work, we find that the PL decays are strongly non-exponential underlining a strong inhomogeneity of the recombination rates. The extracted average PL lifetimes shorten with increasing the temperature. Crucially, when increasing the temperature from 2 K, we find that the short lifetime components are less sensitive to temperature change. We argue that this effect is incompatible with the excitonic mechanism while expected for the free-to-bound mechanism, where the position of the Cu ions within a QD governs the recombination rates. Furthermore, we investigate the PL decays recorded in two circular polarizations as a function of the magnetic field. This allows us to evaluate the spin relaxation rates. The rates are two orders of magnitude smaller than for CdSe QDs, which exhibit excitonic PL. On the other hand, the rates are on the same order as those evaluated for Cu-doped CdSe, in which the free-to-bound mechanism is responsible for the PL. We argue that the low spin relaxation rates originate from a limited interaction of the electron-hole pairs with the QD surface. Finally, we show that the PL polarization exhibits a particular temporal dependence: the equilibrium polarization decays with the time delay from the excitation laser. This effect can be interpreted as originating from a negative correlation between the fine structure splitting of the luminescent excited state and the PL lifetime. Crucially, this correlation is expected for the free-to-bound mechanism, while an opposite, positive correlation, is well established for excitonic photoluminescence. Thus, our results strongly support the free-to-bound recombination process as responsible for the PL of $CuInS_2$ QDs.

Photoluminescence Signatures of Energy Transfer in $CuInS_2$ Colloidal Quantum Dot Films Pushkar S. Joshi, Magdalena Duda and Lukasz

Klopotowski; Institute of Physics Polish Academy of Sciences, Poland

In this work, we demonstrate spectroscopic signatures of energy transfer (ET) in a solid film prepared from $CuInS_2$ colloidal quantum dots (QDs). Energy transfer in colloidal QDs has been a highly studied area in pursuit of applications such as solar cells. The size-dependent optical properties of QDs make them ideal candidates for such exploration. The environmentally safer QD materials such as $CuInS_2$ (CIS) have not been explored as much as Pb and Cd chalcogenide QDs in this regard. The significant Stokes shift of CIS and the scope for changing its stoichiometry provide additional parameters, which may influence ET efficiency. Here, we study steady-state photoluminescence (PL) and time-resolved photoluminescence (trPL) on QD films and solutions. Comparison of the results between the film and solution samples unveils three signatures of ET in QD films: (i) red-shift of the film PL spectrum, (ii) increase/decrease of the relative PL decay rate at the blue/red end of the film PL spectrum, and (iii) presence of a PL rise dynamics at the red end of the film PL spectrum. In agreement with studies on other QD systems, all these effects point to an ET from small to large QDs within the ensemble.
The CIS QDs studied here are synthesized at 230°C for 1 minute with Cu-to-In precursor ratio of 1:4. The PL spectrum of QDs in solution form peaks at 652 nm and exhibits a broad full width at half maximum (FWHM) of about 100 nm. This is the sign of the presence of highly inhomogeneous QD size distribution in the ensemble. The PL peak of the same ensemble when drop cast to form a solid film is red-shifted by over 50 nm (140 meV) to 705 nm. Since the FWHM of the film PL hardly changes from the solution PL, we interpret the red-shift as a signature of non-radiative ET from donor QDs of smaller sizes to the larger acceptor QDs when deposited as a film. The spectrally integrated PL lifetime in solution phase is of the order of 300 ns while for the films is shorter, i.e., of the order of 200 ns. The faster PL decays point to the existence of additional recombination channels in the case of films. Furthermore, the spectrally resolved trPL studies unveil the shortening of PL lifetimes from the red end of the spectrum to the blue end. In solution phase, the lifetimes at the red and blue ends relative to that of the peak are 1.3 and 0.6, respectively. This shows that the QD ensemble exhibits an intrinsic spectral dependence of the lifetimes. On the other hand, in the film, the lifetimes at the red and blue ends relative to that of the peak are 1.6 and 0.32, respectively. Thus, in the film form, an additional contribution to the spectral dependence of lifetimes is manifested. An analogous effect was previously ascribed to non-radiative ET within inhomogeneous ensembles of QDs. Accordingly, we interpret this additional contribution as a result of ET between donors and acceptors in the film. This conclusion is further supported by the observation of PL rise dynamics at the red end of the film spectrum, which is absent in the case of the solution trPL. The existence of rise time at the red end together with very short decay at the blue end can be explained by the non-radiative transfer of energy from the small QDs into the larger QDs. Similar effects are observed with varying degrees in 4 other CIS QD ensembles made of different QD sizes and Cu-to-In precursor ratios. Results for all samples support the conclusion that ET occurs in CIS QD films. For more detailed insight into this effect, the future research will include temperature dependent studies and fine selection of QD-sizes to assert an improved control over ET.

4:30 PM NM03.04.08
Stimulated Emission from Bulk-Like CdS Quantum Dots Through Strong Band Gap Renormalization Ivo Tanghe[1], Margarita Samoli[1], Isabella Wagner[2], Servet A. Cayan[1], Ali H. Khan[3], Kai Chen[2], Justin Hodgkiss[2], Iwan Moreels[1], Dries Van Thourhout[1], Zeger Hens[1] and Pieter Geiregat[1]; [1]University Ghent, Belgium; [2]Victoria University of Wellington, New Zealand; [3]S.N. Bose National Centre for Basic Sciences, India

Nanostructured semiconductors are heavily investigated for their applications in light emission such as light emitting diodes and, more challenging, lasers. Using quantum confined Cd-based QDs, several groups have shown light amplification and ensuing lasing action in the red part of the spectrum. Although further work is necessary to reduce gain threshold densities for efficient lasing action, there has been some push toward moving away from the current red gain band region, toward green emission.

In this work, we take a look at weakly confined “giant” CdS Quantum Dots, which display disruptive optical gain properties in the green optical region. While showing similar gain thresholds compared to state-of-the-art materials, the gain window (440-600nm), magnitude (up to 50000/cm) and gain lifetime (up to 3ns) vastly outpace other materials in the same optical region.

These remarkable results are explained by using a bulk semiconductor gain model, which is possible due to the large size of the CdS Quantum Dots (8-12 nm). We can very accurately reconstruct the gain window with this model, by including large bandgap renormalization (up to 70 meV). This inclusion helps us to understand the gain mechanism in these particles.

SESSION NM03.05: Nanoparticle Assembly
Session Chairs: Elena Shevchenko and Marinella Striccoli
Wednesday Morning, November 30, 2022
Hynes, Level 2, Room 209

Mesoscale Quantum Confined Nanoplatelets Stephanie Tenney and Justin R. Caram; University of California, Los Angeles, United States

We have synthesized mesoscale semiconductor (II-VI) nanoplatelets (NPLs) for the first time using colloidal seeded growth. These nanoplatelets are quantum-confined and atomically precise but grown to a length scale compatible with conventional optical imaging and microscopic manipulation offering an opportunity to bridge the application space between nanocrystals and 2D materials. Using CdTe as a model system we develop a seeded growth procedure, show the parameters which control extension, and apply them to a variety of thicknesses and compositions. In-situ spectroscopy demonstrates that addition onto the nanoplatelet seeds is not continuous, and likely occurs through ripening. Finally, we use correlative optical and electron microscopy to demonstrate that at large sizes, PL mapping of the entire structure can be resolved including spatial inhomogeneities. Overall, these results show that nanoplatelets can be compared to 2D semiconductors while maintaining the advantages of scalable colloidal synthesis, thickness tunability and solution processability.

9:00 AM NM03.05.02
Single Photon Emitting Arrays by Capillary Assembly of Colloidal Semiconductor CdSe/CdS Nanocrystals Matteo Barelli[1], Cynthia Vidal[2], Sergio Fiorito[1], Alina Myslovska[3], Dimitrie Cielecki[2], Iwan Moreels[3], Riccardo Sapienza[2] and Francesco Di Stasio[1]; [1]Istituto Italiano di Tecnologia, Italy; [2]Imperial College London, United Kingdom; [3]Ghent University, Belgium

Interest in the physics and materials science of nanocrystals (NCs) has exponentially increased over the last couple of decades. Colloidal semiconductor NCs present remarkable properties in sight of optoelectronic device fabrication, as they are synthetized by wet chemistry methods that offer a seemingly endless amount of freedom on the parameters that determine their optoelectronic properties such as crystal size, shape, crystallinity, chemical composition and architecture (e.g. core/shell NCs). All these various optoelectronic devices are based on thin films; however, complex small-footprint devices

exploiting single NCs require controlled placement of isolated NCs on particular sites of a planar surface and this step is not easily achievable as for quantum-dots fabricated by pure top-down methods. For example, a specific emerging application of isolated colloidal semiconductor NCs is to employ them as single photon sources, in the emerging fields of quantum communication, computing and encryption.[1] A whole range of techniques have been explored to place colloidal NCs from solution to a controlled site on a solid substrate.[2] In particular, a method called capillary assembly, exploits the force exerted on NCs at the interface between the moving meniscus of the solution solvent and a solid substrate to allow the entrapment of NCs in pre-patterned features on the surface, typically realized by means of lithographic methods such as electron beam lithography.[3] However, most results in literature employ metallic NCs in the fabrication of plasmonic metasurfaces and polymeric colloidal units; while the placement of semiconductor NCs has been less explored. The controlled placement of colloidal semiconductor NCs remain crucial in sight of the fabrication of small footprint optoelectronic nanodevices built around them.

In this work, we show the fabrication of periodic arrays of giant shell CdSe/CdS NCs by a capillary assembly method based on a simple and fast drop casting technique. Before proceeding with the array fabrication, the CdSe/CdS NCs have been overcoated with a SiO2 shell. The large area arrays here presented (2500 holes over 100×100 μm^2) contain hundreds of single NCs filled holes, each. The nanoholes filling efficiency follows a Poisson distribution, with 60% of the nanoholes containing one or more NCs. We have characterized the arrays with steady state and time-resolved photoluminescence, and photon correlation measurements. We associated the morphological data collected by scanning electron microscopy with optical data to unveil how the effective density of single photon emitters depends on an interplay between NCs photoluminescence quantum yield and Poisson statistics of the nanohole filling process. That is, why we observe single photon emission by nanoholes filled with multiple NCs. We believe the proposed technique is the first step toward the realization of affordable and reproducible arrays of single photon sources based on colloidal semiconductor NCs. Most importantly, the technique enables future implementation of addressable networks of nanodevices, such as single-NC light-emitting diodes, and it should be applicable to a wide range of semiconductor NCs with variable composition and shape.

Coupling Interactions of Molecular Assembled Colloidal Quantum Dot in Solution and Solid-State Carlo N. Dibenedetto[1,2], Elisabetta Fanizza[1,2], Rosaria Brescia[3], Liberato De Caro[2], Cinzia Giannini[2], Angela Agostiano[1,2], Maria Lucia Curri[1,2] and Marinella Striccoli[2]; [1]University of Bari "Aldo Moro", Italy; [2]CNR, Italy; [3]Istituto Italiano di Tecnologia, Italy

The design of colloidal quantum dots (QDs) assemblies, as well as the investigation of their interactions, mutual and with the surrounding chemical-physical environment, is of great interest for increasing the performance of QD based optoelectronic devices. The coupling, which occurs when only a few QDs are organized in molecular assembly at suitable interparticle distance, can promote electron/energy transfer processes and coherent interactions, relevant for novel technological applications. Here, small molecular assemblies of QDs have been properly prepared by playing with the nanocrystal surface chemistry in solution, and then deposited samples have been fabricated, maintaining the assemblies individuality, to further investigate the electronic coupling between the nano objects in solid state.
Specifically, molecular assemblies composed by colloidal CdSe QDs of same (homo) and different (hetero) sizes,[1,2] connected by short alkyl chain dithiols, have been prepared in solution. The interparticle distance has been finely tuned by varying the chain length of the bifunctional linker down to sub-nanometer range. Depending on their size, separation distance and mutual energy levels position, an extensive spectroscopic examination has allowed to attribute the coupling mechanisms between the QDs. The findings demonstrate the higher heteroassemblies' potential in terms of transfer rate for charge transfer/wavefunction delocalization, taking advantage of the contact zone's cascade-like energy levels. FRET systems, on the other hand, would greatly benefit from the design of homoassemblies, which can couple more efficiently via an energy transfer mechanism due to quasi iso-energetic electronic states.
The next step has been the fabrication of solid-state architectures, realized depositing the molecular assembly of QDs prepared in solution by means of dithiols or diamines as linkers, on a quartz substrate properly functionalized with an amino terminated self-assembled-monolayer (SAM). The presence of SAM guarantees the effective anchorage of the nano-objects to the substrate and ensures a good uniformity of the deposition. Layer-by-Layer approach has been used as deposition technique and every layer of QD molecular assembly has been alternated with a long molecular spacer, in order to maintain as much as possible the ‘’molecular’’ nature of the assemblies. For comparison, samples in which the QD capping ligands have been completely exchanged with short bifunctional linker have been fabricated in order to connect collectively all the QDs in the layer, as usually used in conventional optoelectronic devices. The use of amines or thiols deeply influences the morphology of the assemblies, giving rise to fascinating flowered or roundly shaped hierarchical structures, respectively. The spectroscopic investigation reveals interesting electronic properties of these structured materials, that can add another brick to the knowledge of these systems.

Superfluorescence in Lead Halide Perovskite Nanocrystal Assemblies and Giant Nanocrystals Etsuki Kobiyama[1], Gabriele Raino[2,3], Ihor Cherniukh[2,3], Yuliia Berezovska[2,3], Maryna Bodnarchuk[2,3], Rainer F. Mahrt[1], Maksym V. Kovalenko[2,3] and Thilo Stoeferle[1]; [1]IBM Research GmbH Zurich Research Laboratory, Switzerland; [2]ETH Zürich, Switzerland; [3]Empa–Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Cooperative effects among electric dipoles lead to drastic changes in photon emission processes. In particular, spontaneous synchronization of dipole oscillation leads to an emission of an intense burst of photons, so-called superfluorescence (SF). Because SF is based on coherent interactions among excited dipoles, the SF response reflects the presence of quantum many-body states. As lead halide perovskite nanocrystals (NC) exhibit giant oscillator

strength and long dephasing times, they have been shown to be excellent solid-state SF platforms[1]. So far, several types of perovskite NC systems, e.g., mono-component or binary component NC assemblies, exhibit SF[1,2]. However, how the different structures of the material systems affect the SF process is not fully elucidated yet.

Here, we investigate the photoluminescence (PL) dynamics in several NC assemblies with different lattice geometry. By analyzing the characteristic signatures of SF, e.g., excitation-dependent decay acceleration, super-linear power law of emission intensity, and ringing of emission pulses, we found that the volume fraction of perovskite NCs within the assemblies is a pivotal factor in supporting SF[3]. Besides, we studied SF dynamics in the different types of material systems, namely bulk-like giant NCs. We observed the characteristic SF signatures with lower excitation power than NC assemblies. Furthermore, we observed that the dominant emission process gradually evolves from SF to amplified spontaneous emission by increasing the temperature.

Our results show that SF responses depend on material systems' geometry or structure (bulk or NC assemblies). The results suggest the possibility of controlling SF responses and quantum many-body states by engineering the geometry or structure of the material systems.

Short-Ranged Attractive Forces Enable the Self-Assembly of Binary Nanocrystal Superlattices Emanuele Marino[1], R. Allen LaCour[2], Timothy C. Moore[2], Sjoerd van Dongen[1], Austin W. Keller[1], Shengsong Yang[1], Daniel J. Rosen[1], Guillaume Gouget[1], Esther H. Tsai[3], Cherie R. Kagan[1], Thomas E. Kodger[4], Sharon Glotzer[2] and Christopher B. Murray[1]; [1]University of Pennsylvania, United States; [2]University of Michigan–Ann Arbor, United States; [3]Brookhaven National Laboratory, United States; [4]Wageningen University & Research, Netherlands

The self-assembly of nanocrystals into binary superlattices enables the targeted integration of orthogonal physical properties, like photoluminescence and magnetism, into a single superstructure, unlocking a vast design space for multifunctional materials. Yet, the formation of binary nanocrystal superlattices remains poorly understood, restricting the use of simulation to predict structure and properties of the final superlattices. Here, we use *in situ* scattering experiments to unravel the time-dependent self-assembly of nanocrystals into 3D binary superlattices, and molecular dynamics simulations to obtain interparticle interactions consistent with experimental observations. We show definitively that short-ranged, attractive interparticle forces are necessary to obtain the binary crystalline phases observed in experiment. The short-ranged attraction stabilizes these crystalline phases relative to fluid phases, dramatically enhancing their formation kinetics over the purely repulsive interactions of the hard-sphere model. In these conditions, the formation of binary nanocrystal superlattices proceeds through homogeneous nucleation in the absence of intermediate ordered structures. These results establish a robust correspondence between experiment and theory, paving the way towards *a priori* prediction of binary nanocrystal superlattices.

Chiral Conjugated Polymer/Perovskite Quantum Dot Nanowired-Hybrids Juhong Min, Junho Hwang, Seon-Mi Jin and Eunji Lee; Gwangju Institute of Science and Technology, Korea (the Republic of)

Recently, chiral semiconductor quantum dots with chiral ligand have attracted attention because of potential applications such as chiral memory effect and tunable circularly polarized luminescence(CPL) property. Especially, chiral perovskite quantum dots recently receive attention as next-generation circularly polarized photodetectors and spintronic memory devices with high external quantum efficiency and tunable band gap. However, the chirality of perovskite can be degraded during ligand exchange of the organic ligands surrounding the perovskite quantum dot for the hybrid system. I assume that a more easily controlled and stable chiral perovskite system can be induced by arranging the achiral perovskite quantum dot along the self-assembled chiral polymer template in the solution state. Crystalline-driven self-assembly of a conjugated polymer in a solution state is promising high performance optoelectronic devices with excellent charge carrier transport through the solution. Herein, we report the synthesis of chiral enantiomer containing conjugated building block and self-assembly in water as a green solvent for an ecofriendly large scale solution process. Additionally, through co-assembly between chiral conjugated nanowires and achiral perovskite quantum dot, we successfully generated chiral conjugated polymers/perovskite nanoparticles(NPs) hybrid nanowire with preferred handedness. A controlling array of perovskite quantum dots on the chiral self-assembly template was defined by 3D TEM tomography. This work is expected to suggest a new hybrid system to enhance the chirality parameter, circularly polarized luminescence property and synergistic functional application with perovskite quantum dots on the chiral conjugated template.

Approaching Bulk Mobility in PbSe Colloidal Quantum Dots 3D Superlattices Jacopo Pinna, Razieh Mehrabi, Dnyaneshwar Gavhane, Majid Ahmadi, Suhas Mutalik, Loredana Protesescu, Bart Kooi, Giuseppe Portale and Maria Antonietta Loi; University of Groningen, Netherlands

Progress in optoelectronics has been hindered by the discrete nature of band gap for inorganic semiconductors and the difficulty of tuning both band gaps and transport properties for a given material. Semiconducting colloidal quantum dots (CQDs) have been in the spotlight thanks to their wide tunability and solution-based synthesis. It is in particular the ability to change the bandgap with their dimensions that makes them excellent candidates for the fabrication of optoelectronic metamaterials, while several other physical properties can be controlled by composition and surface chemistry.
In particular, lead chalcogenides CQDs (PbS, PbSe) have the potential to revolutionize the field of light emission and detection in the short-wavelength infrared range thanks to their tunable bandgap between 800-3000 nm. In this spectral range there is poor or no availability of cheap bulk semiconductors that can be used in applications like telecommunications and sensing in automated transport. Therefore, growing interest in this family of CQDs has risen especially in the last decade. But technological application has been limited by the poor transport properties of thin films fabricated with such materials. This is due to the fact that implementations in devices is performed with techniques that yields disordered films and charge transport is limited by the thermally activated hopping mechanism.
More recently, the self-assembly of CQDs in ordered arrays, the so called superlattices, has been proposed as a solution to the problem. Superlattices are expected to lead to coherent transport through minibands therefore approaching the electronic properties of the bulk counterparts. While the shape and truncation of these quantum dots are highly favorable for self-assembly, as shown by several work on 2D systems, the poor control on the ordering from the nanoscale to the mesoscale, on the electronic coupling and on surface trap passivation has lead to the observation of rather disappointing charge transport properties. In the current state-of-the-art reports, electron field-effect mobilities of 24 cm^2/Vs have been reported for 2D superlattices (1) and of 2.13 cm^2/Vs for the 3D ones (2).
Here we report the self-assembly of highly ordered 3D superlattices with tunable structure and thickness (single layer precision). The superior quality of the fabricated samples is demonstrated with a combination of advanced structural characterization techniques like atomic resolution electron microscopy and grazing incidence X-Ray scattering. We observe coherence lengths in the order of 100 nm in the in plane direction while the superlattice is fully coherent

along its entire thickness. This outstanding ordering, combined with the excellent large scale morphology, results in record electron mobilities up to 257 cm^2/Vs as measured in a field effect transistor using ionic gel as gate dielectric. This value is not only approaching the bulk mobility but it is a record among any self-assembled superlattice with fully quantum-confined nanocrystals as building blocks.

Kovalenko[2,1]; [1]Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]ETH Zurich, Switzerland; [3]IBM Research Europe — Zurich, Switzerland; [4]Paul Scherrer Institute, Switzerland; [5]Iowa State University, United States; [6]University of Cyprus, Cyprus; [7]Graz University of Technology, Austria; [8]Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland

Cesium lead halide perovskite nanocrystals (NCs), owing to their outstanding optoelectronic properties (high oscillator strength of bright triplet excitons, slow dephasing, minimal inhomogeneous broadening of emission lines), are promising materials for creating coherent macroscopic states that can be utilized in quantum applications. Perovskite NCs self-assembled into ordered superlattices (SLs) with simple cubic packing of cubic NCs have been shown to emit ultrafast (*ca.* 20 ps) superfluorescent light. Further advancement in the field, required for programmable tuning of the collective emission and for building a theoretical framework, relies on the higher-level, exquisite structural engineering of the perovskite NC structures, wherein the use of additional building blocks may allow control over the mutual arrangement and orientation of perovskite nanocubes. We present a wide structural diversity in multicomponent, long-range ordered SLs obtained by shape-directed co-assembly of cubic $CsPbBr_3$ NCs with the spherical, truncated cuboid, and disk-shaped NCs. When combined with spherical Fe_3O_4 or $NaGdF_4$ NCs, SLs of five structure types form, namely, NaCl-, AlB_2-, and novel, uncommon to all-sphere assemblies AB_2- as well as quasi-ternary ABO_3- and ABO_6-types with cubes occupying B- and O-sites. Targeted incorporation of truncated cuboid PbS NCs on B-sites results in the formation of ternary ABO_3-type SLs. We then demonstrate the effect of superlattice structure on the collective optical properties. Combining perovskite nanocubes with other shape-anisotropic building blocks extends the library of accessible SL structures. With truncated cuboid PbS NCs as a larger component, in addition to binary NaCl-, AlB_2- and ABO_3-type SLs, CuAu-type SL was obtained. Co-assembly of $CsPbBr_3$ nanocubes with larger disk-shaped LaF_3 NCs results in the formation of six columnar structures with AB, AB_2, AB_4, and AB_6 stoichiometry. In the systems with comparable dimensions of nanocubes (8.6 nm) and nanodisks (6.5–12.5 nm), other, non-columnar structures are observed, such as ReO_3-type SL, featuring intimate intermixing and face-to-face alignment of disks and cubes. With large and thick $NaGdF_4$ nanodisks the orthorhombic SL resembling CaC_2 structure with clusters of $CsPbBr_3$ NCs was obtained. In the above-mentioned structures, 8.6 nm perovskite nanocubes exhibit a high degree of orientational ordering. We also explore the substrate-free assembly methods that allow obtaining binary supraparticles and free-floating SL films comprising perovskite nanocrystals.

Sub-Nanosecond Radiative Decay Time of Excitons in Large Size Nanocrystals and Nanoplatelets Alexander L. Efros; Naval Research Laboratory, United States

Sub-nanosecond radiative decay time was first observed for weakly bound excitons in bulk semiconductors and was understood in terms of the phenomenon known as giant oscillator strength (GOS).[1] GOS is a quantum phenomenon connected with coherent excitation of excitons over entire volume of exciton localization and is counterintuitive because the radiative decay time is inversely proportional to this volume. Consequently, it was predicted theoretically[2] that exciton weakly confined in a spherical nanocrystal (NC), which radius a is much larger than the exciton radius a_{ex} is characterized by GOS which strength, $f_{NC}=f_0(a/a_{ex})^3 >> f_0$, where f_0 is the exciton oscillator strength. Indeed ~ 100 ps radiative decay times was observed in $CuCl$[3] and large size $CsPbX_3$ (X=Cl,Br,I) perovskite NCs.[4] The sub-nanosecond radiative decay time connected with GOS was also observed in quantum wells and nanopletelets.[5] In all cases the superfast radiative decay time observed generally at liquid helium temperatures increases with temperature. In my talk I will discuss the origin of the GOS of excitons and their sub-picosecond decay time, the effect of the temperature and line broadening in in nanoplatelets.

Density Functional Theory Investigation of Trap States in Indium Phosphide Quantum Dots Ezra A. Alexander, Matthias Kick and Troy Van

Voorhis; MIT, United States

Cadmium selenide, one of the premier quantum dot (QD) materials for light emission, solar cells, and biomedical imaging, is highly toxic to both humans and the environment. Alternative, nontoxic III-V QDs are held back by a high density of surface-localized mid-gap states, which trap photoexcited charge carriers and reduce device efficiency. Despite the prevalence of density functional theory (DFT) in past investigations of surface trapping in the II-VI family of QDs, very few studies have applied DFT to the substantially different III-V family of QDs. In this work, we show that trap states can form in indium phosphide QDs as the result of both 2- and 3-coordinate surface indium and phosphorous atoms. However, not all 3-coordinate surface atoms lead to localized midgap states; in particular, structures with many 3-coordinate surface atoms often form delocalized surface states near the band edge. Moreover, we observe the formation of both trap-inducing phosphorous dimers and trap-inert indium dimers on the surface of our model dots. Ultimately, our results suggest that a single-atom picture is insufficient to explain the surface trapping in indium phosphide QDs, hinting at new passivation strategies for improving nontoxic III-V QD devices.

Exciton Fine Structure in Lead Salt Nanocrystal Quantum Dots Serguei Goupalov[1,2], Ivan Avdeev[2], Mikhail Nestoklon[2] and Eougenious Ivchenko[2]; [1]Jackson State University, United States; [2]Ioffe Institute, Russian Federation

Lead salt (PbX, X = S, Se, Te) quantum dots (QDs) are widely used in optoelectronics and *in vivo* fluorescence imaging due to tunability of their fundamental optical transition with the QD size within the near-infrared and mid-infrared ranges. These materials have both conduction and valence band extrema located at the four L points of the Brillouin zone forming four inequivalent anisotropic valleys. This leads to a high degeneracy of the energy spectrum in bulk materials which is partially lifted in QDs, resulting in the exciton fine structure. Understanding and controlling the exciton fine structure in PbX QDs is of key importance for full utilization of their unique optical properties.

We report a tight-binding calculation of the exciton ground-state fine structure in PbS QDs of different sizes and shapes, complemented by a thorough symmetry analysis[1]. We show that the exciton fine structure in PbX QDs is governed by the competition of two main mechanisms [1,2]. One is the electron-hole exchange interaction which can be best understood within the isotropic **kp** model and is not sensitive to QD shape or valley anisotropy. This interaction has both intra-valley and inter-valley parts and promotes formation of a single ultra-bright state. Emergence of the ultra-bright state is a manifestation of valley coherence which is akin to super-radiance in the reciprocal space. The other competing mechanism is mixing of the valley states due to the scattering at the QD surface. The lower cubic symmetry of the crystal lattice dictates that exciton states from different valleys form combinations representing basis functions of irreducible representations of the symmetry group. While the inter-valley electron-hole exchange interaction tries to arrange the exciton states from different valleys in a fully symmetric combination, valley mixing favors combinations prescribed by the lattice symmetry. Thus, valley mixing distorts the ultra-bright state and leads to redistribution of its oscillator strength among 8 radiative triplets allowed by the symmetry. The radiative triplet having lowest energy is responsible for low-temperature photoluminescence and has radiative lifetime in the microsecond range in agreement with experimental findings. The exciton fine structure splittings between various bright states in core/shell PbS/CdS colloidal nanocrystals have been directly measured by means of single-QD spectroscopy at cryogenic temperatures and are in agreement with the results of our calculations [3].

Plasmonic Nanocrystals and Hybrids with Complex Shapes for Hot Electron Generation and Photochemistry Alexander Govorov and Oscar Avalos-Ovando; Ohio University, United States

The generation of energetic (hot) electrons and the photoheating are intrinsic properties of any optically excited plasmonic nanocrystal [1,2]. In addition, high-energy hot electrons and phototemperature contribute to the kinetic processes observed in colloidal nanocrystals, metal-semiconductor hybrids, plasmonic Schottky photodetectors, and metastructures [1,2]. In this talk, we will focus on the theory of hot electron injection and present related applications for plasmonic photochemistry and plasmonic photocatalysis [3,4,5,6].

4:00 PM NM03.06.05
Computational Investigation of Generation of Entangled Photon Pair from Biexcitonic-to-Exciton Cascade Decay in Semiconductor Nanoparticles Arindam Chakraborty; Syracuse University, United States

This computational work aims to investigate the generation of entangled photon pairs in quantum dots. Entangled photon pairs (EPP) are important in quantum optics and are essential for quantum information, quantum teleportation, quantum key distribution, and controlled logic operations. Semiconductor nanoparticles such as quantum dot (QD) are especially well suited for EPP generation and have been proven to have high-entanglement fidelity, extraction efficiency, and photon indistinguishability.
Accurate description of biexcitonic and exciton states are crucial for accurate prediction of generation of EPPs. In this work, we have used the frequency-dependent geminal-screened electron-hole interaction kernel method (FD-GSIK) for treating the excitonic and biexcitonic states. The FD-GSIK is a first-principles, explicitly-correlated, real-space method that avoids using unoccupied orbitals to construct the electron-hole interaction kernel by performing a complete infinite-order diagrammatic summation of particle-hole excitations and deriving a renormalized R12 real-space electron-hole correlator operator. The FD-GSIK method also bypasses the computationally expensive AO-to-MO integral transformation step by computing all integrals directly in the real-space numerically using Monte Carlo integration. The frequency-dependent component of the FD-GSIK method implements the necessary quasiparticle

screening needed for describing biexcitonic states.
In this work, the combination of dressed-atom approach and FD-GISK method was applied to investigate exciton binding energies and biexciton binding energies for large quantum dots ($Pb_{140}S_{140}$, $Pb_{140}Se_{140}$, $Cd_{144}Se_{144}$). Chemical insights from biexciton binding energies, exciton binding energies, fine-structure splitting, oscillator strengths, degree of entanglement, and time-dependent electron-hole recombination probability for these quantum dots will be presented. The results from these calculations demonstrate the efficacy of the FD-GSIK method for capturing electron-hole correlation and treating 2-electron 2-hole excitation in large clusters and nanoparticles. Future and ongoing work in this direction including enhancing photon-entanglement characteristics by optimizing surface ligands and adding core/shell heterojunctions will be discussed.

4:15 PM NM03.06.06
First Principles Simulations of $Hg_xCd_{1-x}S$ and $Hg_xCd_{1-x}Se$ Optical Properties Erick I. Hernandez Alvarez, Andrew M. Smith and Andre Schleife; University of Illinois at Urbana-Champaign, United States

Mercury cadmium chalcogenide quantum dots (QDs) are promising fluorescent materials for bio-imaging and device applications due to facile tuning of their emission wavelength from the visible to short wave infrared (SWIR; 900 – 2000 nm). High-quality nanocrystals are achieved via cation exchange-mediated synthesis as de novo syntheses of alloy nanocrystals are hard to control. While the relative degree of exchange of cadmium to mercury is used to control the emission wavelength, precise control of the final emission wavelength remains elusive. A first-principles prediction of the relationship between the mercury-to-cadmium ratio in the alloyed QDs and their optical properties can inform the design and synthesis of these materials.

This talk will describe calculated optical spectra of both bulk mercury cadmium chalcogenide materials and nanocrystals composed of HgS, HgSe, CdS, and CdSe. We used density functional theory to calculate the band gap energies and the optical properties via complex dielectric functions and absorption spectra of zinc blende $Hg_xCd_{1-x}S$ and $Hg_xCd_{1-x}Se$ alloys as a function of alloy composition. We then applied the generalized quasi-chemical approximation to describe the relationship between band gap energies and optical features with respect to the material composition under different synthesis conditions, including thermodynamic equilibrium. We found that the optical absorption features at the band edge are highly sensitive to even a small mercury fraction ($x<0.2$) in the material. We considered the effects of spin-orbit coupling and found that while it did alter the band gap energies by up to 0.5 eV, the complex dielectric function features were similar and only shift in energy. Our bulk alloy calculations are consistent with trends observed experimentally and our nanocrystal calculations can be used to adjust the energy range to account for the effect of quantum confinement. Together these results can be used to identify target compositions of mercury cadmium alloy QDs needed to achieve desired optical properties.

4:30 PM NM03.06.07
Rapid Evaluation of Time Dynamics and Excitation Spectra of Quantum Dots Matthias Kick, Ezra A. Alexander and Troy Van Voorhis; Massachusetts Institute of Technology, United States

QDs have attracted a lot of interest in recent years due to their potential use in solar cells, light-emitting diodes (LEDs), displays, photo-detectors and biological sensing and imaging. Due to their size (1-10 nm) their electronic structure resembles that of both a molecule and a solid. At the band edges QDs show a set of discrete states like those in a molecule, while the orbitals lying deeper in the bands form a continuum resembling the electronic structure of a solid. The size of the quantum dots makes their optical properties difficult to describe from a theoretical perspective. For example, a CdSe/ZnS core shell QD, with a diameter of around 2 nm, consists of more than 500 atoms, possible ligand atoms not included. This QD is on the upper end of what is possible to describe computationally, but is still rather small compared to the experimentally observed average size of 3.5 nm. Moreover, hybrid density functional theory (DFT) is required to obtain reasonable accuracy for semiconductors, which further increases the computational cost. Furthermore, in order to reveal the full optical properties of QDs one needs to apply time-dependent DFT (TDDFT). However, the high computational cost of TDDFT, on top of everything mentioned previously, usually allows the computation of only a few, low-lying excited states for rather small QDs.
In this computational study, we present a way to obtain accurate excitation spectra for quantum dot sizes which are not feasible by current standard TDDFT approaches. By combining of short real-time propagation TDDFT (RT-TDDFT) and approximated linear-response TDDFT (LR-TDDFT), we are able to rapidly obtain excitation spectra for the entire optical range. We demonstrate the capabilities of our approach by studying the optical properties of CdSe/ZnS core shell QDs.

4:45 PM NM03.06.08
Theoretical Optical Performances of Semiconductor Nanocrystals for Image Sensors and Photovoltaics Applications Bilal Chehaibou[1], Christophe Delerue[1], Gabriel Mugny[2], Peter Reiss[3] and Arthur Arnaud[2]; [1]Institut d'Electronique, de Microélectronique et de Nanotechnologie, France; [2]STMicroelectronics, France; [3]CEA, France

Colloidal quantum dot (CQD) thin films are emerging materials that are expected to be used more and more in the microelectronics industry. One of their greatest strengths lies in the capability to tune their optical properties across a wide spectral range by changing their size, shape, and composition. Due to these excellent optical properties, research on QDs has experienced extremely rapid development during the last few decades, accompanied by the emergence of various semiconductor materials (II-VI, III-V, IV-VI, and group IV) and various technologies relying on QD thin films (LEDs, displays, photovoltaics, image sensors), driven also by their low-cost synthesis and easy integration into conventional microelectronic fabrication flows.

QD thin films are made of chemically-synthesized semiconductor nanocrystals, embedded in an insulating matrix made of organic and/or inorganic ligands. The role of these ligands is to passivate dangling bonds on the surface of the QDs, stabilize both mechanically and chemically the QDs, and allow charge carrier transfer between QDs without affecting their optical absorptions. As a consequence, it is important to model the dielectric behavior of the QD thin films and see how the properties of the ligands matrix and the choice of the nanocrystals' shape, composition, and size impact the final performances of the CQD thin films.

In this presentation, we will present a methodology to predict the optical properties of CQD thin films based on nanocrystal quantum simulations coupled with effective medium theory. By using Tight-Binding (TB) simulations, we computed the electronic structure of several nanocrystals of different sizes and made of various bulk semiconductors to find empirical laws describing the evolution of the QDs' optical bandgap as a function of their diameter. For all these materials, we then determined the influence of the QD size on the oscillator strength [1], enabling us to establish empirical laws to forecast the absorption coefficient and optical dielectric permittivity of single QDs. We then used the Bruggeman formula [2] to extrapolate the complex optical indices of thin films made of QDs embedded in a ligand matrix [3]. This allowed us to assess the influence of the ligand and volume fraction on the optical performances. Adjusting the model parameters (QD size, ligand length, and volume fraction), we provided an abacus giving the maximum theoretical optical performances of CQD thin films for various semiconductor materials.
Finally, using the optical indices calculated previously, we performed stack diode simulations using the transfer matrix method (TMM), to see how intrinsic CQD film absorption impacts the design and the quantum efficiency of photodiodes embedding QDs.

The presented work thus provides a detailed understanding of the various physical and chemical parameters at the origin of the optical properties of QDs as

well as elements allowing to compare the performances of QDs with other photosensitive materials used in photonics, image sensors, and photovoltaics. It provides a useful resource and a guide for chemists and physicists synthesizing and characterizing new types of QD.

NM03.07.01
Effect of Redox-Active Ligand Shell on Photocatalysis by Cadmium Sulfide Quantum Dots Florence Dou and Brandi Cossairt; University of Washington, United States

The chemical manufacturing industry accounts for 10% of global energy consumption and 7% of total greenhouse emissions.Endergonic reactions are performed under high temperatures and pressures, but photocatalysis offers a carbon neutral route under ambient conditions. Colloidal quantum dots (QDs) are efficient photocatalysts of organic reactions due to their high extinction coefficients, wide absorption profiles, and highly tunable band edge potentials. Despite the ligand shell taking up such a large portion of the surface, there have only been a few studies probing fundamental effects of the ligand shell on catalysis. These studies typically explore the effect of ligand sterics and surface accessibility, but not ligand electronic properties. Herein, we design a redox-active ligand shell that actively participates in shuttling charge from QD to reactants. We functionalise the surface of our QDs with a series of carboxylic acid derivatives of ferrocene (Fc). We demonstrate that these ligands are efficient quenchers of the excitonic hole. We next test the effect of this hole-accepting ligand shell on a carbon-carbon coupling reaction wherein the rate-limiting step is hole transfer from QD to substrate. We find that the rate of reaction depends on both the driving force for hole transfer and the binding strength of Fc ligands in a dynamic ligand shell. Our findings indicate that direct hole transfer is still more efficient than a hole shuttle, however our strategy seems to protect the surface of the catalyst from oxidation and subsequent aggregation.

NM03.07.02
Antibiotic-Resistant Bacteria Biosensor via Quantum Dot and DNA Hybridization on Magnetic Silica Nanoparticles Guncem O. Eren[1], Alexander Kleimann[2], Saad Ullah Khan[1], Siti Nurul Aisyiyah Jenie[3], Holger Schönherr[2,2] and Sedat Nizamoglu[1,1]; [1]Koç University, Turkey; [2]University of Siegen, Germany; [3]Research Centre for Chemistry, National Research, and Innovation Agency (BRIN), Indonesia

Among the pathogenic bacteria, *Staphyloccoccus aureus* (SA), which is one of the most common human pathogens, is particularly prone to resistances to most antibiotics. Due to its severe infection disease burden, SA is a worldwide concern in health care facilities[1]. In order to screen patients in hospital admission, to analyse the pathways of resistance spread and to administer the appropiate treatment, it is required to develop on-site tests, which are rapid, ultrasensitive, selective, economic and sustainable[2]. In this regard, nanoparticle-enabled techniques provide unique ways to combine the aforementioned properties with the requisite high performance[3].
In our study, we aim to design a sandwich DNA hybridization biosensor to detect bacterial infections via genomic DNA by fluorescence. Non-toxic and highly efficient InP/ZnS core/shell QDs and functional porous silica nanoparticles (NPs) are used for signaling and separation process, respectively. InP core QDs are synthesized via amine-derived synthetic approach. The red-shift in the absorption spectra occurs with the ZnS shell, which demonstrates the increase of the size of QDs. After the ZnS shell growth, InP/ZnS core/shell QDs exhibit comparatively narrow PL emission with a 58 nm of full width at half-maximum (FWHM) and 77.5% of photoluminescence quantum yield (PLQY). Time-resolved PL (TRPL) decay measurements show that the average lifetime of the InP/ZnS QDs is 38.33 ns. In order to make the QDs water-soluble, ligand exchange process is performed using MPA.
Porous silica NPs, which possess (a) superparamagnetic or (b) fluorescent properties by incorporating iron oxide or dye molecules such as Rhodamine B, are produced. The MPA-capped InP/ZnS QDs are used as alternative label. The surface of the silica particles is functionalized by a passivating polymer brushes grafting from polymerization. Moreover, to ‘catch’ complemantary DNA molecules, polymer brushes are functionalized via EDC-NHS chemistry technique. Transmission electron microscopy (TEM), X-ray Photoelectron Spectroscopy (XPS) results confirm the functionalization of silica NPs.

Synthesis of Eco-Friendly and Stable I-III-VI QD Impregnated Al_2O_3 Microbeads Eunha Hong, Minji Ko, Yun Jae Eo, Seo Yeon Shin, Soyeon Yoon and Young Rag Do; Kookmin university, Korea (the Republic of)

Recently, ternary I-III-VI quantum dots (QDs) such as Zn-Cu-InS and Zn-Ga-In-S have received much attention as replacements for the toxic Cd- and Pb-

based QDs used in optoelectronic devices. Broadband green and red emitting I-III-VI QD-impregnated Al_2O_3 (QD@Al_2O_3) microbeads, for application to down-converted white light-emitting diodes (DC-WLEDs), were synthesized in an stable and easy-to-use QD material using an integrated synthetic process of electrospray and rapid hydrolysis to be applied to down-converted white light-emitting diodes (DC-WLEDs). An aluminum tri-sec-butoxide solution was choosedchosen as a rapid hydrolysis precursor, which ; this material contains QDs to and can realize a spherical form of QD@Al_2O_3 powders during the electro-spraying process. To improve the stability of I-III-VI QDs, we treated them with zirconium isopropoxide ($Zr(PrO)_4$) during the synthesis process. The photoluminescence quantum yields (PLQYs) of the resultant green $Zr(PrO)_4$- Zn-Ga-In-S and red $Zr(PrO)_4$- Zn-Cu-InS QD solutions were 94.5% and 95%, respectively. Their PLQY values and operational stability were improved by via reduction of reducing the ligand loss via passivation and by the encapsulation role of the $Zr(PrO)_4$ complex over the QD surface in the $Zr(PrO)_4$-treated QD@Al_2O_3 powders. A WLED single package implemented with GR $Zr(PrO)_4$-treated QD@Al_2O_3 microbeads showed comparable luminous efficacy (LE = 77.0 lm/W) with a high color rendering index (> 92). The LE of a a WLED with $Zr(PrO)_4$-QD@Al_2O_3 microbeads was improved by 41% compared to that of a WLED with pristine QD@Al_2O_3 microbeads. We also realized relative LE stability tests of green and red QD@Al_2O_3 microbead films at 60 mA for over an an application time for of 72 hours. The electro-sparyingspraying hydrolysis process of QDs and a reactive metal alkoxide solution provides a simple and novel synthetic platform process to produce easy-to-use spherical QD-embedded solid materials for PL-DC applications into of future QD-based lightings and displays.

NM03.07.04
Highly Efficient (>9%) Lead-Free $AgBiS_2$ Colloidal Nanocrystal/Organic Hybrid Solar Cells Changjo Kim and Jung-Yong Lee; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Colloidal nanocrystals (NCs) have received considerable attention in optoelectronics because of their high reproducibility in synthesis, solution processability, near-infrared (NIR) absorption, and facile bandgap tunability. In particular, solar cells using lead chalcogenide-based NCs, such as lead sulfide (PbS) and lead selenide (PbSe), have exhibited high power conversion efficiencies (PCEs) of over 13% and 10%, respectively. Despite their high PCEs, there has been growing interest in chalcogenide-based NCs combined with lead-free cations (since lead is not environmentally friendly), such as silver, copper, bismuth, indium, zinc, and antimony. Although various combinations of binary and ternary compound NCs have been developed as photoactive materials, their performances are still inferior to those of lead-based NCs.
Silver bismuth disulfide ($AgBiS_2$) NCs have attracted attention as suitable alternatives owing to their narrow bulk bandgap, high extinction coefficient, and light absorption in NIR region. Recently, PCE of 9.17% was achieved in NC/organic hybrid structure, but there was not enough discussion on the NC/organic interfacial electronic structure. Therefore, issues such as the low open-circuit voltage (V_{OC}) compared to the bandgap of the $AgBiS_2$ NCs and the unoptimized energy level structure at the NC/organic hole transporting layer (HTL) interface should be resolved for higher performance of devices. In this study, a design strategy to obtain efficient energy level structure in $AgBiS_2$ NC/organic hybrid solar cells is proposed.[1] By selecting PBDB-T-2F as an HTL with a lower highest occupied molecular orbital level than that of PTB7, the V_{OC} of the device is increased. Furthermore, iodide- and thiolate-passivated $AgBiS_2$ NC surfaces are generated using tetramethylammonium iodide (TMAI) and 2-mercaptoethanol (2-ME), which leads to the energy level optimization of NCs for efficient charge extraction. This improves the PCE from 3.3% to 7.1%. In addition, the polymer is replaced with a PBDB-T-2F:BTP-4Cl blend to achieve a higher short-circuit current density through complementary absorption. Accordingly, an $AgBiS_2$ NC-based solar cell with a PCE of 9.1% is fabricated.

Downconverting Mn/Yb Codoped $CsPbCl_3$ Nanocrystals for Silicon-Based Tandem Solar Cell Application Hyunju Lee[1,2], Yoshio Ohshita[3] and Atsushi Ogura[1,2]; [1]Meiji Renewable Energy Laboratory, Japan; [2]Meiji University, Japan; [3]Toyota Technological Institute, Japan

Silicon-based tandem solar cells are intensively being investigated as a promising candidate for next generation solar cells combining low costs and high power conversion efficiency potential than currently dominating, but inherently limited, single-junction solar cells. For instance the world record efficiency of perovskite/silicon tandem solar cells is 29.8% [1] which is well above ideal efficiency of single-junction silicon solar cells. Despite this exciting performance, the tandem solar cell was still limited not only by a relatively low perovskite top cell voltage output but also by the silicon bottom-cell photocurrent. For instance, the total photocurrent density of the world record perovskite/silicon tandem solar cell was only 39.9 mA cm^{-2} [1]. For comparison, 42.7 $mAcm^{-2}$ was reached in the world record SHJ cell [2], which is very close to the theoretical maximum for silicon of about 43.3 $mAcm^{-2}$ [3]. An important optical loss mechanism in this tandem cell, in comparison to an optimized single-junction silicon cell, is the increased reflection and reduced absorption in the near infrared (NIR) part of the spectrum, hence reduced photocurrent in the silicon bottom cell. In addition, the highest reported current density for perovskite/silicon tandem solar cells has not yet reached 21 $mAcm^{-2}$ [4]. Therefore, the enhacement of the light absorption in both perovskite top cell and silicon bottom cell becomes increasingly important to achieve cell efficiency > 30%. Meanwhile, doped lead-halide perovskite (LHP) nanocrystals have emerged as unique materials combining strong, tunable broadband absorption in the ultraviolet region of the spectrum with visible and NIR photoluminescence quantum yields (PLQYs) approaching 99% [5] and 200% [6] at ambient temperature, respectively. These remarkable properties make doped LHP nanocrystals an extremely promising candidate for spectral shaping in high-efficiency solar cells. Previous theoretical assessments of such downconversion material has predicted single-junction efficiencies up to 40% [7]. In this contribution we report the synthesis of Mn^{2+}/Yb^{3+} codoped $CsPbCl_3$ nanocrystals through a hot-injection technique. The resulting nanocrystals show a unique triple-wavelength emission covering ultraviolet/blue, visible, and near-infrared regions. In addition, owing to the high PL QYs, the codoped nanocrystals are demonstrated to be used as efficient emitters in downconverting layers, with the enhanced external quantum efficiency of silicon solar cells compared to that of using solely Mn^{2+} doped $CsPbCl_3$ nanocrystals. This study presents a new model system for enriching doping chemistry studies and future applications of LHP nanocrystals.
This work was supported by NEDO.

Enhanced Stability of Quantum Dots via Core-Shell Type Organic-Inorganic Hybrid Encapsulation Jeong Min Moon, Young Soo Seo and Jung Woo Park; interface lab, Korea (the Republic of)

Quantum dots (QDs), semiconductor nanoparticles with outstanding optical properties, is currently used in QD display. However, in the form of submicron

sized capsule, it still easily lose optical properties by oxidative degradation caused by external factors such as heat, oxygen, and moisture. Many encapsulation methods have been suggested but its reliability is still unsatisfactory for applications including QD-(O)LED or molecular diagnosis. In this study we developed a core-shell type encapsulation method where QDs are encapsulated with organic-inorganic hybrid with tens to hundreds nanometer in size via one-step process. Individual QD is surrounded by the hybrid and then aggregates to form a core and additional hybrid builds a shell. It is noted that during the process quantum yield has not been reduced. Barrier performance of the hybrid structure was performed in two ways. The hybrid capsule was kept at 60°C water solution for a month. And also it was mixed with polymer via a melt-mixing process at 180°C to fabricate a film which was exposed under blue light (450 nm) or at 60°C/95% relative humidity for a month. Quantum yield, emission wavelength and FWHM of the samples were unchanged indicating that the hybrid shell effectively prevented oxygen and water vapor penetration to the core. The hybrid structure and optical properties was mainly confirmed by TEM and PL analysis.

NM03.07.08
Spectroscopic Insight into High Luminescence Efficiency of Isotropic InP/ZnSe/ZnS Quantum Dots Jumi Park[1], Yu-Ho Won[2], Yongseok Han[2], Hyun-Mi Kim[3], Eunjoo Jang[2] and Dongho Kim[1]; [1]Yonsei University, Korea (the Republic of); [2]Samsung Advanced Institute of Technology, Korea (the Republic of); [3]Korea Electronics Technology Institute, Korea (the Republic of)

In this study, we propose a strategy to increase the luminescence efficiency in eco-friendly InP quantum dots (QDs). When synthesizing InP/ZnSe/ZnS QDs, we manipulated the shell growth rates by controlling the ZnSe shell growth temperature.[1] In a pristine synthesis of InP/ZnSe/ZnS QDs, ZnSe shell growing was conducted at 320 °C and these QDs exhibit irregular shell shape. Meanwhile, isotropic InP/ZnSe/ZnS QDs with regular shell can be prepared at a high reaction temperature (340 °C), which facilitates ZnSe shell growth on random facets of the InP core. HR-STEM images showed that the InP/ZnSe/ZnS QDs with irregular shell have considerable stacking faults and twin defects. On the contrary, isotropic QDs presented a well-ordered crystalline structure and good structural quality without stacking faults. In other words, fast ZnSe crystal growth eliminates the stacking faults leading to anisotropic crystal growth.
These isotropic QDs achieved a photoluminescence quantum yield (PL QY) improvement of nearly 20%. To investigate the correlation between the QD morphology and the emission properties, we analyzed the PL blinking and ultrafast charge carrier dynamics. Time- and space-resolved PL measurements showed that the charge trapping significantly decreases in isotropic QDs. The excitation wavelength-dependent transient absorption kinetics revealed that hot hole trapping is considerably suppressed for QDs with regular shape. These results highlight that QD shape-dependent PL QYs are ascribed to the degree of the hole trapping. The tactic, growing the ZnSe shell fast at the elevated reaction temperature, significantly reduced the hole trapping and improved the PL QY of InP/ZnSe/ZnS QDs. Our findings shed light on the relationship between QD shapes and hot carrier dynamics and present a way to design highly luminescent QDs for further promising display applications.

NM03.07.09
Swelling-Induced Surface Instability of Crosslinked Nanocrystals Seyoung Park and Moon Sung Kang; sogang university, Korea (the Republic of)

Colloidal assemblies of semiconductor nanocrystals (NCs) are promising active materials for electronics/optoelectronic devices. These materials are typically processed into thin films based on solution processes. Chance of swelling of these assemblies during the processing can dramatically affect the morphology of the film. Here, we report experimental study on mechanical instability of crosslinked nanocrystal assemblies swollen by various solvents. When a crosslinked NC film is attached to a rigid substrate, swelling induced compressive strain causes delaminated buckling of the film from the substrate. To investigate the feature of delamination, we control the delamination through experimental parameters such as the solvent-colloids interaction parameter, the degree of crosslinking, and the surface energy. The mathematical model of delamination offers a physical approach to elucidate the properties of delamination including wavelength and amplitude. Also, the experimental parameters are substituted to mismatch strain, modulus of film, and adhesion energy, respectively. Finally, we apply various physical models of film delamination describe our observation.

Predicting Coherent Nanocrystal Orientation in PbS Superlattices by Minimizing Ligand Packing Frustration Eliza Price and William Tisdale; Massachusetts Institute of Technology, United States

For many optoelectronic device applications, colloidal nanocrystals (NCs) must be assembled into ordered superlattices (SLs). Since the SL structure influences the photophysics of NC thin films, it is desirable to obtain robust engineering control over SL topology. A number of factors influence the self-assembly of colloidal NCs, such as the well-studied impact of nanocrystal size and shape. In more recent years, the importance of both bound and unbound organic ligands on self-assembly outcomes has been highlighted; the ligand length, ligand coverage, bound and unbound ligand fractions, and ligand interactions can all influence the resulting NC SL structure. In this work, we consider how the classic influence of nanocrystal shape can impact ligand packing frustration and influence the coherent orientation of non-spherical NCs in superlattice structures. Through the application of the freely jointed chain model to predict conformational entropy, we find that minimizing the packing frustration of the ligand layer may explain experimental observations of NC alignment in NC SLs. We validate our model by comparing to prior X-ray scattering data showing the kinetics of PbS superlattice formation. These data show that as solvent is evaporated, the SL exhibits a Bain-like distortion, contracting from an fcc to bcc structure, and the coherent NC tilt relative to the substrate changes from 9.7° to 0° [1]. In future work, other contributions to the free energy of NC SL formation may be considered in an effort to create a coarse-grained, thermodynamic model capable of predicting superlattice structure.

NM03.07.12
Lead Chalcogenide Quantum Dot Assembly and Attachment on Fluid Interfaces Wenxin Qi, Isaiah Y. Chen and Paulette Clancy; Johns Hopkins University, United States

The formation of tiles composed of quantum dots are thought to constitute a new class of self-assembled nanostructured material. Understanding the dynamic physicochemical processes that govern the assembly of quantum dot monomers at a functionalized fluid interface is crucial for material processing strategies. However, the mechanism of this assembly and attachment is still unclear. What is clear is that a functionalized liquid interface potentially provides more control in the diffusion, coupling, and orientation of the nanocrystals (NCs), which increases the complexity of the assembly process. To investigate this self-assembly process, we look to insight from the fundamental molecular-level interactions; we use Molecular Dynamics (MD) simulations to watch NCs assembly on a surfactant monolayer. The specific model system studied here was composed by lead chalcogenide nanocrystals, covered with lead oleate molecules and assembling on a monolayer composed of 1,2-dipalmitoyl-sn-glycero-3-phosphocholine (DPPC) molecules. In this approach, a reactive force field is used to model the interactions between species in the system. For the PbS NCs, we use the existing Simple Molecular

Reactive Force Field (SMRFF) as an effective force field. The ligands and DPPC molecules are represented by the OPLS force field. All the simulations aimed to reveal the role of the nature of the surface monolayer. Before testing the impact of monolayer parameters, we used density functional theory to confirm that the energy barrier for ligand dissociation was high and are unlikely to detach readily. We adjusted the density of the DPPC molecules in the monolayer from 0.5 to 2.5 molecules/nm^2 to determine the effect of ML density on assembly and attachment behavior of NCs on a DPPC monolayer. We studied the degree of NC in-plane and out-of-plane orientation during the process and the alignment and tendency to form interconnecting bridges. We found that the NCs prefer to diffuse and assemble rather than interacting with the monolayer. Our studies of the interaction energy and the potential of mean force (PMF) provide quantitative metrics for the interaction between the NCs and the monolayer. We show that there is a similar trend in the interaction energy between NCs and monolayer, which can help us to predict an optimal monolayer structure for NC assembly. We also studied the effect of hydrocarbon chain length in the monolayer molecule, varying the molecule from DPPC to DLPC and DMPC. This property indicates that NC assembly is facilitated by shorter lipid molecules.

NM03.07.13
Indium Phosphide Magic Sized Clusters: Templates for Synthesizing Chiral Nanomaterials Youngjae Ryu and Sungjee Kim; Pohang University of Science and Technology, POSTECH, Korea (the Republic of)

Chiral materials are of great interest promising various applications that include asymmetric catalysis, chiral sensing, polarization control, and gene engineering. Compared to metallic nanoparticles and II-VI group semiconductor nanoparticles, chiral properties of III-V group semiconductor nanomaterials are less explored. Herein, we aim to understand the chiroptical activities of III-V semiconductor magic sized clusters (MSCs), also known as quantum dot (QD) intermediates. We introduce chiral InP MSCs with unprecedented large circular dichroism signals compared to previously reported chiral semiconductor nanocrystals. To investigate the chiroptical origins of our chiral MSCs, characterizations using XPS, FT-IR, Raman, XRD, TGA, and EXAFS are conducted to explore ligand geometry and structural properties. It is discovered that chiral ligands are bound to MSC surface by double anchoring modes, with both thiolate and carboxylate group. Based on the structural characterizations, the inorganic core was observed to exhibit low-symmetry polytwistane structures. Similar sized chiral InP QDs are prepared as the control counterpart, where their optical chirality was marginal. The low crystal symmetry and large transition dipole moments are attributed to the high chiroptical activity of MSCs. Interestingly, chiral MSCs can induce chiroptically active QDs when used as templates (or seeds) to synthesize the QDs. Halide atoms (Cl, Br, I) can be introduced as dopants into MSCs, which also alters the chiroptical properties. Our findings emphasize the unique characteristics of MSCs as prospective chiral materials and gives intuition on designing chiroptical nanomaterials.

NM03.07.14
Integration of Synaptic Phototransistors and Quantum Dot Light-Emitting Diodes for Visualization and Recognition of UV Patterns Hyojin Seung and Dae-Hyeong Kim; Seoul National University, Korea (the Republic of)

Neuromorphic photodetectors feature photon-triggered synaptic plasticity, which enables efficient image recognition. However, even with a synaptic device, the visualization and recognition of invisible ultraviolet (UV) patterns are still challenging owing to intense background noise. Here, we develop an integrated device of synaptic phototransistors (SPTrs) and quantum dot light-emitting diodes (QLEDs) for noiseless visualization and efficient recognition of UV patterns through on-device preprocessing inspired by all-or-none potentiation of synapse. The SPTrs convert noisy UV inputs into a weighted photocurrent, which is applied to the QLEDs as a voltage input through an external current–voltage converting circuit. The QLEDs exhibit threshold switching characteristics, *i.e.*, they either derive the exponentially increasing current output and visible illumination by the suprathreshold input voltage or nearly zero current output and no visible illumination by the subthreshold input voltage. The preprocessed image data obtained by the SPTr-QLED has an exponentially amplified signal-to-noise ratio, which is helpful for high-accuracy image recognition based on deep neural networks.

NM03.07.16
Upconversion Photoluminescence Properties of High Quantum Yield Nitrogen Doped Graphene Quantum Dots Synthesized by Pulsed Laser Ablation Muhammad Shehzad Sultan[1], Vladimir I. Makarov[1], Wojciech Jadwisienczak[2], Brad R. Weiner[1] and Gerardo Morell[1]; [1]University of Puerto Rico at Río Piedras, United States; [2]Ohio University, United States

The graphene quantum dots (GQDs), a zero-dimensional graphene quantum structure, have triggered an intense research worldwide. GQDs possess unique optical, chemical and physical properties as compared to conventional quantum dots (QDs), such as low toxicity, biocompatibility, optical stability, chemical inertness, high photostability and good water-solubility and therefore hold great application potential in biomedical, optoelectronics and energy storage devices. The doping of GQDs with heteroatoms is one of the most effective ways to tune their photoluminescence emission and to increase quantum yield. In this study, we developed a novel approach to synthesize high-quality Nitrogen-doped graphene quantum dots (N-GQDs) with high quantum yield, via irradiation of s-triazene in a solution with benzene by using pulsed laser. The TEM, HRTEM, XPS, XRD, Raman spectroscopy and FTIR were carried out to observe the morphology, size distribution, crystalline structure and to prove successful doping of GQDs with nitrogen atoms. To observe optical properties of as synthesized N-GQDs, the UV-vis and Photoluminescence measurements were carried out. The as-synthesized NGQDs exhibit high quality crystalline structure of graphene with an average size of about 3.7 nm. A high quantum yield was exhibited by the obtained N-GQDs as compare to the pristine GQDs. The obtained N-GQDs with oxygen-rich functional groups exhibit a strong emission and excellent upconversion PL properties. These outcomes result in an ample opportunity for the biomedical and optoelectronic applications.

NM03.07.17
In(Zn)P Core-Multishell Colloidal Quantum Dots Engineering for Narrow FWHM and Enhanced Bright Green-Luminescence via Halide and Alcohol Surface Treatment Derrick Allan Taylor[1], Justice Agbeshie Teku[1], Sinyoung Cho[1], Weon-Sik Chae[2], Seock-Jin Jeong[1] and Jong-Soo Lee[1]; [1]Daegu Gyeongbuk Institute of Science and Technology, Korea (the Republic of); [2]Korea Basic Science Institute, Korea (the Republic of)

Semiconductor colloidal quantum dots (CQDs) have made remarkable progress since their discovery as multifunctional materials due to their attractive size-tunable electronic and optical properties, low-cost production, high efficiency, and high stability. Cd, Hg, and Pd containing CQDs have reached commercial-scale optical properties, yet they are restricted in commercial applications due to their toxicity. For the light-emitting display applications, indium phosphide (InP) QDs have emerged as the best intrinsically low toxic alternative for Cd and Pb-based QDs but still lag in the optical properties of emission linewidth and size dispersity with its counterpart CdSe. In this work, we report the importance of precisely controlling the reaction kinetics of InP QDs by a two-step growth process to achieve uniform size distribution (<4% polydispersity index). Engineering the shell coating to reduce interfacial defects yielded high photoluminescence quantum yield (PLQY) and surface treatment with halides and alcohols enhanced the PLQY through improved surface defect passivation. After the sample purification, the as-synthesized core-multishell QDs exhibited a bright green emission with a very high quantum yield and the narrowest emission linewidth of 71% and 33 nm, respectively. This work aims to expand the understanding of InP QDs synthesis and open up a new surface treatment approach using alcohol.

NM03.07.18

Colloidal Synthesis of Blue Emitting Cadmium Free ZnSe-ZnSeTe Core-Multishell Quantum Dots. Justice Agbeshie Teku, Derrick Allan Taylor, Bowon Moon, Somi Lee and Jong-Soo Lee; Daegu Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of)

Size-tunability, narrow optical properties, high efficiency, low cost of production, and good stability of colloidal semiconductor quantum dots (QDs) are one of the most promising candidates for future light-emitting materials for display. Due to toxicity and environmental concerns of well-developed Cd and Pb-based QDs, researchers and the display industries have tried to develop an alternative to the Cd and Pb-based QDs with similar optical properties. The Indium Phosphide (III – V) QDs, has proven to be a perfect alternative to Cd and Pb-based QDs due to their optical properties similarity. However, the development of Blue InP QDs compare to the Red and the Green remains a major challenge to date. In this work, we developed a non-InP and Cd-Pb free Blue emitting ZnSe-ZnSeTe core-multishell QDs by carefully controlling and optimizing the growth of the core and the shell. The designed synthesis procedure has multiple intermediate shelling, with gradient ZnSeS shelling and outer ZnS shelling. To enhance surface passivation and luminescence the surface of the QDs was treated with halides. The as-synthesized QDs show a pure blue emission (450 – 455nm), symmetrical PL spectra (absence of defect associated with Te materials), the narrowest FWHM for Te-based QDs, and improved PLQY. Our work has a great outcome to be implemented into the RGB patterning system, efficient QLED fabrication, and full-color panel displays.

NM03.07.20
Flexible and Transparent Electrode of Hybrid $Ti_3C_2T_X$ MXene−Silver Nanowires for High-Performance Quantum Dot Light-Emitting Diodes Wei Jiang and Cheolmin Park; Yonsei University, Korea (the Republic of)

The development of electrodes with high conductivity, optical transparency, and reliable mechanical flexibility and stability is important for numerous solution-processed photoelectronic applications. Although transparent $Ti_3C_2T_X$ MXene electrodes with high conductivity are promising, their suitability for displays remains limited because of the high sheet resistance, which is caused by undesirable flake junctions and surface roughness. Herein, a flexible and transparent electrode has been fabricated which is suitable for a full-solution-processed quantum dot light-emitting diode (QLED). An MXene-silver nanowires (AgNWs) hybrid electrode (MXAg) consists of a highly conductive AgNWs network mixed with solution-processed MXene flakes. Efficient welding of wire-to-wire junctions with MXene flakes yields an electrode with a low sheet resistance and a high transparency of approximately 13.9 Ω sq^{-1} and 83.8%, respectively. By employing a thin polymer buffer layer of poly (methyl methacrylate) (PMMA), followed by mild thermal treatment, a hybrid PMMA-based MXene-AgNWs (MXAg@PMMA) electrode which the work function of an MXAg hybrid FTE physically embedded in PMMA (MXAg@PMMA) can be tuned by controlling the amount of MXene in a hybrid film facilitates the development of a high performance solution-processed QLED that exhibits maximum external quantum and current efficiencies of approximately 9.88% and 25.8 cd/A, respectively, with excellent bending stability. This work function-tunable flexible transparent electrode based on solution-processed nanoconductors provides a way to develop emerging high-performance, wearable, cost-effective, and soft electroluminescent devices.

NM03.07.21
The Study of QDs-TiO_2 Nanocomposites for Solar Fuels Production Francesca S. Freyria[1], Nicola Blangetti[1], Sandra Doria[2,3], Simelys Hernandez[1], Mariangela Di Donato[2,3], Maela Manzoli[4], Sergio Brovelli[5] and Barbara Bonelli[1]; [1]Politecnico di Torino, Italy; [2]LENS - European Laboratory for Non-Linear Spectroscopy, Italy; [3]Institute of chemistry of organometallic compounds (ICCOM), Italian National Research Council (CNR), Italy; [4]University of Torino, Italy; [5]Università degli Studi di Milano-Bicocca, Italy

During these last decades, we are facing every day an increase of both energy shortage and environmental pollution due to the still voracious use of fossil fuels to produce energy. In this scenario, solar energy conversion is an encouraging approach to address these crucial issues, especially because the current global energy consumption in a year could be easily covered by the bihourly solar energy that strikes the Earth.[1] Taking inspiration from leaves, an environmental-friendly way to produce renewable fuels is to exploit the incident solar photon energy to drive energetically uphill reactions such as the water splitting and CO_2 conversion. Currently, one of the most applied photocatalyst is TiO_2 due to its great efficiency, affordable cost and contained toxicity. The three main crystalline phases of TiO_2 are anatase (indirect band gap), rutile and brookite (direct band gap), whose presence and possible heterojunction formation can affect the photogenerated electrons and holes and, consequently, the final photocatalytic efficiency.[2,3] The crystalline structure of the TiO_2 photocatalyst has been tuned by adopting template-free synthesis followed by a mild thermal treatment. One of the main drawbacks of the TiO_2 is its inability to absorb visible and NIR photons. Colloidal quantum dots (QDs) are receiving great attention to be applied either as sensitizer or as photocatalyst thanks to their excellent optoelectronic properties.[1] NIR emitting toxic-metal-free $CuInS_2$ (CIS QDs) were chosen as sensitizer for different types of TiO_2 substrates.[4] We have been testing the photocatalytic behavior for CO_2 reduction under simulated sunlight at 1 Sun (i.e., 100 mW/cm^2 of intensity) with pure and mixed TiO_2 phases coupled with different loading amounts of CIS QDs. The structure and the properties of QDs-TiO_2 nanocomposites have been investigated with different techniques, such as X-ray powder Diffraction (XRPD) with Rietveld refinement for quantitative phase analysis, Diffuse Reflectance (DR) UV−Vis spectroscopy, N_2 adsorption/desorption at −196 °C, electrophoretic mobility (ζ-potential), FT-IR measurements, X-rays photoelectron spectroscopy (XPS) and electron microscopy (TEM/SEM). Charge transfer and recombination processes are under study by using different spectroscopy techniques. Preliminary chromatographic analyses show a different amount of C_1 and C_{2+} products based on the polymorphs types present in the nanocomposite.

Colloidal Quantum Dot Laser Diodes Victor I. Klimov and Clement Livache; Los Alamos National Laboratory, United States

Colloidal quantum dots (CQDs) combine superior light-emission characteristics of quantum-confined semiconductors with chemical flexibility of molecular systems. These properties could, in principle, enable solution processable laser diodes with an ultrawide range of accessible colours. However,

the realization of such devices has been hampered by fast optical gain decay due to nonradiative Auger recombination and poor stability of CQD solids at high current densities required for the lasing regime. Recently, we have resolved these problems and achieved a lasing regime with electrically pumped CQDs. The active layer of our devices is made of novel “compact continuously graded CQDs” (ccg-CQDs) that feature strongly suppressed Auger recombination and a large material gain coefficient. The ccg-CQDs are incorporated into an LED-like device stack assembled of low-loss materials and engineered so as to maximize optical field confinement within the CQD layer. The developed design allows us to boost the modal gain coefficient for the active medium and to reduce optical losses in the adjacent charge transport/injection layers. Further, we incorporate an integrated photonic structure which allows for highly efficient light trapping in the CQD waveguiding layer. To lessen the deleterious influence of thermal effects, we reduce the injection area with a small “current-focusing” aperture inserted into a hole injection path and use a pulsed bias to drive our devices. Using this approach, we achieve the lasing effect due to electrically excited stimulated emission from the CQDs. These prototype CQD laser diodes demonstrate a low-threshold laser action at both the band-edge, 1S (637 nm) and the excited-state, 1P (586 nm) transitions at room temperature.

9:00 AM NM03.08.02
Improved Infrared Photoresponse Through Coupling of Lead Sulfide Colloidal Quantum Dots and Amorphous Selenium Håvard Mølnås[1], Haripriya Kannan[1], Atreyo Mukherjee[2], Shlok Joseph Paul[1], A.H. Goldan[2] and Ayaskanta Sahu[1]; [1]New York University, United States; [2]Stony Brook University, The State University of New York, United States

Infrared photodetectors are playing an increasingly important role in our modern society, and the use of colloidal quantum dot active layers have reduced the complexity at which these detectors can be fabricated and tuned. However, a compromise between maximizing charge transfer and absorbance is often necessary to optimize detector performance. Amorphous selenium (a-Se) is known for its uniform properties and ease of deposition scalable to a large area, as well as its ability to provide avalanche gain via hole impact ionization at high applied electric fields. In this work, we combine an a-Se hole transport layer with a lead sulfide (PbS) colloidal quantum dot active layer in order to decouple charge transport and absorption, and we show that this is beneficial for the infrared photoresponse. Although more work remains to improve device performance and stability, preliminary specific detectivity of 2.5 x 10^{11} Jones at 980 nm and 3dB frequency of 2.5 MHz demonstrate that this technology has the potential to compete with and surpass the current state of the art.

9:15 AM NM03.08.03
A Path to Heavy Metal-Free Infrared Photodetection Using Silver Selenide Colloidal Quantum Dots Shlok Joseph Paul, Håvard Mølnås, Michael R. Scimeca, Navkawal Mattu, Ingrid J. Paredes, Minh N. Tran, Eray S. Aydil and Ayaskanta Sahu; New York University, United States

The deployment of infrared cameras has so far been limited to military and defense applications because of the high costs involved in high temperature epitaxy and hybridization (1). The advent of low cost colloidal quantum dot (QD) infrared detectors will help persuade device adoption in the commercial detector markets. However so far toxic heavy metal compounds like Lead and Mercury chalcogenides have dominated the QD Photodetector space (1,2). In this work we establish a route to environmentally benign Near Infrared (NIR: 0.7 - 1.4 μm) and Short Wave Infrared (SWIR: 1.4 - 3 μm) active Ag_2Se CQDs. Herein we study the dynamics of an alternate Ag_2Se synthesis with exquisite size control. We report the effects of various parameters (Synthesis Time, Injection Temperature, Growth Temperature and Precursor Ratios) and highlight the size tunable excitonic peak and room temperature photoluminescence observed in the NIR and SWIR regions. Furthermore, we demonstrate IR active devices using ligand exchanges with short chain molecules such as 3-Mercaptopropionic acid (MPA), Thiocyanate (SCN) and 1,2-Ethanedithiol (EDT). Our results demonstrate that an EDT/HCl/IPA mixture results in a room temperature responsivity ~50mA/W at 1150 nm. To the best of our knowledge, this device provided the highest responsivity at 1150 nm among Ag2Se photoconductors to date. Prior work (3) has shown tunable absorption into the MIR (3-5 μm) as well and future work will involve fabricating photodiodes using these MIR particles.

Unraveling the Transition Dipole Orientation in Lead Halide Perovskite Nanoplatelets and Its Role in QD-LED Light Outcoupling Efficiency Tommaso Marcato, Sudhir Kumar and Chih-Jen Shih; ETH Zürich, Switzerland

In recent years, quantum dot light-emitting diodes (QD-LEDs) have arisen as ideal candidates to compete with organic light-emitting diodes (OLEDs) in display applications. The outstanding photophysical characteristics of colloidal semiconductor nanocrystals (NC), especially CdSe, InP and lead-halide perovskites (LHP), have led to a rapid surge in their use as active layers in high-efficiency devices, with multiple reports of external quantum efficiencies (EQE) surpassing 20%. To date, the major steps in enhancing device efficiency have come from the development of passivation strategies to reduce NC defects and boost internal quantum efficiency (IQE). As IQE approaches unity, the major bottleneck to device efficiency remains light outcoupling. A well-known intrinsic strategy for improving light extraction in OLEDs is transition dipole moment (TDM) engineering. Accordingly, EQEs approaching 40% have been demonstrated by designing efficient phosphorescent or thermally activated fluorescence (TADF) emitters with preferential orientation of their TDMs parallel to the device substrate.
At the same time, recent studies on few-monolayer-thick colloidal CdSe nanoplatelets (NPLs) have shown highly anisotropic TDM orientation, suggesting that similar strategies might be extended to QD-LEDs. Inspired by these results, we wanted to tackle the following fundamental question: can we develop a model to understand and predict the TDM orientation in semiconductor NC films?
In general, in contrast with organic semiconductor molecules, inorganic materials tend to have highly symmetric crystal lattices, leading to isotropic electronic structure and strong degeneracy at the band-edge. However, nanostructuring offers the possibility of introducing favorable symmetry breaking and anisotropy by controlling the NC shape. In this talk, I will first present a multiscale model of the preferential horizontal TDM orientation in LHP NPLs that highlights three fundamental contributions: (i) anisotropic conduction band Bloch states and large fine exciton splitting, (ii) anisotropic dielectric screening, (iii) ordered assembly in thin film. This model identifies the NPL thickness and the film order parameter as the two fundamental degrees of freedom allowing for continuous tuning of the TDM orientation.
We showed that these criteria can already be satisfied in devices by inducing the formation of 2D ordered assemblies of LHP anisotropic NCs on a hole transport layer with low surface energy. This resulted in a ratio of horizontal dipoles up to 0.75, which allowed our optimized green QD-LEDs to achieve peak EQE up to 24.96%.

Perovskite Quantum Dots on Polymer Matrix for Stretchable LED Geon-Hui Lee[1], Xiwen Gong[2] and Sei Kwang Hahn[1]; [1]Pohang University of Science and Technology, Korea (the Republic of); [2]University of Michigan–Ann Arbor, United States

Most intrinsically stretchable LEDs are developed using a polymer emitting layer, but the organic LED cannot produce vivid colors because of its low color purity with large full width half maximum (FWHM). In the case of organic LED, the FWHM is about 70-90 nm and it achieved 96% of the National Television Standards Committee (NTSC) standard in the Commission Internationale de l'éclairage (CIE) chromaticity chart. However, perovskite quantum dot (QD) LED can produce vivid colors due to its high color purity (low FWHM). The perovskite QD LED has 15~25 nm of FWHM and it achieved 140% of the NTSC standard CIE chromaticity chart. Accordingly, the perovskite QD LEDs can reproduce a vivid image closer to natural color than organic LEDs. Here, we developed an intrinsically stretchable perovskite QD LED by introducing perovskite QD in the semiconducting polymer matrix. The energy band of the polymer matrix must be larger than the energy band of perovskite QD for the energy transfer to perovskite QD. In addition, the polymer matrix has to interact with the perovskite QD physically, so the perovskite QD should be evenly dispersed in the polymer matrix. The stretchable LED was fabricated using the polymer matrix, which had a larger band gap and physical interaction with perovskite QD on the TPU substrate. The fabricated LED could be stretched up to 75% and emitted light under strain with high color purity (~18 nm of FWHM). This intrinsically stretchable LED would be successfully harnessed for stretchable free-form wearable devices, enabling accurate bio-signal analysis and phototherapy for various biomedical applications.

Colloidal CdSe/CdS Quantum Dots as Bright and Tunable Single-Photon Emitters Iwan Moreels[1], Francesco Di Stasio[2] and Riccardo Sapienza[3]; [1]Ghent University, Belgium; [2]Istituto Italiano di Tecnologia, Italy; [3]Imperial College London, Togo

Single-photon emitters are a key component of quantum technology, and often based on epitaxial quantum dots, NV-centers in diamond, or strongly attenuated lasers. However, colloidal quantum dots are becoming a viable, solution-processed alternative. For instance, in contrast with epitaxial quantum dots, they can operate at room temperature, and their emission can be tuned to any desired wavelength by simply controlling the composition and size of the quantum dots. In addition, their inherent nanoscale dimensions allows for miniaturization, and on-chip implementation.
In this talk, I will discuss how to synthesize highly fluorescent CdSe/CdS colloidal quantum dots that show (nearly) no intermittence.[1] Next, as these quantum dots have intrinsic fluorescence lifetimes that extend beyond 100 nanosecond, I will show how one can increase the emission rate by charging them with up to 20 electrons, which increases the radiative recombination rate, while at the same time the nonradiative Auger rate remains suppressed due to the proper choice of quantum dots core and shell dimensions.[2] Finally, I will demonstrate that the single-photon emission can be improved by spectrally filtering out the biexciton emission, which, due to the unique features of our quantum dots, can be performed at room temperature due to the exceptionally large blue shift of the biexciton emission.[3] In particular, this blue shift is achieved by exploiting strain and piezoelectric fields in our CdSe/CdS pure-phase wurtzite quantum dots, which is know to increase the electron-hole separation and exciton-exciton repulsive interactions, especially for quantum dots with a large CdSe core.[4,5]

Novel Detection System for the Characterization of Single Photon Sources Based on a SPAD Array Detector Davide Piccinotti, Eli Slenders, Matteo Barelli, Giuseppe Vicidomini and Francesco Di Stasio; Fondazione Istituto Italiano di Tecnologia, Italy

Future quantum technologies promise to deliver unprecedented computing power, guarantee secure communications, and yield ultra-high precision measurements. In quantum optics, the capability to analyze quantum signatures of the emitted light from single photon sources is essential and current experimental configurations offer limited capabilities for the metrology of quantum-light sources. So far, the primary method to probe non-classical properties of light is measuring the second order correlation function ($g^{(2)}(\tau)$) with a Hanbury-Brown and Twiss (HBT) intensity interferometer. Most of these experiments use single-photon counting detectors based on avalanche photodiodes or superconducting nanowires. These are so-called “click detectors”, since the arrival of a single photon causes the detector output state to move from 0 to 1 followed by a dead-time, where photon detection is not possible. Therefore, click detectors cannot discriminate the number of photons present in a light field at a given time offering limited capabilities for the metrology of quantum-light sources. Hence, the development of detectors capable to resolve the number of photons hitting them (so-called photon-number-resolving (PNR) detectors) is crucial for many applications in quantum-information science. Single photon avalanche diode (SPAD) array detectors provide PNR functionality by having the incoming photons hitting an array of parallel SPADs. Here, we take advantage of the exceptional properties of SPAD array detectors for the implementation of a new detection method for the measurement and analysis of single photons emitted by colloidal quantum dots (QDs). The data collected with this system provide a complete characterization of the analyzed single photon emitter giving information on the lifetime, antibunching effect and enable also quantum-imaging microscopy. In order to evaluate the performance of this new detection system, we performed spectroscopic measurements of photons correlation using commercial single photon detectors in Hanbury-Brown and Twiss (HBT) configuration on a sample composed by an array of 50x50 holes filled with single QDs. This type of sample enable us to compare directly the measurements performed with both experimental configurations on the exact same colloidal QDs. The work proposed here could lead to a new technological platform for the characterization of single photon sources that overcomes the limitation of conventional standard click detectors in HBT configuration.

11:15 AM NM03.08.08
Mid-infrared Electroluminescence of HgTe Colloidal Quantum Dots Xingyu Shen, John Peterson and Philippe Guyot-Sionnest; The University of Chicago, United States

HgTe colloidal quantum dots show great potential in many infrared regions because of the zero band gap of bulk HgTe. They have been explored for infrared detection as photoconductors, photovoltaics, and phototransistors, and for electroluminescence in the short-wave region (< 2.5 μm). Here, we report mid-infrared electroluminescence using HgTe CQD photovoltaic devices previously designed for mid-IR detection.

Mid-infrared electroluminescence is challenging because of the low photoluminescence efficiency. To reach a certain radiance, a much higher operation current is required, compared to visible devices. This could relax the requirement of band alignment between layers, but gives extra challenges on material stability and device efficiency. Strong thermal signal from Joule heating also becomes a consideration.

Using a p-n HgTe homojunction sandwiched between ITO and a gold electrode, we demonstrate band-edge electroluminescence at 4 μm (and at 2.5 μm with smaller HgTe quantum dots) when operated at forward bias modulated at 100 kHz. Fast modulation helps reduce the contribution from thermal

emission. By comparing the photoluminescence and electroluminescence of the same device, we found that the electroluminescence efficiency at low current was limited by the photoluminescence efficiency of the quantum dots while the diode structure provided efficient electron-hole recombination. The power efficiency is limited by the resistance of transparent electrode, and we show that the efficiency can be improved through the incorporation of a metal conductive grid.

11:30 AM NM03.08.09
Siloxane-Encapsulated Perovskite Quantum Dot Nanocomposites for Highly Stable Color-Converting White Organic Light-Emitting Diodes Junho Jang[1,1], Young-Hoon Kim[2], Yongmin Shin[1,1], Byoung-Hwa Kwon[3] and Byeong-Soo Bae[1,1]; [1]Korea Advanced Institute of Science and Technology, Korea (the Republic of); [2]Hanyang University, Korea (the Republic of); [3]Electronics and Telecommunications Research Institute, Korea (the Republic of)

Perovskite quantum dots (PQDs) have emerged as a high-performance color converting materials in displays because of low material cost, facile color tunability depending on size or composition, high photoluminescence quantum yield (PLQY), and very narrow emission spectra, which allow them to achieve wide color gamut. Although they show high optical performance, PQDs in humid or high temperature environments are vulnerable to decomposition of perovskite crystals, to ion migration, and to development of metastable states. Stability of PQDs have been increased by various methods such as formation of an inorganic shell, Janus structures, and QD/polymer nanocomposites. However, such strategies still showed limited stability of PQDs under ambient air or in water, and entail complex processes to prevent aggregation of QDs in polymer matrixes. Moreover, PQDs that are stable under harsh conditions (acid or base solutions, polar solvents, high temperature with high humidity) have not been reported. Especially methylammonium ($CH_3NH_3^+$, MA) based PQDs decay faster in the presence of moisture than do others such as formamidinium or cesium or mixed cation based PQDs even it can be fabricated by simple process. Therefore, highly stable and uniformly dispersed OIHP NP composites without complex processes such as ligand-exchange and formation of an inorganic shell are desirable.
Herein, we report a simple but effective materials-design approach to achieve extraordinarily-long stability of crosslinked MA lead bromide ($MAPbBr_3$) QDs in various environments (air, water, chemicals, high temperature (85 °C) with high relative humidity (85%RH) (85 °C/85%RH)) by employing sol-gel derived methacrylate-functionalized siloxane hybrid matrix. The methacrylate in the siloxane matrix induces a chemical crosslinking with unsaturated hydrocarbon in acid and base ligands in PQDs at a molecular scale, to form a crosslinked perovskite QDs (CPN) that prevents decomposition of MA from the perovskites and achieves homogeneous distribution of QD in the siloxane matrix. Moreover, the low concentration of moisture that diffuses through the siloxane matrix during aging can chemically heal surface defects in the QDs, and thereby reduce nonradiative recombination in CPN. As a result, CPNs showed high PLQY of ≈70% which remained for >600 d in air, water and acid or base solutions, and various polar solvents, and for >100 d under 85 °C/85%RH. We demonstrate wide color gamut and stable color-converting white LEDs and OLEDs by integration with red-emissive Cd-based QDs. Moreover, water- and chemical-persistent CPNs were successfully applied to cell proliferation which has been impossible with water-sensitive materials with toxic elements (*e.g.*, Cd and Pb).

Exciton-Polaritons Arising from CdSe Nanoplatelets Strongly Coupled to Dielectric Optical Cavities Ovishek Morshed and Todd Krauss; University of Rochester, United States

Exciton-polaritons, arising from the strong coupling of excitons with the confined cavity photon modes, are an emerging platform for exploring light-matter interactions at the nanoscale. However, the use of organic molecules for generating polaritons poses a fundamental limitation to the magnitude of light-matter interactions due to their short lifetime and relatively small transition dipoles. Our focus lies on studying the coupling between CdSe nanoplatelets (NPLs) and metal-dielectric Fabry-Perot (FP) optical cavities. The large oscillator strength of NPLs along with exceptionally narrow photoluminescence linewidth makes them a promising candidate for achieving strong light-matter coupling. We have found that NPLs strongly couple to FP cavities with a Rabi splitting of 83 meV, characterized from angle-resolved reflectance and photoluminescence measurements. Numerical simulations using mixed quantum-classical dynamics accurately model our experimental data, providing a fundamental explanation for the observed spectra. Specifically, the light emission properties of the polariton are highly dependent on the coupling of dark (i.e., uncoupled) exciton states with the upper and lower polariton states, as well as their relative photonic character. Also to be presented will be measurements of the polariton photoluminescence lifetime in the strong coupling limit. Our work provides a new platform for investigating cavity-mediated physical and chemical processes which could potentially unlock new types of chemical reactions.

1:45 PM NM03.09.03
Electrically Excited Multi-Color Amplified Spontaneous Emission from Colloidal Quantum Dots Namyoung Ahn, Clement Livache and Victor I. Klimov; Los Alamos National Laboratory, United States

Solution-processable materials, including organic semiconductors, perovskites, and colloidal quantum dots (QD), have been under intense investigation as optical-gain media for future laser technologies. However, the realization of electrically driven laser action with these materials still remains an unrealized objective. Colloidal continuously-graded QDs (cg-QDs) have recently emerged as a promising system for achieving lasing with electrical excitation. Thanks to strong suppression of Auger recombination, they showed optical gain under electrical pumping and allowed for demonstrating dual-function devices that operated as an optically pumped laser and a high-brightness light-emitting diode (LED).[1-3] Notably, cg-QDs exhibit good stability at current densities of over 1 kA cm^{-2}, which allowed for realizing unusual two-band electroluminescent (EL) wherein the higher-energy 1P feature was more intense than the band-edge 1S emission.[2] This is indicative of very high per-dot excitonic occupancies that were sufficient to generate strong, broad-band optical gain spanning the 1S and 1P transitions. However, light amplification due to stimulated emission from the QDs was not observed because of strong optical losses in charge-conducting layers of the EL device.[3] Here, we tackle this problem but integrating QDs with a specially engineered photonic waveguide. Using this approach, we maximize the mode confinement factor for the gain-active QD layer and reduce the field intensity in the optically lossy charge conducting layers. As a result, the developed devices generate large net optical gain under pulsed bias and demonstrate ASE-type laser action at three optical transitions (abbreviation ‘ASE’ stands for ‘amplified spontaneous emission’).[4] The realization of the ASE regime is indicated by multiple observables including a super-linear growth of the EL intensity above the ASE threshold, a pronounced line narrowing, the emergence of preferred polarization, high directionality of edge-emitted light, and an exceptionally high output intensity which reaches ~2 kW cm^{-2}.

2:00 PM NM03.09.04
Ultrathin High-Resolution Optoelectronic Devices for Skin-Attachable Electronic Applications Moon Kee Choi[1] and Jiwoong Yang[2]; [1]Ulsan National Institute of Science and Technology, Korea (the Republic of); [2]Daegu Gyeongbuk Institute of Science and Technology (DGIST), Korea (the Republic of)

Soft electronic devices, in particular healthcare-related ones, have been intensively studied over the past decade due to their unique advantages in wearable applications over the conventional rigid electronics, including conformal contacts on human skin and high deformability that minimizes unwanted inflammatory responses. To achieve the soft nature in high performance electronics and to apply this technology to wearable biomedical electronics/optoelectronics, several strategies have been employed, such as the designed assembly of high-quality nanomaterials, combination of unconventional manufacturing processes with existing micro-processing technologies, new design of individual devices with deformable structures, and disease-specific system-level integration of diverse soft electronics. Here, we describe ultrathin high-resolution optoelectronic devices for skin-attachable electronic applications. New dry transfer printing techniques using intaglio trench and elastomeric stamp are demonstrated for the high resolution RGB sub-pixels up to ~2500 pixels per inch. Ultrathin high-resolution red-green-blue quantum dot LEDs and perovskite LEDs can be utilized next-generation skin-attachable electronic tattoo, transparent smart display, and display of healthcare monitoring wearable devices.

2:15 PM BREAK

2:45 PM NM03.09.05
Printed Quantum Dots—Graphene IR Photodetector on a Curved Surface Gökhan Kara[1], Sami Bolat[1], Khushdeep Sharma[1], Patrik Rohner[1], Matthias J. Grotevent[1,2], Dmitry N. Dirin[3], Dominik Bachmann[1], Roman Furrer[1], Luciano F. Boesel[1], Yaroslav E. Romanyuk[1], Dimos Poulikakos[3], Maksym V. Kovalenko[3,1], Michel Calame[1,4] and Ivan Shorubalko[1]; [1]Empa – Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [2]Massachusetts Institute of Technology, United States; [3]ETH – Swiss Federal Institute of Technology Zurich, Switzerland; [4]University of Basel, Switzerland

Shortwave infrared (SWIR) imaging is well known for night vision and seeing through foggy weather conditions. Thus a perfect match for autonomous driving, it is also used for environmental pollution monitoring or smart farming. Furthermore, the integration into smart textile patches is of great interest for human health monitoring of vital signs or wound healing in particular. The lack of monolithic integration with CMOS read-out circuits (ROIC) and the high-temperature processes used to fabricate state-of-the-art InGaAs detectors, though, limits its potential for broad commercial use. Low dimensional materials offer an easy technological edge to launch the next generation of SWIR photodetectors. Phototransistors based on graphene as the channel layer and PbS QDs for light-to-charge conversion, benefit from conformal adaptation and solution processing enabling novel device architectures for high-quality imaging at low light levels.
Most commonly though, detectors are fabricated on flat substrates and the deposition of QDs is performed by spin coating, dip coating, or drop-casting. This limits the substrate choice, wastes a lot of material, and does not allow selective deposition on desired regions only. Here, we present two different emerging drop-on-demand approaches for optoelectronic applications. On the one hand, by electrohydrodynamic nanoprinting of PbS QDs, we reach sub-micrometer resolution with an exceptional film thickness control in the nanometer range suited for small pixel dimensions. With inkjet printing, on the other hand, we can cover large areas (print head speed up to 500 mm/s) with a resolution below 50 µm. In particular, we demonstrate an inkjet-printed phototransistor on a flat rigid substrate (Si/SiO2), reaching a 1.8 µm spectral cut-off wavelength. Our temperature versus gate voltage map reveals responsivities in the order of 10^3 A/W at the first excitonic peak of 1.6 µm wavelength. To demonstrate the versatility of this technological approach, we wrap graphene around a polymer optical fiber with a diameter of 1 mm and print PbS QDs on these active areas solely. We then use this smart cladding layer to detect light (telecom wavelength of 1.3 µm and 1.55 µm) propagating through the fiber without interrupting its path.

3:00 PM NM03.09.06
Quantum Dot-Based Near-Infrared-Sensitive Optoelectronic Biointerface for Neurostimulation Onuralp Karatum, Humeyra Nur Kaleli, Guncem O. Eren, Afsun Sahin and Sedat Nizamoglu; Koc University, Turkey

Optoelectronic neural interfaces offer non-genetic and wireless bioelectronic neuromodulation via light. For minimally invasive communication with neurons inside the deep neural structures, transition of optoelectronic neural interfaces to near-infrared (NIR) spectrum is critical. Colloidal quantum dots (QDs) have size-tunable absorption that can cover visible and infrared wavelength spectrum. QDs also have high absorption coefficient that enables fabrication of thin and flexible optoelectronic devices. In this study, we demonstrated a wireless, and flexible QD-based optoelectronic neural interface that can evoke light-induced action potentials in primary hippocampal neurons via 780 nm light in tissue transparency window.[1] We designed a multilayer photovoltaic device architecture with an ultrathin QD layer of 25 nm to generate a safe capacitive ionic current and integrated supercapacitor ruthenium oxide (RuO_2) into the return electrode for improving the photogenerated charge density. Fully solution-processed neural interfaces preserve their functionality after different stability tests and show low in vitro cytotoxicity. Overall, our results disclose the potential of QDs for tether-free bioelectronic photomodulation of neurons in tissue transparency window.

A Living System for Robust Photocatalytic Hydrogen Evolution from CdSe Quantum Dots Emily Edwards[1], Jana Jelušić[1], Kevin McClelland[1], Wesley Chiang[1], Ryan Kosko[1], Sanela Lampa-Pastirk[2], Kara Bren[1] and Todd Krauss[1]; [1]University of Rochester, United States; [2]Nazareth College, United States

Developing systems that interface nanomaterials and microorganisms is an attractive approach to solar fuels production that can take advantage of the extraordinary properties of both components. For example, nanomaterials have been utilized to provide electrons to microorganisms in photo(electro)chemical processes to fuel metabolic pathways for desired products. While semiconductor nanocrystals are known to be highly active and robust photocatalysts for hydrogen evolution, their use is for all practical purposes severely hampered by the need for an inexpensive and sustainable source of electrons from oxidative side of the reaction. Direct water oxidation is thermodynamically challenging and inefficient, and consequently, easily oxidized electron donors are typically supplemented in high concentrations to drive photocatalysis, which is a major limitation. Here, an alternative approach to constructing living bio-nano artificial photosynthetic systems will be discussed.

Rather than catalysis regulated by electron transfer *from* the nanomaterial *to* the microorganism, we show that exceptional photocatalytic activity of semiconductor nanocrystals (NCs) is sustained by extracellular electron transfer (EET) *from* electrogenic bacteria *to* the NCs. In our fully light-driven system, *Shewanella oneidensis* MR-1 (MR-1), a non-photosynthetic facultative anaerobe, respires CdSe NCs, via EET. Under illumination from visible light (530 nm LEDs), we observe sustained H_2 evolution from the NCs for over a week without the requirement of an external voltage. EET from MR-1 is a natural anaerobic respiratory process, and thus, replenishing the growth medium allows catalysis to continue over a second week. To test the hypothesis that the H_2 production in the complete system results from bacterial respiration of CdSe NCs, the MR-1 gene knockout variant *hyaA (ΔhyaA*) was used. This variant of MR-1 has impaired hydrogenase activity, and thus is not expected to produce H_2 on its own. Indeed, *ΔhyaA* cultures produced no detectable H_2 over the course of one week. However, the system consisting of *ΔhyaA* and CdSe NCs, produced H_2 at a similar rate and efficiency to the wild type MR-1, confirming that respiration of CdSe NCs was essential and sufficient to complete the oxidative portion of the catalytic cycle. There exists many possible barriers to MR-1 EET directly to colloidal NCs: surface area needed for bacterial adhesion, the oxidative damage from photocatalytic processes, biocompatibility of the NCs, and efficiency of electron transfer. The strategy we will outline demonstrates that these challenges are surmountable in a remarkably simple system and suggests a new solution to the oxidative roadblock in NC photocatalysis. Success here opens the door to pairing this strategy with a host of different NC photocatalytic reactions to yield sustainable systems for NC-mediated photocatalysis.

Carrier Transport in Colloidal Nanocrystal Arrays Mengxia Liu; Yale University, United States

Colloidal nanocrystals are an emerging type of solution-processed semiconductors that offer a powerful platform for the scalable manufacturing of optoelectronic devices. Understanding carrier dynamics and transport in nanocrystal is crucial for unlocking their full potential for optoelectronic applications. This presentation will introduce a novel optical methodology to investigate the nanoscale photophysics in thin film semiconductors and present the direct visualization of non-equilibrium carrier propagation in PbS nanocrystal arrays. I will discuss the impact of nanocrystal polydispersity on carrier dynamics, the influence of imbalanced carrier transport on solar cell performance, how these can be controlled and optimized through novel materials processing and structure engineering. These findings offer promising strategies to harness transport phenomena for more efficient optoelectronic devices.

SESSION NM03.10: QD Based Devices III

8:30 AM *NM03.10.01
0D-1D Nano-Heterostructures for Solar Energy Conversion Oomman K. Varghese; University of Houston, United States

The advent of zero dimensional (0D) nanomaterials such as quantum dots (QD) of semiconductors has brought renewed expectations in direct solar energy conversion technologies such as solar photovoltaics and photoelectrochemical (PEC) fuel generation. The few-atom construction of the QDs furnishes them with very large surface area relative to volume leading to unique characteristics. The phenomena such as quantum confinement effects and associated blue shift in the absorption edge are not only scientifically intriguing but also capable of bringing paradigm shifts in the solar power as well as fuel generation technologies. The efficiency of the single junction devices from these technologies can reach levels significantly beyond the Shockley-Queisser limit utilizing phenomena such as multiple exciton generation and hot carrier extraction. While this milestone has not yet been achieved, there has been substantial improvements in the efficiency of the QD based solar cells. These solar cells have utilized materials from chalcopyrites to inorganic iodide perovskites as light absorbers and the efficiency has reached 18%. Carbon dots and band gap engineered QDs of wide band gap materials such as boron nitride appeared promising for solar PEC water splitting and carbon dioxide reduction. It has also been demonstrated that the potentials of the quantum dots can be extended further if they are supported by high surface area ordered nanostructures. This presentation will review the advances in supported QD based solar cells and solar fuel generation processes.

9:00 AM NM03.10.03
Near-Infrared Photodetectors Based on Silver Chalcogenide Colloidal Quantum Dots Neil Graddage, Jianying Ouyang and Jianping Lu; National Research Council Canada, Canada

Detection of near-infrared (NIR) radiation is essential for a wide variety of applications in industries as varied as healthcare to agriculture. In the healthcare application space in particular, NIR radiation shows good penetration of tissue with low scattering making it ideal for a variety of diagnostic sensors. The primary spectral ranges for this sensing are commonly referred to as NIR-I between 650 nm to 950 nm, and NIR-II from 1000 nm to 1400 nm. The first window can be partially detected by Si based detectors, which are commonplace and low cost, though limited in form factor. The second window typically requires detectors using materials such as InGaAs, which perform well but are expensive to fabricate and also limited to rigid form factors. Therefore the identification of materials capable of photodetetction in these regimes while compatible with solution-based fabrication techniques such as printing is of significant interest, as it could result in low-cost devices which can be integrated into new form factors such as wearable electronics.

Colloidal quantum dots (CQDs) are a class of materials which offer tunable optoelectronic properties and solution processbility. A number of CQD materials have shown promise for NIR detection, however primary materials have all been Pb based, with associated toxicology concerns. This has inspired a search for less toxic alternatives. One such family of materials identified are silver chalcogenides, in particular Ag_2Se and Ag_2Te. To date there has been much interest in these materials, but little reported synthesis optimisation and demonstration in photodiodes, which is essential for low power applications. In this work we investigate the potential for these materials for use in NIR sensitive photodiodes, optimising synthesis and developing novel structures to enable such devices.

We developed Ag_2Se based photodiodes with sensitivity in the NIR-II window. Ag_2Se CQDs were synthesised using a hot injection method. We achieved CQDs with a mean diameter of 3.7 nm and a narrow size distribution by employing a secondary phosphine. These CQDs were then used in a photodiode structure which included a porous TiO_2 scaffold inspired by dye-sensitised solar cells. This structure maximises the absorption of the Ag_2Se CQDs, while minimising the risk of device shorting due to the high conductivity of the Ag_2Se CQDs. The ligand exchange process used for CQD layer fabrication is compatible with low-temperature substrates, and devices demonstrated an EQE of over 1% at a wavelength of 1150 nm and sensitivity up to 1400 nm. We also developed Ag_2Te based photodiodes. Ag_2Te CQDs synthesis was comprehensively optimised by investigation of multiple factors including feed ratio, ligand selection and synthesis method. After optimisation we achieved relatively large Ag_2Te QDs with distinct excitonic absorption peaks (~1050–1450

nm) and a PL emission peak from 1.3–1.7 µm. These Ag_2Te CQDs were used to fabricate photodiode devices which demonstrated sensitivity beyond 1400 nm, with an EQE of 0.14% and a responsivity of ~1.5 mA/W at 1400 nm.

The combination of good material processability, exciting material properties and promising device performance has demonstrated that silver chalcogenide CQDs offer a reduced-toxicity route for low-cost additive fabrication of NIR-II photodiodes. Further work is still needed to improve device performance and unlock the full potential of these materials.

Hybrid Inorganic/Organic Nano-Systems for the Development of Light-Driven Storage Devices Andrea Camellini, Michele Ghini, Andrea Rubino and Ilka Kriegel; Istituto Italiano di Tecnologia, Italy

The efficient harvesting of solar radiation and subsequent steady-state storage of photo-charges are now becoming one of the main challenges for the development of sustainable energy sources. The growing demand to reduce the usage of rare [1] and toxic materials, as well as the need to overcome current limitations in solar energy storage (such as the intermitting nature of the source and inevitable conversion losses) calls for completely innovative approaches. A promising new approach relies on combining light absorption, charge separation, and storage into one single set of solution-processable, environmentally friendly, and Earth-abundant materials as well as the possibility to exploit light-driven multi-electron and hole transfer reactions to improve the charge-storage capability. In this direction, hybrid inorganic/organic nano-systems employing metal oxides nanocrystals (MO NCs) and graphene quantum dots (GQDs) are emerging as potential candidates to fulfill these purposes. In this work, by means of spectro-chemical tools, we investigate the ability of MO NCs (Sn doped In_2O_3 NCs) to quasi-permanently accumulate electrons upon UV light illumination [2] as well as their efficient extraction [3]. Moreover, by using a widely employed electron-acceptor molecule, namely F4TCNQ, we show the potential of specifically functionalized GQDs to store one hole in their ground state. These evidences point toward the possibility to exploit hybrid inorganic/organic nano-systems as novel multi-charge accumulation components for the development of solution-based light-driven storage devices.

10:00 AM NM03.10.06
$CuInS_2$/ZnS Colloidal Quantum Dots as a Luminescent Nanothermometers Magdalena Duda[1], Kamil Sobczak[2], Roman Minikayev[1], Elzbieta Dynowska[1], Bozena Sikora[1] and Lukasz Klopotowski[1]; [1]Polish Academy of Sciences Institute of Physics, Poland; [2]University of Warsaw, Poland

In this work, we present the performance of $CuInS_2$/ZnS (CIS/ZnS) quantum dots (QDs) employed as fluorescent nanothermometers. We find that both the intensity and wavelength of the photoluminescence (PL) peak is sensitive to temperature and optimize the growth time of ZnS for maximum thermometer sensitivity.
CIS/ZnS QDs are particularly suitable for bio-applications because of environmentally friendly synthesis and absence of photobleaching. Moreover, the size-dependent photoluminescence (PL) and absorption, low power excitation, and long PL lifetimes make them ideal fluorescence markers. In this work, we demonstrate a dual functionality of CIS/ZnS QDs: as biolabels and nanothermometers.

We synthesised $CuInS_2$ QDs, according to the method described in Ref. [1]. As a result, we obtained CIS QDs with a pyramidal shape, chalcopyrite structure, and an average size of about 2.3 nm. As recently reported, CIS QDs exhibit significant cytotoxicity. In order to produce non-toxic QDs, a ZnS layer was grown around the CIS QD cores as reported in Ref. [2]. We investigated 5 samples with ZnS growth time varied from 0 to 180 minutes. Increasing the growth time resulted in a blue-shift of the PL peak from 673 to 606 nm. Concomitantly, the PL quantum yield increased from 0,9% to 13%. Due to dodecanethiol capping ligands, as-synthesized QDs were hydrophobic. The use of QDs as nanothermometers requires aqueous environment. Therefore, QDs were encapsulated by micelles, as reported in Ref. [3]. To test the optical and thermal stability of the hydrophilic QDs, the PL was measured in 2 hours and 3 cycles of temperature changes from 20ºC to 54ºC. After this time, the PL intensity decreased only by up to 15%. The nanothermometers were then calibrated by measurements in steps of 2ºC. Increasing the temperature to 54ºC, resulted in a PL intensity decrease by up to 70%. We interpret this decrease as a result of thermal activation of non-radiative processes. Moreover, the PL peak red-shifted by up to 10 nm. We interpret the red-shift as a result of closing of the band gap. The two effects afford a precise calibration of the nanothermometer. We found the highest sensitivity — reaching 1.3 %/ºC — is at least comparable to other QD systems. Confocal imaging demonstrated successful entering of CIS/ZnS QDs into HeLa cells. Finally, preliminary Presto Blue cell viability assay revealed negligible CIS/ZnS QD cytotoxicity in HeLa cells.

Quantum Dot Mimetics of SARS-CoV-2 for Understanding Origins of Neurologic Disease Associated with Long Covid Wesley Chiang, Harris Gelbard and Todd Krauss; University of Rochester, United States

Colloidal semiconductor quantum dots (QDs) are exceptional fluorescent probes for bioimaging applications; their enhanced photophysical properties, such

as photostability and brightness, compared to conventional fluorophores are essential for achieving high-resolution precision. Additionally, the synthetic tunability of QD emission makes them viable candidates for multiplexed imaging and various biosensing applications. However, conventional applications of fluorescent probes, including QDs, investigate biomolecular interactions by conjugation of a biomolecule to the probe. While such material design is functionally justifiable for single proteins, such designs are incompatible with probing the function of more complex structures such as protein aggregates or virus particles in a manner that is representative of their native environment.

Thus, to study the physiochemical interactions relevant to SARS-CoV-2 mediated disease in the central nervous system (CNS), we have constructed a QD biomimetic for SARS-CoV-2 (COVID-QDs) with a focus on achieving high structural fidelity to native virus particles. The COVID-QDs act as a proxy for SARS-CoV-2 virus particles by accurately mimicking the general shape, size, and surface density of spike proteins. Specifically, the COVID-QDs were constructed by linking SARS-CoV-2 spike (S) proteins to polymeric phospholipid chains that formed a micellar envelope around the QDs; this forms a decorated capsid-like structure in native virus particles. By ensuring structural fidelity, we are able to fluorescently probe the physicochemical interactions between COVID-QDs and various cell types in a context that better reflects the native function of SARS-CoV-2.

We found that the COVID-QDs mediate dysfunction in a model system for the neurovascular unit, comprising endothelial cells, neurons, and glia. Interestingly, by correlating fluorescent micrographs, acquired by structured illumination, with functional biological assays, we have determined that the COVID-QDs primarily bind to the endothelial cells, leading to increased inflammation and leakage. This functional modulation of the endothelial cells by the COVID-QDs subsequently results in inflammation of the neuroglia underneath the endothelial monolayer. Our data shows that the dysfunction of the neural cell types is not mediated by direct interaction with COVID-QDs that have migrated through the endothelial monolayer. These results add to a body of evidence indicating that the neurological effects associated with COVID-19 are primarily driven by inflammation through virus particle-mediated dysregulation of the endothelium. Furthermore, we have identified a potential small molecule that could reverse the effects of the COVID-QDs, leading to inhibition of inflammation in both the monolayer and the CNS.

Evolution of Colloidal Compound Semiconductor Quantum Dots and Magic-Size Clusters Kui Yu; Sichuan University, China

The synthesis of photoluminescent (PL) colloidal semiconductor quantum dots (QDs) has been performed as an empirical art, while colloidal semiconductor magic-sized clusters (MSCs) are reported as a side product. Their growth relation has been addressed only in a limited fashion, with different opinions expressed in the literature. It is critical to develop fundamental understanding, especially regarding the pre-nucleation stage also called the induction period (IP). Here, I will talk about chemical reactions including the effect of the impurity in tri-*n*-octylphosphine (TOP) in Part 1 and the nucleation pathway with the proposed two-pathway model (Yu) in Part 2. For the latter, we suggest that there are two individual pathways in the prenucleation stage of QDs. The self-assembly of metal (M) and chalcogenide (E) precursors followed by the formation of binary II-VI ME MSCs inside each assemble depicts Pathway 1. The LaMer model of the classical nucleation theory (CNT) describes Pathway 2. The two pathways are inter-connected via a special intermediate, called the precursor compound (PC) of MSCs. I will introduce our latest advances on the PC-enabled pathway (with monomer substitution or addition) for transformations among various MSCs, as well as on the PC-enabled synthesis of various nano-species. Hopefully, this presentation brings a deeper understanding into the prenucleation stage of QDs. We believe that the synthesis of colloidal nanocrystals is slowly and quietly transforming from an empirical art to science.

Heterostructures Involving Halide Perovskite Nanocrystals and Chalcohalide Nanocrystals Liberato Manna; Instituto Italiano di Tecnologia, Italy

Halide perovskite semiconductors can merge the highly efficient operational principles of conventional inorganic semiconductors with the low temperature solution processability of emerging organic and hybrid materials, offering a promising route towards cheaply generating electricity as well as light. Following a surge of interest in this class of materials, research on the corresponding halide perovskite nanocrystals (NCs) as well has gathered momentum in the last years. Another class of materials that has been recently investigate by us is that of metal chalcohalides. These materials offer a broad solid-state chemistry and they been investigated for applications in solar energy conversion, thermoelectrics, hard radiation detection, and superconductivity. Among them, lead chalcohalides have been rarely studied in the past. We have recently reported the synthesis of a series of lead chalcohalides, by means of colloidal approaches, delivering phases and compositions that had not been previously identified in the bulk. These materials present indirect band gaps, they emit in the NIR region of the spectrum at cryogenic temperatures and have unique crystal structures. We will also show our recent results on the synthesis and advanced characterization of heterostructured nanocrystals in which one domain is a lead chalcohalide and the other domain is a cesium lead halide perovskite. The two domains are separated by a flat, atomically defined, epitaxial interface. In these materials, the photogenerated carries are separated at their interface, and as such they might be promising in applications ranging from catalysis to photovoltaics. We will also discuss how halide perovskite nanocrystals can be used to template the synthesis of chalcohalide nanocrystals in phases and compositions that are different from the case in which the latter are homogeneously nucleated. This templating effect is due to the formation of an epitaxial interface between the two materials. In a second step, the perovskite domain can be selectively etched, delivering the free standing chalcohalide nanocrystals. This use of perovskite nanocrystals as disposable templates is new and can be used as a tool to discover new materials.

Colloidal Nanoparticles Decorated Graphene—Functional Materials Towards Energy Conversion and Sensing Applications M L. Curri[1,2]; [1]Consiglio Nazionale delle Ricerche, Italy; [2]University of Bari, Italy

Graphene (G) is an extraordinary material for advanced devices, due to its superior electrical conductivity, (electro)catalytic activity and surface chemical

reactivity. The last enables the implementation of non-covalent routes for its decoration with inorganic nanostructures, thus resulting in hybrid nanocomposites exhibiting original and ingenious combination of the properties of both G and inorganic components. Nanoparticles (NPs) prepared via colloidal chemistry approaches possess original size- and shape-dependent properties and are particularly suited for decorating G [1,2], thanks to the possibility to engineer their surface chemistry. Different types of colloidal nanomaterials, as NIR emitting PbS quantum dots, oxides as TiO_2 and plasmonic Au NPs, have been used to decorate G, [1-3] and the nanocomposite materials have been thoroughly investigated, from a morphological, spectroscopic, electrical and (photo)electrochemical points of view. Distinct decoration approaches have been designed, both for immobilizing pre-synthesized inorganic NPs onto the G based structures, and for performing *in situ* synthesis. In both strategies, suitable anchoring molecules are key element to enable a close interaction between G and NPs and thus direct the chemical and electronic properties of the resulting hybrids. In all the investigated systems, a controlled and uniform NP coverage has been obtained. The photoactivity and photoelectrochemical behavior of the hybrid nanocomposites demonstrate that this class of materials holds a great promise for photo-conversion, sensing and life science applications [4-6]. Selected examples of nanocomposites will be described and their possible integration in devices presented.

High-Performance Green and Blue Quantum-Dot Light-Emitting Diodes by Suppressing the Electron Leakage Yunzhou Deng[1], Feng Peng[2], Yao Lu[1], Xitong Zhu[1], Wangxiao Jin[1], Jing Qiu[1], Jiawei Dong[1], Yanlei Hao[1], Dawei Di[1], Yuan Gao[3], Tulai Sun[4], Ming Zhang[5], Feng Liu[5], Linjun Wang[1], Lei Ying[2], Fei Huang[2] and Yizheng Jin[1]; [1]Zhejiang University, China; [2]South China University of Technology, China; [3]Najing Technology Corporation Ltd., China; [4]Zhejiang University of Technology, China; [5]Shanghai Jiao Tong University, China

Solution-processed light-emitting diodes (LEDs) using colloidal quantum dots (QDs) as the emissive layers (EMLs) have emerged as a promising class of color-pure, low-cost and large-area electroluminescent (EL) devices. Progress in synthetic chemistry and surface chemistry have enabled CdSe-based QDs with near-unity photoluminescent (PL) quantum yields and outstanding photostability across the visible spectral range. However, the EL performances of QDs incorporated into QD-LEDs, especially for the blue-color devices, are still inferior to their PL properties. This apparent “EL-PL gap” implies the inefficient generation of excitons in the operating QD-LEDs with short wavelengths. Hence, in order to fully exploit the potential of QDs in EL applications, in-depth understanding on the charge dynamics in electrical excitation of QDs as well as the associated efficiency-loss mechanism is demanded.
Here, we report our recent findings [1] of the disorder-enhanced electron leakage from the wide-bandgap QDs to amorphous hole-transport layers (HTLs), which was identified as the limiting efficiency-loss channel in the blue QD-LEDs. According to the parasitic emission from HTLs in EL spectra of the QD-LEDs, we revealed that the electron leakage from QDs to HTLs is more severe in green and blue QD-LEDs than that in red QD-LEDs. Our theoretical work shows that the unique electron-transfer dynamics from QD (rigid) to organic (flexible) materials, which are distinctive from those at organic/organic and inorganic/inorganic interfaces, are greatly enhanced due to the different strength of energetic disorder in the two materials. To resolve this problem, we develop hole-transport polymers, i.e., poly[(9,9-dioctylfluorenyl-2,7-diyl)-alt-(9-(2-ethylhexyl)-carbazole-3,6-diyl)] (PF8Cz), with shallower lowest unoccupied molecular orbital (LUMO) energy level and reduced energetic disorder.
By using the PF8Cz HTLs, we realized high-performance green and blue LEDs with high peak external quantum efficiencies (28.7% and 21.9%, respectively) and wide high-efficiency luminance windows. The QD-LEDs also show superior operational stability with the T95 lifetimes (initial luminance: 100 cd m^{-2}) of ~580,000 h for green and ~4,400 h for blue QD-LEDs, respectively. The advance in device performance demonstrates that our design of HTL/QD interfaces can effectively block the electron leakage and enable ~100% conversion of the injected charge carriers into emissive excitons. We expect that our strategy could offer a general approach to eliminating electron leakage in solution-processed LEDs incorporating organic-HTL/inorganic-EML interfaces.

Mid-Infrared Photodiodes Using HgTe Colloidal Quantum Dots John Peterson and Philippe Guyot-Sionnest; The University of Chicago, United States

HgTe colloidal quantum dot photodetectors offer an inexpensive alternative to the conventional, epitaxially grown, mid-infrared detectors. Recent work describing the thermodynamic limits of these materials suggest that their long Auger lifetime may allow for better performance over such conventional detectors in that region. Previous work has produced HgTe quantum dot photodiodes which are background limited at cryogenic temperatures. However, they exhibited a ~20-fold decrease in the quantum efficiency from 150K to 300K.

Modeling the IV curves has helped to better understand the mechanism of this limited performance. The temperature dependence, the origin of the shunt resistance (recombination mechanisms) and the series resistance (electrodes and the dots themselves) are rather well understood with a simple model. This model suggests that, in the regime where the shunt resistance is on the order of the series resistance, the quantum efficiency is expected to drop substantially. Modifications to the p and n-doping as well as microfabrication methods have been applied to increase the shunt resistance of the devices relative to the series resistance. Methods of producing low resistance, transparent electrodes for the infrared have also been explored. The diffusion length of the materials used requires that these devices remain thin, and so microfabrication is also employed to enhance to optical absorption of the diodes. Together, these efforts to improve single element detectors allow for higher temperature thermal imaging with this technology, closer to the

thermodynamic limit of the material.

Fabrication and Characterization of Four-State Inverter utilizing Quantum Dot Gate Field-Effect Transistors (QDGFETs) Bilal Khan[1], Raja Gudlavalleti[1], Roman Mays[1], Evan Heller[2] and Faquir Jain[1]; [1]University of Connecticut, United States; [2]Synopsis Corporation, United States

Abstract: This paper presents experimental results of nMOS quantum dot gate field-effect transistor (QDG-FET) based four-state inverter fabricated and tested with Si/SiO_2 and Ge/GeO_2 quantum dots(QD). The site-specific self-assembly of SiOx-cladded Si and GeOx-cladded Ge QD layers in the gate region implements both the driver and load FETs in enhancement nMOS inverters. A four-state inverter will allow reduction of FET count in logic block in microprocessors.
Keywords: QDGFET, Multi-State, Multi-Bit, Inverters

I Introduction: Quantum dot gate (QDG) FETs exhibiting three-state I-V characteristics have been reported using two layers of thin barrier SiOx-cladded Si quantum dots in the gate region [1]. This has been followed by reports of four-state QDG-FETs and enhancement mode inverters using self-assembled Si-Ge quantum dots [2]. This paper presents new results presented in our recent paper [3]. Moore's *law* states that the number of transistors doubles every two years [4], and reducing transistor size sub 5nm presents challenges.
II QDG-FET comprising of 2 layers of SiOx-Si and 2-laeyrs of GeOx-Ge QDs: A quantum dot (QD) is a semiconductor structure that is confined in all three dimensions. A QD has two main layers, a small semiconductor core such as Si or Ge surrounded by a cladding layer of either SiOx or GeOx respectively. The cladding layer acts as a barrier layer which helps to trap charge inside the quantum dots. When a number of quantum dots are placed next to each other they form a quantum dot superlattice (QDSL). The formation of a QDSL results in mini energy bands which allows the FET device to exhibit multiple states [1]. Three-state inverters using SiOx-Si and GeOx-Ge QDG-FETs have been reported [1, 2]. We are reporting the QDG-FET based inverter employing both SiOx-Si QDs and GeOx-Ge QDs in the gate region that resulted in four-states for the inverter. In this device, we have two layers of cladded Si QD layers over tunnel gate oxide and two additional layers of Ge QDs are self-assembled on Si QDs. Every two layers of QDs provides a new threshold voltage which can be used to program the inverter at different states. The QDs are assembled using a colloidal solution over the gate region via a self-assembly method in which QDs are deposited on the p-Si channel region over the tunnel gate oxide. The Si sample was placed in the colloidal solution for 3 minutes after which an annealing process was preformed, this was done for every two layers of QDs.
III Conclusion: Formation of a Si QDSL and Ge QDSL in the gate region results in a four-state inverter. QD-NVRAMs have been experimentally demonstrated with a fast erase/write time [5]. The integration of QDG-FETs with QD-NVRAMs has been envisioned [6]. Finally, Moore's law is prolonged by using extra states exhibited in QDG-FETs.

Synthesis, Properties and Applications of MXenes Beyond $Ti_3C_2T_x$ Yury Gogotsi and Christopher E. Shuck; Drexel University, United States

MXenes are potentially the largest class of 2D materials discovered so far. With a general formula of $M_{n+1}X_nT_x$, M is an early transition metal (Ti, V, Nb, Ta, etc.), X is C and/or N, T_x represents the surface groups (-O, -OH, -F, -Cl), and n = 1–4, over 30 stoichiometric phases have already been discovered, with many more predicted computationally. MXenes have been widely studied owing to their exceptional properties, including hydrophilicity, scalability, mechanical strength, thermal stability, redox capability, and ease of processing. While the majority of research has focused on $Ti_3C_2T_x$, each MXene composition has its own unique optical, electrical, and mechanical properties. The incorporation of two metals into MXenes further imparts novel properties, and stabilized structures that cannot be formed otherwise. For ordered double transition metal MXenes, this allows for the incorporation of elements such as Cr, giving these MXenes unique magnetic properties. One other important class of MXenes are solid-solution MXenes, where multiple elements are randomly distributed within the M layers. These MXenes exhibit tunable properties that are directly related to their chemistry, whether optical, electronic or electrochemical. Moreover, solid-solution MXenes allow for the synthesis of MXenes with unique structures, such as $M_5X_4T_x$. By studying these, and other MXenes, it allows us to understand why MXenes have the properties they do, allowing us to rationally produce MXenes with desired properties.

11:00 AM *NM04.01.02
Two-Dimensional Transition Metal Carbo-Chalcogenide "TMCC" Bridging the Gap Between MXene and TMDC Ahmad Majed[1], Manish Kothakonda[1], Fei Wang[1], Eric N. Tseng[2], Kaitlyn Prenger[1], Xiaodong Zhang[1], Per O. Persson[2], Jiang Wei[1], Jianwei Sun[1] and Michael Naguib[1]; [1]Tulane University, United States; [2]Linköping University, Sweden

A new two-dimensional (2D) materials family of transition metal carbo-chalcogenides (TMCCs) can be considered as a merge between two well-known families of 2D materials: MXenes and transition metal dichalcogenides (TMDCs), at the atomic scale. In this presentation, we will report on the synthesis, characterization, and properties of 2D Nb_2S_2C and Ta_2S_2C which are the first two members of TMCCs. Both are delaminated from their parent multilayered counterpart via electrochemical lithiation followed by liquid exfoliation in water. Electronic and magnetic properties of Nb_2S_2C multilayers were studied, a superconductivity transition is observed at 7.55 K. The effect of delamination on the electrochemical performance of Nb_2S_2C as electrode materials for Li-ion batteries was examined, and the delaminated Nb_2S_2C was found to surpass both multilayered Nb_2S_2C and delaminated NbS_2 in terms of capacity and stability. In addition, Ab initio calculations predicted elastic constant of TMCCs to be 50% higher than that of TMDCs.

Anhydrous Etching of MAX Phases for Faster and More Efficient Synthesis of MXenes Taegon Oh[1], Seungjun Lee[1,2] and Chong Min Koo[3]; [1]Korea Institute of Science and Technology, Korea (the Republic of); [2]Korea University, Korea (the Republic of); [3]Sungkyunkwan University, Korea (the Republic of)

Anhydrous synthesis of MXene facilitates the control over the surface functionalization and the final physicochemical properties. Here, we propose a novel anhydrous etching solution, consisting of high-boiling-point dimethylsulfoxide as organic medium, NH_4HF_2 as etchant, CH_3SO_3H as acid, and NH_4PF_6 as intercalant. This anhydrous solution does not only enable one to increase the reaction temperature up to 100 °C for accelerating the etching and delamination of Ti_3AlC_2 MAX crystals, but also suppresses the destructive side reaction of the produced $Ti_3C_2T_x$ MXene flakes. Consequently, the etching reaction is completed in 4 h at 100 °C and produces high-quality monolayer $Ti_3C_2T_x$ MXene with an electrical conductivity of 8,200 S cm^{-1} and a yield of over 70%. The synthesized $Ti_3C_2T_x$ exhibits more F-terminations than conventional aqueous $Ti_3C_2T_x$. The atypical surface structure of $Ti_3C_2T_x$ MXene leads to an exceptionally high ultimate tensile strength (167 ± 8 MPa), which is about 5 times larger than the ones synthesized in aqueous HF solution (31.7 ± 7.8 MPa).

SESSION NM04.02: MXenes Synthesis and Structure II

1:30 PM +NM04.02.01
Quat Derived Nanomaterials and Their Properties Michel W. Barsoum; Drexel Univ, United States

One- (1D) and two-dimensional (2D) materials offer advantages that their 3D counterparts do not. To produce such materials in *bulk* there are two conventional approaches: bottom-up and top-down. MXenes are an excellent example of the latter. The main drawback of this approach is high cost in first making the layered solid and then the many steps needed to etch and delaminate them. The bottom-up approach is in principle much more scalable. There are several bottom-up approaches, the one of interest here is the sol-gel approach common in the processing of ceramic powders, especially oxides of Ti and Si. The man disadvantages of this approach are the need to rely on the solubility of the precursor salt or compound in water and the need for a calcination and/or hydrothermal step that is usually needed to crystallize the products made at lower temperatures. In trying to etch the MAX phases without HF, we stumbled on a very powerful method to make 1D and 2D materials. The general idea is to dissolve inexpensive, non-water soluble, precursors in quaternary ammonium cation salts, or quats, at temperatures < 100 °C under ambient pressures for a few days. The aim of this talk is to describe the resulting materials and some of their properties in two systems: Ti and Mn. In the former, we converted 10 binary and ternary titanium carbides, nitrides, borides, phosphides, and silicides into anatase-based, 1D sub-nano filaments ≈ 6x10 Å in cross-section that self-assemble into 2D flakes

by immersing them in a tetramethylammonium hydroxide, TMAH, solution at temperatures in the 50 to 85 °C range. The 2D flakes are quite well-ordered in the stacking direction. In some cases, the conversion is 100 % precluding the need for centrifuges, filters, etc. We currently routinely make 100 g batches in a lab setting. In some cases, we also make mesoscopic powders. Electrodes made from some of filtered films performed well in lithium-ion and lithium-sulphur systems. These materials also biocompatible and reduce the viability of cancer cells thus showing potential in biomedical applications. In the Mn-case, five water-insoluble Mn-bearing precursors, viz. Mn_3O_4, Mn_2O_3, MnB, Mn_5SiB_2, and Mn_2AlB_2, were converted to birnessite 2D MnO_2 flakes, that are remarkably crystalline. Here again, the precursor powders are immersed in 25 wt. % TMAH aqueous solutions at 50 °C to 80 °C, for 4 to 2 days, respectively. The 2D sheets demonstrate reversible O_2 electrocatalysis with activities comparable to those of a commercial Pt/C catalyst. Synthesizing 1D and 2D materials in bulk, at near ambient conditions, starting with non-layered precursors (e.g., TiC, Mn_3O_4) could usher a new age where 1D and 2D materials can be mass produced inexpensively using earth abundant elements and a green process.

2:00 PM NM04.02.02
Synthesis and Characterization of 2D MoN Crystals and the Effects of Process Parameters Omer R. Caylan, Elif Okay, Derya Karadeniz and Goknur Cambaz Buke; Tobb University of Economics and Technology, Turkey

Molybdenum Nitride (MoN), hardest superconducting material is estimated to have a critical superconducting temperature of 16 K. Although that these properties attract the attention of many researchers, there are limited studies investigating the effects of process parameters of chemical vapor deposition synthesis of MoN crystals. The melt catalyst method in which a catalyst (Cu or In) is placed on top of a metal foil (Mo) and after reaching the melting temperature of the catalyst, synthesis gasses (CH4, NH3) are supplied to produce 2D Mxene materials such as Mo2C and MoN. This method is advantageous to produce large area 2D crystals with reduced defects and once the process is optimized, the reproducibility and reliability of the method is makes it perfect for advanced electronic applications. We studied the effects of process parameters (effect of catalyst, catalyst thickness, catalyst type, reaction temperature, growth duration, gas amounts) on the growth of 2D MoN crystals and discussed the results. SEM, EDS and OM studies are used to investigate the morphology of these crystals and to further understand the structure of the produced crystals Raman spectroscopy, XPS, TEM and XRD studies are used. We also showed that it is possible to synthesize Molybdenum CarboNitride structures by treating previously synthesized Mo2C crystals with ammonia gas. This is the first study that investigates the transition of priorly synthesized Mo2C crystals to MoCN and MoN. Depending on the ammonia exposure duration, Mo2C crystals can be replaced by MoN crystals completely. For future work, it is aimed to find the corelation between superconducting transition temperature with the different nitriding durations. This study is based on work supported by the Air Force Office of Scientific Research under Award Number FA9550-19-1-7048.

2:15 PM NM04.02.03
Large Flakes of $Ti_3C_2T_x$ MXene Mikhail Shekhirev[1], Jeffrey Busa[1], Christopher E. Shuck[1], Angel Torres[2], Saman Bagheri[2], Alexander Sinitskii[2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]University of Nebraska–Lincoln, United States

The size of individual flakes is critical for 2D materials and their devices. For materials produced *via* a top-down approach, such as graphene oxide produced from graphite, every step of the synthesis process, including the particle size of the precursor and the exfoliation protocol, affects the size of the resultant material. The size, in turn, affects the properties of assembled films and fibers, and the synthesis of ultra-large flakes has been a target for multiple dedicated studies.
Titanium carbide MXene ($Ti_3C_2T_x$) is one example of 2D material produced *via* a top-down approach by selectively etching Al from the parent Ti_3AlC_2 phase, followed by delamination of the multilayer material into individual flakes. $Ti_3C_2T_x$ has found promise in multiple applications, including energy storage, flexible electronics, and membranes, where the size of the flakes is an important parameter, and the increased average size can be beneficial. In this work, we will discuss the factors affecting the lateral size of MXene and ways to synthesize ultra-large individual flakes. Starting with the synthesis of the MAX precursor, etching, and delamination, each step of the process affects the resulting flake size. In particular, the delamination process is critical and must be controlled to achieve large individual flakes of MXene. We will demonstrate a new soft delamination protocol, which preserves the size of the flakes and provides an approach to fabricating individual flakes of up to 40 μm in lateral size.

2:30 PM *NM04.02.04
Two-Dimensional Materials from Selective Etching—MXenes and Beyond Johanna Rosen; Linkoping University, Sweden

Formidable efforts are invested world-wide on two-dimensional (2D) materials research. Most 2D materials are based on van der Waals crystals, that can be mechanically exfoliated (*cf.* graphene). The primary exception, two-dimensional metal carbides and nitrides (MXene), is produced by chemical exfoliation, i.e. selective etching of recurring layers in 3D layered precursor solids. The first MXene, Ti_3C_2, was first reported in 2011, and since then the family has increased drastically, to also include members with in-plane and out-of-plane ordering of metal atoms, and high entropy metal configurations. Synthesis of new MAX phases designed as precursors for specific MXenes have been crucial for this development, being inspired from exploratory theoretical predictions in uncharted structural and compositional space. The present talk will briefly summarize our work in this area, and show some light on how MXene development can serve as inspiration for selective etching of other layered solids. One such example is a new type of chemically ordered, quaternary metal borides, that can be chemically exfoliated into 2D sheets, and selectively prepared in multilayer form, as delaminated single-layer sheets in colloidal suspension, or as additive-free filtered films, for property evaluation. Furthermore, future two-dimensional materials from selective etching will be discussed, looking beyond MXenes and 2D materials derived from metal borides. Based on the vast library of layered solids, new families of 2D materials are expected through an interplay of computationally driven atomistic design and development of new chemical exfoliation pathways.

3:30 PM NM04.02.05
Direct Synthesis and Chemical Vapor Deposition of Vertically Aligned MXene Di Wang[1], Chenkun Zhou[1], Alexander Filatov[1], Wooje Cho[1], Francisco Lagunas[2], Mingzhan Wang[1], Chong Liu[1], Robert F. Klie[2] and Dmitri V. Talapin[1]; [1]University of Chicago, United States; [2]University of Illinois at Chicago, United States

MXenes are attracting ever growing attention for applications in energy storage, electromagnetic interference (EMI) shielding, superconductivity, and catalysis. Traditional preparation of MXenes involves high-temperature synthesis the MAX phase followed by its chemical etching and exfoliation. This synthetic route has high energy consumption, and uses large amounts of hazardous HF or Lewis acidic molten salts. The development of fast, facile, and atom-economic synthetic methods would greatly facilitate widespread practical applications of the rapidly developing family of functional MXenes. An ideal approach would involve direct interconversion of inexpensive precursors into MXenes bypassing intermediate MAX phases.
Here we report direct synthesis of Ti_2CCl_2 MXene via novel chemical reactions. The reactions are easily scalable, inexpensive, energy efficient, and more environmentally friendly compared to the traditional route. The directly synthesized MXene also showed excellent energy storage capacity for Li-ion intercalation. Besides convenience and scalability, the direct synthesis route offers new synthetic modalities not compatible with traditional MAX phase etching methods. Thus, we demonstrated chemical vapor deposition (CVD) synthesis of Ti_2CCl_2, Ti_2NCl_2, Zr_2CCl_2, and Zr_2CBr_2 MXenes, producing

carpets of MXene sheets oriented perpendicular to substrate. Such orientation makes MXene surface easily accessible for ion intercalation and exposes catalytically active edge sites.
Overall, direct synthesis and CVD of MXenes opens up new options in making previously unrealized MXenes and fabricating MXene devices. The development of vapor phase synthesis further expands the capabilities for integration of 2D MXenes into electronic and optoelectronic devices, including cross-platform integration with silicon microelectronics.

3:45 PM *NM04.02.06
Highly Conductive MXene with Improved Environmental Stability for Electronics Shun Sakaida, Akari Seko, Masashi Koyanagi and Takeshi Torita; Murata Manufacturing Co., Ltd., Japan

With growing interest in two-dimensional (2-D) materials group and their outstanding properties, considerable attention has been paid to a family of 2-D transition metal carbides (MXene). Herein we summarize our recent works on electrically conductive MXene, especially for $Ti_3C_2T_x$ in thin-film state at humid conditions. Our scale-up production system provides high quality crystalline MXene flakes to exhibit remarkable electrical conductivity as high as 18000 S/cm at 5 μm thickness. Several techniques were successfully used to monitor the stability of MXene dispersion and the fabricated films. X-ray crystallographic studies indicated that the interlayer spacing change by water uptake has a significant effect on the conductivity, and therefore further investigation to prevent degradation are highly required for applications under humid condition at high temperature.

4:15 PM *NM04.02.07
Formation and Characterization of 2D Mo_2C Crystals *via* Biased CVD Omer R. Caylan[1], Furkan Turker[1,2], Omer Tarik Ogurtani[3] and Goknur Cambaz Buke[1,2]; [1]TOBB ETU, Turkey; [2]The Pennsylvania State University, United States; [3]Middle East Technical University, Turkey

2D ultrathin transition-metal carbides (TMCs), nitrides (TMNs), and carbonitrides are a family of important functional nanomaterials for various applications due to their properties that are directly dependent on the structure of the crystals, which can be controlled by processing. MXenes formed by wet etching which may consist of defects and surface functional groups (due to the use of acids) are especially useful for applications like composites, energy storage; however, for advanced electronics it is necessary to develop a versatile technique to produce high quality MXenes with controlled thickness, area, and high reproducibility.

Biased CVD is a promising technique to produce large area MXenes. In Biased CVD, a stack of metal substrate (e.g. Mo and Cu) is exposed to a volatile precursor (e.g., CH_4) which decomposes on the substrate surface (e.g., Cu) and reacts with the Metal (e.g., Mo) that is biased towards the surface to produce the desired deposit (e.g., Mo_2C). It is called biased because the catalyst layer (Cu) is used like a diode: Cu lets Mo atoms to diffuse through Cu to the surface but does not let carbon atoms to diffuse through Cu (due to the difference in solubilities). Hence the diffusion is simply called biased.

Studies in literature showed that the morphology and the thickness of Mo_2C crystals are strongly affected by catalyst type, thickness, composition, and the simultaneous graphene growth during CVD. To produce controlled morphology (thin, large area, high quality MXene crystals), the understanding of the growth mechanism via biasing reaction is crucial. However, it is still not clear and reproducible control of thickness and morphology is still a problem. Although it is revealed that simultaneous graphene growth affects the morphology and the thickness of Mo_2C crystals; there are conflicts in literature and the effect of its presence on the Mo_2C formation is not well understood. Moreover, fundamental physico-chemical and kinetic parameters related to the bulk and surface diffusion (associated with graphene, M and X) are missing in the literature and there is lack of data on the nucleation and growth kinetics of MXenes for physico/chemical modelling.

In this presentation, we present an investigation on the controlled growth of thin Mo2C crystals on both Cu and In substrates *via* CVD using CH4. SEM, EDS, Raman spectroscopy, XPS, and XRD studies show that hexagonal Mo2C crystals, which are orthorhombic, grow along the [100] direction together with graphene and an amorphous carbon thin film on Cu and In, respectively. The growth mechanism is examined and discussed in detail, and a model is proposed. AFM studies agree well with the proposed model.

This material is based on the work supported by the Air Force Office of Scientific Research (Award number: FA9550-19-1-7048).

NM04.03.01
New Methods of Functionalizing Organic Molecules onto 2D Ti_3C_2 MXene Surfaces Alicia Tripp and Robert J. Hamers; University of Wisconsin–Madison, United States

2D transition metal carbides, nitrides, and carbonitrides (MXenes) have unique and tunable physical, chemical, and mechanical properties that drive their application in chemical sensing, energy storage, and water purification. Among these properties, the excellent dispersion of Ti_3C_2 MXene in water remains one the most important for applications that require solution processibility. However, MXene susceptibility to oxidation in aqueous environments remains a challenge for suspension storage and environmental applications. While there are many computational works that predict property changes for MXenes with altered surface chemistry, successful and controlled experimental manipulation of MXene surfaces remains challenging. This work investigates new methods of controlled MXene surface functionalization that take advantage of the material's intrinsic -OH and -O surface terminations. These methods are based on past group work involving the formation of organic molecular monolayers on metal oxides with hydroxylated surfaces. The organic molecules were bound to the metal oxide surface through alkoxy bonds, and the monolayers were found to be stable in aqueous environments. Current work utilizes X-ray photoelectron spectroscopy and Fourier-transform infrared spectroscopy to elucidate the intrinsic and altered surface chemistry of lab synthesized 2D Ti_3C_2 MXene. This work is important for the development of a simple and controlled functionalization method for MXenes with the potential to bind a wide variety of molecules to the surface.

NM04.03.02
Ultrathin, Single Crystal Tungsten Carbide Phases via Liquid-Metal-Assisted Chemical Vapor Deposition—Controlled Synthesis and Superconducting Transitions Alexander J. Sredenschek, David Sanchez, Jiayang Wang, Da Zhou, Susan B. Sinnott, Mauricio Terrones, Morteza Kayyalha and Le Yi; The Pennsylvania State University, United States

The transition metal carbide (TMC) family, historically studied as refractory metals for chemical and mechanical applications, is receiving increasing attention in the ultrathin limit. The study of TMCs has been extended to this limit first with the isolation of MXenes, atomically-thin layers of TMCs bound by interlayer van der Waals (vdW) forces;[1] and second with the development of a liquid-metal-assisted chemical vapor deposition (LMCVD) approach to produce nonlayered, ultrathin TMC (UThTMC) crystals with tunable lateral size (1-10 μm) and controllable thickness (less than 100 nm).[2] MXenes are typically produced as high yield, textured powders, while UThTMCs are high quality, single crystal platelets, ideal for electronic transport studies. Tungsten carbides have received little attention in the ultrathin limit, never isolated in the MXene family due to the lack of proper tungsten precursors. LMCVD, then, is an alternative method to produce ultrathin tungsten carbides as demonstrated in two studies.[3,4] These LMCVD studies typically produce one carbide phase, and to promote the study of novel UThTMCs phases, we probe the growth parameters to determine whether different tungsten carbide phases can be isolated. In this work, we use LMCVD to synthesize WC and W_2C phases via copper/tungsten (Cu-W) and gallium/tungsten (Ga-W) substrates, respectively. Moreover, we perform detailed structural and transport property characterization to understand the carbide phase-dependent transport properties in these ultrathin crystals.

In our LMCVD approach, we use two substrates, Cu-W and Ga-W, and tune remaining growth parameters to form tungsten carbide nanoplatelets. Scanning electron microscopy reveals differences in the carbide morphology, with triangular and hexagonal crystalline platelets formed on Cu-W and Ga-W, respectively. Moreover, we find that these crystals are ultrathin *via* atomic force microscopy measurements. To determine the crystal structure of these platelets, we carry out selected area electron diffraction, X-ray diffraction, and planar and cross-sectional transmission electron microscopy, and we find that the tungsten carbide is isolated in two phases with high crystallinity: WC (P-6m2) on Cu-W, and W_2C (Pbcn, $P6_3$/mmc, or P-3m1) on Ga-W, corroborated with first principles density functional theory calculations of the tungsten carbide equation of state. We also measure the superconducting transition temperatures and critical fields of both tungsten carbide phases.

Our work highlights some of the challenges inherent to the phase and polymorph identification of UThTMCs. While we can distinguish between WC and W_2C phases, further studies are required to determine the W_2C polymorph in the Ga-W system, and we conclude that we have one or more of the Pbcn, $P6_3$/mmc, and P-3m1 polymorphs. Our results suggest that proper choice of substrate in LMCVD can lead to novel, single crystal UThTMCs, and these carbide phases require careful structural characterization to identify accurately.

The Synthesis and Characterization of Mo_2CT_x Mxene by Hydrothermal Etching with Different Fluoride Salts for EMI Shielding Applications Elif Okay[1], Omer R. Caylan[1,2], Eren Atli[1], Begum B. Incecik[1,3] and Goknur Cambaz Buke[1]; [1]TOBB University of Economics and Technology, Turkey; [2]Bilkent University, Turkey; [3]Roketsan Missiles Industries Inc., Turkey

MXenes are the novel two-dimensional metal carbides or nitrides derived from their MAX phases. Recently discovered Mxenes, attracted the attention of many researchers and widely studied for the applications of energy storage, catalysis, gas sensing, wastewater treatment etc. More than twenty Mxenes have been successfully synthesized and Mo_2CT_x holds a great potential due to its theoretically predicted electrochemical, thermoelectric properties and chemical stability. Nonetheless, the long synthesis duration which can amount up to several days due to the strong bonding between the Mo-Ga atoms is challenging. In order to overcome this problem, scientist have used hydrothermal etching and lowered the duration drastically. Additionally, due to the hazardous nature of hydrofluoric acid, there have been studies on using HCl as etchant in hydrothermal conditions to increase the chemical potential between gallium and chloride ions which have proven successful. In this study, the hydrothermal etching of Mo_2Ga_2C to produce Mo_2CT_x using different fluoride salts with hydrochloric acid and only using hydrochloric acid is investigated and effects of different salts (LiF, BaF_2, MgF_2 and MnF_4) and no salt is discussed. The fluoride salts are mixed with hydrochloric acid to obtain in-situ hydrofluoric acid, and two different reaction temperatures for the hydrothermal etching process is studied (140 °C and 160 °C) for 24 hours (5-7 days for HCl). The synthesized Mxenes are characterized by; SEM and EDS for investigating morphology and chemical composition, and XRD for structural analysis. After studying the process parameters, such as temperature and etchant type on the synthesis of Mo_2CT_x powders, Mo_2CT_x powders are hand-mixed with epoxy resin with differing weight percentages to produce epoxy/Mo_2CT_x composites. Then these samples' electromagnetic interference shielding effectiveness performance is measured. The EMI Shielding properties of Mo_2C Mxene composite is reported for the first time in this study. EMI Shielding properties of the epoxy/Mxene composites are reported in accordance with "ASTM D4935 Standard Test Method for Measuring the Electromagnetic Shielding Effectiveness of Planar Materials" using a vector network analyzer in the frequency range of 1.5–10 GHz. This study is supported by Air Force Office of Scientific Research grant number FA9550-19-1-7048.

NM04.03.05
Kinetics and Mechanism of MXene Synthesis Mark Anayee, Christopher E. Shuck, Mikhail Shekhirev and Yury Gogotsi; Drexel University, United States

The family of 2D carbides and nitrides called MXenes has grown to encompass numerous structures and compositions. These materials have been explored in a variety of applications such as energy storage, wireless communication, optoelectronics, and medicine because of their high electrical conductivity, redox-active surfaces, plasmonic behavior and other attractive properties. MXenes are typically derived via topochemical etching of atomically thick layers from precursor layered MAX phases using aqueous corrosive etchants. Knowledge of the reaction mechanism and process kinetics are of fundamental importance for synthesis and property control of MXenes. Prediction of the optimal synthesis approaches will facilitate new MXene composition discovery and prediction of optimal processing time as a function of various parameters will also facilitate scaling up wet chemical synthesis of MXenes for industrial use. Despite their importance, such studies have been challenging because of the atomic thickness of the A-element layers being etched and the aggressive etchants that hinder in-situ studies. Herein, we explore various ex-situ techniques to probe the effect of critical etching parameters on the structure, chemistry, and properties of the resulting MXenes; as well as develop an in-situ analytical technique to quantitatively measure the etching kinetics through byproduct hydrogen gas collection and tracking; and finally develop an in-situ optical microscopy and profilometry technique to directly visualize the structural evolution during the etching reaction. Through these methods, we are able to derive empirical models for prediction of etching kinetics, and gain a fundamental understanding of how the etching reaction starts, proceeds, and finishes.

NM04.03.06
Strategies for Optimizing Etching and Delamination Toward High-Quality $Ti_3C_2T_x$ MXenes Annabelle Harding, Anupma Thakur, Karis Davidson, Nithin Chandran Balachandran Sajitha, Brian Wyatt and Babak Anasori; IUPUI, United States

MXenes, two-dimensional (2D) transition metal carbides, nitrides, or carbonitrides, are a rapidly growing family of nanomaterials that have potential uses ranging from energy storage, catalysis, and electromagnetic interference shielding to medical applications. To recognize these applications, it is known that etching and subsequent delamination play a vital role in the quality and scalability of MXenes. Here, we present the experimental strategies to synthesize the most studied MXene, $Ti_3C_2T_x$, using different precursor powder, etching conditions, and delamination methods. For etching, we compare different etchants, including hydrofluoric acid (HF)/hydrochloric acid (HCl) mix and HCl/lithium fluoride (LiF) mix, and conditions such as time and temperature. For delamination, we investigate the effect of time, temperature, and environment (air or argon) on the quality of the $Ti_3C_2T_x$ MXene. We analyze the resultant $Ti_3C_2T_x$ MXene using x-ray diffraction, scanning electron microscopy, and electrical conductivity to illustrate the relation between different synthesis methods on the quality of single-to-few layer MXene flakes of $Ti_3C_2T_x$. With this detailed synthesis study on etching and delamination methods, we suggest updated optimal parameters for the synthesis of high quality $Ti_3C_2T_x$ MXenes.

NM04.03.07
3D Assembly of 2D Molybdenum Carbide(Mo2C) Using Chemical Vapor Deposition Syam S. Ravuri, Sandeep Gorantla, Krzysztof Lis and Alicja Bachmatiuk; Sieci Badawczej Lukasiewicz PORT-Polish Center for Technology Development, Poland

Among the burgeoning of novel MXene materials, Molybdenum carbide stands out as they are successfully synthesized by conventional selective chemical etching and chemical vapour deposition growth methods. Molybdenum carbide (Mo2C) is garnering growing research attention due to their interesting chemical and electronic properties. Their properties make them a promising material for future electrochemical energy storage applications. In this work, we show the 3D self-assembly architectures of 2D Molybdenum carbide grown successfully using a chemical Vapor deposition for the first time, to the best of our knowledge. Our controllable CVD approach allows to engineer several aspects of the as grown Mo2C flakes, in particular their orientation of growth with respect to the surface of growth substrate. The as synthesized Mo2C was further investigated by X-ray diffractometry, Raman spectroscopy, scanning electron microscopy and aberration-corrected scanning transmission electron microscopy to gain understanding of the influence of growth conditions on their chemical and structural characteristics.

NM04.03.08
MXenes-Mining—A Decade with MXenes Yiannis Georgantas, Francis Moissinac, Mark A. Bissett and Sarah J. Haigh; University of Manchester, United Kingdom

MXenes is a family of transition metal carbides, nitrides or carbonitride materials that includes more than 20 different chemical compounds, that can be each synthesized with different methods and post-processed in multiple ways, enabling them to be used in a variety of applications. Consequentially, several thousand articles have been published that either mention MXenes or target them. Herein, we have gathered 15,116 articles since 2011, including the first publication about MXene, up to 31 December 2021 from 12 main scientific journal publishers (1. Cambridge University Press, 2. Elsevier (ScienceDirect), 3. Institute Of Physics Publishing (IOP), 4. John Wiley & Sons: Wiley Online (Wiley), 5. Nature Publishing Group (Nature), 6. Oxford Academic Press, 7. SAGE, 8. Springer, 9. Taylor & Francis, 10. American Association for the Advancement of Science (AAAS), 11. Royal Society of Chemistry (RSC) and 12. American Chemistry Society (ACS)). We visualize the results in a range of graphs and figures and try to find trends, correlations between them, but also to identify the gaps that this domain may have for future investigations. We probe the growth of MXenes through the year, statistical occurrence of keywords, MXenes' properties, cluster of applications, specific applications, synthesis methods, which MXenes have been investigated the most over the last decades, 3D architectures, theoretical against experimental articles and combinations of these areas. On one hand, it is obvious that the MXenes research community grows every year dramatically, but on the other hand the investigations are very limited towards specific aspects of this 2D family. Initially, the scientific body has related MXenes with the Ti_3C_2 and there is very little attention for the rest of the materials. Hence, the properties and the applications that are targeted are also limited and on the way that Ti_3C_2 can achieve high performance. There is the need to investigate MXenes further than the titanium carbides, to gain a more comprehensive knowledge for these 2DMs from their synthesis to in what applications can be used. In addition, the problems that occur from the HF-based synthesis also must addressed either with post-process of the MXenes or by using a different path to synthesize these extortionary 2DMs, such as alkali treatment, electrochemical-etching and molten salts; especially the last one, due to the homogeneous surface chemistry of MXenes which is the most crucial advantage and disadvantage of these materials at the moment.

NM04.03.09
Mussel-Inspired Interface Engineering of $Ti_3C_2T_x$ MXene for Practical Applications Gang San Lee and Sang Ouk Kim; Korea Advanced Institute of Science and Technology, Korea (the Republic of)

Two-dimensional (2D) MXene has shown enormous potential in scientific fields, including energy storage and electromagnetic interference (EMI) shielding. Unfortunately, MXene-based material structures generally suffer from mechanical fragility and vulnerability to oxidation. Herein, mussel-inspired dopamine successfully addresses those weaknesses by improving interface interaction and ordering in MXene assembled films. Dopamine undergoes *in situ* polymerization and binding at MXene flake surfaces by spontaneous interfacial charge transfer, yielding an ultrathin adhesive layer. Resultant nanocomposites with highly aligned tight layer structures achieve approximately seven times enhanced tensile strength with a simultaneous increase of elongation. The ambient stability of MXene films is also greatly improved by the effective screening of oxygen and moisture. Interestingly, angstrom thick polydopamine further promotes the innate high electrical conductivity and excellent EMI shielding properties of MXene films. This synergistic concurrent enhancement of physical properties proposes MXene/polydopamine hybrids as a general platform for MXene-based reliable applications. Furthermore, tight interfacial integration between MXene and polydopamine can be extended to MXene-based three-dimensional nanocomposite capacitive pressure sensor applications.

8:00 AM NM04.04.01

Observation of Chemical Short-Range Order, Lattice Distortion and Defect Structure in High-Entropy Transition Metal Carbides Xiangyu Zhu[1], Zijiao Wu[2], Qingxiao Wang[3], Yuan Wu[2], Xiongjun Liu[2], Hui Wang[2], Suihe Jiang[2], Zhaoping Lu[2] and Moon Kim[1]; [1]The University of Texas at Dallas, United States; [2]University of Science and Technology Beijing, China; [3]King Abdullah University of Science & Technology, Saudi Arabia

In recent years, multiple principal elements of two-dimensional transition metal carbides (MXenes) and its precursor high entropy (HE) MAX phase have been synthesized successfully. Mixing multiple transition metals opened a new ideology to explore the attainable chemistries and led to the discovery of new properties of the MAX & MXene family. It has been reported that HE MXenes show improved conductivity, charge storage capacity, and catalytic ability, as well as superior mechanical properties, as compared with single transition metal MAX. The unprecedented physicochemical properties were found to be closely related to short-range orderings, local lattice distortion, sluggish diffusion, and other features resulted from high configuration entropy.

This work aims to provide fundamental information on structural & chemical configurations at the atomic scale via the S/TEM characterization of HE MXene & MAX materials. The primary equipment used for characterization is JEOL ARM 200F and FEI Titan Themis 300, equipped with a spherical aberration corrector to achieve sub-angstrom imaging resolution and sub-nano spatial resolution. The STEM shows a hexagonal crystal structure of the MAX phase (space group P63/mmc, 194), and stress analysis indicates a strong correlation between lattice distortion and configurational entropy. The detailed chemical arrangement of multiple transition metals was revealed by atomic resolution EDS mapping while the HE MXene lattice and defect configuration was analyzed by Z-contrast (HAADF) images. The apparent atoms exhibit a stochastic arranged variation in brightness, revealing the randomly multiple principal atomic occupation. Our preliminary results offer a chance to garner in-depth understanding of the complex mechanism among multicomponent HE MAX & MXene materials.

Using Multiple M-Elements to Understand the Chemistry and Structure of MXenes Christopher E. Shuck, Marley Downes, Jonathan Shochat and Yury Gogotsi; Drexel University, United States

MXenes are potentially the largest class of 2D materials discovered so far. With a general formula of $M_{n+1}X_nT_x$, M is an early transition metal (Ti, V, Nb, Ta, etc.), X is C and/or N, T_x represents the surface groups (-O, -OH, -F, -Cl), and n = 1–4, over 30 stoichiometric phases have already been discovered, with many more predicted computationally. This class of materials has been widely studied owing to their exceptional properties, including hydrophilicity, scalability, mechanical strength, thermal stability, redox capability, and ease of processing. Because MXenes inherit their structure from MAX phase precursors, understanding MAX phase synthesis leads to control over flake size, defect density, and chemical composition of the resultant MXene. One understudied, yet important class of MXenes are solid-solution MXenes, where multiple elements are randomly distributed within the M layers. Herein, a set of multi-M chemistries (Mo, V, Ti, Nb) are used to study the effect of structure and chemistry on MXenes. While solid-solution MXenes have unique and tunable chemical, optical, and electronic properties, they also enable the formation of novel MXenes that cannot exist otherwise. By choosing specific chemistries, we can then begin to understand fundamental aspects of MXene chemistry and structure.

***In Situ* Transmission Electron Microscopy of MXenes** Per O. Persson; Linköping University, Sweden

Technical developments that have improved the optical performance in transmission electron microscopes have also enabled significant developments of in situ and in operando experiments under the electron beam. In the field of MXenes, in situ investigations have hitherto remained scarce, although there is much to learn about the interactions between MXene and ambient gas or liquid.
In the present talk, I will review state of the art technical possibilities and their boundary conditions. I will also review our efforts to understand the interactions between MXene, gas and vapor, and how results from these interactions help build an understanding for the stability of MXene and MXene terminations.

9:00 AM NM04.04.04
The Surface Science of MXenes Chenkun Zhou, Di Wang, Vladislav Kamysbayev and Dmitri V. Talapin; University of Chicago, United States

Two-dimensional (2D) transition-metal carbides and nitrides (MXenes) show impressive performance in applications, such as supercapacitors, batteries, electromagnetic interference shielding, or electrocatalysis. These materials combine the electronic and mechanical properties of 2D inorganic crystals with chemically modifiable surfaces, and surface-engineered MXenes represent an ideal platform for fundamental and applied studies of interfaces in 2D functional materials.
The comprehensive understanding of MXene surfaces will be required for prescriptive engineering of their physical and chemical properties. We discuss general strategies to install and remove surface groups by performing substitution and elimination reactions. Successful synthesis of MXenes with oxo-, imido-, thio-, seleno-, or telluro- terminations, as well as bare MXenes (no surface termination), and hybrid organic-inorganic MXenes are demonstrated. The description of MXene surface structure requires an intricate mix of concepts from the fields of coordination chemistry, self-assembled monolayers and surface science. MXene surface groups control biaxial lattice strain, phonon frequencies, electrochemical performance, the strength of electron-phonon coupling, making MXene surfaces not spectators but active contributors to conductivity, superconductivity and catalytic activity.

9:15 AM NM04.04.05
Hybrid Organic-Inorganic Two-Dimensional Metal Carbide MXenes with Amido- and Imido-Terminated Surfaces Chenkun Zhou[1], Di Wang[1], Francisco Lagunas[2], Benjamin Atterberry[3], Alexander Filatov[1], Aaron Rossini[3] and Dmitri V. Talapin[1]; [1]The University of Chicago, United States; [2]University of Illinois Chicago, United States; [3]Iowa State University, United States

Two-dimensional (2D) transition-metal carbides and nitrides (MXenes) show impressive performance in applications, such as supercapacitors, batteries, electromagnetic interference shielding, or electrocatalysis. These materials combine the electronic and mechanical properties of 2D inorganic crystals with chemically modifiable surfaces, and surface-engineered MXenes represent an ideal platform for fundamental and applied studies of interfaces in 2D functional materials. A natural step in structural engineering of MXene compounds is the development and understanding of MXenes with various organic functional groups covalently bound to inorganic 2D sheets. Such hybrid structures have the potential to unite the tailorability of organic molecules with the unique electronic properties of inorganic 2D solids.
Here, we introduce a new family of hybrid MXenes (*h*-MXenes) with amido- and imido-bonding between organic and inorganic parts. The description of *h*-MXene structure requires an intricate mix of concepts from the fields of coordination chemistry, self-assembled monolayers and surface science. The optical properties of *h*-MXenes reveal coherent coupling between the organic and inorganic components. *h*-MXenes also show superior stability against hydrolysis in aqueous solutions.

9:30 AM *NM04.04.06
Synthesis of New Types of MAX Phases as Precursors for Novel MXenes Rose Snyder[1] and Christina S. Birkel[1,2]; [1]Arizona State University, United

States; [2]Technische Universität Darmstadt, Germany

Transition metal-based carbides that belong to the family of MAX phases are an intriguing class of materials and have attracted a lot of attention as precursors for the relatively young class of 2D materials, the family of MXenes. Our group utilizes a diverse set of synthesis techniques to prepare new MAX phases as well as known ones with unique morphologies. Cr_2GaC in the shape of carbonaceous microwires, hollow and full microspheres as well as hitherto unknown carbonitride phases, such as $Cr_2GaC_{1-x}N_x$ and $V_2GaC_{1-x}N_x$, are a few examples of our recent works. We strive to exfoliate these compounds into the respective 2D structures to study their electrochemical properties. All products are structurally characterized by diffraction and electron microscopy techniques.

10:00 AM BREAK

10:30 AM NM04.04.07
$Ti_4C_{(3-y)}N_yT_x$: New 2D Carbonitride MXenes Derived from New 413 Carbonitride MAX Phases Anika Tabassum[1], Christopher E. Shuck[2], Kaitlyn Prenger[1], Ahmad Majed[1], Yury Gogotsi[2] and Michael Naguib[1]; [1]Tulane University, United States; [2]Drexel University, United States

Being a single member of carbonitride family, Ti_3CNT_x exhibited unique properties and behavior compared to its carbide counterpart in applications including energy storage, electromagnetic shielding, optics, sensing, etc. It had been the only carbonitride MXene for more than 10 years until we reported on $Ti_2C_{0.5}N_{0.5}T_x$ in 2021 which exhibited the highest specific capacity among all reported multilayer MXene electrodes. Previously, we have also shown that Ti_3CNT_x is an excellent electrocatalyst for hydrogen evolution reaction with an onset potential of 56 mV which is significantly lower than that of $Ti_3C_2T_x$. All of the reports of carbonitride MXenes support the hypothesis that replacing carbon partially with nitrogen in X cites can increase the number of electrons as well as active sites in MXenes. Hence, we focused on enriching the carbonitride MXene family with new members to gain a further understanding of the synthesis and property of carbonitrides. It is noteworthy to mention that synthesis of carbonitride MXene is challenging due to the lower stability of nitride MXenes compared to carbides and also the lower number of Carbonitride MAX Phases to start with. Herein, for the first time, we report on the synthesis of new four titanium carbonitride MXenes $Ti_4C_{(3-y)}N_yT_x$ (y = 2.2, 2.4, 2.6, and 2.8) derived from four new 413 MAX phases. By tuning the synthesis conditions using potassium fluoride and hydrochloric acid and changing various etching parameters we realized $Ti_4C_{(3-y)}N_yT_x$ MXenes from $Ti_4AlC_{(3-y)}N_yT_x$ (y = 2.2, 2.4, 2.6, and 2.8). MXene thin films were also achieved by delaminating the multilayers. The synthesis of $Ti_4C_{(3-y)}N_yT_x$ (y = 2.2, 2.4, 2.6, and 2.8) MXenes is unique because this is the first study of carbonitride MXenes' where carbon to nitrogen ratio has been modified systematically in X cites. Finally, we will present our new findings on their performances in electrochemical energy storage.

10:45 AM *NM04.04.08
Molten Salt Assisted Synthesis and Oxidation Kinetics of Water-Dispersible Ti3C2Tx and Nb2CTx MXene Nanosheets Micah Green, Kailash Arole, Jodie Lutkenhaus and Miladin Radovic; Texas A&M University, United States

Despite numerous prior reports of molten salt etching of MAX phases, there have been few successful reports of water-dispersible MXene nanosheets, and none for Nb-based MXenes. We recently demonstrated that molten salt etching can be used to create water-dispersible Ti3C2Tx nanosheets. Here we demonstrate the synthesis and aqueous dispersion of Nb2CTx nanosheets via molten salt etching by utilizing a KOH wash to add hydroxyl group to obtain water-dispersible Nb2CTx nanosheets. However, little is known about the oxidation of molten salt etched MXenes compared to acid-etched MXenes. Our results indicate slower oxidation kinetics for MXenes etched by molten salts, which may be due to the decreased amount of oxygen-containing terminal groups.

11:15 AM *NM04.04.10
Understanding Chemistry of 2D Transition Metal Carbides and Carbonitrides (MXenes) to Prolong Stability Vadym Mochalin; Missouri University of Science and Technology, United States

A large family of two-dimensional transition metal carbides and nitrides (MXenes) raises interest for many applications due to their high electrical conductivity, mechanical properties [1], potentially tunable electronic structure [2], nonlinear optical properties [3], and the ability to be manufactured in the thin film state [4]. However, their chemistry that is key to development of these applications, still remains poorly understood [5,6]. In this presentation we will discuss recent progress in understanding fundamental MXene chemistry and harnessing it for suppressing unwanted reactions and prolonging stability of these materials.
For example, suppressing oxidation and hydrolysis at high pH was demonstrated as an effective way to prolong shelf-life and stability of MXene aqueous colloids [7].
Other selected examples illustrating connections between understanding MXene chemistry and development of their applications will also be considered.

MXenes as Possible Solid Lubricants—Effects of Termination, Vacancies and Intercalated Water on the Resistance to Sliding and Oxidation of

Titanium-Based MXenes Edoardo Marquis, Michele Cutini, Francesca Benini and Maria Clelia Righi; University of Bologna, Italy

Understanding the interlayer interaction in two-dimensional (2D) transition metal carbides and nitrides (MXenes) is important to improve their exfoliation/delamination process and application in (nano)-tribology. The layer-substrate interaction is also essential in (nano)-tribology as effective solid lubricants should be resistant against peeling-off during rubbing. In our study, Ti-based MXenes with both homogeneous and mixed terminations are modeled using density functional theory (DFT). An *ad-hoc* modified dispersion correction scheme is used, capable of reproducing the results obtained from a higher level of theory. The nature of the interlayer interactions, comprising van der Waals, dipole-dipole, and hydrogen bonding, is discussed along with the effects of MXene sheet's thickness and C/N ratio. Our results demonstrate that terminations play a major role in regulating MXenes' interlayer and substrate adhesion to iron and iron oxide and, therefore, lubrication, which is also affected by an external load. Using graphene and MoS_2 as established references, we verify that MXenes' tribological performance as solid lubricants can be significantly improved by avoiding –OH and –F terminations, which can be done by controlling terminations via post-synthesis processing. Our study on the interaction of Ti-based MXenes with water molecules confirms their extremely high hydrophilicity. The presence of -OH groups and vacancies on the surface inevitably strengthens their interaction with water. The dissociative chemisorption of water is found to be a favorable process when it occurs on both MXene' edges and surface' vacancies cluster, leading to material degradation. Our results try to explain the mechanisms of the spontaneous oxidative degradation of MXenes under aqueous environment.
These results are part of the "Advancing Solid Interface and Lubricants by First Principles Material Design (SLIDE)" project that has received funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation program (Grant agreement No. 865633).

2:00 PM *NM04.05.03
Role of Heterogeneities on the Mechanical Strength and Deformation of 2D MXene Flakes—Insights from Atomistic Models and Simulations
Gabriel Plummer[1] and Garritt J. Tucker[2]; [1]NASA Ames Research Center, United States; [2]Colorado School of Mines, United States

The mechanical properties of MXenes are of crucial importance in a number of applications currently being studied, including electrochemical energy storage, flexible electronics, and structural composites. However, the difficulty of performing mechanical characterization experiments on 2D materials has limited the study of these important properties. Ab initio computational techniques have helped to fill in some knowledge gaps, but the length scale limitations of these methods preclude the study of more realistic MXenes containing heterogeneities such as point defects and surface terminations. Atomistic simulations, operating at larger length-scales, provide a solution, enabled by the recent development of a highly scalable bond-order interatomic potential for the titanium carbide MXenes. Large-scale simulations utilizing this potential can be used to study both in-plane and out-of-plane elastic properties as well as fracture behavior, crucially eliminating any system size effects. Results indicate a typical tradeoff between in-plane strength and out-of-plane flexibility depending on MXene structure and composition. The inclusion of surface vacancies has a deleterious effect on MXene mechanical properties, which may be unavoidable due to the harsh nature of MXene synthesis. However, via appropriate surface termination engineering, these effects can be mitigated and, in some cases, even overcome entirely. These newly gained insights at the atomic-scale should help inform synthesis and post-processing techniques seeking to produce mechanically superior MXenes.

2:30 PM BREAK

3:00 PM NM04.05.04
$Ti_3C_2T_x$ MXene—Silicon Carbide for High Temperature Applications Nithin Chandran B S[1,2], Kartik Nemani[1,3], Yooran Im[3], Ravi Kumar[2] and Babak Anasori[1,3]; [1]Purdue School of Engineering and Technology, Indiana University-Purdue University Indianapolis, United States; [2]Indian Institute of Technology Madras, India; [3]Indiana University-Purdue University Indianapolis, United States

2D transition metal carbides (MXenes) are promising as additives in ceramic systems due to their high temperature phase stability of their resulting carbides and in-plane stiffness. High temperature annealing studies on $Ti_3C_2T_x$ MXene have shown phase transformation to lamellar, non-stoichiometric cubic TiC_y. Silicon carbide (SiC) is known for the high hardness, high wear resistance and stability for a wide range of temperatures. However, the low fracture toughness limits monolithic SiC applications. A ceramic structure with layers of TiC can potentially improve the fracture toughness of SiC. In the present work, we investigated the tailorable preparation of green bodies of nanometer thin $Ti_3C_2T_x$ MXenes with SiC powders via electrostatic self-assembly, in a surfactant-free, scalable aqueous media. Because of negative surface charges (zeta potential of -35 to -50 mV) of MXene flakes, they can be mixed with SiC in pH ~ 5 and lead to a uniform self-assembly of $Ti_3C_2T_x$ and SiC, thereby eliminating the need for additional surfactants. Prepared green bodies are sintered by pressure-assisted pulsed current sintering. Addition of 2D MXene fillers into SiC system improves the densification and lowers the sintering time and temperature. The effect of temperature, dwell time and pressure on the densification of the green bodies are studied, which can provide insights on the role of MXenes in improving SiC mechanical properties and their stability.

3:15 PM NM04.05.05
US Army DEVCOM Soldier Center Technology Needs—Applied Research Opportunities for MXenes Joshua R. Uzarski; US Army DEVCOM Soldier Center, United States

The US Army DEVCOM Soldier Center is the Army's Warfighter-centric research facility. To continuously improve protection and effectiveness of our Soldiers, new technologies, particularly in advanced materials are needed. The MXene research community has continued to demonstrate the vast potential and feasibility of MXenes in accelerating the performance of many relevant technologies. Of particular interest to the Department of Defense community, and specifically at Soldier Center, are water filtration and remediation, portable power and energy generation and storage, sensors, environmental protection, and signature management. This presentation will focus on providing an overview of these critical needs areas, highlighting prior and on-going MXene research with direct relevance to the Soldier Center mission.

Ordered Double Transition Metal MAX Phases and Their Etching into MXenes—Synthesis and Electrochemical Studies Yaqoob Khan and Husnu E. Unalan; Middle East Technical University, Turkey

Ordered Double Transition Metal MXenes (DTMs) and their MAX phases are a more recent addition to the rapidly growing MXene family of 2D materials. The few reports published on the electrochemical charge storage properties of DTMs suggests that they perform much better than their mono metal counterparts. This is true for both ordered and solid solution DTMs. Despite the theoretical predictions on the stability of a number of double transition metal MAX phases, only a few have been synthesized and etched into their corresponding MXenes. In attempt to scale up the synthesis and processing of DTMs, we present the synthesis and structural studies of ordered $Mo_2Ti\ AlC_2$, Cr_2TiAlC_2, $Cr_2Ti_2AlC_3$ and solid solution Ti_2NbAlC_2 MAX phases and their etching into corresponding MXenes. In-situ high temperature XRD data collected on the admix of activated metal powders was used to optimize and model the MAX phase synthesis in high temperature tube furnace. Electrochemical studies such as CV, EIS and CCD of the DTMs compared with Ti_3C_2Tx will be presented and discussed.

Note: This abstract was submitted initially to the MRS-spring meeting but couldn't be presented due to late issuance of US visa to the author.

MXene Scrolls—A Vanadium Carbide (V_2C) Papyrus-Like Structure for Energy Applications Yiannis Georgantas, Francis Moissinac, Mark A. Bissett and Sarah J. Haigh; University of Manchester, United Kingdom

V_2C MXene theoretically has one of the highest energy capacitance properties compared to other MXenes and as a result there is big interest toward this area. Herein, we report one of the purest V_2C results without any impurities (V_2AlC, AlF_3, etc.) through "in-situ" HF synthesis at <60ºC (No need for autoclave) with high delamination rate and low oxidation level due to the self-assembling nanoscrolls of single and/or few flakes of V_2C during the post-synthesis procedure of the intercalation/delamination step with an organic solvent (e.g. quaternary ammonium salt: TMAOH, TPAOH, TBAOH). The morphology and structure of the V_2CT_Z MXene was characterized by X-ray diffraction, scanning/transmission electron microscopy, Raman spectroscopy, X-ray photoelectron spectroscopy and BET Surface Area Analysis. Furthermore, the papyrus-like V_2C structure capacitance properties are investigated by cyclic voltammetry, galvanostatic charge–discharge and electrical impedance spectroscopy.

NM04.06.03
Evaluation of Oxidation Processes in $Ti_3C_2T_x$ MXene Using *In Situ* Electrochemical Raman Spectroscopy Kateryna Shevchuk, John Wang and Yury Gogotsi; A.J. Drexel Nanomaterials Institute, United States

MXenes, a large family of two-dimensional materials, have attracted a lot of interest due to their large chemistry space and the diverse chemical, electrical, mechanical, and optical properties. In particular, MXenes' metallic conductivities and redox-active surfaces make them attractive for electrochemical energy storage. Recently, we demonstrated that partial oxidization of $Ti_3C_2T_x$ MXene led to enhanced pseudocapacitance in water-in-salt electrolyte by cycling the material at 1.2 V vs. Ag wire. However, there is a fine line between partial oxidation of $Ti_3C_2T_x$ MXene and complete oxidation that leads to the formation of titania and carbon. The extent of oxidation is difficult to measure with conventional X-ray and electron-based techniques. Raman spectroscopy has proven to be a powerful technique for detecting the degradation of $Ti_3C_2T_x$ MXenes. This work focuses on using *in situ* electrochemical Raman spectroscopy to analyze the oxidation processes in $Ti_3C_2T_x$ MXenes at a high anodic potential. The findings allow us to expand the knowledge of MXene electrochemistry and its degradation processes to achieve higher energy density in MXene-based energy storage devices.

NM04.06.04
Tuning the Nitrogen Reduction Reaction Activity of the Ti_2N Nitride MXene Through Modifying pH and Electrolyte Choice Denis Johnson and Abdoulaye Djire; Texas A&M University, United States

Electrochemical nitrogen reduction reaction (NRR) is used to convert atmospheric nitrogen (N_2) to ammonia (NH_3) at ambient conditions. In general, acidic electrolytes are used for NRR to provide protons (H^+) for the electrocatalytic reduction process. However, this leads to a low NH_3 selectivity due to the formation of the H_2 by-product via the hydrogen evolution reaction (HER). Recently, we showed that a Ti_2N MXene is active and selective for NRR in acidic electrolyte. We demonstrated that this new catalyst works through a Mars-van Krevelen (MvK) mechanism instead of the conventional associative/dissociative mechanisms. However, the effect of pH and electrolyte on the catalytic activity and selectivity was not well understood. Here, we investigate these effects by performing experiments in varying electrolytic conditions and pH values and develop relations between pH, electrolyte choice, and performance. The Ti_2N nitride MXene was synthesized via an oxygen-assisted molten salt fluoride etching technique and characterized through XRD, SEM, and FTIR spectroscopy. Our findings showed that changing pH does not affect the onset potentials for NRR, but does affect yield and selectivity. Alongside this, it was also found that pH changes the charge storage and HER performance of the material. It was found that as pH increases, selectivity towards NH_3 production increases due to the lower concentration of H^+ able to participate in the HER. Favorable NRR selectivity values were obtained in non-aqueous protic electrolytes, such as 2-picoline/trifluoro-acetic acid because of the suppression of HER. These findings are being expanded to other MXene materials to advance our knowledge of the reactivity of MXenes in NRR, and to design optimal electrolytic conditions for the production of NH_3 through NRR.

NM04.06.06
***In Situ* Conversion of V_2CT_x MXene in CS_2 Ambient to Boost Sodium-Ion Battery Anodes Performance** Gang Huang, Zahra Bayhan and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

Transition metal carbides and nitrides (MXenes) materials have distinctive properties that make them suitable for storing various mobile metal ions. For instance, MXenes have layered structures with large interlayer spacing, high electrical conductivity, and chemical diversity. However, MXenes lose

electrical conductivity and redox activity due to restacking of the layers. Additionally, the uncontrolled attachment of surface functional groups like O, OH, and F influence their pristine electrochemical characteristics.
It is possible to take advantage of the properties of MXene by deriving hybrid materials from MXene. We developed a facile but efficient method to convert V_2CT_x MXene into V_2S_3@C@V_2S_3 heterostructures within 1 minute. Our results indicated that hybrid materials synergistically improve the performance of NIBs by combining the advantages of individual 2D materials.
The synergistic effect is shown in this unique design by alleviating conductivity, structural degradation, and sluggish kinetics of V_2S_3. Whereas the carbon interlayer in the anode behaves like flexible conductive support and an anchoring network. Moreover, the ultrathin V_2S_3 nanosheets and the V_2S_3-C heterointerfaces enhance the Na^+ adsorption and migration abilities. As a result, this V_2S_3@C@V_2S_3 anode achieves a highly reversible capacity (628 mAh/g at 0.1 A/g) and excellent rate performance (477 mAh/g at 10A/g), and impressive cycling stability (2000 cycles at 20 A/g, record-high value). Considering the rich compositional diversity of MXene, the in-situ conversion strategy developed here can be extended to construct a wide range of high-performance electrode materials for advanced batteries.

NM04.06.07
Molecular Dipole Assisted Tuning of Work Function in $Ti_3C_2T_x$/n-Si and $Ti_3C_2T_x$/p-Sb_2Se_3 Heterojunctions Kunal J. Tiwari[1,2], Eloi R. Costals[2], Francesc Xavier[2], Axel Medaille[1,2], Sergio Giraldo[2], Marcel Placidi[2], Cristobal Voz[2], Joaquim Puigdollers[2], Edgardo Saucedo[2] and Zacharie Jehl Li Kao[2]; [1]Catalonia Institute of Energy Research, Spain; [2]Universitat Politècnica de Catalunya, Av. Eduard Maristany, 16, 08019 Barcelona, Spain., Spain

MXene-class materials have emerged as promising candidates in areas currently dominated by graphene, transition metal dichalcogenide (TMD) and related 2D materials, and hold several assets for applications to energy related fields including storage and conversion. Since the first report of $Ti_3C_2T_x$ synthesis in 2011 [1], this ever growing family of materials has garnered significant attention from the research community owing to their remarkably tunable physicochemical properties and ease for large area synthesis using low-cost methods. $Ti_3C_2T_x$ MXene has been utilized as a functional layer/additive in various opto-electronic devices such as solar cells, photodetectors etc. [2]. $Ti_3C_2T_x$ has particularly shown remarkably promising results when used as charge selective contacts in conventional c-Si and Perovskite solar cells [3]. The high conductivity, fully tunable work function, and thickness dependent transparency coupled with a high chemical stability make $Ti_3C_2T_x$ an ideal material to partner with Si and possibly other emerging chalcogenide thin film absorbers as a replacement of the standard p-n junction.
In the present work, we aim at investigating the interplay of a model MXene/c-Si interface with different organic molecular dipole interlayers in terms of carrier transport, carrier selectivity, and chemical compatibility. Initially, a screening of different organic dipoles is performed to identify the most suitable candidates out of PEDOT, PEI, PAMAM, APTES. Multilayer MXene is synthesized from the bulk Ti_3AlC_2 MAX phase through Minimum Intensive Layer Delamination (MILD) technique and 2D sheets are subsequently deposited by drop casting and spray coating on the n-Si/dipole stack. Optimization routes are investigated to tune the band alignment at the MXene/n-Si interface by using the self-assembled mono layers of different organic dipoles. An in-depth characterization of the as prepared MXene sheets by means of XPS, Raman Spectroscopy, AFM and other methods is presented to assess the chemical and structural properties of the heterojunctions, along with the complete electrical characterization of the MXene/n-Si Schottky diodes where the fundamental properties of the interface formed between the 2D charge selective contact and the 3D semiconductor are investigated. Additionally, optoelectronic properties of first proof of concept devices, both solar cells as well as photodetectors, are reported and the complete set of results is presented in regard to the state of the art. Finally, the use of MXene in combination with emerging Sb_2Se_3 photovoltaic absorbers is investigated using the c-Si as reference framework.

Industrial-Scale MXene-Contacted Silicon Heterojunction Solar Cells with >20% Power Conversion Efficiency Jehad K. El-Demellawi, Erkan Aydin, Stefaan De Wolf and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

Two-dimensional (2D) transition metal carbides (MXenes) are of great interest as electrode materials for a variety of applications, including photovoltaics (PV), thanks to their tunable optoelectronic properties, high metallic conductivity, and attractive solution-processability. However, thus far, MXene electrodes have only been exploited for small-scale solar cells with modest power conversion efficiencies (PCEs). Hence, herein, to unveil the potential of MXene electrodes at the industrial level, we implemented a scalable spray coating technique to deposit highly conductive (ca. 8000 S/cm) $Ti_3C_2T_x$ MXene films via an automated spray system. We successfully employed these $Ti_3C_2T_x$ films as rear electrodes for silicon heterojunction (SHJ) solar cells. The conformal alignment of the MXene flakes on the random pyramidal textured silicon wafers has provided an intimate contact with the underneath ITO, leading to >20% PCE over both small (4.2 cm^2) and large (243 cm^2, *i.e.*, using industry-sized 6-inch pseudo-square wafers) cell areas. Notably, the $Ti_3C_2T_x$-rear contacted devices have almost retained 99% of their initial PCE after 600+ days of ambient air storage. Their performance is comparable with state-of-the-art solar cells contacted with sputtered silver electrodes, offering a potential cost reduction for SHJ solar cells. Besides, such high-throughput fabrication of large-scale MXene-based devices brings this technology closer to industrial maturity.

NM04.06.09
A Moisture-Stable MXene-Based OLED for Free-Form Displays with Long-Term Stability So Yeong Jeong[1], Yonghee Lee[2], Yongmin Jeon[3] and Kyung C. Choi[1]; [1]Korea Advanced Institute of Science and Technology (KAIST), Korea (the Republic of); [2]National Nano Fab Center (NNFC), Korea (the Republic of); [3]Gachon University, Korea (the Republic of)

In current research on free-form displays to provide hyper-interconnection between users via e-textiles or e-skins, 2D Titanium Carbide MXene is emerging as an attractive material, specifically as an alternative electrode in flexible devices to brittle ITO and other transparent conducting polymers. MXenes provide high transparency, metallic conductivity, tunable work function, and solution-processability.[1–4] The use of MXene electrodes in OLED devices is expected to drive an exceptional technical advance in the display research field. OLED devices have demonstrated excellent compatibility with free-form displays, by virtue of their high flexibility, low power consumption and heat, light weight and nanometer-scale thickness. The synergetic effect of the MXene material and OLED devices offers a new paradigm in free-form displays. However, the low moisture-stability of the MXene OLED remains a major challenge. The Mxene electrode and organic constituent layers are easily oxidized under water or high humidity conditions. Therefore, a reasonable passivation system which can protect them from the moisture molecules is required. If it can be realized, the advanced development of matrix-form transparent MXene OLEDs which are capable of displaying complex information will follow.
In this work, we developed a highly moisture-stable MXene OLED by exploiting an encapsulation system that combines a water-resistant TiO_2 based nanolaminate layer/SiO_2-siloxane polymer/attachable PET. Despite the near-room temperature process (40°C), the TiO_2 based nanolaminate layer showed outstanding impermeability (WVTR on the order of 10^{-5} g $m^{-2}day^{-1}$) even with nanoscale thickness (30 nm) due to its low residual stress.[5] The SiO_2-

siloxane polymer contained compressive stress that could be used to offset the tensile residual stress of the TiO_2-based nanolaminate layer, reducing the total residual stress of the barrier to zero.[5,6] And then, to achieve not only physical scratch resistance but also water endurance, ultra-thin PET (30m) was attached to the top of the device. Using the encapsulation system, a highly stable MXene OLED was fabricated which exhibited a long life-time in ambient conditions (> 2,000 hours). In addition, the MXene OLED displayed a stable J-V-L (current density-voltage-luminance) curve after repetitive high curvature (1.000 times / 1.5 mm) folding deformation, and maintained 70% of its initial luminance after water immersion for 6 hours. In conclusion, the proposed development is expected to be applicable to deformable see-through displays in smart windows, automotive displays and augmented reality systems and provide a technical model that can advance MXene applications.

Probing Changes in the Electronic Structure of Ti_3C_2 MXene Sheets with Electron Energy-Loss Spectroscopy Asra Hassan[1,2], Josh Kennedy[1], Hilmar Koerner[1], Jinwoo Hwang[2] and David McComb[2]; [1]Air Force Research Laboratory, United States; [2]Ohio State University, United States

Layered metal carbides and nitrides (MXenes) are a rapidly expanding family of 2D material that have attracted substantial research interest due to their unique properties of hydrophilicity, good metallic conductivity, and structural diversity. Surface terminations are a natural consequence of the MXene synthesis, traditionally consisting of O, OH, and F. The location of these surface-terminating functional groups and/or their chemical nature play a crucial role on the overall MXene properties and affects their performance in different applications. Therefore, to better understand how MXenes properties are governed by their surface terminations, and to develop design strategies that are independent of surface composition, a detailed atomic resolution understanding of electronic structure of MXene is needed. In this contribution, we present fundamental studies aimed at understanding the role of surface functional groups on modifying the electronic structure and related optical properties of single and multilayer $Ti_3C_2T_2$ (T refers to surface termination group) MXene sheets using aberration-corrected STEM-EEL. This work furthers our understanding of MXene chemistry-property relationships and opens the door to termination-engineered MXenes.

NM04.06.11
Probing Photoexcited Free Carrier Dynamics of Two-Dimensional MXene, Nb_2C, Using Ultrafast Terahertz Spectroscopy Andrew M. Fitzgerald[1], Laura Londono[2], Javery Mann[1], Kiana Montazeri[3], Michel W. Barsoum[3] and Lyubov Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]Rhode Island College, United States; [3]Drexel University, United States

Discovered in 2013, 2D niobium carbide (Nb_2C) MXene has been shown to have many extraordinary properties, such as high photothermal conversion efficiency, strong electron-phonon interactions, strong optical absorption in the near-infrared, and even saturable optical absorption. These unique properties of Nb_2C render this MXene potentially useful for a variety of applications, including photonic and optoelectronic devices and even photothermal cancer therapy. Here, we employ both terahertz time-domain spectroscopy (TDS) and time-resolved terahertz spectroscopy (TRTS) to investigate intrinsic and photoinduced conductivity and dynamics of optically injected carriers with 1.55 eV and 3.1 eV excitations in order to understand the photoinduced processes taking place in Nb_2C. We find that the photoinduced conductivity in this MXene shows an initial rapid decay over a picosecond time scale, followed by a much longer-lived component that lasts for nanoseconds. We also observe that the long-range conductivity is strongly limited by the nanoflake boundaries. We explore the impact of post-synthesis treatments on the carrier lifetime and mobility with the goal of optimizing its optical response for applications in photocatalytic and optoelectronic devices. A. M. Fitzgerald acknowledges support by NSF NRT CEDAR Fellowship, Award Number 2021871.

NM04.06.12
Dynamics of Photoexcitation in Ti3C2Tz, Mo2Ti2C3Tz, and Nb2CTz 2D MXenes Erika Colin-Ulloa[1], Kiana Montazeri[2], Michel W. Barsoum[2] and Lyubov Titova[1]; [1]Worcester Polytechnic Institute, United States; [2]Drexel University, United States

MXenes are two-dimensional (2D) transition metal carbides, nitrides and carbonitrides with a general formula $M_{n+1}X_nT_z$, where M is a metal, X = C or N, and n = 1–3; T_z denotes surface terminations such as –OH, –O, and/or –F. Unlike most other 2D materials, MXenes are intrinsically metallic. They have a high density of states at the Fermi due to a large contribution from transition metal d-orbitals. Many of them also exhibit strong surface plasmon modes in the visible to infrared range. High conductivity, pronounced plasmonic properties and optical nonlinearities, high damage thresholds for exposure to high-intensity laser light suggest MXenes as a promising platform for optoelectronic devices and underscore the need to understand dynamics of photoexcitations in these materials.
We investigate the photoexcited carrier dynamics in three different MXenes, in $Ti_3C_2T_z$, $Mo_2Ti_2C_3T_z$, and Nb_2CT_z, using ultrafast transient optical absorption, which provides access to excited state dynamics and changes in the optical absorption the visible range. We find that absorption at the proposed plasmon peak is suppressed by the photoexcitation, with an absorption bleach recovery time increasing with increasing intrinsic free carrier density: recovery time is the fastest in Nb_2CT_z, and it is slower in $Mo_2Ti_2C_3T_z$ and in $Ti_3C_2T_z$.
Uncovering the exact mechanisms behind the observed rich palette of MXene optoelectronic properties and their relationship to MXene chemistry, structure, and morphology, will lay foundations for MXene-based and visible photonic devices.

NM04.06.15
EMI Shielding Mechanisms of Pristine MXene Films Roman Rakhmanov, Gennady Friedman and Yury Gogotsi; Drexel Unviersity, United States

The rapid development of Internet of Things (IOT) and new generations of telecommunication networks bring forward a demand for thin, lightweight shielding materials and microwave circuit components. MXenes, two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides, are a large family of 2D materials that are promising for use in EMI shielding, antennas, transmission lines, etc., owing to their high electrical conductivity. However, the underlying mechanisms are currently unknown. This work focuses on experimental and theoretical methods for extracting electromagnetic properties of MXene films in the microwave region. This, coupled with the variety of chemistries and structures available to MXenes gives rise to unprecedented tunability of their properties, creates the possibility to adjust MXenes for specific applications and provides a roadmap to their stable performance.

NM04.06.16
Development of TeNWs/MXene ($Ti_3C_2T_x$) Nanohybrid-Based Flexible Piezoresistive Pressure Sensor for Wireless Safety Communication Using

Morse Code Vivek Adepu, Manav Tathacharya, Raghuram CS and Parikshit Sahatiya; BITS-Pilani, Hyderabad Campus, India

Due to the growing need for personal safety applications for emergency communication purposes, two-dimensional (2D) and one-dimensional (1D) nanomaterials-based physical sensors have been actively examined for communication applications owing to their captivating properties such as tunable semiconducting properties, high electrical conductivity/mobility, etc.[1] The combination of Tellurium (Te) nanowires (NWs) and MXene (2D/1D nanohybrid) has not been explored as the active material in fabricating flexible, piezoresistive sensors which provide exciting electromechanical properties.[2], [3] In this perspective, 2D $Ti_3C_2T_X$ film was deposited on cellulose paper substrate followed by 1D Te NWs using the vacuum filtration method to fabricate the piezoresistive pressure sensor. The fabricated sensor was later encapsulated in polydimethylsiloxane (PDMS) and utilized as a wireless communication system button. The fabricated sensor displayed an admirable sensitivity of 6.032 kPa^{-1} (applied pressure ~1.477 – 3.185 kPa) and outstanding stability of ~2500 cycles. The underlying transduction mechanism of the TeNWs/ $Ti_3C_2T_X$ nanohybrid pressure sensor for enhancement in sensor current at the metal-semiconductor junction was explained by the increment of tunneling current upon applying external pressure owing to the decrement in an interlayer resistance of the 2D $Ti_3C_2T_X$ and tunneling distance between 1D Te NWs. Furthermore, an android application was developed to wirelessly receive data *via* Bluetooth from the fabricated piezoresistive sensors connected to a microcontroller. In addition, the application displayed the pattern based on the pressure load acting on the sensors as a Morse dash or dot. Also, it can be used similarly to a telegraph to send complex messages such as "HELP." The effective demonstration of a TeNWs/MXene nanohybrid-based flexible, low-cost and biodegradable physical sensor opens new avenues in wireless monitoring and communication applications.

Evaluating Cellular Stress and Phototoxicity of Photothermal Stimulation on Neurons Yingqiao Wang[1], Jane E. Hartung[2], Adam Goad[3], Michael S. Gold[2], Yury Gogotsi[3] and Tzahi Cohen-Karni[1]; [1]Carnegie Mellon University, United States; [2]University of Pittsburgh, United States; [3]Drexel University, United States

Photothermal modulation is a remote and non-genetic technique to control neural activities with high spatiotemporal resolution and cell-type specificity. During the modulation, the interface between photothermally active nanomaterial and neuron is illuminated with light pulses, leading to transient local temperature rise which will elicit an action potential. Recently, we demonstrated that two-dimensional nanoflake, $Ti_3C_2T_x$ (MXene), is an outstanding candidate for photothermal modulation of neural activity with low needed incident energy per pulse. However, the safety of $Ti_3C_2T_x$ flakes for neural modulation is unknown. Namely, cytotoxicity of $Ti_3C_2T_x$ flakes, phototoxicity, and hyperthermia damage. Here, we investigated the biosafety of $Ti_3C_2T_x$ flakes across multiple assays, including viability, cellular stress (mitochondria membrane potential), and oxidative stress to determine the safety threshold of photothermal modulation. We demonstrated that culturing neurons on a ca. 100 nm $Ti_3C_2T_x$ film and illuminating it with laser pulses (635 nm) with incident energy from 2 - 14 μJ per pulse and different pulse frequencies (1 pulse, 1 Hz, and 10 Hz pulses) neither reduced the cell viability nor generated cellular stress. The upper limit of this safety range is higher than the needed incident energy for neural excitation (< 10 μJ). However, applying laser pulses with high incident energy (e.g., 22 μJ per pulse) will result in irreversible damage. We further investigated the generation of reactive oxygen species (ROS) and revealed that culturing neurons on $Ti_3C_2T_x$ film will not induce ROS generation. The safety evaluation with multiple assays will guide the design of the operation parameters and protocols of photothermal modulation both *in vitro* and *in vivo*.

NM04.06.18

Solution-Processed 2D MXene/Silver Nanowire Transparent Conducting Electrode for Light-Emitting Diodes Bongjun Choi[1], Byoung Wan Lee[1], Sang Hyuk Im[2] and Youngseok Kim[1]; [1]Korea Electronics Technology Institute, Korea (the Republic of); [2]Korea University, Korea (the Republic of)

2D titanium carbide (Ti_3C_2) MXene is a suitable candidate as a transparent conducting electrode (TCE) for optoelectronic devices due to its high conductivity, high work function (~5.1eV), and decent optical transparency. Although MXene TCE with high conductivity is a promising electrode for optoelectronic devices, their eligibility as a TCE for displays is still challenging due to their high sheet resistance compared to conventional TCE such as indium tin oxide (ITO). To fabricate the highly conductive MXene TCE, well exfoliated two-dimensional MXene with a large flake size of MXene is essential. Herein, we synthesized 2D MXene through the minimally intensive layer delamination (MILD) method with an additional delamination process with Couette-Taylor reactor which can realize the well delaminated 2D MXene. Ascribed to the ultra exfoliated 2D MXene formation, the MXene TCE film which is achieved by simple solution processing showed high optical transparency and low sheet resistance of 75.8% at 550nm and 132.5ohm/sq. Furthermore, we introduced the 2D Mxene/Silver Nanowire (AgNW) hybrid TCE to enhance the conductivity further. The optimized hybrid TCE showed 72.6% optical transparency at 550nm and 18.03ohm/sq sheet resistance respectively which are 6.04 times improved values in terms of the figure of merit (FoM). In order to adapt MXene/AgNW hybrid TCE as a transparent bottom electrode for organic light-emitting diodes (OLEDs), we patterned hybrid TCE by using the photolithography process and lift-off technique. The hybrid TCE-based OLEDs exhibited clear red electroluminescence (EL) peak at 620nm. They showed a maximum external quantum efficiency (EQE), current efficiency (CE), and luminance of 5.25%, 5.25cd/A, and 7563cd/m^2 respectively. Furthermore, the hybrid TCE was readily formed on a flexible poly(ethylene terephthalate) (PET) substrate by using a solution process. The hybrid TCE gave rise to the enhancement of flexibility of OLEDs. These works demonstrate the potential of 2D MXene/AgNW TCE in flexible optoelectronic devices.

NM04.06.19

L-cys/AuNPs/Ti_3C_2-MXene Modified Thread Electrode for Non-Invasive Sweat Cortisol Sensor Thidarut Laochai[1], Jutiporn Yukird[2], Nadtinan Promphet[2], Jiaqian Qin[2], Orawon Chailapakul[1,3] and Nadnudda Rodthongkum[2,4]; [1]Chulalongkorn University, Thailand; [2]Metallurgy and Materials Science Research Institute, Thailand; [3]Electrochemistry and Optical Spectroscopy Center of Excellence (EOSCE), Thailand; [4]Center of Excellence in Responsive Wearable Materials, Thailand

Non-invasive electrochemical immunosensor is developed by fabricating L-cysteine/gold nanoparticle/titanium carbide (L-cys/AuNPs/Ti_3C_2-MXene) onto the thread electrode surface for the detection of sweat cortisol to indicate adrenal gland disorders. Herein, Ti_3C_2-MXene and AuNPs offer high surface area, high electrochemical conductivity and facilitate antibody immobilization leading to enhanced immunosensor sensitivity. The morphologies of MXene are characterized using transmission electron microscope (TEM) and the surface morphologies of the L-cys/AuNPs/Ti_3C_2-MXene modified thread are investigated by scanning electron microscope (SEM) coupled with energy dispersive X-ray spectroscopy (EDX). For the functionalization of antibodies, a direct conjugation between antibody and antigen is performed. Anti-cortisol antibodies are covalently immobilized onto L-cys/AuNPs/Ti_3C_2-MXene modified on thread-based electrode using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide and N-hydroxysulfosuccinimide coupling agents to enhance the sensor specificity. The electrochemical measurements are performed on a potentiostat using cyclic voltammetry (CV) and electrochemical impedance spectroscopy (EIS) for the electrode characterization and amperometry for determination of cortisol from the current change by using a solution of 5 mM

$[Fe(CN)_6]^{3-/4-}$ in 0.5 M KCl. The detection principle is based on the decrease of oxidation current towards the antigen-antibody binding interaction owing to blocking of electron transfer process by cortisol. This system offers two linear ranges from 5 to 40 ng/mL **(**R^2 = 0.9880**)** and from 40 to 180 ng/mL **(**R^2 = 0.9560**)** with a limit of detection (LOD) of 0.54 ng/mL with negligible effect from interferences. Furthermore, this immunosensor provides high specificity towards cortisol detection with high reproducibility, and long-term storage stability. Ultimately, this immunosensor is successfully applied for the detection of cortisol in artificial sweat with satisfactory results.

NM04.06.20
Patterned Titanium Carbide ($Ti_3C_2T_x$) MXene Electrode for Electrochemical Detection of Phosphates Shiseido Robinson, Thiba Nagaraja, Rajavel Krishnamoorthy and Suprem R. Das; Kansas State University, United States

The discovery of two-dimensional transition metal carbides and carbonitrides (*MXene*) has laid the foundation of layered materials for number of potential future applications. The material embodies countless desired properties such as hydrophilic surfaces, high electrical conductivity, large surface to volume ratio and efficient absorption of electromagnetic waves. The unique properties of these 2D layered *MXene* materials have been explored largely in energy storage devices and electromagnetic shielding applications for decades. More recently, the material has attracted enormous interest in the field of chemical and biomolecule sensing owing to its varied chemical structure and ease of functionalization for sensitive and selective detection of different analytes. Phosphorus in the form of phosphates is an essential nutrient for many biological, environmental and agricultural processes that often needs strict monitoring to avoid detrimental effects. However, the complex oxidation states of phosphate in various pH conditions and its interferences with many ions in natural waters and the human body have made it difficult to develop a reliable and accurate method of sensing. Hence, the development of low cost, highly sensitive sensor materials are imperative for the rapid detection of phosphates. In this study, we explored the large-scale exfoliation of the widely studied $Ti_3C_2T_x$ *MXene* materials by adopting minimally intensive layer delamination (MILD) etching route. Controlled chemical exfoliation conditions lead to selective removal of Al layer from Ti_3AlC_2 to form few layer *MXene* that are confirmed from structural and morphological conditions such as XRD, SEM, and AFM. The exfoliated $Ti_3C_2T_x$ was used as an active electrochemical sensing platform for detection of phosphate by exploiting the redox behavior of phosphate complexed with molybdenum. The sensing of phosphates in the presence of interfering ions indicated low detection limit and high sensitivity along with a large linear detection range with reliable performance. Such an application of 2D MXene could make it a potential candidate for future environmental monitoring and sensing.

Effects of Synthesis Conditions on the Properties of MXenes Emre Kayali[1], Brian Wyatt[2], Babak Anasori[2] and Majid Beidaghi[1]; [1]Auburn University, United States; [2]Indiana University−Purdue University Indianapolis, United States

Recent research on the synthesis of MXene shows a strong dependence of MXene properties on the synthesis conditions. MXenes are synthesized by selective etching of A-layer atoms from the structures of MAX phases. So far, several etching processes have been introduced, and recent reports show that the morphology of the synthesized MXenes, their size, their surface chemistry, and the amount and the type of various defects in their structures depend on their synthesis conditions. Therefore, synthesis conditions inevitably control the physical and chemical properties of MXenes, and understanding these processing-structure-property relationships may lead to innovative new ways to tune the properties of MXenes for a variety of applications. This talk will first provide a short review of the effects of synthesis methods and conditions on the structure and morphology of MXenes. Then, some of our recent work on tuning various properties of MXenes by changing synthesis conditions will be discussed. In particular, the effects of etching parameters on the electrical, electrochemical, and mechanical properties of the various MXenes will be presented.

9:00 AM NM04.07.02
High-Performance V_2C MXene/Bilayered V_2O_5 Asymmetric Aqueous Supercapacitors Mohit Saraf, Teng Zhang, Timofey Averianov, Armin VahidMohammadi, Ekaterina Pomerantseva and Yury Gogotsi; Drexel University, United States

Two-dimensional transition metal carbides and nitrides (MXenes) have shown great potential in electrochemical energy storage applications. Their high electrical conductivity coupled with surface redox reactions make them suitable candidates for high-rate pseudocapacitive energy storage. However, MXene supercapacitors often exhibit a limited voltage at higher anodic potentials due to possible oxidation. One of the possible strategies to expand their voltage is by pairing them with suitable candidates such as oxides to design asymmetric supercapacitors. Among them, lithium intercalated bilayered V_2O_5 (Li-V_2O_5) is one of the promising candidates thanks to its high capacity and improved structural stability. In this study, we have explored free-standing films of lithium intercalated V_2C MXene (Li-V_2C) as negative electrode with Li-V_2O_5-CNT as positive electrode in aqueous LiCl electrolyte. This results in an electrochemically stable 2 V supercapacitor with high energy density and good cycling stability. The work highlights that MXenes, beyond Ti_3C_2, have great possibilities in electrochemical energy storage applications.

9:15 AM NM04.07.03
Understanding the Effects of Transition Metal Intercalation on Electronic and Electrochemical Properties of $Ti_3C_2T_x$ MXene Shianlin Wee[1], Evgeniya Vorobyeva[1], Netanel Shpigel[2], Dario Gomez Vazquez[1], Fabio La Mattina[3], Akhil Tayal[4], Erik Mayr[1,3], Inge K. Herrmann[1,3] and Maria Lukatskaya[1]; [1]ETH Zurich, Switzerland; [2]The Hebrew University of Jerusalem, Israel; [3]Empa - Swiss Federal Laboratories for Materials Science and Technology, Switzerland; [4]Deutsches Elektronen-Synchrotron DESY, Germany

MXenes are two-dimensional (2D) transition metal carbides, nitrides and/ or carbonitrides.[1] It is well-established that MXenes can be intercalated by a variety of cations, both chemically and electrochemically.[2] Predominant attention so far has been devoted to the studies of the intercalation of alkaline and alkaline earth cations such as Li^+, K^+, Na^+, Mg^{2+} or alkylammonium cations into $Ti_3C_2T_x$ MXenes. [3][4] Transition metal ions and clusters are known for their attractive electrochemical response.[5][6] However, the effects of intercalation of transition metal ions on electronic and electrochemical properties of MXenes have not been explored in detail.
Herein, we studied the effects of intercalated Cu ions on $Ti_3C_2T_x$ and vice versa, with the purpose of providing a comprehensive understanding on how the chemical, physical and electrochemical properties of both pre-intercalated transition metal ion and MXene itself were altered. Specifically, in-situ Raman and electrochemical quartz crystal microbalance (EQCM) were used to track the changes of chemical speciation in between the confined environment of

Cu-$Ti_3C_2T_x$ layers during charging/ discharging in aqueous electrolytes. In addition, in-situ X-ray absorption spectroscopy (XAS) was applied to track the oxidation changes of both intercalated Cu ions and Ti atoms of the MXene under different applied potentials, providing insights into the charge transfer between Cu ions and $Ti_3C_2T_x$. We discovered that the interactions between $Ti_3C_2T_x$ and Cu ions resulted in altered electronic and electrochemical properties compared to the Cu^{2+} ions in solution and pristine $Ti_3C_2T_x$. Using Cu^{2+} and $Ti_3C_2T_x$ MXene as an example, this work offers mechanistic understanding of the interactions between multi-valent transition metal and MXene layers, providing foundation for the rational design and utilization of transition metal ion intercalants to tune properties of MXenes for their applications in different electrochemical systems and beyond.

Electrochemical Properties of MXene Electrodes in Aqueous Zinc Electrolytes Kyle Matthews[1], Armin VahidMohammadi[1], Danzhen Zhang[1], Liyuan Liu[2], Patrice Simon[2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]Université Paul Sabatier Toulouse III, France

MXenes are a family of two-dimensional (2D) transition metal carbides, nitrides and carbonitrides, with a general structure of $M_{n+1}X_nT_x$, where M is the transition metal, X is carbon or nitrogen, T represents the surface terminations (F, O, OH), and *n* can vary from 1-4. MXenes have shown promise in multiple electrochemical systems including aqueous supercapacitors and non-aqueous batteries containing monovalent cations. However, there have been limited works studying the electrochemical properties of these materials in aqueous electrolytes with multivalent cations such as Zn^{2+} and Mg^{2+}. MXenes have high (electro)chemical stability in halide zinc electrolyte systems unlike many oxide materials. Herein, the charge storage mechanism of $Ti_3C_2T_x$ was studied in multiple Zn containing aqueous electrolytes. In-situ XRD and in-situ UV-Vis were employed to monitor the intercalating species and redox response in the electrodes. $Ti_3C_2T_x$ electrodes could deliver battery-like performance at low rates with supercapacitor performance at high rates. This work demonstrates the potential of using MXenes in zinc ion capacitors and zinc hybrid energy storage devices.

Wearable Energy Storage with MXene Textile Supercapacitors for Real World Use Alex Inman[1], Tetiana Hryhorchuk[1], Lingyi Bi[1], John Wang[1], Ben Greenspan[2], Taylor Tabb[2], Eric Gallo[2], Armin VahidMohammadi[1], Genevieve Dion[1], Andreea Danielescu[2] and Yury Gogotsi[1]; [1]Drexel University, United States; [2]Accenture Labs, United States

Successful implementation of wearable electronics requires practical wearable energy storage systems that can meet certain power and energy metrics. However, flexible, stretchable, and truly textile-grade energy storing platforms have so far remained missing from most e-textile systems due to the insufficient performance metrics of current available materials and technologies. Two-dimensional (2D) transition metal carbides and nitrides (MXenes) offer unique combinations of properties including metallic conductivity, high specific capacitance, hydrophilicity, and solution processability, as well as mechanical flexibility and robustness that render these materials promising for flexible wearable energy storage technologies. Here we demonstrate textile-based electrochemical capacitor devices with high areal loading of $Ti_3C_2T_x$ that can be integrated in series via a stacked design approach and meet the real-world power requirements for wearable electronics. A demo textile supercapacitor with 5 cells in series and a footprint area of 25 cm^2 and a MXene loading of 24.2 mg cm^{-2} could operates in a 6 V voltage window delivering an energy density of 0.401 mWh cm^{-2} at a power density of 0.248 mW cm^{-2}, and an areal capacitance of 146 mF cm^{-2} at a 0.16 mA cm^{-2} discharge current. The MXene textile supercapacitor powers a temperature monitoring system requiring high current densities with wireless data transmission to a receiver for 96 minutes. This initial report of a MXene textile supercapacitor powering a practical peripheral electronics system demonstrates the potential of this family of 2D materials to support a wide range of devices such as motion trackers and biomedical monitors in a flexible textile form factor.

10:30 AM NM04.07.07
MXene-Derived Chemically Pre-Potassiated Bilayered Vanadium Oxides as Cathodes in Non-Aqueous K-Ion Batteries Timofey Averianov and Ekaterina Pomerantseva; Drexel University, United States

As demand for Li-ion batteries (LIBs) continues to rise, concerns about the scarcity of raw materials like lithium present a challenge for large-scale distribution of energy storage devices. Potassium ion (K-ion) batteries (PIBs) present an attractive alternative to devices based on lithium ions due to the abundance of potassium in the earth's crust and potassium's lower cost to lithium. However, many traditional electrode materials cannot reliably accommodate potassium ions due to the ion's large ionic radius. As a result, materials with interlayer regions tailored for K^+ ion accommodation and diffusion are necessary to fully realize potassium-ion batteries.
Potassium-preintercalated bilayered vanadium oxide (KVO) has been previously identified as a suitable cathode material for K-ion batteries due to its wide d-spacing of 9.65 Å and high theoretical capacity through multiple reversible vanadium reduction steps. Aqueous synthesis of KVO from an α-V_2O_5 precursor produces particles with one-dimensional (1D) nanorod/nanobelt morphologies with promising performance as electrodes in PIBs, but substantial capacity fading during cycling. Alternatively, use of vanadium-based 2D MXene as a precursor has been shown to produce chemically preintercalated bilayered vanadium oxides (BVOs) with centrally nucleated 2D nanosheet morphologies, akin to a flower. Cycling of these nanoflower BVOs resulted in improved cycle-life stability and rate performance in Li-ion batteries as compared to the performance of α-V_2O_5-derived BVOs. In this work we explored if similar improvements may be possible for K-ion batteries. We report, for the first time, the electrochemical behavior of MXene-derived δ-$K_xV_2O_5{\bullet}nH_2O$ (KVO) electrodes in non-aqueous K-ion cells. Through this study, the KVO synthesis, processing, and cycling conditions that produced the most promising performance have been identified. Initial cycling of the KVO between 2.0 – 3.7 V showed stable cycling with comparable capacities (~70 mAh/g) of other KVOs, but it was found that water content in the hydrated KVO limited cycle stability when the potential limits were extended. Interlayer water dynamics and reactivity can cause parasitic reactions, such as electrolyte decomposition, poorly reversible formation of foreign compounds and vanadium oxide structure transformation, leading to the capacity decay. Vacuum drying the KVO powder at 200°C and vacuum drying the prepared electrode film at 120°C significantly stabilized cycling performance, even when cycling down to 1.5 V, due to the partial removal of the interlayer water molecules. Cycling of the vacuum-dried materials/electrodes up to 4.3 V appeared to introduce new electrochemical behavior with minimal improvements to stability. In the interest of highlighting cathodic performance,2.0 – 3.7 V was kept as the operating potential window. We show that by adequately drying before and after electrode fabrication, the MXene-derived δ-$K_xV_2O_5{\bullet}nH_2O$ electrodes demonstrated enhanced electrochemical stability while maintaining improved specific

capacities in K-ion batteries.

Photonic Curing of PDMS Intercalated Ti_3C_2 MXenes for Li-Ion Batteries Electrode Najma Khatoon, Binod Subedi, Ahmad Majed, Shiping Wang, Julie Albert, Michael Naguib and Douglas B. Chrisey; Tulane University, United States

Silicon-based nanomaterials are promising candidates for rechargeable anode material in Lithium-ion batteries (LIBs), due to their higher theoretical specific capacity, and low lithium insertion potential. The challenge to utilize these tremendous properties of Si for LIBs is to decrease volume changes and capacity loss during the lithiation/delithiation process along with dealing with their poor electrical conductivity and low lithium-ion diffusivity. Dispersing Si in a carbon like matrix is one of the approaches to tackle these challenges. Titanium carbide (Ti_3C_2 -T_x), where T_x are surface terminations, is a class of two-dimensional materials called MXenes. Ti_3C_2 have high conductivity and excellent Li-ion diffusion properties. Herein, PDMS (Polydimethylsiloxane) is intercalated in Ti_3C_2 (with d-spacing ~1 nm) for introducing the silicon within layers of MXene. The intercalated MXene (with d-spacing ~12 nm) is further processed by a unique process of photonic curing to convert intercalated PDMS to silica (SiO_2), leaving behind Si nanomaterial within the MXene layers. The as-converted silica ash on outer surface of MXene will protect it from oxidation due to its oxygen diffusion resistant ability. Photonic curing of 5K and 25K PDMS intercalated MXene is carried out at 350 V, 450 V and 550 V bank voltage for 7 pulses. Our results show that using PulseForge photonic curing of PDMS intercalated MXene changes the d-spacing from 12 nm to ~ 5 nm using a 450 V bank voltage, 7 pulses, and 28 Jcm^{-2} overall fluence. The change in d-spacing and loud photoacoustic signal during the process implies that photonic curing removed organic part of PDMS and left mostly SiO_2. Cyclic voltammetry of cured PDMS intercalated MXene shows that reversible electrochemical reactions are stable with continued cycling. We aim to cure the intercalated MXene under vacuum and reactive gas environment, with varying pressure for controlling nucleation and growth of intercalated material. The present work shows that the photonic curing process is a promising instantaneous and roll-to-roll amenable synthetic route for low-cost large scale-controlled synthesis of Si-MXenes composite with the ability to tune the Si nanostructure within the MXenes layers.

SESSION NM04.08: MXenes for Clean Environment

Wednesday Afternoon, November 30, 2022
Hynes, Level 2, Room 201

1:30 PM NM04.08.01
Tailoring of the Exterior Transition Metal on the Electrocatalytic Performance of Double Transition Metal MXenes Anupma Thakur, Nithin Chandran Balachandran Sajitha, Brian Wyatt, Wyatt Highland and Babak Anasori; Indiana University-Purdue University, United States

Two-dimensional transition metal carbides, known as MXenes, have shown great promise as active materials in catalytic applications such as the hydrogen evolution reaction. Double transition metal (DTM) MXenes, in which two different transition metals occupy the metal sites, can enhance the tunability of MXenes electrocatalytic properties. The transition metal occupying the outer atomic layers controls the HER performance based on their basal plane activity. We investigated out-of-plane ordered DTM MXenes, with inner layers of transition metal (M″: Ti) sandwiched by outer layers of different transition metals (M′: Mo, W, Cr) in a layered $M'_2M''C_2T_x$ structures. We demonstrate the role of exposed basal plane transition metals on the HER catalytic activity of these out-of-plane ordered DTM MXenes and compare their behaviour to a mono-transition metal MXene, $Ti_3C_2T_x$. $W_2TiC_2T_x$ MXene shows the lowest HER overpotential under acidic conditions over $Mo_2TiC_2T_x$, $Cr_2TiC_2T_x$ and $Ti_3C_2T_x$ MXenes. The improved electrocatalytic performance of $W_2TiC_2T_x$ can be due to the presence of tungsten atoms in the outer M' layers. Additionally, we assessed $W_2TiC_2T_x$ MXene for its long-term stability of more than 24 hours. Our findings, further demonstrate MXenes are precious-metal-free 2D flakes with highly HER active basal planes as well as promising and tunable electrocatalysts for clean energy applications.

Copper-Modified 2D Transition Metal Carbide (MXene) Electrocatalysts for CO_2 Reduction Shiba P. Adhikari, Alice Gao, Sixbert Mohuza and Zachary Hood; Argonne National Laboratory, United States

Abstract for NM04 - 2D MXenes—Synthesis, Properties and Applications
Copper-Modified 2D Transition Metal Carbide (MXene) Electrocatalysts for CO_2 Reduction
Shiba P. Adhikari[1], Alice Gao[1, 2], Sixbert Mohuza[1], and Zachary D. Hood[1]
[1]Applied Materials Division, Argonne National Laboratory, Lemont, IL 60439, USA
[2]University of Illinois Urbana-Champaign, Champaign, IL 61801, USA

Carbon capture and sequestration, as well as industrial decarbonization, are among the primary methods to tackle rising carbon dioxide (CO_2) concentrations in the atmosphere. The CO_2 reduction reaction (CO_2RR) has long been recognized as a promising strategy to capture and convert industrial CO_2 which may help to reduce atmospheric pollution strongly associated with climate change.[1] Although multiple strategies have shown CO_2 reduction to C1 and C2 liquid fuels, two major hurdles still exist for the most recent examples of catalysts for this reaction, namely 1) the preparation of the catalysts is generally complicated, and 2) the selectivity of the catalysts towards specific C1 and C2 products requires better control.[2] Here, we present recent results highlighting new Cu-based MXene electrocatalysts that overcome the preparation and CO_2RR selectivity issues. The preparation of these electrocatalysts leverages reductive adsorption of Cu ions directly onto hydroxy-terminated $Ti_3C_2T_x$ (T_x = -O, -OH, etc.) [3] that yields unique metal-ceramic heterostructures with tunable nanoscale hierarchy.[4] This hierarchy is important towards the structure-property relationships for C1 and C2 production during the CO_2RR. The Cu-based MXene electrocatalysts involved in this study reveal the importance of electrocatalyst selection for enhanced selectivity on electrocatalytic C2 production. These insights suggest new approaches for controlling the MXenes' behavior for optimal characteristics for the CO_2RR.

MXene Surface Functionalization for Energy Storage and Catalysis Zdenek Sofer; University of Chemistry and Technology Prague, Czechia

The surface chemistry of MXene can be modified and tuned in order to tune its properties by covalent functionalizations and chemical modifications. The surface chemistry of MXene including introduction of various heteroatoms like chalcogens (S, Se, Te) as well as covalent functionalization of MXene surface will be discussed. Changes of MXene termination significantly improve performance of MXene for supercapacitor applications as well as water splitting. Introduction of zwitterion molecules was used to significantly enhanced capacitance of MXene in both aqueous and non-aqueous electrolytes including ionic liquids. For these modification were used trietoxysilane linkers which is universal tools for introduction of different functionalities on various MXene surface (like $Ti_3C_2T_x$, V_2CT_x, Nb_2CT_x) including various zwitterion molecules and complex supramolecular structures like alfa- and beta-cyclodextrin. Functionalized MXene were used to improve compatibility with polymer matrix for 3D printing of MXene using FMD method providing highly conductive materials for energy storage applications and electromagnetic shielding.

Optical Properties and Photocatalytic Activity of the Oxidation Stabilized $Ti_3C_2T_x$ MXene Agnieszka M. Jastrzebska, Dominika Bury, Michal Jakubczak and Muhammad A. Purbayanto; Warsaw University of Technology, Poland

Two-dimensional (2D) MXenes are well known for their excellent photocatalytic properties. However, their oxidation stability is far from satisfactory, which makes controlling the photocatalytic processes challenging. Herein, we investigate the influence of oxidative stabilization of delaminated MXene on its optical and photocatalytic properties. The model 2D $Ti_3C_2T_x$ MXene was synthesized via two well-established approaches such as HF/TMAOH (TMAOH-MXene) and minimum intensive layer delamination with HCl/LiF (MILD-MXene) coupled with L-ascorbic acid (Vit.C) stabilization. Our approach revealed that the TMAOH-MXene showed a wider optical band gap than MILD-MXene. The MILD-MXene was therefore most efficient, showing almost 100 % effectiveness in the photocatalytic decomposition of model dyes. The industrial viability was achieved on a commercial textile dye, having a 100-times higher concentration than model dyes. The MILD-MXene needed only several seconds of UV-light and simulated white light irradiation to fully decompose the commercial dye. Further in-detail analysis at various visible light ranges showed that irradiation with 625 nm (red light) gave the highest efficiency of dye decomposition with MILD-MXene catalyst. The photocatalytic mechanism was associated with the interplay between surface dye adsorption and reactive oxygen species (ROS) generated by the MXene under light irradiation. However, excellent dye adsorption was a major driving force in the process. Importantly, both MXenes could be further successfully reused while retaining about 70 % of their activity. Collectively, the obtained results revealed that oxidative stabilization with Vit.C preserved MXene's original surface functionalization. It was further possible to understand MXene's genuine properties such as optical activity and performance in the photocatalytic process, thus supporting its practical use in industrial water remediation technologies.

3:45 PM NM04.08.05
Scalable and Sustainable Production of $Ti_3C_2T_z$ MXene and Fluorine Recovery from Wastewater Through Cryolite Precipitation Michael Carey and Michel W. Barsoum; Drexel University, United States

Traditional synthesis of $Ti_3C_2T_z$ MXene obtained by the selective etching of aluminum from Ti_3AlC_2 MAX phase with hydrofluoric acid, requires a large amount of water to obtain a colloidal suspension of few to single flake $Ti_3C_2T_z$. Typically, the amount of water needed is about 640-800 mL per gram of MXene, as this volume is thought to both wash away residual salts formed in the etching process, and to bring the solution pH to neutral at which point a stable colloidal MXene suspension forms. While MXenes have been shown to be quite promising in terms of their performance across a wide variety of applications, their widescale production has lagged. One of the limiting steps at this time is the large cost of their production and the need for fluorine in the etching medium. Additionally, the treatment of HF containing wastewater is both a major industrial and environmental concern. For MXene production to occur at industrial scales, the large amount of acidic wastewater that is currently a byproduct of its methods of production must be addressed. Furthermore, the presence of F- in this wastewater is problematic as this treatment is quite costly and produces a large amount of industrial waste sludge that becomes difficult to dispose of due to environmental regulations. Herein we show that by modifications made to the synthesis process, we can obtain $Ti_3C_2T_z$ colloidal suspensions with 75% less water utilized in the washing procedure. Additionally, the fluorine in the remaining wastewater can also be recovered through the precipitation of cryolite, Na_3AlF_6, a value-added compound used extensively in the aluminum production cycle. This cryolite can then be used as a quantitative tool to determine the efficiency of aluminum extraction from Ti_3AlC_2 MAX phase, allowing for optimization of parameters such as etching time, temperature, reagent concentrations, and/or pH of etchant.

Significant Enhancement in the Seebeck Coefficient and Power Factor of a Thermoelectric Polymer Through the Incorporation of MXene Jianyong Ouyang; National University of Singapore, Singapore

Thermoelectric (TE) materials are important for sustainable development because they can directly convert heat into electricity. Compared with inorganic TE materials, conductive polymers have demonstrated unique advantages. But their TE properties, particularly the Seebeck coefficient, must be greatly enhanced for practical application. Here, I will present the significant enhancement in the Seebeck coefficient and thus the overall thermoelectric properties of poly(3,4-ethylenedioxythiophene):poly(styrenesulfonate) (PEDOT:PSS) that is hte most popular thermoelectric polyme through the incorporation of MXene. MXene can enhance the Seebeck coefficient from 23 up to 57.3 $\mu V\ K^{-1}$ and the power factor from 44.1 to 155 $\mu W\ m^{-1}\ K^{-2}$. Tjhis is the first time to achieve the enhancement in the Seebeck coefficient of a p-type TE polymer by an n-type filler.

8:45 AM NM04.09.02

Molecular Doping of $Ti_3C_2T_x$ MXene Yields Surface-Termination-Independent Tunable Work Function Jehad K. El-Demellawi, Ahmed E. Mansour, Omar Mohammed and Husam N. Alshareef; King Abdullah University of Science and Technology, Saudi Arabia

MXenes are highly regarded for their localized surface plasmons (SPs), broadband optical absorption, and tunable work functions. These unique features strongly depend on the dipole moments between the transition metal (*e.g.*, Ti) and the functional surface species (T_x) of MXenes. Hence, tailoring the surface terminations of MXenes is expected to alter their work functions, plasmon energies, and optical properties simultaneously, making it hard to modify one property (*e.g.*, work function) without affecting the other properties. In this work, we introduce an alternate method for surface-termination-independent controlling of the work function of $Ti_3C_2T_x$ MXene *via* a well-controlled molecular doping process. Utilizing Tris(4-bromophenyl)ammoniumyl hexachloroantimonate, viz. magic blue (MB), as a dopant, we finely tune the work function of $Ti_3C_2T_x$, achieving an increase of ~ 500 meV. The incremental changes in the work function of our spray-coated $Ti_3C_2T_x$ films (20-nm-thick) are proven to be entirely independent of T_x, as denoted by the invariant absorption and relaxation dynamics of the transversal (out-of-plane) plasmonic band throughout the doping process. Using ultraviolet and X-ray photoemission spectroscopy (UPS and XPS) along with electron paramagnetic resonance (EPR) spectroscopy, we attribute the work function modulation to an electron transfer from the energy states below the Fermi level in $Ti_3C_2T_x$ to the dopant cations, accompanied by the physisorption of the dopant anions (antimony hexachloride) on the MXene surface, leading to the formation of polarons as additional charge carriers. The demonstrated ability to engineer the work function of MXenes without altering their surface-termination-dependent properties (*e.g.*, SPs) allows for higher operational degrees of freedom, which is alluring for MXene-based device applications.

9:00 AM NM04.09.04
Environmentally-Stable High Work Function Titanium Carbide MXene for Large-Area Organic Light-Emitting Diodes Huanyu Zhou[1], Shin Jung Han[1], Hyeon-Dong Lee[1], Danzhen Zhang[2], Mark Anayee[2], Seung Hyeon Jo[1], Gogotsi Yury[2] and Tae-Woo Lee[1]; [1]Seoul National University, Korea (the Republic of); [2]Drexel University, United States

This paper presents a transparent conducting electrode (TCE), which is an environmentally-stable two-dimensional titanium carbide ($Ti_3C_2T_x$, MXene) that has a high work function WF. High-temperature annealing reduced the d-spacing of $Ti_3C_2T_x$ from 1.33 to 1.06 nm; the result was a highly-compacted thin film that can resist inward diffusion of moisture intercalants. The MXene had high WF = 5.84 eV, which is the highest yet; it was achieved by p-type molecular doping using perfluorosulfonic acid. With benefits from the highly compacted structure of $Ti_3C_2T_x$ and superior chemical stability of overcoated PFSA, the p-doped $Ti_3C_2T_x$ exhibited only a 4.8% increase in sheet resistance with WF maintained > 5.60 eV even after 22-day exposure to ambient air. Lastly, the $Ti_3C_2T_x$ TCE was successfully applied as the anode for both large-area and ten-by-ten passive matrix flexible organic light-emitting diodes on 6 cm × 6 cm substrates. The significant increases in environmental stability and WF provides a new method to develop practical applications of MXene as TCEs for optoelectronics and photovoltaics.

9:15 AM NM04.09.05
Scalable Wet-Spinning of MXene Assembly and Their Applications Rohan B. Ambade and Tae Hee Han; Hanyang University, Korea (the Republic of)

MXenes, a fascinating large family of two-dimensional (2D) layered transition metal carbides and nitrides, have aroused substantial interest in various applications owing to their unprecedented ultrahigh metallic conductivity, mechanical properties, and hydrophilicity. This work demonstrates scalable, straightforward, continuously controlled, additive-free wet-spinning assembly of 2D titanium carbide ($Ti_3C_2T_x$) MXene fibers. MXene flakes are perfectly aligned under a mechanical drawing force using concentrated MXene colloids in a coagulation bath to produce $Ti_3C_2T_x$ MXene fibers *via* a wet-spinning process. The wet-spun $Ti_3C_2T_x$ MXene fibers demonstrated excellent electrical conductivity and mechanical properties. As a result, $Ti_3C_2T_x$ MXene fiber-based miniaturized devices are promising for portable applications. Furthermore, the $Ti_3C_2T_x$ MXene hybrid fibers with the synergistic effect of gas-adsorption and electronic properties significantly improved NH_3 sensing response ($\Delta R/R0$ = 6.77%) at room temperature for wearable gas sensors. Additionally, fabricated wet-spun $Ti_3C_2T_x$ MXene fibers are integrated into electrical wires to switch on a light-emitting diode light and transmit electrical signals to earphones to demonstrate their application in electrical devices. Furthermore, the wet-spun electroconductive $Ti_3C_2T_x$ MXene fibers exhibited an enhanced electrochemical performance when assembled as supercapacitor applications. Thus, we envisage that these exciting features of 2D $Ti_3C_2T_x$ MXene hybrid fiber materials will provide a novel pathway for designing next-generation portable miniaturized devices.

10:00 AM *NM04.09.06
MXene Surface Chemistry for Electronic and Energy Applications Chong Min Koo; Sungkyunkwan University, Korea (the Republic of)

Surface chemistry controls not only the physicochemical, electrochemical, and optoelectronic properties, but also environment stability and processability of nanomaterials. MXenes have been attracted in many electronic, electrochemical, and optoelectronic applications, due to their high electronic conductivity (~15000 S/cm), hydrophilicity, and solution processability. MXenes, transition metal carbides/carbonitrides/nitrides, are a very large family of 2D materials with the general formula Mn+1XnTx, where M, X, Tx, and n represent transition metal(s), carbon or nitrogen, surface terminal groups such as –OH, -O and -F, and integers ranging from 1 to 4, respectively. The surface terminations determines the surface properties of MXenes. In this presentation, the presenter will briefly demonstrate two ways to control the surface chemistry of MXenes, including anhydrous synthesis and post-surface functionalization methods. The developed surface chemistry not only control the surface functionality and physicochemical properties of MXenes, but also enables preparation of stable MXene dispersions with good oxidation stability. The surface chemistry also provides an opportunity to prepare printable flexible MXene electrodes for various applications including EMI shielding, flexible joule heater, LED display and energy storage.

Two-dimensional (2D) MXenes are a newly discovered family of transition metal carbides, nitrides, and carbonitrides. Their outstanding electrical conductivities of $>10^4$ S cm^{-1} in 2D morphology, low density, mechanical flexibility, easy processability, and structural controllability extends their application scope to compete with existing conventional 2D materials. $Ti_3C_2T_x$, the representative candidate of the MXene family, exhibits an EMI shielding effectiveness of 92 dB at 45 micrometer thickness, whereas a 55-nanometer thick film can provide 99% shielding against EMI, which is outstanding for highly compacted electronics. A transition metal carbonitride, Ti_3CNT_x MXene, with a moderate electrical conductivity provides a shielding effectiveness of 116 dB at 40 micrometer thickness, higher than the more-conductive $Ti_3C_2T_x$ or metal foils of the same thickness. This exceptional shielding performance of Ti_3CNT_x was achieved by thermal annealing and is attributed to an anomalously high absorption of electromagnetic waves in the layered metamaterial-like porous structure. With high absorption of EM waves at minimal thickness, MXenes are ideal for real applications in smart 5G electronics.

Keywords: Transition metal carbides, carbonitrides, MXenes, electromagnetic shielding, porous structure.

10:45 AM NM04.09.08
The Environmental Impacts of $Ti_3C_2T_x$ MXene Synthesis for Electromagnetic Interface Shielding of Communication Satellites Mostafa Dadashi Firouzjaei[1], Daqian Jiang[1], Mark Elliott[1] and Babak Anasori[2]; [1]The University of Alabama, United States; [2]Indiana University-Purdue University Indianapolis, United States

Scaling up and environmental impacts associated with nanomaterials synthesis is a major challenge in the industries nowadays. As one of the cutting-edge nanostructures, MXenes, have significantly impacted materials science and nanotechnology since their discovery in 2011. Theoretical calculations have predicted more than 100 possible compositions of MXenes, and lab-scale fabrication of more than 40 MXene structures has been reported to date. The unique characteristics of MXenes have made them an ideal fit for a wide variety of applications, including energy storage, environmental, electronics, communications, gas, and liquid separations and adsorption, biomedical, and optoelectronics. By 2021, MXenes have already shown promise in several research areas, including energy storage devices, electromagnetic interference shielding, nanocomposites, and hybrid materials. In parallel, new applications are emerging where MXenes outperform other nanomaterials, such as in tribology. Despite all the new development in the MXenes field, there is no study of the environmental impacts of MXene synthesis. Here, we investigate the environmental impacts associated with the fabrication of $Ti_3C_2T_x$ MXene as a coating layer for electromagnetic interface (EMI) shielding of communications satellites. We use aluminum and copper as an external normalization alternate to show the gaps and recommend solutions for improving the scalability of the $Ti_3C_2T_x$ MXene. Two $Ti_3C_2T_x$ synthesis systems, a small laboratory scale (19.2 g per batch) and a large laboratory scale (800 kg per batch) were compared. We also investigated the use of TiO_2 instead of Ti for the synthesis of the MXene precursor as well as the effects of laboratory location on the environmental impacts of MXene. In summary, this work would help through the more efficient and environmentally friendly synthesis of MXenes, which is vital for considering the scale-up of MXenes.

11:00 AM NM04.09.09
$Ti_3C_2T_x$ MXene Film with High Electrical Conductivity and Moisture Resistance Akari Seko, Shun Sakaida and Takeshi Torita; Murata Manufacturing Co., Ltd., Japan

With high metallic conductivity, a new family of two-dimensional transition metal carbides (MXene) is a promising candidate for electronics. However, one of challenges in MXene application is poor stability to moisture, degradation of electrical properties by swelling (lattice expansion by water intake) and oxidation [1, 2]. For applications in the field of electronics, MXene with improved environmental stability (e.g. no significant degradation under 60°C/RH85%) is highly required. A number of works has been reported to improve MXene stability in humid conditions, including surface modification [3], but most of them have resulted in ruining their superior properties derived from diversity in surface terminating groups. In this work, we propose a facile strategy to fabricate MXene films exhibiting excellent conductivity and stability under 60°C/RH85% without tailoring of MXene surface functional groups.

SESSION NM04.10: MXenes Sensing and Biomedical Applications
Session Chairs: Mostafa Dadashi Firouzjaei and Anupma Thakur
Thursday Afternoon, December 1, 2022
Hynes, Level 2, Room 201

1:30 PM *NM04.10.01
Automatic MXene Strain Sensor Design via Active Learning and Data Argumentation for Soft Machines Po-Yen Chen; University of Maryland, United States

Emerging soft machines require high-performance strain sensors to achieve closed-loop feedback control. Predicting the performance of a soft robotic sensor from its composition and morphology is nearly impossible with traditional computational approaches. Machine learning (ML) is a versatile tool to uncover complex correlations between fabrication recipes and sensor performance, yet the limited acquisition rate of high-quality data hinders the development of high-accuracy prediction models at the device level. In this talk, I will demonstrate our recent work of using an ML model to predict device-level performance and recommend new material compositions for soft machine applications. I will present a three-stage ML framework to construct a prediction model capable of automating the design of strain sensors across a wide strain range from <0.5% to 350%. First, a support-vector machine classifier is trained by using 351 compositions of various nanomaterials, including Ti3C2TX MXene nanosheets, single-walled carbon nanotubes, and polyvinyl alcohol. Second, through 12 active learning loops, 125 strain sensors are stagewise fabricated to enrich the multi-dimensional dataset. Third, data augmentation is implemented to synthesize >10,000 virtual data points followed by genetic algorithm-based selection to optimize the prediction accuracy of ML model. An ultimate prediction model is finally constructed and able to (1) predict sensor characteristics based on fabrication recipes and (2)

recommend feasible fabrication recipes for adequate strain sensors. As final demonstrations, model-suggested strain sensors are integrated into soft gripper and batoid-like swimmer to endow them with real-time sensing capabilities.

2:00 PM NM04.10.02
Scalable Production of MXene Dip-Coated Yarns and Cords Lingyi Bi[1,1], William Perry[1], Robert Lord[1], Stepan Vorotilo[1], Alex Inman[1], Tetiana Hryhorchuk[1], John Wang[1], Vitaliy Balitskiy[2], Veronika Zahorodna[2], Oleksiy Gogotsi[2], Genevieve Dion[1] and Gogotsi Yury[1]; [1]Drexel University, United States; [2]Materials Research Center, Ukraine

Fibers, yarns, and textiles have long established themselves in many sectors of society from our daily wear to medicine and structural composites. The rise of the Internet of Things (IoT) has prompted incorporation of conductive materials into textiles that enable real-time monitoring of external stimuli (e.g., stretch, pressure, temperature, and humidity) and body responses. Sensors, antennas, energy storage sources need to be incorporated into textiles. New functions, such as IR stealth, EMI shielding or passive and active temperature control, can be enabled by conductive or optically active coatings. Among the many conductive materials and fabrication methods demonstrated, few met the performance and cost requirements of real-world applications. MXenes are an emerging class of 2D nanomaterials that possess excellent electrical conductivity, attractive optical/plasmonic properties, solution processability and hydrophilic surfaces, making them ideal for imparting conductivity to textiles in a simple dip coating fashion. In this work, a high throughput continuous coating method was demonstrated with a customized automatic yarn dip coater. Thanks to the shear force present in the dip coater and the preferred interactions between Kevlar and MXene, viscous MXene solutions and fast coating speeds could be used. Kilometers of highly conductive MXene coated Kevlar cords were produced with consistent quality. Tensile test with *in-situ* electrical resistance tracking showed the multifunctionality of $Ti_3C_2T_x$ coated Kevlar for composites, both as structural reinforcement and damage sensing.

2:15 PM NM04.10.03
UV-Crosslinked Ti_3C_2 MXene Composite Hydrogel for Selective Detection of Neurotransmitters Mina Kim, Nakwon Choi, Seon Joon Kim and Hyejeong Seong; Korea Institute of Science and Technology, Korea (the Republic of)

Detecting neurotransmitters in the system is critical to diagnosing nervous system diseases. Many studies have been reported to produce high-performance sensors for sensing dopamine. Among the various materials, 2-dimensional Ti_3C_2 MXene, which is highly conductive and electrochemically active, has been investigated to detect neurotransmitters including dopamine, uric acid, and serotonin. However, MXene oxidizes quickly in aqueous conditions, hindering MXene from being widely applicable for biosensing applications.
Herein, we report a composite of MXene and poly (ethylene glycol) diacrylate (PEGDA), enabling selective detection of neurotransmitters. PEGDA is a porous, UV-cross-linkable material with a low degradation rate, protecting MXenes from oxidation in aqueous conditions. The composite thickness was easily controllable by changing UV irradiation time and the guide mold. Also, the composite structure was porous enough to assist small molecules diffused inside, facilitating electrochemical detection of neurotransmitters.
Electrochemical detection of dopamine was confirmed via cyclic voltammetry (CV) and differential pulse voltammetry (DPV), confirming that the composite could detect dopamine in aqueous conditions up to 50 nM. The limit of detection (LOD) is estimated to be lower than 50 nM, suggesting out MXene composite hydrogel would be further applicable for detecting neurotransmitters sensitively but selectively.

2:30 PM BREAK

3:00 PM NM04.10.04
Immune Profiling and Single-Cell Label-Free Detection of Two-Dimensional MXenes by Mass Cytometry and High-Dimensional Imaging Laura Fusco[1,2,3], Arianna Gazzi[1,4], Christopher E. Shuck[2], Marco Orecchioni[5], Sènan Mickael D'Almeida[6], Darawan Rinchai[3], Eiman Ahmed[3], Leeat Ahmed[7], Davide Bedognetti[3], Yury Gogotsi[2] and Lucia Delogu[1]; [1]University of Padua, Italy; [2]Drexel University, United States; [3]Sidra Medicine, Qatar; [4]University of Trieste, Italy; [5]La Jolla Institute for Allergy and Immunology, United States; [6]Ecole Polytechnique Fédérale de Lausanne (EPFL), Switzerland; [7]Weizmann Institute of Science, Israel

There is a critical unmet need to detect and image two-dimensional (2D) materials within single cells and tissues while surveying a high degree of information from single cells. Here, we propose a versatile multiplexed label-free single-cell detection strategy based on single-cell mass cytometry by time-of-flight (CyTOF) and ion-beam imaging by time-of-flight (MIBI-TOF). [1] This strategy, “Label-free sINgle-cell tracKing of 2D matErials by mass cytometry and MIBI-TOF Design” (LINKED), enables nanomaterial detection and simultaneous measurement of multiple cell and tissue features. As a proof of concept, we selected a set of 2D materials, transition metal carbides, nitrides, and carbonitrides (MXenes), to ensure mass detection within the cytometry range while avoiding overlap with more than 70 currently available tags, each able to survey multiple biological parameters. In addition, MXenes have received substantial attention for their promise as biomedical nanotools. [2-5]
First, we demonstrated their detection and quantification in 15 primary human immune cell subpopulations. Together with the detection, mass cytometry is used to capture several biological aspects of MXenes, such as their biocompatibility and cytokine production after their uptake. *In vivo* biodistribution experiments using a mixture of MXenes in mice confirmed the versatility of the detection strategy and revealed MXene accumulation in the liver, blood, spleen, lungs, and relative immune cell subtypes. Finally, we applied MIBI-TOF to detect MXenes in different organs revealing their spatial distribution. The label-free detection of 2D materials by mass cytometry at the single-cell level, on multiple cell subpopulations, and in multiple organs simultaneously, is expected to enable exciting new opportunities in biomedicine.

3:15 PM NM04.10.05
The Behavior of MXenes in Biological Media Swapnil Ambade, Robert Brown, Aditi Gupta, Michal Zalzman and Zeev Rosenzweig; University of Maryland, United States

The rapidly growing family of ultrathin layered two-dimensional (2D) transition metal carbides, nitrides, and carbonitrides, referred to as MXenes are steadily advancing as novel inorganic nanosystems for various electronic and optoelectronic applications. The metallic conductivity, hydrophilic nature,

and other unique physiochemical properties qualifies 2D MXenes to meet the requirements of biomedicine such as in stem cell research. Stem cell therapies show great promise for the cure of neurological disorders, as stem cells can serve as cell replacement, while also secreting factors to enhance endogenous tissue regeneration. We investigate the impact of outstanding electrical and surface functional properties of MXenes in the application areas of stem cells. Our synthesis strategies allow us to synthesize highly conductive and stable colloidal aqueous dispersions of MXenes that are coated or drawn as films. These freestanding films of MXenes exhibit electrical conductivities ranging from 10 $S.cm^{-1}$ ($V_4C_3T_x$ MXene) to 20,000 $S.cm^{-1}$ ($Ti_3C_2T_x$ MXene). By the virtue of such high electrical conductivities, MXene nanosheets are explored as interfaces for regulating stem cells. The stem cells grown using a technology that allows for the culture of stem cells in combination with 3D printing technology can be translated to novel therapies for bone regeneration and reconstruction. Stem cells cultured on MXene films enable higher synchronous electrical activities and higher proliferative ability. Our preliminary results suggest that owing to the 2D network, MXenes can be engineered as guided bone regeneration membranes that serve as a scaffold to induce stem cell attachment. This study is an important step toward understanding the potential of MXenes in stem cell research and biomedicine, in general.

3:30 PM NM04.10.06
Stability of $Ti_3C_2T_x$ MXene Electrode Arrays Under Different Sterilization Conditions Spencer R. Averbeck, Brendan B. Murphy, Doris Xu and Flavia Vitale; University of Pennsylvania, United States

Recently, $Ti_3C_2T_x$ MXene has attracted increasing interest for use in sensing and stimulation applications for monitoring electrophysiological activity in the body. The electrochemical properties of MXene-based electrode arrays have consistently demonstrated superior recording quality with increased signal to noise ratios (SNR) compared to clinically standard arrays. Further, the high capacitance of the MXene nanostructure paired with the large charge injection capacity (CIC) make these devices very desirable for high-quality, micron-scale recording and electrical stimulation. For MXene wearable and implantable devices to become clinically and commercially viable, however, they must be able to withstand routine sterilization procedures. Standard sterilization modalities used widely across the world include steam autoclave sterilization at 120 °C, Ethylene Oxide (EtO) gas, and hydrogen peroxide (H_2O_2) plasma. Here, we present a comprehensive analysis of the structural, functional, and electrical effects of these common sterilization protocols on thin-film spray-coated $Ti_3C_2T_x$ neural microelectrode arrays as well as $Ti_3C_2T_x$ infused 'MXtrodes'. To confirm that bacteria could be effectively eradicated from the $Ti_3C_2T_x$ MXene devices, *E. Coli* inoculated samples were first tested in each sterilization machine, and the resulting colony-forming units (CFU) were counted. Across all sterilization modalities, the bacterial colony units were below the threshold of detection which confirmed the devices could be effectively sterilized. Post-sterilization analysis reveals that for both autoclave and EtO sterilized devices, the crystalline structure, contact adhesion, and electrical properties remain unchanged. Furthermore, there were no changes in the XRD and Raman spectra for autoclave or EtO sterilized thin-films or MXtrodes. Finally, electrochemical impedance and conductivity were statistically unchanged, and SEM did not reveal any delamination or morphological changes to the devices. Hydrogen Peroxide plasma sterilization, however, resulted in severe damage of $Ti_3C_2T_x$ MXene films as confirmed by SEM, XRD, and Raman. Further, plasma sterilization significantly increased the recoding impedance measurements and revealed a significant loss in conductivity. Ultimately, our findings indicate that EtO and Autoclave sterilization do not alter $Ti_3C_2T_x$ MXene devices and should be considered for all future MXene wearables and invasive implants.

3:45 PM NM04.10.07
MXenes-Mediated Photermal Therapy on Reliable 3D Models of Breast Cancer Ginevra Friggeri[1], Giordano Perini[1], Valentina Palmieri[2], Massimiliano Papi[1] and Marco De Spirito[1]; [1]Università Cattolica del Sacro Cuore, Italy; [2]sistemi complessi, Italy

Breast cancer is the most commonly diagnosed invasive cancer among women globally. Current therapies (e.g. chemotherapy) show numerous limitations due to the lack of selectivity and the consistent side effects. This led to investigating novel approaches aimed at improving tumor-killing efficacy. We previously demonstrated the effect of new bioactive nanomaterials with promising photophysical properties, the MXenes, used to increase the efficiency of targeted breast cancer Photothermal Therapy (PTT). In this work, we investigated the effect of Few and Multi layers MXenes mediated-PTT on two different three-dimensional reliable models of breast cancer; conventional spheroids and bioprinted spheroids. We performed PTT on the two models of breast cancer by using a non-toxic concentration of MXenes (50 µg/mL). After PTT, a significant reduction in cell viability was observed along with a strong increase in reactive oxygen species (ROS). We furthermore investigated the effect of PTT on the migration of macrophages and endothelial cells towards cancer region in both 3D models. Our results indicate that PTT mediated by both Few and Multi layers MXenes significantly modulate tumor progression by inducing the cells death by increasing the temperature, particularly in the bioprinted model.

SESSION NM04.11: Virtual Session I: MXenes I
Session Chairs: Babak Anasori and Anupma Thakur
Tuesday Morning, December 6, 2022

8:00 AM NM04.11.02
Chemical Imaging of 2D Titanium Based MXenes During *In Situ* Annealing by Scanning Transmission X-Ray Microscopy Faidra Amargianou[1], Tianxiao Sun[1], Markus Weigand[1], Tyler Mathis[2], Yury Gogotsi[2] and Tristan Petit[1]; [1]Helmholtz-Zentrum Berlin für Materialien und Energie GmbH, Germany; [2]Drexel University, United States

MXenes include transition metal carbides/nitrides with intercalated cations, such as Li-$Ti_3C_2T_x$ and K-$Ti_3C_2T_x$, where T_x represents surface terminations (typically O, OH and F). They have shown promising performance for energy storage, which is highly dependent on the surface chemistry and the Ti oxidation state. Nevertheless, contributions of different oxygen bonds in the local chemistry of MXene flakes and interlayers are difficult to disentangle without high chemical and spatial sensitivity.

In this presentation, we will show that Scanning Transmission X-ray Microscopy (STXM) is well suited for chemical imaging on individual MXenes particles. This synchrotron-based method allows the recording of soft X-ray Absorption Spectra (sXAS) with <60 nm spatial resolution, hence enabling the characterization of single MXene particles with high chemical sensitivity to Ti oxidation state and oxygen bonding, as well as bulk sensitivity. We will present here the first STXM characterization of $Ti_3C_2T_x$, Li -$Ti_3C_2T_x$, and K-$Ti_3C_2T_x$ MXenes at the Ti L-, C K- and O K-edges. The data analysis with unsupervised machine learning algorithms of STXM measurements for intercalated MXenes achieved the identification of different oxygen-containing compounds. Moreover, STXM measurements in transmission and total electron yield detection mode at Ti L- and O K-edge allowed the comparison between surface and bulk properties for $Ti_3C_2T_x$ MXene.

A decisive step towards understanding the migration of oxygen as a termination and water species was also achieved with *in situ* temperature-dependent

STXM measurements for these MXenes. The local behaviour of oxygen during annealing up to 650°C was mapped at the Ti L- and O K-edge. These are the first bulk-sensitive measurements able to map oxygen redistribution inside MXene interlayer during annealing. The aforementioned experimental results advocate for the importance of spaces between MXene layers and overlapping flakes in the formation and control of oxygen-containing species in MXenes.

8:15 AM *NM04.11.03
2D Molybdenum Carbide (MXene) for CO_2 Hydrogenation Hui Zhou; Tsinghua University, China

Currently, the conversion of captured CO_2 into value-added chemicals or fuels is considered a key strategy to mitigate the yet increasing anthropogenic CO_2 emissions, in particular when combined with H_2 obtained using renewable energy. Depending on the catalyst and the reaction conditions used, thermocatalytic CO_2 hydrogenation can give CO, methanol, dimethyl ether (DME), methane, or heavier hydrocarbons. MXene materials, that is, a family of two-dimensional (2D) carbides, nitrides and carbonitrides with the general formula of $M_{n+1}X_nT_x$ (where M is an early transition metal, n = 1, 2, 3, X is C and/or N and *T* are surface –O–, –OH and/or –F groups), are currently emerging in thermocatalytic applications as catalysts or supports with reactive metal–support interactions. Enabled by the scalable synthesis of MXenes, we report a gram-scale synthesis of a phase-pure multilayered hexagonal 2D-Mo_2C material with only Mo-terminated basal planes. 2D-Mo_2C is by a factor of six per mass of catalyst more active for CO formation than the reference β-Mo2C catalyst and shows no deactivation on stream for more than 100 h. We also report that silica-supported, dispersed, reducible nanosheets of a delaminated molybdenum MXene, Mo_2CT_x, can be used to engineer a Cu/Mo_2CT_x interface that shows an at least six times increased intrinsic formation rate of methanol by the direct hydrogenation of CO_2 compared to Cu/SiO_2.

8:45 AM NM04.11.04
Probing the Hydration Shell of Cations Intercalated Between Two-Dimensional $Ti_3C_2T_x$ MXene Layers Using Infrared Spectroscopy Mailis Lounasvuori[1], Tyler Mathis[2], Yury Gogotsi[2] and Tristan Petit[1]; [1]Helmholtz-Zentrum Berlin, Germany; [2]A.J. Drexel Nanomaterials Institute, United States

MXenes are a large family of 2D materials [1] with excellent potential for energy storage applications [2]. $Ti_3C_2T_x$ (where T_x refers to surface terminations -O, -OH, -F, etc, present in varying amounts depending on synthesis conditions) is one of the most studied MXenes to date. Due to hydrophilic surfaces and weak attractive forces between the negatively charged layers, MXenes can retain significant amounts of water between the layers, and they can be intercalated with a variety of cations and molecules [3]. Understanding the structure and dynamics of intercalated species within MXene electrodes is important for the development of practical energy storage devices. Infrared spectroscopy is sensitive to the hydrogen bonding environment of water molecules and thus well suited for the study of water structures [4]. We have recently demonstrated that this method can be applied to probe proton intercalation into the MXene interlayer space [5].

Here, we use infrared spectroscopy in the attenuated reflectance mode to probe confined water between $Ti_3C_2T_x$ MXene layers as a function of relative humidity. The MXene was intercalated with various cations (Li, Na, K, Cs, …) or treated with an acidic solution to remove all intercalants [6]. Clear changes in the amount and hydrogen-bonding structure of the confined water are observed depending on the identity of the intercalated cation as well as the relative humidity. Because anions do not intercalate into MXenes [7], we are able to study the hydration shell of the cation without interference of anions or contact ion pairs. This work provides new understanding on the solvation of cations confined between MXene layers.

Cation Intercalation and Its Role in Designing Electrochemical Response of MXenes Maria Lukatskaya; ETH Zurich, Switzerland

As electronic technology advances, the need in safe and long-lasting energy storage devices that occupy minimum volume arises. Short charging times of several seconds to minutes, with energy densities comparable to those of batteries, can be achieved in pseudocapacitors. These are sub-class of supercapacitors, where capacitance is mediated by fast redox reactions and can enable at least an order of magnitude more energy to be stored than in typical electrical double layer capacitors. Transition metal oxides (e.g. RuO_2, MnO_2) and conducting polymers (e.g. polyaniline) serve as typical examples. However, these materials are often high in cost and/or suffer from low cycling stability. As a result, the search for new pseudocapacitive materials constitutes an important direction today.
In this talk, I will discuss how the key performance metrics of pseudocapacitors – capacitance and charging rates – can be pushed to the limits in the materials that combine good electrical and ionic conductivities (ensuring fast charge transfer and hence charging rates) with high density of redox-active and ionically accessible sites (enabling high capacitance and charging rates). In particular, the electrochemistry of 2D transition metal carbides (MXenes), with an emphasis on the mechanism of charge storage and factors affecting the overall capacitive response in these materials will be discussed. Moreover, the role of the cation intercalation in layered MXenes as means to manipulate its electrochemical response are examined.
